Background. The successes of genome-wide association studies (GWAS) in mapping over 100 loci associated with high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), and triglyceride (TG) levels have advanced our understanding of genomic influences on common diseases. However, the translation of such knowledge into clinical and public health applications requires exploration of the epidemiological architecture of these variants. For example, the environmental specificity of such effects has largely been unexplored. We investigated whether GWAS-identified SNPs previously associated with lipid traits exhibited heterogeneity by sex in the multi-ethnic Population Architecture Using Genomics and Epidemiology (PAGE) study. **Methods.** We genotyped 49 GWAS-identified SNPs associated with one or more lipid traits in at least two PAGE studies and across four population groups. We performed a meta-analysis testing for SNP associations with fasting HDL-C, LDL-C, and ln(TG) levels in self-identified European American (~20,000), African American (~9,000), American Indian (~6,000), and Mexican American/Hispanic (~2,500) adults, regardless of lipid-lowering medication use. A Chi-square heterogeneity test (1 df, resulting in P_{het}) was used to determine whether the effect of each SNP differed significantly by sex. **Results.** Examining 49 SNPs across three phenotypes, there was evidence for heterogeneity by sex (Bonferroni-corrected P_{het}<0.001) for six SNPs across five loci: *HNF4A, PLTP, HMGCR, LDLR*, and *APOA1*. Whereas heterogeneity by sex at *HMGCR* rs12654264 had been previously noted for total cholesterol, heterogeneity was novel for the other loci. Heterogeneity for the *APOA1* and *LDLR* SNPs was observed in multiple ancestrally diverse populations with consistent effect estimates. For *LDLR, PLTP*, and *HNF4A*, the sex-combined, meta-analyzed main effect P-value did not indicate an association, but a meta-analysis allowing for heterogeneity by sex was statistically significant (main effect P<0.001). **Conclusions.** We replicated and discovered several sex-specific effects of SNPs on fasting lipid concentrations in the ancestrally diverse PAGE study population. Our findings suggest a complex architecture for lipid-related traits and emphasize the need for considering context-specific population differences in interpreting the increasing body of genetic associations emerging from well-replicated GWAS.

Background. Previous genome-wide association studies (GWAS) have identified loci associated with central adiposity. Gene-sex interactions are of particular interest for this phenotype because adiposity patterns differ markedly by sex. However, appropriate interaction identification methods in genetic epidemiology are still under development. In an effort to identify sex-specific genetic effects, we implemented two distinct analytical methods in a meta-analysis of 42820 European descent individuals. **Methods.** We conducted association analyses of waist circumference (WC), WC adjusted for BMI (WCadjBMI), and waist-to-hip ratio adjusted for BMI (WHRadjBMI) in 25776 females and 16975 males from the Candidate Gene Association Resource (CARe) consortium and ten other population-based studies. Individuals were genotyped using a cardiovascular disease-related gene-centric array, which includes ~50K densely mapped SNPs across ~2K genes. Each trait was modeled as a function of age, study site, and ancestry. We conducted a fixed-effects, inverse variance-weighted meta-analysis, stratified by sex. Heterogeneity by sex was assessed using a Wald Chi-square test (1df, yielding P_{het}). We ranked the results two ways: first by main effect association P-values (lowest P_{assoc}), and second by heterogeneity P-values (lowest P_{het}). We then compared the top 10 findings from these two approaches. **Results.** Using the first method (lowest P_{assoc}), we detected varying levels of heterogeneity across sex for all phenotypes, with P_{het} ranging from $1.2x10^{-4}$ to 0.97. Directions of effect were consistent across sex but with differing magnitudes. Using the second method, P_{het} values were lower, ranging from $1.3x10^{-5}$ to $3.7x10^{-4}$. The effect coefficients for males and females generally had opposite directions of association, but standard errors were larger than those reported using the first method. The two methods yielded different results with just one locus in common, rs2299656 in *CACNA1C*, for WCadjBMI. For this locus, there was a notable negative association among males (beta, SE = -0.12, 0.03; $P=5.5x10^{-6}$), but no effect was noted in females (0.02, 0.02; P=0.51) ($P_{het}=1.2x10^{-4}$). **Conclusions.** Two methods of evaluating heterogeneity across sex identified distinct loci. Replication studies are needed to distinguish real from spurious interactions. Moreover, it is clear that new methods to evaluate gene-environment interactions will be required.

Autoimmune myocarditis induced by coxakie virus,suggesting novel loci on chromosome17. *R.M.T. Issa.* molecular diagnostics, institute of genetic engineering and biotechnology, cairo, Egypt.

Myocarditis is a major cause of heart failure.Disease is often initiated by pathogen insult in the heart.Enterovirus, coxsackie is the most prevelant.Following viral infection,disease progression to autoimmune myocarditis occurs only in genetically susceptible individuals. we use chromosome substitution strain(css)mice, to identify chromosome that contain autoimmune myocarditis.we used chromosome 17 to confer susceptibility to viral induced myocarditis.There are four susceptibility loci within the chromosome.The first locus in the distal portion of the chromosome,and moderately confer disease susceptibility.The second locus contain the MHC locus and TNFalpha.Two novel loci between 4 1cM and 16 cM,these loci contain no gene previously associated with disease development. However both contain a type 1 diabetes susceptibility locus suggesting the presence of global auto immune susceptibility genes.

344F

Association of Adiponectin Plasma Levels in African Americans with SNPs from Two Arrays. *S.G. Buxbaum[1], S. Musani[2], M. Allison[3], J. Kizer[4], S. Redline[5], J.G. Wilson[2], A. Bidulescu[6].* 1) Jackson Heart Study, Jackson State Univ, Jackson, MS; 2) Jackson Heart Study, University of Mississippi Medical Center, Jackson, MS; 3) Department of Family and Preventive Medicine, University of California, San Diego School of Medicine, La Jolla, CA; 4) Weill Cornell Medical College, Ithaca, NY; 5) Division of Sleep Medicine, Harvard Medical School, Boston, MA; 6) Morehouse School of Medicine, Cardiovascular Research Institute and Department of Preventive Medicine and Community Health, Atlanta, GA.

INTRODUCTION: Adiponectin is a moderately heritable biomarker of systemic inflammation and insulin resistance and is a putative predictor of subclinical and clinical cardiovascular disease. Adiponectin levels also have been associated with asthma control and may be associated with rheumatoid arthritis. Four cohorts with adiponectin measurements that included African Americans were analyzed to identify genetic variants associated with adiponectin levels. **METHODS**: Using both the Affymetrix 6.0 (Affy) and the ITMAT Broad-CARe (IBC) SNP arrays, we performed a meta-analysis that included up to 2487 African-Americans for association with log-Adiponectin blood plasma level adjusted for age, sex and body mass index. The IBC chip comprises densely typed SNPs in over 2000 candidate genes for CVD pathways. Samples were from the Candidate gene Association Resource (CARe) cohorts and included data from Jackson Heart Study, the Multi-Ethnic Study of Atherosclerosis (MESA), the Cleveland Family Study (CFS) and the Cardiovascular Health Study (CHS, IBC data only). The thresholds for genome-wide significance were 5×10^{-8} for the Affy data and 2.2×10^{-6} for the IBC data. **RESULTS**: No SNPs were observed to be genome-wide significant in either array. The strongest association for the Affy-based analysis (N=2375) adjusting for global ancestry was at rs4686807 at 3q27.3, $p = 6.01 \times 10^{-7}$. Further adjustment for local ancestry modestly increased the strength of association (1.69×10^{-7}). The most strongly associated SNP in the IBC array (N=2487) was at 6p21.1 with a p-value of 1.37×10^{-5}.

CONCLUSION: Although not genome-wide significant, these analyses confirmed a known locus for adiponectin and identified a potential novel locus. The association at 3q27.3 is of interest because this SNP is within the allergic/atopic asthma related QTL 45 and rheumatoid arthritis QTL 6. Further, the closest gene in RefSeq is *ADIPOQ*, 21.1 kbp away. The association at 6p21.1 is within a gene, *TREM2*, coding for a membrane protein that is a receptor for tyrosine kinase binding protein (TYROBP), a protein that may be involved in signal transduction, bone modeling, brain myelination, and inflammation. *TREM2* is included in the GO pathway 0004872 for receptor activity. Similar to the Affy SNP, this IBC SNP is within the allergic/atopic asthma related QTL 34 and osteoarthritis QTL 22. These findings require replication in other cohorts and a meta-analysis is ongoing.

Family based association analysis of variants in activating FCgR with Kawasaki Disease (KD) susceptibility, IVIG refractoriness, and coronary artery disease. *S. Shrestha[1], H.W. Wiener[1], A. Shendre[1], J.C. Edberg[2], M.A. Portman[3].* 1) Department of Epidemiology, University of Alabama at Birmingham; 2) Division of Clinical Immunology and Rheumatology, Department of Medicine, University of Alabama at Birmingham; 3) Department of Pediatrics, University of Washington, Seattle Children's Hospital.

Kawasaki disease (KD) is the leading cause of acquired heart disease in children. FCg receptors (FCgR) modulate action of gamma-globulin, and the frequencies of single nucleotide polymorphisms (SNPs) in these FCgR genes also vary by race. Trios from three populations (156 Caucasians, 43 Asians, and 52 Hispanics) were genotyped for 11 single nucleotide polymorphisms (SNPs) in FCgRIIA, FCgRIIIA and FCgRIIIB, all located at chromosome position 1q23 within a span of about 200kb, by pyrosequencing using a nested polymerase chain reaction (PCR) approach to ensure gene-specific amplification. In this hypothesis-driven study, we performed the transmission disequilibrium test (TDT) using FBAT on individual SNPs to assess the associations for susceptibility to Kawasaki disease, IVIG refractoriness (IVIG-R) - defined by AHA guidelines, and coronary artery disease (CAD) - defined by persistence of coronary artery Z-score > 2.5 or aneurysm > 6 weeks after IVIG. Race was defined by the principle component analysis using 155 Ancestry Informative Markers (AIMs) and the analyses were limited to families where all members were from the same race. In the additive TDT model, the Fc. RIIA+559 variant showed excess A allele (Histidine) transmission from parents ($z = 3.12$, $p = 0.001$) to KD patients in 182 informative trios. This effect was consistent separately in 26 informative Asian ($z = 2.34$, $p=0.02$) and 105 informative Caucasian families ($z = 2.04$, $p = 0.04$). Likewise, excess transmission of the same A allele in Fc. RIIA+559 occurred among IVIG non-responders (156 informative trios; $z = 2.78$, $p= 0.005$), and mostly in Asians (25 informative trios, $z = 2.66$, $p=0.008$) and patients with CAD ($n = 43$, $z = 2.45$, $p = 0.01$), and mostly in Hispanics (12 informative trios, $z = 2.14$, $p = 0.03$). Other variants examined did not indicate any significant associations. Variants in Fc. RIIA+559 alter recognition of ligand where; the A variant binds human IgG2 with high affinity than the G variant. In our study, excess transmission of the more effective Fc. RIIA+559A variant is related to increased KD susceptibility, IVIG refractoriness, and CAD persistence in different races.

346F

Synergistic effect of ANRIL and BRAP polymorphisms on ankle-brachial index in a Taiwanese population. *P.C. Tsai[1], Y.C. Liao[2,3,4], T.H. Lin[5,6], E. Hsi[1,2], Y.H. Yang[1,7], S.H. Juo[1,8,9].* 1) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 4) Department of Neurology, National Yang-Ming University School of Medicine, Taipei, Taiwan; 5) Division of Cardiology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Department of Internal Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 7) Department of Oral Hygiene, Kaohsiung Medical University, Kaohsiung, Taiwan; 8) Department of Neurology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 9) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan.

Objectives: Single nucleotide polymorphisms (SNPs) on chromosome 9p21 are found to be associated with peripheral artery disease (PAD) in several studies, but have not been investigated in Asians. PAD was often diagnosed by ankle-brachial index (ABI) value. The aim of the present study is to evaluate the effects of SNPs on 9p21 region alone with the BRAP gene on ABI in a Chinese population. Methods: A total of 739 high-risk subjects were enrolled. SNP rs11066001 on BRAP and three SNPs (rs1333040, rs2383207 and rs1333049) on 9p21 were genotyped. The genotype-phenotype associations were tested by multivariate regression analysis. The combined effects of 9p21 and BRAP were evaluated by both multiplicative and additive models. The gene-environmental interaction between genes and smoking was examined. Results: SNP rs2383207 on 9p21 was significantly associated with lower ABI values (adjusted p=0.02). Similar to our previous findings, G allele of rs11066001 on BRAP was associated with lower ABI values (adjusted p=0.017). A dose-responsive relationship between ABI values and the number of risk alleles from both significant SNPs was observed (trend p =0.0003). The association between ABI and combined genetic effect was stronger in ever-smokers than in non-smokers. A significant interaction between genes and smoking were found (adjusted p=0.043). Conclusion: Chromosome 9p21 was associated with ABI in a Taiwanese population. An additive effect between variants on 9p21 and BRAP were shown. The combined genetic effect might be enhanced by smoking exposure. The findings of potential gene-gene interaction and gene-environment interaction are interesting, but need further investigation.

347F

Genetic and molecular characterization of variants associated with circulating interleukin-18 levels and cardiovascular disease. *T. Zeller[1,3], R.B. Schnabel[1,3], J. Dupuis[2], P.S. Wild[3], R. Castagne[4], J. Baumert[5], J. Kruppa[6], A. Schillert[6], B. Thorand[5], T. Munzel[3], K.J. Lackner[7], A. Ziegler[6], W. Koenig[8], E.J. Benjamin[2], L. Tiret[4], S. Blankenberg[1,3].* 1) Department of Cardiology, Medical University Hamburg-Eppendorf, Hamburg, Hamburg, Germany; 2) National Heart, Lung and Blood Institute's and Boston Univ's Framingham Heart Study, Boston, MA, USA; 3) Medical University Center Mainz, Department of Medicine 2, Mainz, Germany; 4) INSERM UMRS 937, Pierre and Marie Curie University and Medical School, Paris, France; 5) Helmholtz Zentrum Muenchen, Neuherberg, Germany; 6) Insitut für medizinische Biometrie und Statistik, IMBS Lübeck, Universitätsklinikum Schleswig-Holstein, Campus Lübeck, Lübeck, Germany; 7) Medical University Center Mainz, Institute of Clinical Chemistry and Laboratory Medicine, Mainz, Germany; 8) Department of Internal Medicine 2, Cardiology, University of Ulm Medical Center, Ulm, Germany.

Interleukin-18 (IL-18) is a pleiotropic cytokine centrally involved in the immune response. A role of IL-18 in cardiovascular disease has been suggested. In a recent genome-wide association study we explored the genetic underpinnings of circulating IL-18 levels and identified a novel locus around in the NLRC4 (NLR family, CARD domain containing 4) gene. NLRC4, a member of the NOD-like receptor family, is a critical component of the inflammasome involved in caspase-1 and IL-18 activation. The aim of this study was to further explore the genetic and molecular basis of the relation of the NLRC4 locus to IL-18 levels and subsequently to cardiovascular diseases. As NLRC4 is involved in the activation of caspase-1, we investigated the functional consequences of genetic variations identified by GWAS analysis in relation to caspase-1 activity in PBMCs and IL-18 serum levels in healthy individuals (n=398). Carriers of the allele associated with lower IL-18 levels showed reduced capase-1 activity. Further, analyses of linkage disequilibrium (LD) structures identified two different LD blocks associated with IL-18 levels: one LD block encompassing single nucleotide polymorphisms (SNPs) spanning genes NLRC4, SLC30A6 and SPAST, and one LD-block encompassing SNPs spanning genes YIPF4 and BIRC6. Additional expression quantitative trait loci (eQTL) analysis showed association of SNPs located in the 5'and 3' UTR of NLRC4 (rs479333 p=2.41x10-5 and rs430759 p=1.08x10-5), as well as downstream of SPAST (rs7601267 p= 4.92x10-5) to expression of NLRC4 transcript levels, indicating different regulatory regions involved in the regulation of NLRC4 expression. Investigating the genetic and molecular basis of the NLRC4 locus revealed different regulatory regions involved in NLRC4 expression and function of the protein and provides further insights into the genetic basis of circulating IL-18 levels and its relation to cardiovascular disease.

Mutations in *ACTA2* in a British cohort of TAAD patients. *G. Arno[1], J.A. Aragon-Martin[1], S. Harris[1], A. Saggar[2], M. Jahangiri[3], A.H. Child[1].* 1) Cardiac and Vascular Sciences, St George's University of London, London, United Kingdom; 2) Clinical Genetics Unit, St George's University of London, London, United Kingdom; 3) Department of Cardiothoracic Surgery, St George's Healthcare NHS Trust, London, United Kingdom.

Background: Thoracic aortic aneurysm and dissection (TAAD) is a feature of several genetic conditions, such as Marfan (MFS) and Loeys-Dietz (LDS) syndromes. However, there is a growing body of work suggesting that non-syndromic TAAD is also of genetic origin. Furthermore, up to 21 % of non-syndromic cases of TAAD have been found to be familial. Recently studies have implicated mutations in *ACTA2* (MIM#102620) as a cause of 14-21% of familial and 2.5-3.8% of sporadic TAAD. It was the aim of this study to determine the frequency of *ACTA2* mutation in a consecutive series of TAAD patients attending a British MFS cardiac genetics clinic. Diagnosis was based on pedigree, physical examination, echocardiogram, CT and MRI studies and operative reports. **Method:** A total of 78 UK patients (62M:16F, mean age 48.16, ±13.43) with known TAAD who did not fulfill the revised Ghent criteria for MFS, and with no demonstrable mutations in *FBN1* or *TGFBR2* were recruited to this study. These patients were screened for mutations in all exons of *ACTA2* including intron/exon boundaries. **Results:** Novel non-synonymous missense mutations were identified in 3/78 (3.85%) probands. These mutations comprised: in exon 3, p.Arg64Lys (c.191G>A); in exon 6 p.Arg179Cys (c.535C>T) affecting the same amino acid as a previously reported TAAD mutation (p.Arg179His); in exon 7 p.Lue244Phe (c.732G>T). None of the mutations were found in 100 control chromosomes or are reported in any SNP databases. **Conclusion:** This study supports data from previous studies that link mutations in *ACTA2* with TAAD. In our cohort of UK patients, the detection rate is similar to that found in previous studies of consecutive sporadic cases of TAAD and lower than that found for familial cases. This reflects the mixed familial and sporadic nature of the UK patient population studied.

349F

Identification of rare variants in familial hypoalphalipoprotenemia using exome sequencing. *N. Gonzaludo[1,2], P.L.F. Tang[2], C. Pullinger[2], M. Malloy[2], J. Kane[2], P.Y. Kwok[2].* 1) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA; 2) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA.

Hypoalphalipoproteinemia (HA) is characterized by decreased serum high-density lipoprotein cholesterol (HDL-C) levels (< 10th percentile for age and sex) and low apolipoprotein A-1 (APOA1). HDL demonstrates antiatherogenic properties and mediates removal of cholesterol from the artery wall through reverse cholesterol transport. Low HDL-C is a risk factor for coronary artery disease and is a key element in the metabolic syndrome. Serum HDL-C levels have heritability estimates of 40-60%. While common variants in lipid metabolism-related genes are associated with HA, family-based studies suggest the disorder is polygenic, and the primary genetic causes of familial HA are still largely unknown. Rare variants and private mutations, in addition to common variants in candidate genes, may account for variations seen within a family. In order to assess the genetic basis of familial HA, we analyzed a family of four with HA using whole exome sequencing. Levels of HDL-C varied among family members, with the son displaying severely low levels (as low as 4 mg/dL). While less severely affected, the parents and a daughter also displayed low levels of HDL-C. Exome sequencing was performed using paired-end sequencing on Illumina HiSeq 2000. We used Illumina TruSeq Exome Enrichment for capture, targeting 201,121 exons from 20,794 genes. For each individual, approximately 50 million sequence reads were generated, with a median base coverage of ~50X and 85% of reads having at least 10x coverage. Of these reads, ~80% aligned to hg19 version of the human genome. We identified ~35,000 SNPs per individual, with 5% not reported in dbSNP version 130. Preliminary analysis shows a common non-synonymous variant in ABCA1 (V825I) in the 3 most affected individuals. Deficiency in ABCA1 is known to result in HA or Tangier disease. Additionally, previously reported SNPs in approximately 20 genes related to lipid metabolism were found in all individuals. All family members had reference alleles for known SNPs in APOA1. While these common variants may explain some portion of the phenotype, we suspect that rare variants in the son may be responsible for his severely low HDL-C levels. Current analysis is underway to identify such variants, as well as interacting genes that may be causal for the severe phenotype in the male child. Findings from our analysis may help to elucidate the genetic basis of this disorder.

350F

Mutation spectrum of aortic hypoplasia-vascular calcification syndrome by whole exome sequencing. *I.J. Kullo, K. Ding, K. Shameer.* Division of Cardiovascular Diseases, Mayo Clinic, Roichester, MN.

We conducted whole exome sequencing (WES) in two affected siblings with premature vascular disease and their unaffected parents. The affected siblings had aortic hypoplasia and diffuse arterial calcification, calcific aortic valve stenosis, and premature cataracts. The male sibling presented with hypertension at age 17 and the female sibling presented with cataract at age 30. Both were subsequently noted to have a hypoplastic aorta with extensive calcification, features that were not present in the parents. Using WES, we investigated the mutation spectrum of the two siblings and their parents. Exome capture was performed using the SureSelect Human All Exon 50 MB System (Agilent Technologies). Sequencing was performed using Illumina Hiseq 2000™ platform and 100 base paired-end reads were generated. A bioinformatics pipeline was created for variant discovery, including quality control, sequence alignment, base quality score recalibration, and variant calling and filtering. The analysis-ready variants were annotated using SeattleSeq Annotation server, including both known (dbSNPs) and private variants. Analysis of depth of coverage indicated that at least 80% of the exonic regions were present >8 times in the four patients. We assumed a recessive pattern of inheritance and identified 10 missense mutations in 10 genes and one splice-site mutation in one gene, segregating in the affected siblings but not in the unaffected parents. Further studies are underway to confirm the causal mutation that led to aortic hypoplasia-vascular calcification in the two siblings.

A Genome-Wide Association Scan of Lipids and Lipoprotein subclasses in African Americans Including the Sea Island Gullah. *W.M. Chen[1], Y. Huang[1], F. Chen[1], K.L. Keene[1], J. Divers[2], J.C. Mychaleckyj[1], U. Nayak[1], X. Hou[1], D.L. Kamen[3], K.J. Hunt[3], I.J. Spruill[3], J.K. Fernandes[3], M. Cushman[4], W.T. Garvey[5], M.M. Sale[1].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Dept. Biostatistical Sciences, Wake Forest University, Winston-Salem, NC; 3) Medical University of South Carolina, Charleston, SC; 4) University of Vermont; 5) Dept. Nutrition Science, University of Alabama at Birmingham, AL.

To identify genetic basis of variations in lipids and lipoprotein subclasses in populations with African ancestry, we conducted a GWAS scan of lipoprotein subclasses, measured using Liposcience's NMR-based Lipoprofile assay, in 3,888 participants, including 1,492 Gullah-speaking African Americans from Project SuGAR in families living on the coastal islands of South Carolina (the Gullah) and 2,396 African Americans residing in the Southeast from REGARDS study. The lipoprotein subclasses include 24 heritable quantitative traits. The variance component model adjusting for sex, age, diabetes status, lipid medication, and ancestry principal components was used to take into account family structure in the association analysis at each of 851,705 autosome and X-chromosome SNPs. All traits were transformed to be normally distributed according to their normal quantiles prior to association analysis. There was no inflation in our GWAS scan results (GC lambda ≤ 1.01 in all scans). The strongest association was at the *CETP* gene on chromosome 16 for trait HDL ($P=1.1\times10^{-21}$) and the variant explained 2.7% of total phenotypic variance. This gene was also associated with large HDL particles (HLP, $P=2.6\times10^{-13}$), NMR calculated HDL cholesterol (NHC, $P=3.2\times10^{-12}$), LDL mean particle size (LZ, $P=2.5\times10^{-8}$) and HDL mean particle size (HZ, $P=7.2\times10^{-8}$). The second strongest association was at the *APOE* gene on chromosome 19 for trait triglyceride ($P=1.4\times10^{-13}$), and this gene was also associated with LDL particles (LDLP, $P=2.4\times10^{-10}$), medium HDL particles (HMP, $P=3.9\times10^{-10}$), LDL ($P=1.0\times10^{-9}$), and total cholesterol ($P=6.2\times10^{-8}$). We confirmed association at the *PLTP* gene on chromosome 20 for trait small HDL particles (HSP, $P=9.1\times10^{-8}$). In addition to the successful replication of *CETP, APOE* and *PLTP* genes for lipid traits in African Americans, we also identified a novel association at *SNTG1* gene (chromosome 8) for small VLDL particles (VSP, $P=3.9\times10^{-9}$) and marginally significant association at *ARNT2* gene (chromosome 15) for Lipoprotein insulin resistance (LPIR, $P=7.4\times10^{-8}$). Additional genetic variants with associations of lower statistical significance will be further investigated by meta-analysis with other GWAS studies. These data advance our understanding of the genetic influences on lipoprotein subclass phenotypes in people of African ancestry, and provide the basis for studies assessing the role of these genes in mediating cardiometabolic disease risk in African Americans.

352F

Genome-wide association analyses in up to 181,171 individuals reveal 14 new loci associated with heart rate. *M. den Hoed[1], T. Esko[2], M. Eijgelsheim[3], D.M. Evans[4], I.M. Nolte[5], A.V. Segre[6], Y.S. Cho[7], H.J. Westra[8], R.E. Handsaker[9], D.P. Strachan[10], T. Johnson[11], K. Stefansson[12], M.C. Cornelis[13], P.F. O'reilly[14], C. Ladenvall[15], N.R. Poulter[16], D. Cusi[17], P. van der Harst[18], W. Zhang[19], D. Albanes[20], Z. Kutalik[21], O.T. Njajou[22], T. Tanaka[23], A.U. Jackson[24], P. Salo[25], R.J.F. Loos[1], HRgen consortium, RRgen consortium, Global BPgen consortium and CARDIoGRAM consortium.* 1) Epidemiology Unit, Medical Research Council, Cambridge, Cambridgeshire, United Kingdom; 2) Estonian Genome Center and Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia and Estonian Biocenter, Tartu, Estonia; 3) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 4) MRC CAiTE centre, School of Social and Community Medicine, University of Bristol, Bristol, UK; 5) Unit of Genetic Epidemiology & Bioinformatics, Department of Epidemiology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 6) Center for Human Genetic Research and Department of Molecular Biology, Massachusetts General Hospital, Boston, Massachusetts, USA and Program in Medical and Population Genetics, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambrid; 7) Center for Genome Science, National Institute of Health, Seoul, Korea; 8) Department of Genetics, University Medical Center Groningen and University of Groningen, Groningen, The Netherlands; 9) Department of Genetics, Harvard Medical School, Boston, Massachusetts, USA and Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 10) Division of Population Health Sciences and Education, St George's, University of London, UK; 11) Clinical Pharmacology and the Genome Centre, William Harvey Research Institute, Barts and The London School of Medicine and Dentistry and NIHR Cardiovascular Biomedical Research Unit, Queen Mary University of London, London, UK; 12) deCODE genetics and Faculty of Medicine, University of Iceland, Reykjavik, Iceland; 13) Nutrition, Harvard School of Public Health, Boston, MA, USA; 14) Department of Epidemiology and Biostatistics, Imperial College London, London, UK; 15) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University and Lund University Diabetes Centre, Malmö, Sweden; 16) ICCH, Imperial College London, UK; 17) Department of Medicine, Surgery & Dentistry, University of Milano and Filarete Foundation, Milano, Italy; 18) Department of Cardiology, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 19) Epidemiology and Biostatistics, Imperial College London, London, UK; 20) Division of Cancer Epidemiology and Genetics, US National Cancer Institute, Bethesda, Maryland, USA; 21) Department of Medical Genetics, University of Lausanne, Lausanne, Switzerland; 22) Department of Medicine, Institute for Human Genetics, University of California, San Francisco, California, USA; 23) Clinical Research Branch, National Institute on Aging, Baltimore, Maryland, USA; 24) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Michigan, USA; 25) Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland and The Institute of Molecular Medicine, University of Helsinki, Helsinki, Finland.

A higher resting heart rate has been associated with an increased risk of cardiovascular diseases and (cardiovascular) mortality. To date, genome-wide association studies have identified seven loci that showed associations with heart rate. We aimed to identify novel genetic loci by examining associations between ~2.7 million SNPs and resting heart rate in up to 92,364 individuals of white European and Indian Asian descent. Variants from 42 loci ($p<1x10^{-5}$) were followed up in up to 88,823 additional individuals of white European descent. Combined analyses in up to 181,171 individuals confirmed associations with heart rate for variants in 21 loci ($p<5x10^{-8}$); we identified 14 new loci and confirmed the seven previously established loci. A genetic predisposition score, comprising the number of heart rate increasing alleles in the most significant signals for the 21 loci, was significantly associated with heart rate in 4,000 12-year old children (beta=0.35±0.06 beats/min/effect allele, $p=2.8x10^{-9}$) and in 5,053 adults (beta=0.47±0.07 beats/min/effect allele, $p=1.9x10^{-11}$). Some variants tagged copy number variants (in *C6orf170*, near *GNG11*/*GNGT1*), missense variants (in *MYH6*, *UFSP1*, *KIAA1755*, *CCDC141*, *B3GNT7*, *TFPI*) and variants in transcription factor binding sites (*C6orf204*, *GJA1*) ($r^2>0.8$). Five variants showed association with expression levels of 11 nearby transcripts in blood (*C11orf10*, *FADS1*, *BEST1*, *FTH1*, *FADS2*, *RAB3IL1*, *C6orf204*, *TRIP6*, *NCL*, *SNORD20*, *GNG11*, $p<1.6x10^{-3}$). Many of the 21 loci contain known regulators of angiogenesis (*EPHB4*, *TIMP1*, *PLXNA2*, *TFPI2*, *CALCRL*), calcium metabolism (*FADS1*/*FADS2*, *PLN*), cardiac contractility (*MYH6*/*MYH7*, *TTN*), pace making (*GJA1*, *HCN4*, *CHRM2*), and cardiac development (*FLRT2*, *NKX2-5*). Mutations in many of these positional candidate genes have previously been associated with cardiovascular diseases. Pathway analyses (MAGENTA) confirmed enrichment for genes involved in cardiomyopathies. None of the 21 most significant SNPs showed significant associations with risk of coronary artery disease and myocardial infarction, while four variants associated with increased heart rate tended to be associated with reduced systolic blood pressure (in/near *GJA1*, *PLXNA2*, *FLRT2*, *TFPI*, $p<0.05$). In conclusion, many of the confirmed loci harbour genes that point towards plausible and promising pathways that may provide new insights in the aetiology of heart rate regulation and potentially also cardiovascular risk factors and diseases.

353F

Functional Analysis of the TRIB1 Locus in Coronary Artery Disease (CAD). *A. Douvris, P. Lau, O. Jarinova, T. Naing, R. McPherson.* University of Ottawa Heart Institute, Ottawa, Ontario, Canada.

Genome-wide association studies (GWAS) have identified several common genetic variants associated with CAD and CAD risk factors. The TRIB1 locus (8q24.13) is a novel locus associated with plasma TGs, LDL-c, and CAD risk. As part of the Ottawa Heart Study, we have demonstrated that the relationship of this locus to CAD risk is entirely mediated by effects on plasma lipids. Trib1 is a regulator of MAPK activity, and recently, it has been has been shown that Trib1 also regulates hepatic lipogenesis and VLDL production in mouse models. However, the functional relationship between common single nucleotide polymorphisms (SNPs) at the TRIB1 locus and plasma lipid traits is unknown. Specifically, the TRIB1 locus as identified by GWAS comprises a cluster of SNPs significant for TGs, LDL-c, and CAD within an intergenic region 25kb to 50kb downstream of the TRIB1 coding region. By phylogenetic footprinting analysis, we identified an evolutionarily conserved region (CNS1) within the risk locus. DNA sequencing revealed that this region harbors two common SNPs in tight linkage dysequilibrium with GWAS risk SNPs and that also associate significantly with CAD. We investigated the regulatory potential of CNS1 using various luciferase reporter assays in HepG2 cells and demonstrate that this region has promoter activity and that the risk allele of one SNP in this region significantly reduces luciferase activity. Furthermore, a database search for ESTs within the risk locus revealed an EST directly downstream of CNS1, which we believe to be its promoter. We performed 3'/5' RACE using HepG2 RNA and identified multiple variants of this EST. We hypothesize that this EST is a long non-coding RNA since it lacks any significant ORF. Given that it is an intergenic RNA, and has proximity to TRIB1, we hypothesize that it may function to regulate the expression of the neighboring genes. Further, our promoter studies indicate that one of the risk alleles may contribute to decreased levels of this non-coding RNA, thereby constituting a link between the GWAS risk locus, plasma lipids, and CAD.

354F

A genome-wide association study of essential hypertension in an Australian population using a DNA pooling approach. *J.Y. Fowdar[1], Y. Lu[2], S. Macgregor[2], L.R. Griffiths[1].* 1) Genomics Research Centre, Griffith Health Institute, Griffith University, Gold Coast, Queensland, Australia; 2) Qld Statistical Genetics Laboratory, Queensland Institute of Medical Research, Brisbane, Queensland, Australia.

Essential hypertension (EH) is the leading cause of cardiovascular disease and is implicated in more than 7 million deaths each year from ischaemic heart disease and stroke. The prevalence of hypertension worldwide has reached epidemic proportions with more than 1 billion people suffering from the condition. Elucidating the underlying mechanisms of EH is therefore highly important for improved treatment and prevention strategies. We conducted a genome-wide assocation study (GWAS) using Illumina 1M-Duo SNP arrays on an Australian Caucasian population using DNA pools. DNA-pooling has been shown to significantly reduce the cost of array-based GWAS. 409 cases and 409 age-, sex-, and ethnicity-matched controls were combined into separate DNA pools consisting of equimolar amounts of each DNA sample. Four replicates of each pool were hybridized to the SNP arrays (a case and a control pool on each duo array) according to the manufacturer's protocol, and scanned using an Illumina Beadarray station. Raw fluorescence intensity data was processed for quality control and pooled allele frequencies were calculated. The following seven markers were found to have the highest p-values: rs34870220 (4.32E-07), rs4836667 (5.54E-07), rs1928277 (6.76E-07), rs1599961 (6.86E-07), rs11170043 (7.09E-07), rs12711538 (7.72E-07) and rs11177752 (8.08E-07), although none of them reached genome-wide statistical significance. These markers were located in or close to the following genes respectively: ASGR1, PRRX2, NHSL1, NFKB1, KRT7, GLI2 and LRRC10. The markers for NFKB1 and GLI2 were then genotyped on individual samples using Taqman assays (ABI 7900HT). Both markers were in Hardy-Weinberg equilibrium. Both allele and genotype frequencies for NFKB1 (p=0.01 and p=0.04 respectively) and GLI2 (p=0.001 and p=0.004 respectively) were found to be significantly different between the hypertensive and normotensive populations. The remaining five markers are in the process of being genotyped on individual samples. A gene-based association test, which is more appropriate for pathway analysis, is currently being conducted to investigate potential candidate gene pathways and the implicated SNPs for NFKB1 and GLI2 will be investigated in an independent hypertensive sib-pair population.

355F

Evidence for several genetic variants affecting lipoprotein (a) level on chromosome 6q25-26 in the Old Order Amish. *M. Fu, W. Lu, Q. Gibson, X. Shi, J. O'Connell, B. Mitchell, A. Shuldiner.* Dept Med, Div Endocrinology, Univ Maryland, Baltimore, MD.

Lipoprotein (a) [Lp(a)] is an independent risk factor for atherosclerosis-related events such as coronary artery disease, stroke, and restenosis after angioplasty. We performed a genome-wide association scan (GWAS) for genetic variants that associated with serum Lp(a) levels in the Old Order Amish, a relatively homogenous population in terms of both genetic ancestry and lifestyle characteristics. Using the Affymetrix 500K chip, we successfully genotyped 382,935 single-nucleotide polymorphisms (SNPs) in 861 subjects from the Heredity and Phenotype Intervention (HAPI) Heart Study, which were used to impute all autosomal SNPs in HapMap (~2.5 million SNPs) by MACH (version 1.0.15), using the publicly available phased haplotypes from HapMap (release 22, build 36, CEU population) as a reference panel. We identified 81 common variants showing significant association with age-, age2- and sex-adjusted Lp(a) level (P =5 x 10-8 to 2.83 x 10-25). The 81 common variants span ~3.3 Mb on chromosome 6q25-26 and were within or flanking 26 genes including LPA. Common variants in four genes (SNX9, FNDC1, IGF2R, and AGPAD4) were significantly associated with Lp(a) levels; however, no SNP in LPA itself was significantly associated with Lp(a) levels. Together, these variants explained 14.2% of the variation in Lp(a) levels. Linkage disequilibrium analysis revealed that these significantly associated SNPs distribute into different blocks suggesting that multiple genes on chromosome 6q25-26 may regulate Lp(a) levels. We further analyzed these variants with LDL, HDL, triglyceride, aortic calcification score, coronary calcification score, and diastolic carotid luminal diameter. After adjusting for multiple comparison, a number of the common variants associated with Lp(a) were also significantly associated with diastolic carotid luminal diameter (rs1982291; P < 5 x 10-5). Association of the SNPs with Lp(a) in this region have been reported in other populations. In conclusion, we have confirmed that common variants on chromosome 6q25-26 are significantly associated with Lp(a) levels and diastolic carotid luminal diameter. Studies characterizing further variation in the genes in this region and their functional consequences on Lp(a) levels are warranted.

A GWAS from the Vitamin Intervention for Stroke Prevention (VISP) clinical trial identifies variants that influence measures of one carbon metabolism. *K. Keene[1], F. Chen[1], W.M. Chen[1], F.C. Hsu[2], J. Mychaleckyj[1], K. Doheny[3], E. Pugh[3], H. Ling[3], C. Laurie[4], S. Gogarten[4], E. Bookman[5], B. Worrall[1], M. Sale[1], GARNET.* 1) University of Virginia, Charlottesville, VA; 2) Wake Forest University School of Medicine, Winston Salem, NC; 3) Johns Hopkins University School of Medicine, Baltimore, MD; 4) University of Washington, Seattle, WA; 5) National Human Genome Research Institute, Bethesda, MD.

Every 40 seconds, someone in the United States will have a stroke. Unfortunately, nearly 40% of stroke survivors will suffer a recurrent stroke within 5 years of their first stroke. The concept that genetics influence stroke risk is well supported by epidemiological studies. We have performed a Genome-wide association study (GWAS), using the Illumina Omni 1M SNP platform, in 2,100 stroke patients from the Vitamin Intervention for Stroke Prevention (VISP) trial. VISP was a controlled, double blinded clinical trial, designed to determine whether the daily intake of high dose folic acid, vitamins B6 and B12 reduce recurrent cerebral infarction. Extensive quality control (QC) measures were performed, resulting in a total of 737,081 SNPs for analysis. We have performed genome wide association analyses for baseline quantitative measures of homocysteine (baseline and post methionine load measures), folate, Vitamins B12 and B6, using linear regression approaches implemented in PLINK. Multidimensional Scaling (MDS), implemented in KING, was utilized to address confounders due to population substructure. Inverse normal transformation was performed for each of the quantitative traits, prior to analysis. Genome wide association analyses were performed using age, sex and the top 10 principal components as covariates. There is no inflation in our GWAS scan results (GC lambda ≤ 1.01 in all scans). We have observed several associations that exceed genome wide significance (≤10 -8). The strongest association was observed with a non-synonymous SNP (nsSNP), located in the CUBN gene, for baseline Vitamin B12 (P=1.76×10-13; beta=-0.22). Two additional CUBN intronic SNPs were also strongly associated with B12 (P= 2.92×10-10; beta=-0.19 and 4.11×10-10; beta=-0.18). A second nsSNP, located in the TCN1 gene, was also associated with baseline measures of Vitamin B12 (P= 5.148×10-11; beta=-0.29). Additionally, we identified several hits on chromosome 6, in the CNPY3-GNMT-PEX6 gene region, that were associated with post methionine load homocysteine measures (P values ranging from 2.14×10-13 to 9.95×10-9). Our GWAS scans have successfully replicated associations for SNPs in the ALPL gene for measures of Vitamin B6. Our GWAS study has identified novel associations while also replicating previous GWAS hits for genes that contribute to measures of post methionine load homocysteine, Vitamins B12 and B6.

357F

Genome-wide Association Study, Meta-Analysis and Linkage Study of von Willebrand Factor and Gamma-Prime Fibrinogen Plasma Levels in a Healthy Young Cohort. *A. Ozel[1], K. Desch[2], D. Siemieniak[3], D. Ginsburg[1,3], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 3) HHMI, University of Michigan, Ann Arbor, MI.

von Willebrand factor (VWF) is an abundant plasma glycoprotein that regulates hemostasis. Gamma-prime fibrinogen (GPF) is an isoform of fibrinogen and a component of the blood-clotting complex. Its role in cardiovascular risk prediction has been recently proposed. Plasma levels of VWF and fibrinogen are highly variable among healthy people, with ~70% and ~50% of their variance, respectively, attributable to inherited factors. We performed genome-wide association studies on a healthy sibling cohort of 1152 subjects (ages 14-35) in 502 sibships, focusing on the European subset (940 subjects), using >800,000 genotyped SNPs (Illumina Omni1-Quad) and ~7.5 million imputed SNPs (based on the 1000 Genomes Project data). Plasma VWF and GPF levels were determined by Alphalisa (Perkin Elmer) assay; and heritability (h^2) was 68% and 54%, respectively. VWF plasma levels show significant association with variants at the ABO locus ($p\sim10^{-36}$), consistent with previous reports. Suggestive evidence of association and linkage is found near the VWF gene and a number of other loci. Preliminary linkage analysis identified the ABO locus on chromosome 9 and novel loci on chromosomes 2, 7 and 21. The latter 3 loci were not detected in the current or previously reported association studies. Similar analyses of GPF levels reveal significant association and linkage signals in the fibrinogen gene cluster on chromosome 4 ($p\sim10^{-126}$, LOD>9) and a novel locus on chromosome 16 ($p\sim10^{-5}$, LOD>4). A meta-analysis of VWF involving the Atherosclerosis Risk in Communities Study (ARIC) data confirms several previously identified loci, with strong agreement in the direction of the effects. Replication in another healthy young cohort of Irish origin is underway. These results provide new insight into the regulation of hemostasis, may identify novel genetic modifiers of bleeding and thrombosis risk, and suggest that linkage analysis of blood clotting traits may reveal novel loci undetectable by association studies. The study is supported by NIH grant HL039693 and is part of the GENEVA (Gene Environment Association Studies) Consortium.

358F

Genome-wide association analysis identifies TYW3/CRYZ and NDST4 loci associated with circulating resistin levels. *Q. Qi[1], C. Menzaghi[2], S. Smith[3], L. Liang[4], J. Ding[3], T. Harris[3], V. Trischitta[2, 5], F. Hu[1, 4, 6], Y. Liu[3], L. Qi[1, 6].* 1) Department of Nutrition, Harvard School of Public, Boston, MA; 2) Research Unit of Diabetes and Endocrine Diseases, IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo, Italy; 3) Division of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 4) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 5) Department of Experimental Medicine, Sapienza University of Rome, Italy; 6) Channing Laboratory, Department of Medicine, Harvard Medical School, Boston, MA.

Resistin has been associated with insulin resistance, inflammation, and risk of type 2 diabetes and cardiovascular disease. However, little is known about the genetic determinants for circulating resistin levels. We conducted the first genome-wide association (GWA) study on the plasma resistin levels in individuals of European ancestry drawn from the two independent studies: the Nurses' Health Study (NHS, N=1587) and the Health, Aging and Body Composition Study (HABC, N=1661). The SNPs identified in the GWA analysis were replicated in an independent cohort of Europeans (N=626). Gene expression quantitative trait loci (eQTL) analyses were performed to examine the positional candidate genes of the identified loci. We also measured resistin mRNA levels in 47 type 2 diabetic subjects. We identified two novel loci near NDST4 gene (4q25) and TYW3/CRYZ gene (1p31), associated with resistin levels at a genome-wide significant level, best-represented by SNP rs13144478 (P=6.19×10-18) and SNP rs3931020 (P=6.37×10-12), respectively. In eQTL analyses, we observed a significant cis association between the SNP rs3931020 and CRYZ gene expression levels (P=3.68×10-7) (SNP rs13144478 or related SNPs near NDST4 gene was not available in the gene expression database). A SNP rs277369 in strong LD with rs3931020 (r2=0.711) showed the most significant association with CRYZ gene expression levels (P= 6.81×10-24). We also found another SNP rs1969111 (in strong LD with rs3931020, r2=0.783) significantly associated with TYW3 gene expression levels (P=1.86×10-8). Moreover, the SNPs rs3931020 was significantly associated with resistin mRNA levels (P=0.02). Our results suggest that genetic variants in TYW3/CRYZ and NDST4 loci may be involved in regulation of circulating resistin levels.

359F

Genome-wide association studies identify 15 loci with novel associations with plasma fibrinogen levels. *M. Sabater-Lleal[1], J. Huang[2], The FibrinoGEN Consortium.* 1) Atherosclerosis research Unit, Karolinska Institutet, 17176-Stockhom, Sweden; 2) National Heart, Lung and Blood Institute's Framingham Heart Study, Framingham, MA 01702.

Introduction: Fibrinogen is a major coagulation protein under strong genetic regulation with a central role in wound healing and thrombosis, and it also represents an important marker for acute inflammation. In addition, high fibrinogen concentration is an independent risk factor for cardiovascular disease, including coronary artery disease (CAD), stroke, and venous thromboembolism (VTE). Two recent meta-analyses of genome-wide association (GWA) studies confirmed associations with *FGB* and revealed new candidate loci harboring regulatory variants affecting plasma fibrinogen concentration. However, the known variants explain only a small part of the variability of this phenotype and more associated variants are likely to exist. **Methods and Results**: Here we present the largest meta-analysis for fibrinogen GWA studies, including a discovery analysis in 91,435 individuals of European ancestry from 28 cohorts plus further analysis in an additional 8,307 African Americans from 7 cohorts, in total analyzing around 2.7 milion SNPs. Overall, we have identified 23 genome-wide significant loci for fibrinogen levels, among which 8 represent replications of previously described associations and 15 are newly identified fibrinogen-associated loci. Secondary analysis conditional on the 23 most strongly associated SNPs revealed the presence of 2 independent signals on *IRF1* locus. Candidate genes at the newly identified fibrinogen-associated loci include inflammation genes (*LEPR*, *IL1R1*) and transcription activators (*ATF1, JMJD1C*). Validation of these findings in African American samples is ongoing. In addition, we are currently examining the newly identified loci in association with VTE and CAD. **Discussion**: The present study represents by far the largest effort aiming at the identification of novel loci that underlie variation in plasma fibrinogen concentration. Our results could help to understand the regulation of plasma fibrinogen levels as a quantitative trait conferring susceptibility to cardiovascular disease.

360F

Genome-wide Association Study of Vascular Inflammatory Markers Suggests Novel Candidate Genes Associated with Atherosclerosis and Coronary Artery Disease. *B. Suktitipat[1,3], D. Vaidya[2], L.R. Yanek[2], T.F. Moy[2], R.A. Mathias[2], J.H. Young[1,2], L.C. Becker[2], D.M. Becker[2], A.F. Wilson[3], M.D. Fallin[1].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Medicine, the Johns Hopkins Medical Institutions, Baltimore, MD; 3) Genometric Section, Inherited Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

Background: Inflammatory biomarkers in atherosclerosis, such as CRP, IL-6 and MCP-1, have been associated with the risk of coronary artery disease (CAD). In this study, we performed genome-wide association analyses to study all three inflammatory markers in both African Americans and European Americans with the goal to identify novel genetic susceptibility to inflammation and atherosclerosis. **Methods:** Healthy members of European-American and African-American families from the GeneSTAR study, which originally selected families of early-onset CAD patients, were included in this study (556 families, 2065 individuals, mean age 44 ± 12; 42% men). Genotypes from the Illumina human 1Mv1_c SNPchip were screened for association with serum inflammatory marker levels with generalized linear models adjusted for age and sex; Generalized Estimating Equations (GEE) were used to accommodate the family correlations. These statistical analyses were confirmed in family-based variance-components analysis. **Results:** The strongest associations were seen between MCP-1 levels and *FARS2* ($p = 1.6\times10^{-7}$) and *MACROD2* ($p = 1.6\times10^{-7}$). The strongest association for CRP was for a SNP near *BDH1* ($p = 8.3\times10^{-7}$); and the strongest associations with IL-6 levels were at SNPs near *ZNF385D* ($p = 1.5\times10^{-6}$). Additional genetic variants with highly suggestive results ($p \le 1\times10^{-5}$) were found in *BACH2*, *SAP130*, *DENND1B*, *KIF26B*, *SVOPL*, *CDH23*, *C14orf145* for CRP levels; *TAP2*, *CNTN4*, *KIAA0391* for IL-6 levels; and *EPHB2*, *RAD51L1*, *COTL1* for MCP-1 levels. No overlapping signals across the three inflammatory markers reached genome-wide statistical significance despite their biological relationship. However, highly suggestive genetic association signals implied more similar biological control between IL-6 and CRP, than for MCP-1. In addition, previously published GWAS signals were replicated between MCP-1 and *DARC*, and between CRP and variants in *CRP*, *HNF1A*, and *GCKR* ($p \le 0.05$). **Conclusion:** Several suggestive SNP associations implicated plausible novel candidate genes for inflammatory markers and replicated previously reported findings. Further investigation of these signals is warranted and may help identify novel pathways associated with atherosclerosis and CAD.

Cytokine (IFN-. , IL-6, TNF-(, TGF-) 1 and IL-10) genotyping in Turkish Children with acute rheumatic fever. *N. Col Araz[1], S. Pehlivan[2], O. Baspinar[3], S. Oguzkan Balci[2], T. Sever[2], A. Balat[4].* 1) University of Gaziantep, Faculty of Medicine, Department of Pediatrics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Department of Pediatric Cardiology Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine, Department of Nephrology, Gaziantep, Turkey.

Objectives of Study: Acute rheumatic fever (ARF) is a delayed immunologically mediated sequel of throat infection by group A,) -hemolytic streptococci. It is a multisystem inflammatory disease which can effect of different tissues including synovial joints and cardiac valves. Recently, it has been shown that inflammatory cytokines may play a pathogenic role in ARF. The objective of this study was to investigate the potential associations between IFN-. , IL-6, TNF-(, TGF-) 1 and IL-10 gene polymorphisms and childhood ARF. Method: Thirty-eight ARF patients and 40 age-and sex-matched healthy controls were analyzed for 8 polymorphisms in 5 different genes. DNA was extracted from whole blood by standard salting out method. Cytokine genotyping was performed by polymerase chain reaction sequence-specific primer methods. The polymorphisms analyzed in the present study were IFN-. (+874), IL-6 (-174), TNF-((-308), TGF-) 1 (+10, +25) and IL-10 (-1082 , -819 , -592). The results were statistically analyzed by calculating odds ratios (OR) and 95% confidence intervals (CI) using chi-square test. Results: The distribution of genotypes and allele frequencies were compared with the groups. ARF patients had significantly higher frequencies of IFN-. (+874) polymorphism in both TT genotype (p=0.0002, OR:8.10 [95 % CI:2.40-27.26]) and T allele (p=0.0004, OR:3.01, CI: [1.57-5.78]). No statistically significant differences were observed between groups in genotype and allele frequencies of IL-6, TNF-(, TGF-) 1 and IL-10 genes (P>0.05). There were also no statistically significant differences in the haplotypes of ARF patients and controls (P>0.05). Conclusion: We conclude that IL-6, TNF-(, TGF-) 1 and IL-10 polymorphisms are not associated with ARF. However, both TT genotype and high expression IFN-. gene (+874) may have a higher risk for ARF in Turkish children.

362F

Genetic risk scores related to leukocyte telomere length predict incident cardiovascular disease, the Framingham Heart Study. *SJ. Hwang[1,2], JM. Murabito[1,5], SL. Neuhausen[6], SC. Hunt[7], EN. Smith[9], M. Mangino[4], T. Spector[4], AL. Fitzpatrick[3], G. Berenson[9], NJ. Schock[10], JC. Bis[3], BM. Psaty[3], A. Aviv[8], D. Levy[1,2].* 1) Framingham Heart Study, Framingham, MA; 2) Center for Population Studies, National Heart, Lung, and Blood Institute, Bethesda, MD; 3) Department of Epidemiology, University of Washington, Seattle, WA; 4) Department of Twin Research and Genetic Epidemiology at King's College London. Shorter leukocyte telomere length (LTL) has been reported to be associated with higher risk of cardiovascular disease (CVD). Genome-wide association studies (GWAS) have identified common genetic variants associated with LTL. We used the results of GWAS meta-analysis to identify 30 independent SNPs associated with LTL at $p < 1 * 10^{-5}$ to create an LTL genetic risk score and tested the associated of the LTL risk score with new-onset of major CVD events (recognized myocardial infarction, coronary insufficiency, or coronary disease death) in participants from the Framingham Heart Study. The study sample included 4078 participants free of major CVD at time of DNA collection. Generalized estimation equation (GEE) was applied to test the significance of the association between risk score and new-onset CVD, adjusting for CVD risk factors and familial correlation. During 40,994 person-years of follow up, a total of 279 (7%) individuals developed a first major CVD event. Each 1 standard deviation increase in the risk score (mean 30, SD 3) carried a 1.14-fold higher risk of CVD (95% confidence interval, 1.008-1.289; p-value =0.036). These results highlight the potential causal relation of LTL dynamics in the pathogenesis of CVD. The prognostic utility of the LTL genetic risk score warrants confirmation.

363F

A deep-sequencing approach to identify new genes involved in Hereditary Hemorrhagic Telangiectasia (HHT). *M. EYRIES[1,2], J. ROUME[3], F. COULET[1,2], C. LONJOU[4], M. GERMAIN[5], P. LACOMBE[3], T. CHINET[3], J.H. BLONDEL[3], I. BOURGAULT[3], G. LESUR[3], A. OZANNE[3], B. RAFFESTIN[3], D.A. TREGOUET[5], F. SOUBRIER[1,2].* 1) Oncogenetics and Angiogenetics laboratory, Pitié-Salpétrière Hospital, AP-HP, Paris, France; 2) UMRS 956, UPMC-Paris 6, INSERM, Paris, France; 3) HHT pluridisciplinary clinics, Hôpital Ambroise par&, AP-HP, Boulogne France; 4) Bioinformatics and biostatistics platform, UPMC-Paris6, Paris, France; 5) UMRS 937, UPMC-Paris6, INSERM, Paris, France.

Mutations of the Endoglin (ENG) and Activin A receptor type II-like kinase-1 (ACVRL1) genes are known to be the major genetic factors of HHT. Mutations in SMAD4, causing HHT in association with juvenile polyposis, have also been described. However, mutations are not found in about 20% of HHT cases. We investigated a pedigree where the proband was reported to have epistaxis, telangiectasias, pulmonary arteriovenous malformation and a familial history of HHT with 8 affected or potentially affected relatives over 4 generations. Direct sequencing and large rearrangements analysis of ACVRL1, ENG and SMAD4 did not identify any mutation in these genes. A multipoint linkage analysis was performed in this pedigree and confirmed that these 3 gene regions are unlikely to explain the familial segregation of the disease. Following the proof-of-concept that new causal genes for mendelian disorders can be identified by exome sequencing of a small number of affected individuals, we designed a two-generational filtering strategy specially adapted to a genetic disease transmitted as an autosomal dominant trait with complete penetrance. This strategy includes an intra-familial filtering step comparing sequenced data from unaffected and affected parents to their affected offspring. We performed peripheral blood DNA sequencing of all protein-coding regions (exome) in 4 selected individuals of the family using Agilent SureSelect exome hybridization capture and the Illumina DNA sequencing platform. Around 35,000 variants (SNP and INDEL) were identified in each individual. 70 candidate variants were left after successive filtering steps including 2 nonsense variants and one missense variant predicted to be deleterious and located in a gene involved in angiogenesis. These variants are very good candidates to be the causal variant responsible for HHT disease in this family and co-segregation study is now in progress to confirm the implication of one of these candidates.

Multigenic etiology of CHD with heterotaxy involving PCD and cilia genes. *Y. Li[1], H. Yagi[1], E. Onuoha[1], M. Barmada[2], M. Tsang[1], CW. Lo[1].* 1) Department of Developmental Biology, University of Pittsburgh, School of Medicine, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Graduate School of Public Health Pittsburgh, PA.

Introduction: Patients with congenital heart disease (CHD) and heterotaxy show high postsurgical morbidity/mortality, with some developing respiratory complications. We recently showed CHD patients associated with heterotaxy can exhibit respiratory ciliary dysfunction (CD) similar to that of patients with primary ciliary dyskinesia (PCD) - a ciliopathy with airway mucociliary clearance defects. As both PCD and heterotaxy have a 1 in 10,000 incidence, the finding of CD in heterotaxy patients likely reflects the dual role of motile cilia in airway clearance and left-right patterning. Thus, we hypothesize heterotaxy may arise from mutations in PCD genes and other cilia related ciliome genes. **Methods and Results:** CHD patients with heterotaxy, 13 with CD and 13 without CD (no-CD), were sequence captured followed by SOLiD sequencing with average 40X coverage to identify sequence variants in all 13 known PCD causing genes and nearly 1000 other ciliome genes. Coding variants were filtered against dbSNP and the 1000 Genomes databases, and novel coding variants (NCV) were validated by Sanger sequencing. Analysis of the 13 PCD genes revealed 10 NCV in 7 CD patients, and 5 NCV in 3 no-CD patients. The 3 PCD patients had 5 NCV, with 2 siblings having homozygous CCDC39 mutation (1072delA) known to cause PCD. Interestingly, CD-heterotaxy patient 9002 was heterozygous for the most common pathogenic DNAI1 mutation, IVS1+2_3insT, a disease NCV not seen in the general population. As PCD is a recessive disorder, heterozygous mutation cannot alone cause disease. We evaluated NCVs found in DNAH6, a motor dynein gene not yet demonstrated to cause PCD. DNAH6 NCVs were found in 9002 as well as one other CD and one PCD patient, but not in any no-CD patient. Dnah6 morpholino (MO) knockdown in zebrafish embryos showed laterality defects and phenotypes consistent with heterotaxy, suggesting a role in CD and heterotaxy. Further experiments are underway to explore functional synergy between DNAI1 and DNAH6 by observing effects of co-administration of low doses of both MO in zebrafish. **Conclusion:** Our study showed heterotaxy patients with CD can have heterozygous NCVs in PCD genes, including known disease causing DNAI1 mutation. Functional analysis with zebrafish MO showed DNAH6 knockdown can cause heterotaxy. We propose DNAH6/DNAI1 double heterozygous mutation may contribute to CD and heterotaxy. Our results provided evidence for multigeneic etiology of CD and heterotaxy.

365F

Variants in the inflammatory *IL6* and *MPO* genes modulate stroke susceptibility through main effects and gene-gene interactions. *A.M. Vicente[1, 2, 3], H. Manso[1, 2, 3], T. Krug[2,4], J. Sobral[2,4], G. Gaspar[1], S. Oliveira[2,4], J.M. Ferro[4,5].* 1) Instituto Nacional Saude DRJ, Lisbon, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) Center for Biodiversity, Functional & Integrative Genomics BIOFIG, Lisbon, Portugal; 4) Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Lisbon, Portugal; 5) Serviço de Neurologia, Hospital de Santa Maria, Lisbon, Portugal.

A complex interplay between genetic background, clinical and life-style factors and the environment is expected to ultimately regulate the onset, acute phase and outcome of stroke. There is substantial evidence that inflammation within the Central Nervous System contributes to stroke risk, and known clinical risk factors for stroke, like atherosclerosis, diabetes, obesity, hypertension, and peripheral infection, are associated with an elevated systemic inflammatory profile. The inflammatory response is equally of major importance in recovery and healing processes after stroke. In this study we tested the genetic association of major inflammatory players *IL1B* (2q14), *IL6* (7p21), *TNF* (6p21.3) and *MPO* (17q23.1) with stroke susceptibility and with stroke outcome at three months, in a population sample of 672 patients and 530 controls, adjusting for demographic, clinical and life-style risk factors and/or stroke severity parameters. The apparent complexity of the inflammatory mechanisms in stroke, and the multiplicity of players involved suggest a concerted process, in which implicated molecules interact to tightly regulate each other. We therefore examined both independent gene effects and the occurrence of gene-gene interactions among the tested inflammatory genes in stroke risk and stroke recovery. Two *IL6* and one *MPO* SNP were significantly associated with stroke risk after multiple testing correction ($0.022<\text{corrected}P<0.042$), highlighting gene variants of low to moderate effect in stroke risk. An epistatic interaction between the *IL6* and *MPO* genes was also identified in association with stroke susceptibility ($P=0.031$ after 1000 permutations). In the subset of 546 patients assessed for stroke outcome at three months using the modified Rankin Scale (mRS), we found one *IL6* haplotype associated with stroke outcome (corrected$P=0.024$). In the present study we present supporting evidence for a role of the *IL6* and *MPO* inflammatory genes in stroke susceptibility, and show that stroke risk is modulated by main gene effects together with clinical and life-style factors as well as by gene-gene interactions. Our findings are compatible and strengthen previous genetic and biological observations, highlighting the need of further functional studies, particularly in view of the possible utility of IL-6 as a diagnostic and/or prognostic biomarker for stroke.

366F

Genetic Analysis of Lipidomic Profiles in Mexican American Families. *C. Bellis[1], J.E. Curran[1], J.M. Weir[2], M.A. Carless[1], J.B. Jowett[2], M.C. Mahaney[1], T.D. Dyer[1], H.H.H. Göring[1], A.G. Comuzzie[1], L. Almasy[1], P.J. Meikle[2], J. Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Baker IDI Heart and Diabetes Institute, Melbourne, VIC, Australia.

Lipids are a highly diverse class of molecules with essential roles in cellular structure, signaling, and energy storage. Deregulation of lipid metabolism can lead to the development of various diseases including Alzheimer's, diabetes, and atherosclerosis. These lipid molecules may represent endophenotypes that are closer to the gene action than classical lipid markers, and extremely valuable for genetic analysis. Traditional measures of plasma lipids such as HDL-C, LDL-C and total triglyceride represent relatively crude summary measures that are actually composed of multiple components. We hypothesize that by disentangling lipid complexity and focusing on more biologically simple canonical lipid species we may more rapidly identify causal disease genes. Using a unique existing resource, the San Antonio Family Heart Study, we have identified and quantified 356 different canonical lipid species in 1202 Mexican Americans from 40 large pedigrees. Quantitative genetic analysis and genome-wide association analyses using over one million SNPs were performed to examine potential genetic factors involved in lipidomic profile variation. Analyses have revealed statistically significant heritabilities for 349 of the 356 measured lipid species (when controlling for age and sex). Maximal heritability h2=0.61 (p<1x10-15) was calculated for DHC 24:1 (dihexosylceramide) while the average calculated heritability (h2= 0.346) across the spectrum of lipids assayed illustrates a strong genetic component. Genome-wide association analyses revealed many significant QTL localizations for these canonical lipid phenotypes. Most notably, we identified a region on chromosome 11 exhibiting a highly significant genome-wide association with PC 36:4b (phosphatidylcholine) levels (p=5.9×10-68). The peak SNP accounted for ~25% of the variance in PC 36:4b and also showed significant genome-wide association with an additional 18 quantitated lipid components, including 14 other PC species. Residing in this particular region is the human FADS1- FADS3 gene cluster harboring polymorphisms previously shown to influence circulating fatty acids. Our results suggest that these canonical lipid measures represent phenotypes closer to gene action than those of classical lipid markers.

367F

Genetic modifiers of the vasculopathy caused by elastin haploinsufficiency act by extrinsic noncomplementation. *B.A. Kozel[1], R.H. Knutsen[2], L. Ye[1], C.H. Ciliberto[2], T.J. Broekelmann[2], R.P. Mecham[2].* 1) Department of Pediatrics, Division of Genetics and Genomic Medicine, Washington Univ Sch Med, St. Louis, MO; 2) Department of Cell Biology and Physiology, Washington Univ Sch Med, St. Louis, MO.

Background. Elastin haploinsufficiency causes the cardiovascular complications associated with Williams syndrome and isolated SVAS. Alterations in expression of the non-mutated ELN allele and genetic modifiers have been proposed as explanations for the variable vascular phenotype associated with this disease. Using the Eln+/- mouse, we sought to identify the source of this variability. Methods and Results. Following outcrossing of C57Bl/6J Eln+/- mice to four inbred strains, two backgrounds were identified whose cardiovascular parameters deviated significantly from the parental strain. Progeny of the C57Bl/6J; Eln+/- x129X1/SvJ F1 were more hypertensive and their arteries less compliant. In contrast, Eln+/- animals crossed to DBA/2J were protected from the pathologic changes associated with elastin insufficiency. Among the Eln+/-s, aortic elastin and collagen content did not correlate with quantitative vasculopathy traits, suggesting the variability seen in these mice was elastin-independent. Quantitative trait analysis performed on F2 C57 Eln+/- x129 intercrosses identified highly significant peaks on chromosome 1 (LOD 9.7) for systolic blood pressure and on chromosome 9 (LOD 8.7) for aortic diameter. Additional peaks were identified that affect only Eln+/- animals, including a region upstream of Eln on chromosome 5 (LOD 4.5). Bioinformatic analysis of the QTL peaks revealed several interesting candidates, Ren1, Ncf1, and Nos1; genes whose functions are unrelated to elastic fiber assembly, but whose effects may synergize with that of elastin insufficiency to predispose to hypertension and stiffer blood vessels. The candidates identified here are known to affect cardiovascular health in humans and are pharmacologically modifiable. Conclusions. Genes that do not directly affect elastin expression strongly influence the presentation of vascular disease in Eln halpoinsufficient mice. To date, it has not been possible to increase in vivo elastin deposition. However, the cumulative risk of pathology in extrinsic noncomplementation is brought about by interplay among affected genes. Consequently, identification of modifiers may allow better risk modification for these patients through the use of pharmacotherapies aimed at pathways unrelated to elastin production.

368F

Investigation of genome-wide associated regions for triglycerides in the Mexican population. *D. Weissglas[1], JS. Sinsheimer[1], L. Riba[2], B. Bernal-Barroeta[3], D. Gomez[3], W. Zamudio[3], M. Ordoñez-Sánchez[2], ML. Rodríguez-Torres[2], I. Cruz-Bautista[3], RM. Cantor[1], CA. Aguilar-Salinas[3], T. Tusie-Luna[2], P. Pajukanta[1].* 1) Dept. of Human Genetics, UCLA, Los Angeles, CA; 2) Unit of Molecular Biology and Genomic Medicine, IIB-UNAM, INCMNSZ, Mexico; 3) Dept. of Endocrinology and Metabolism, IIB-UNAM, INCMNSZ, Mexico.

Background: Mexicans have a high predisposition to elevated triglyceride levels (TGs) and premature coronary artery disease (CAD). However, this population has been underinvestigated in genomic studies, and to date no genome-wide association (GWA) studies for lipids have been performed in Mexicans. **Methods and Results:** We evaluated whether 24 loci surpassing genome-wide significant threshold ($P < 5 \times 10^{-8}$) for TGs in a recent GWA meta-analysis of Europeans also confer a risk in Mexicans. The median size and number of SNPs per region was 171kb and 31 SNPs, respectively, and in total 3,409 SNPs from associated regions were genotyped in 2,245 Mexican hypertriglyceridemia cases and controls. We observed significant association with $P < 2.5 \times 10^{-3}$ at ten of the loci: ANGPTL3, APOA1, APOB, CETP, CILP2, GCKR, HLA, LPL, MLXIPL, and TIMD4. Our strongest signal was obtained with SNP rs964184 near APOA1 (OR=1.8; $P=1\times10^{-19}$). This SNP has also surpassed genome-wide significant threshold for TGs and CAD in Caucasian GWA studies. However, it is substantially more prevalent in Mexicans (28%) than in Caucasians (12%), and thus of greater attributable risk in Mexicans. Interestingly, except for rs964184 and the missense SNP rs1260326 in GCKR (OR=1.4; $P=2\times10^{-7}$), for all other loci the strongest signal was obtained with a different SNP than in the Europeans ($0<r^2<0.85$), suggesting that Mexicans may assist in localizing the actual susceptibility variants or possess population-specific risk variants in these loci. For instance, the intergenic SNP rs6873137 (OR=1.2; $P=5\times10^{-4}$) between TIMD4 and HAVCR1 is in stronger linkage-disequilibrium with a missense variant in HAVCR1 in Mexicans than in Europeans ($r^2=0.74$ versus 0.52), suggesting that HAVCR1 is more likely the functional gene accounting for this uncharacterized genome-wide significant signal. **Conclusions:** It is important to identify the common variants contributing to the increased susceptibility to hypertriglyceridemia in Mexicans. We show significant associations for ten GWA loci for TGs in Mexican hypertriglyceridemia case-control study samples. The strongest associated SNP, rs964184, is more prevalent in Mexicans than in Europeans and thus may contribute to the high predisposition to dyslipidemias in Mexicans.

369F

Genetic basis of familial hypercholesterolaemia. *A.C. Alves[1, 2], M. Bourbon[1,2].* 1) Cardiovascular Research Group, R&D Unit, Dept Health Promotion and Chronic Diseases, INSA, Portugal; 2) 2 Center for Biodiversity, Functional & Integrative Genomics (BioFIG).

Familial hypercholesterolemia (FH) is a genetic condition characterized by a high cholesterol concentration in the blood. The most frequent causes of FH are inherited defects in the Low Density Lipoprotein Receptor gene (LDLR) but, in a small percentage of patients, mutations in the apolipoprotein B gene (APOB) and in the propotein convertase subtilisin/kexin type 9 gene (PCSK9) are also responsible for FH. These 3 genes are currently studied in the "Portuguese FH study". From the 563 families with a clinical diagnosis of FH studied only 41% of these have a mutation in one of the 3 studied genes, so other gene defects must exist to explain the cause of hypercholesterolemia in the remaining families. The aim of this study was the exclusion of previously unidentified LDLR and APOB gene defects in 65 severely affected patients, as well as the exclusion of mutations in LDLRAP1 and CYP7A1 genes in patients with possible recessive hypercholesterolemia. The whole sequencing of LDLR and APOB genes of the 65 index patients, without mutations in LDLR or PCSK9 genes or in fragments of exon 26 and 29 of APOB gene was performed. A pool of the 65 DNAs was sequenced by pyrosequecing with custom design primers and a total of 227688 nucleotide reads were obtained, corresponding to a mean coverage of 35x/fragment/individual. CYP7A1 and LDLRAP1 genes were analysed by PCR and direct sequencing. A total of 87 alterations were detected by pyrosequencing. More than half were previously described SNPs and 32 were novel possible pathogenic variants. The majority of these variants (25) were in exons 26 and 29. From the 32 novel variations identified by pyrosequencing only 4 were found by Sanger sequencing. Three alterations (2 novel and 1 described) were found by Sanger sequencing and were not detected by pyrosequencing. Three SNP's were also studied do to their low alleles estimated. After family studies of these 10 variants, 3 alterations did not co-segregate in the family, 4 alterations were not possible to verify co-segregation and 3 of the alterations found are possibly mutations causing disease, but functional studies are required to prove pathogenicity. No mutations were found in LDLRAP1 and CYP7A1 genes in 10 patients with possible recessive hypercholesterolemia. Patients, in whom it was not possible to find the genetic cause of the hypercholesterolaemia, will require further studies, since all show a severe clinical phenotype of FH.

Serum microRNA-21 and microRNA-221 as potential biomarkers for stroke. *M. Lu[1], P. Tsai[2], Y. Wang[2], Y. Liao[1], H. Lin[3], R. Lin[3], S. Juo[2].* 1) Grad Inst of Medicine, Kaohsiung Med Univ, Kaohsiung, Taiwan; 2) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Department of Neurology, Kaohsiung Medical University, Kaohsiung, Taiwan.

Background Stroke is one of the leading causes of death and disability worldwide. microRNAs are endogenous non-coding small RNAs that silence gene expression via post-transcriptional inhibition of their target mRNAs. Recent studies revealed that microRNAs can participate in the pathogenesis of stroke, such as endothelial dysfunction, neointimal hyperplasia, and inflammation. We aimed to find some microRNAs as potential biomarkers for stroke by exploring the association between the circulating microRNAs and stroke. Methods A total of 149 stroke patients and 163 non-stroke subjects were recruited in this study retrospectively. The diagnosis of stroke was diagnosed by both clinical neurological examinations and brain CT/MRI. Carotid doppler was performed to measure the extent of the carotid intima thickness (IMT) in the non-stroke subjects. Among non-stroke subjects, a carotid plaque score$\checkmark$ 3 was defined as atherosclerosis, and a plaque score=0 was served as healthy controls. The expression of serum microRNAs were detected by real-time PCR. Results The expression of serum miR-21 was highest in the stroke group, followed by atherosclerosis group, and lowest in the healthy controls (adjusted p=0.0021). On the contrary, miR-221 was significantly decreased in the stroke patients compared with either the atherosclerotic or healthy subjects (adjusted p=0.0005). The association between the severity of vascular disease and serum miRNAs only existed in men (p-trend =0.0011 for miR-21; p-trend =0.0259 for miR-221) but not in women. A predictive model including five risk components (miR-21, miR-221, age, diabetes, and hypertension) was built to assess the possibility of stroke in men. The best predictive model achieved 92.7% positive-predicted rate and 89.3% negative-predicted rate for stroke. Conclusion Circulating miR-21 and miR-221 were potential biomarkers for stroke in men.

371F

The up-regulation of mir-221 in adipose tissue is associated with the development of phenotype of obesity. *Y. Wang[1], W. Chou[1], X. Su[1], S. Juo[1,2].* 1) Medical Genetics, Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Medical Research, Kaohsiung Medical University Hospital.

Background: Obesity and associated diseases are becoming a health-concerned issue as a result of imbalanced diet, especially given the current trend for increases in childhood obesity. Adipose tissue undergoes a dramatic expansion in obesity; however, recent reports indicate the number of adipocytes is established during childhood and stays constant during adulthood. Previous in vitro researches demonstrate specific intracellular microRNAs play a role in regulating adipogenesis. In our study, the aim is to investigate the expression profile of microRNAs in a dynamic obesity model. Methods: We utilized male mice (C57BL/6J) and induced obesity by feeding them with high-fat diet (HFD, 53.3% of total calories from fat) in comparison with chow diet in the control group. During the treatment course, intra-peritoneal glucose tolerance test were repeated to observe glucose and insulin responses at the ends of 4 week, 8 week and 12 week. Afterwards, both serum and epididymal fat tissue were collected to analyze both biochemical tests of lipid profile and the expression patterns of microRNAs reported in association with adipogenesis by real-time PCR. Results: During the dynamic growth of adipose tissue, only mir-221 expression was progressively up-regulated in mice fed a high-fat diet (total n=12) when comparing chow diet treated group (total n=8). The increases were 1.53-fold and 2.75-fold in 8-week and 12-week treatment, respectively (p=0.01). Furthermore, the level of mir-221 in adipose tissue correlated positively with body weight (BW) at sacrificed dates (r=0.580, p=0.003), BW change within treatment course (r=0.503, p=0.02), epididymal fat weight (r=0.553, p=0.005), and the ratios of epididymal fat weight to BW (r=0.535, p=0.007). Moreover, mir-221 expression in adipose tissue also showed positive correlations with blood glucose level at 60min after intra-peritoneal injection of 2mg/g glucose (r=0.506, p=0.03). However, there were no changes in expression patterns of tested adipogenic miRNAs in blood circulation between two groups in different time points. Conclusion: The up-regulation of mir-221 is associated with the dynamics of adipose tissue growth and possibly related to obesity induced insulin resistance. We are investigating the molecular mechanism of mir-221 in regulation of fat mass expansion.

372F

Genetic polymorphisms associated with hypertension in a sample population of Calabar and Uyo, Nigeria. *C.I. ANUMUDU[1], M.E. KOOFFREH[1], L. KUMAR[2].* 1) ZOOLOGY, UNIVERSITY OF IBADAN , IBADAN, Nigeria; 2) International Institute of Tropical Agriculture Ibadan.

Recent research into the molecular genetics of hypertension has the aim of identifying and associating the gene variants of different polymorphisms with hypertension as well as their interaction with environmental factors. This study was designed to determine the frequency and association of gene polymorphisms of the RAAS and ANP with hypertension in residents of Calabar and Uyo, Nigeria. A case-control study design was used, and 1308 participants were recruited into the study, 612 patients and 696 controls. The M235T allele, Insertion/Deletion allele, A1166C allele and C664G allele polymorphisms were investigated using polymerase chain reaction and restriction enzyme digestion to determine allele frequency. Hypertensinogenic factors such as dietary habits, physical activity, smoking and drinking habits were assessed using questionnaires. Descriptive statistics, chi-square, multiple regression analysis and odds ratio were used to analyze data obtained at a probability of 0.05. The frequency of the three genotypes of the M235T allele in both patient and control groups respectively were 88% and 92% (MM); 9% and 7.5% (MT); 0.3% and 0.7% (TT). The Insertion/Deletion allele had a frequency of 45% and 39% for the deletion genotype, the Insertion/Deletion genotype was 43% and 49% while the insertion genotype was 12% in both control and patient populations. For the A1166C allele, 99% of the study population had the wild type AA genotype and 1% was AC heterozygous carriers of the mutation. Only the CC genotype was observed for the C664G allele in the study population. There were no significant differences between the genotype frequencies in hypertensives and the control groups for all the polymorphisms under consideration. Age was a predictor for Systolic Blood Pressure (SBP) and Diastolic Blood Pressure (DBP) in the hypertensive group r=0.604 SBP, r=0.594 DBP, p=0.005; and for DBP in the control group r=0.542. Gender, body mass index, AGT, ANP and ACE genotypes were not predictors for SBP and DBP in the hypertensive group. The Insertion/Deletion allele was a risk factor for hypertension odds ratio 1.15 at 95% CI, (0.92-1.46). Higher carriage of insertion/deletion allele was associated with an increased risk of developing hypertension. There was no association between the frequency of the M235T, A1166C and the C664G alleles and hypertension, suggesting other loci or environmental factors are involved in the disease outcome.

Identification of polymorphisms in NPBWR2 gene associated with hypertension. *J. Klovins[1], R. Petrovska[1], G. Latkovskis[2], V. Pirags[3], H.B. Schioth[4], I. Kalnina[1].* 1) Latvian Genome Ctr, Latvian Biomedical Research and Study Ctr, Riga, Latvia; 2) 2Latvian Centre of Cardiology, Pauls Stradins Clinical University Hospital, Riga, Latvia; 3) University of Latvia and Department of Endocrinology, Pauls Stradins Clinical University Hospital; 4) Department of Neuroscience, Uppsala University, BMC, Box 593, SE751 24, Uppsala, Sweden.

NPBWR1 and NPBWR2 are receptors of neuropeptide B (NPB) and neuropeptide W (NPW). This neuropeptide system is thought to have a role in regulating feeding behaviour, energy homeostasis and neuroendocrine function, however its role in humans remains unknown. The aim of the study was to characterize the genetic variance of NPBWR1 and NPBWR2 and investigate the possible correlation of identified polymorphisms with number of available traits and phenotypes. In total 6 polymorphisms were indentified in both gene loci from direct sequencing of 100 individuals. Genotype based association was performed in randomly selected 1500 individuals from Genome Database of Latvian Population. Among 10 different traits included in this analysis the hypertension was significantly associated with one missense SNPs from NPBWR1 gene (rs33977775) and one missense SNP from NPBWR2 gene (rs4809401). These SNPs were genotyped in additional group of 600 hypertensives and 600 validated controls. rs4809401 were significantly associated with presence of hypertension (P=0.0016). We also present functional importance of three identified missense variants in NPBWR1 and NPBWR1 variants on cAMP inhibition in HEK-293 cells.

Genome-wide Association Study of Cardiac Structure and Systolic Function in African Americans: the Candidate Gene Association Resource (CARe) Study. *E. Fox[1], S. Musani[1], M. Barbalic[2], H. Lin[3], K. Ogunyankin[4], N. Smith[5], A. Kutlar[6], W. Post[7], D. Dries[8], C. Duarte[9], S. Kardia[10], D. Arnett[9], D. Paltoo[11], D. Farlow[12], R. Vasan[3], Candidate Gene Association Resource (CARe) Study Working Group.* 1) Department of Medicine, University of Mississippi Medical Center, Jackson, MS; 2) Human Genetics Center, University of Texas Health Science Center, Houston , TX; 3) Department of Medicine, Boston University School of Medicine, Boston, Massachusetts; 4) Northwestern University School of Medicine; 5) University of Washington; 6) Medical College of Georgia; 7) John Hopkins University schoool of Medicine; 8) University of Pennsylvania School of Medicine; 9) University of Alabama School of Public Health; 10) University of Michigan School of Public Health; 11) Division of Cardiovascular Sciences, National Heart, Lung, and Blood Institute, NIH; 12) Broad Institute.

Background. Variation in cardiac structure and function is unexplained by established environmental factors and may be related to genetics. Using data from four community-based cohorts of African Americans (AA), we tested the association between genome-wide markers (SNPs) and cardiac phenotypes in the Candidate-gene Association REsource (CARe) study. **Methods**. Among 6,765 AA, we related age, sex, height and weight-adjusted residuals for nine cardiac phenotypes (assessed by echocardiogram or MRI) to 2.5 million SNPs (1.0 million genotyped using Affymetrix SNP array 6.0 and the remainder imputed). The primary analysis was conducted within each cohort and meta-analyzed across cohorts using inverse variance weights. 4.0E-7 was used as the prespecified threshold based on one expected false positive. We investigated replication in cohorts of African ancestry and one large consortium of European ancestry (EchoGEN). **Results**: Variants in 4 genetic loci reached genome-wide significance: one locus on chromosome 8 for left ventricular mass (LVM - p=1.43E-07); one locus on chromosome 17 for left ventricular internal diastolic diameter (LVIDD - p=1.68E-07); one locus on chromosome 10 for interventricular septal wall thickness (IVST- p= 2.57E-08); and one locus on chromosome 13 for ejection fraction (EF - p=4.02E-07). In addition, we found associated variants were enriched in three signaling pathways that were involved in cardiac remodeling. None of the 4 genome-wide loci replicated in a meta-analysis of cohorts composed of individuals of African ancestry. None of 3 available loci replicated in the EchoGEN consortium. **Conclusion**: In a genome wide association study of AA, we identified 4 genetic loci significantly related to LVM, IVST, LVIDD, and EF. Supplemental analysis found that associated variants were enriched with genes in three signaling pathways for cardiac remodeling. None of the top 4 loci replicated in cohorts of African and European ancestry suggesting that additional large-scale studies are warranted for these complex phenotypes.

Enriched population from Lebanon improves the understanding of Genetic and Environmental effect on Cardiovascular Disease in the Levant and beyond. *J.-B. CAZIER[1], J.L. DAVIES[2], S. YOUHANNA[3], D.E. PLATT[4], C. HOLMES[1,2], D. GAUGUIER[5], P.A. ZALLOUA[3,6].* 1) Wellcome Trust Centre of Human Genetics, University of Oxford, Roosevelt Drive, Oxford, OX3 7BN, United Kingdom; 2) Department of Statistics, University of Oxford, 1 South Parks Road, Oxford, OX1 3TG, UK; 3) Lebanese American University, School of Medicine, Beirut 1102 2801, Lebanon; 4) Bioinformatics and Pattern Discovery, IBM T. J. Watson Research Centre, Yorktown Hgts, NY 10598, USA; 5) INSERM, UMRS872, Centre de Recherche des Cordeliers, 15 Rue de l'école de Médecine, 75006 Paris, France; 6) Harvard School of Public Health, Boston, MA 02215, USA.

We have collected a unique cohort of 6000 individuals from Lebanon with extensive and precise phenotypic and genotypic information. This cohort is of very special relevance for the improvement of the understanding of cardiovascular diseases and its interaction both in the Levant and how it relates to the rest of the world. The four main coronary arteries were visualized from different angles by angiography and the extent of stenosis in these vessels was assessed and recorded by percentage. Trained healthcare professionals collected further data on the socio-demographic background of the patients. With 2000 individuals genotyped on the Illumina 610-660 chips, this cohort is the largest genotyped patient population from the Levant. This enabled the first Genome-Wide-Association of the region which relative small cohort confirmed association loci found with far larger meta-analysis. Furthermore the extent and quality of the data collected at both genetic and phenotypic level allows us to put in perspective published findings made essentially in cohorts of European and Asian descents. Most importantly, this population from the Levant is ideally placed, geographically and historically, at the centre of the three most common HapMap groups of Europe, Asia and Africa. This unique position should make the Middle East the common denominator of Asian and European dispersion out of Africa, an ideal place to identify old, and common, variants. Furthermore the recent admixture in this population allows for a further refinement in the identification of variants between new and old contributions. We made use of this specificity to explore the stratification of the population by Principal Component Analysis and Admixture Mapping and applied a new robust statistical method to detect susceptibility gene-environment interactions in structured but closely related sub-populations. We looked for evidence of heterogeneous genetic associations across environmental background, either genetic or physiological (e.g. HDL, LDL), and demonstrate the importance of the region in a worldwide context. In conclusion, we have shown that our enriched cohort from Lebanon, not only can improve the understanding of cardiovascular diseases in the region, but also provide extremely valuable information for genomic studies beyond the classic framework of European, Asian and African populations.

Whole-exome DNA re-sequencing in French Canadians with dilated cadiomyopathy using pre-exon capture barcoding. *M. Beaudoin[1], K.S. Lo[1], M. Schlogel[1,2], L. Robb[1], N. Laplante[1], J-C. Tardif[1,3], M. Talajic[1,3], G. Lettre[1,3].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Laboratory of Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Belgium; 3) Universite de Montreal, Faculte de Medecine, Montreal, Quebec, Canada.

Dilated cardiomyopathy (DCM) is characterized by left ventricular dilatation, systolic dysfunction, myocyte death, and myocardial fibrosis. Environmental stimuli, such as viral infection, chronic alcohol consumption, or hypothyroidism can lead to DCM. Studies in families also indicate a strong genetic determinant for DCM, with mutations in more than 40 genes already linked to the development of DCM. Despite this knowledge, a large fraction of familial DCM cases remain unexplained after screening the known DCM genes. Next-generation DNA re-sequencing (NGS) offers new opportunities to find causal mutations in heritable pathologies. Already, NGS has been used successfully to find etiological mutations in several human Mendelian diseases and syndromes. In this project, we tested the use of whole-exome DNA re-sequencing to find novel DCM genes. We selected eight French-Canadian DCM patients from the Montreal Heart Institute Biobank using the following two criteria: (1) they had tested negative for mutations in LMNA, MH7, and TNNT2, and (2) they had to have at least one affected sib or child to enrich for DCM patients with segregating mutations. To minimize costs associated with exon capture, four genomic DNA were barcoded before being captured with a single Agilent's SureSelect Human All Exon 50Mb kit. Libraries were prepared according to standard protocols and sequenced on the Applied Biosystems SOLiD4 sequencer (4 exomes per slide). Sequence quality control and analysis was performed using a robust pipeline built around established software: BWA, SAMtools, Picard, GATK, and PLINKSEQ. Preliminary analysis of the first whole-exome sequence data suggests that our "pre-exon capture barcoding" protocol works relatively well: we obtained a mean coverage of 35X (54% of the targeted exonic sequences covered at ⁄ 20X) and identified 24,148 high-quality DNA sequence variants, including 2,837 variants not previously reported in databases (transition-to-transversion ratio=2.79). Analysis of the whole-exome sequence data for the eight DCM patients will be presented.

Impact of *LIMK1, MMP2 and TNF-*(variations for intracranial aneurysm in Japanese population. *S.-K. Low[1,2], H. Zembutsu[1], A. Takahashi[3], N. Kamatani[3], P.-C. Cha[1], N. Hosono[4], M. Kubo[4], K. Matsuda[1], Y. Nakamura[1].* 1) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 2) Genetics Division, National Cancer Center Research Institute, Tokyo, Japan; 3) Laboratory for Statistical Analysis, Center for Genomic Medicine, The Institute of Physical and Chemical Research (RIKEN), Kanagawa, Japan; 4) Laboratory for Genotyping Development, Center for Genomic Medicine, The institute of Physical and Chemical Research (RIKEN), Kanagawa, Japan.

Genetic factors are known to have an important role in intracranial aneurysm (IA) pathogenesis. The purpose of this study is to identify single-nucleotide polymorphisms (SNPs) that are associated with IA in Japanese population. A total of 2050 IA patients and 1835 controls recruited in Biobank Japan, The University of Tokyo were used in this study. In all, 45 SNPs in 24 genes encoding proteins, which have been considered to be possible risk factors to IA pathogenesis, were genotyped using multiplex PCR-invader assay. Association analysis was evaluated by logistic regression analysis before and after adjustment of age, smoking and hypertension status. This case-control association study revealed a SNP, rs6460071 located on *LIMK1* gene (*P*=0.00069) to be significantly associated with increased risk of IA. In addition, two SNPs, rs243847 (*P*=0.00086) and rs243865 (*P*=0.00090), on matrix metallopeptidase 2 (*MMP2*) gene and one SNP rs1799724 (*P*= 0.0026) on tumor necrosis factor-((*TNF*-( ) gene, are marginally associated with IA in male- and female-specific manner, respectively. In conclusion, a large-scale case-control association study was conducted to verify genetic variations associated with IA in Japanese population. This study gave insights on the importance of stratified analysis between genders, and suggested that the underlying mechanism of IA pathogenesis might differ between females and males.

Genetic Susceptibility to Ischemic Stroke in Moldavians. *E. Mocan[1,2], O. Odainic[1], V. Nacu[1], S. Protopop[1], L. Lysiy[1], N. Barbacar[2].* 1) The State Medical and Pharmaceutical University , Chisinau, Chisinau, Moldova, Republic Of; 2) The Institute of Genetics and Plant Physiology, Chisinau, Moldova, Republic of.

Present research represents the first generalized study of genetic markers for Moldavian IS patients and for a control group of Moldavians similar gender distribution. The frequencies of allele and genotypes for 9 functionally significant SNP were determined in FII, FV, GP1BA, PAI-1, ALOX5AP, PDE4D and ACE genes. We examined samples of blood and genomic DNA from 159 Moldavians IS patients, age 53±12 yr. The control group consisted of 90 Moldavians without IS, age 37±9.7 yr. SNPs were detected with conventional allele-specific fluorescence PCR in real-time protocols (Taqman®) and insertion-deletion polymorphism of ACE gene by simple PCR. Statistically significant differences were found in biochemical parameters such as total cholesterol, triglycerides, HDL-cholesterol in group with ARE compared with the control group. All genotypes and alleles were in Hardy-Weinberg equilibrium. The groups showed no significant differences in the frequencies of individual alleles and genotypes for any studied polymorphism. When subjects were stratified by sex and age, the genetic effect was only evident in men of middle age but not in women of same age and men older 54 years attacked with IS. The statistically significant association with IS and D allele carrying of the ACE gene insertion-deletion polymorphism at men of middle age (till 54 years) were demonstrated with the odds ratio for men carriers of D allele was 3.53 (95%, CI: 1.05-10.86, p=0.026). Also significant correlation were observed between carrying of D allele and next clinical parameters such as hypertension (r=0.3, p=0.02), total cholesterol (r=0.24, p=0.03), LDL-cholesterol (r=0.25, p=0.02) and triglycerides (r=0.26, p=0.02). The prevalence of the studied polymorphisms of the fibrinolytic, coagulation and inflammation systems did not differ significantly between patients and control group that demonstrates an absence of genetic association of studied variants with IS in Moldavian population. But synergism was observed between ACE DD genotype, male sex and environmental risk factors. The genetic structure of the Moldavian population is poorly studied, and these data could be interesting in the historical-cultural context. Acknowledgments: This work was supported by grant ASM-RFBR 08-04-90121, MYSSP-1403 program MRDA-CRDF. We would like to thank the Institute of Molecular Genetics of RAS, Russia; especially we are deeply grateful to S.Limborska, P.Slominsky and E.Bondarenko for support.

ATP2B1 gene polymorphisms are associated with susceptibility to hypertension. *Y. Tabara, K. Kohara, T. Miki.* Ehime University Graduate School of Medicine, Toon, Japan.

Hypertension is one of the most common complex genetic disorders. We have previously described 38 single nucleotide polymorphisms (SNPs) with suggestive association with hypertension in Japanese individuals. In this study we extend our previous findings by analyzing a large sample of Japanese individuals (n=14,105) for the most associated SNPs. We also conducted replication analyses in Japanese of susceptibility loci for hypertension recently identified from GWAS studies of European ancestries. Association analysis revealed significant association of the ATP2B1 rs2070759 polymorphism with hypertension ($p=5.3*10^{-5}$, allelic OR 1.17, 95% CI 1.09-1.26). Additional SNPs in ATP2B1 were subsequently genotyped, and the most significant association was with rs11105378 (OR 1.31 (1.21-1.42), $p=4.1*10^{-11}$). Association of rs11105378 with hypertension was cross-validated by replication analysis with the Global BPgen consortium data-set (OR 1.13 (1.05-1.21), $p=5.9*10^{-4}$). Mean adjusted systolic BP was highly significantly associated with the same SNP in a meta-analysis with individuals of European descent ($p=1.4 *10^{-18}$). ATP2B1 mRNA expression levels in umbilical artery smooth muscle cells were found to be significantly different among rs11105378 genotypes. Seven SNPs discovered in published GWAS were also genotyped in the Japanese population. In the combined analysis with replicated three genes, FGF5 rs1458038, CYP17A1, rs1004467 and CSK rs1378942, odds ratio of the highest risk group was 2.27 (95% CI 1.65 to 3.12, $p=4.6*10^{-7}$) compared with the lower risk group. In summary, this study confirmed common genetic variation in ATP2B1 as well as FGF5, CYP17A1 and CSK to be associated with BP levels and risk of hypertension.

The use of alternative regulatory elements and the problem of missing heritability. *E.A. Ruiz-Narvaez[1,2].* 1) Slone Epidemiology Center, Boston University, Boston, MA; 2) Department of Epidemiology, Boston University, Boston, MA.

Genome-wide association studies (GWAS) have identified a multitude of single nucleotide polymorphisms (SNPs) associated with a wide spectrum of human phenotypic traits. However, the SNPs identified so far do not explain much of the expected phenotypic variation due to genetic factors and they are poor predictors of the occurrence of disease. Proposed explanations for the missing heritability include rare genetic variants, structural variants, gene-environment and gene-gene interactions. I recently advanced the hypothesis that there is person-to-person variation in the use of alternative regulatory elements (e.g. gene promoters) and this new source of variation may explain part of the missing heritability. In the present work I develop a simple mathematical model to explore the biologic consequences of the proposed hypothesis. Major implications of the hypothesis are: i. The total genetic variation due to observed genetic variants will be smaller than the heritable variance of the phenotypic trait. ii. For a particular causal SNP its observed genetic effect will be smaller than its actual genetic effect. iii. The presence of more than one causal SNP may be hidden due to linkage disequilibrium in conjunction with the use of alternative regulatory elements. iv. True genetic variation may completely be hidden if the use of alternative regulatory elements is not taken into account. A particular example of the proposed hypothesis would be the use of alternative gene promoters. It is known that more than 50% of human genes have more than one promoter, with an average of 3.1 promoters per gene. I discuss in the present work the biologic plausibility of the proposed hypothesis based on recent published evidence regarding the use of alternative gene promoters, as well as new paths of research to elucidate this mechanism for missing heritability.

382F

A variant in the promoter of MUC5B is a genetic predictor for survival in patients with idiopathic pulmonary fibrosis. *Y. Zhang[1,2], T. Richards[1,2], K. Gibson[1,2], K. Lindell[1,2], N. Kaminski[1,2].* 1) Dept Med, Div PACCM, Univ Pittsburgh Sch Med, Pittsburgh, PA; 2) Dorothy P. and Richard P. Simmons for Interstitial Lung Disease, Univ Pittsburgh Sch Med, Pittsburgh, PA.

Statement of Purpose: Idiopathic pulmonary fibrosis (IPF) is a complex genetic disease Recently, a SNP in the promoter of MUC5B, rs35705950, was reported to be associated with pulmonary fibrosis (Seibold et al. NEJM 21;364(16):1503-12. 6; Zhang et al. NEJM. 21;364(16):1576-7). In this study, we performed genotype-outcome analyses for rs35705950 to determine genotype correlations with survival in a large IPF cohort. **Methods:** Genetic and survival correlation analyses were performed using a IPF cohort from the University of Pittsburgh. The diagnosis of IPF was based on clinical, physiological, and high-resolution computed tomography (HRCT) findings in accordance with ATS/ERS criteria; surgical lung biopsy results were the basis of diagnosis in 53.7% of the patients. Only US non-Hispanic Whites were included. Genotype-outcome correlation analyses were performed using the R environment and graphing package. **Results:** The demographic and clinical characteristics as well as rs35705950 genotypes for the IPF cohort were reported previously (Zhang et al. NEJM. 21;364(16):1576-7). Survival analysis demonstrated that the T allele was protective with a median overall survival of 4.86 years for patients with GT and TT genotypes compared to 2.35 years for individuals with GG phenotype. The unadjusted hazard ratio for the GT+TT genotypes was 0.587 (p=0.0018) and the age, gender, and baseline forced vital capacity (FVC) adjusted hazard ratio was 0.664 (p=0.016). In addition, correlation of transplant-free survival with rs35705950 genotypes demonstrated a 2.85 years transplant-free survival for patients with GT and TT genotypes versus 1.61 years for patients with GG genotype. The hazard ratio for transplant-free survival of the GT+TT genotypes was 0.661 (p=0.0043, unadjusted) and 0.750 (p=0.047) after adjusted for age, gender, and baseline FVC. **Conclusion:** We identified significant correlations of the rs35705950 T allele (GT + TT genotypes) with better overall and transplant-free survivals in IPF. Interestingly, the rs35705950T allele was both associated with disease in case-control analysis and protective for survival in patients with IPF. Validations of our finding in additional IPF cohorts are warranted and underway. Molecular dissecting of the rs35705950 SNP in IPF will lead to better understanding the roles of MUC5B in the pathobiology and disease progressions of IPF. Prediction of clinical outcomes with genetic variants may result in better management of IPF.

The Human Caveolin 1 Gene Upstream Purine Complex and Multiple Sclerosis - A Replicated Link. *A. HEIDARI, M. Ohadi, H. Darvish, R. Pazhoomand, M. Behmanesh, R. Meshkani.* Genetics Research Center, University of Social Welfare , Tehran, Iran.

The caveolin 1 gene (CAV1) is over-expressed in experimental animal models of multiple sclerosis (MS). Increased expression of this gene has also been reported in the Alzheimer's disease (AD) brain. Loss of this gene, on the other hand, has recently been reported to be associated with neruodegeneration. We have recently reported skew in the homozygote haplotypes of the human CAV1 gene -1.5kb upstream purnie complex in patients afflicted with MS and late-onset AD vs. controls. In order to examine reproducibility of those findings, we sequenced the region in independent groups of MS patients (n=120) and controls (n=150). We report two novel extreme homozygote haplotyes at 86-bp and 142-bp in the patients vs. controls ($p<0.00001$). The range of homozygote haplotypes in the controls was detected at between 106-bp to 122-bp. The above haplotypes were also detected in the previously reported cases of late-onset AD. Following pooling of the neurodegenerative and nonneurodegenerative subjects studied for the human CAV1 purine complex, nineteen haplotypes were found to be homozygous in the neurodegenerative, and not in the control pool ($p<0.000001$). Overlapping haplotypes between MS and AD patients strengthen the role of this region as a common etiological factor in the pathophysiology of neurodegenerative disorders, possibly through inflammatory mechanisms. The CAV1 purine complex GGAA and GAAA motifs contain binding sites for numerous inflammatory transcription factors including the Ets, STAT, and IRF family members. Further work on the functionality of this region will shed light on the downstream events to the linked haplotypes.

Multipoint Linkage analysis using dense SNPs in large pedigrees. *C. Sun, G. Gao.* Biostatistics Dept, Virginia Commonwealth University, Richmond, VA.

Linkage analysis usually is based on sparse markers such as microsatellite markers. Although linkage analysis using dense single-nucleotide polymorphism (SNP) markers has been implemented in small pedigrees, but it is still challenging to be implemented in large pedigrees because existing methods (such as the well known software Loki) for identity-by descent (IBD) probability estimation can be computationally intensive. We have developed an identity-by descent (IBD) matrix estimation method using dense SNP markers in large pedigrees based on using a conditional enumeration haplotyping algorithm to identifying a subset of haplotype configurations with high likelihoods. The haplotyping algorithm eliminates haplotype configurations with relatively low conditional probabilities by use of a threshold for the conditional probabilities of ordered genotypes at every unordered marker and a threshold for the ratio of the conditional probability of a haplotype configuration to the largest conditional probability of all haplotype configurations. We incorporate the estimated IBD matrices into a two-stage variance component method for quantitative trait loci (QTL) mapping. We have done extensive simulation studies to compare our IBD matrix estimation method with Loki by their performance in QTL mapping. We simulated pedigree data with dense markers by using the structure of a Hutterite pedigree. Let d denote genetic distance between adjacent markers. Simulation results show that our methods and Loki generated very similar estimation of the pre-set QTL position. For a large number of dense markers with distance $d \leq 1$cM, Loki could be computationally intensive while our method took reasonable computing time. When $d \leq 0.25$cM, IBD matrices estimated by Loki (with 1,000,000 iterations) were singular at many putative QTL positions while the IBD matrices estimated by our methods were singular at only a few positions. From our simulation studies, we also found that for the same chromosome region, using more SNP markers in the region can generate more accurate estimate of the pre-set QTL position. We simulated a chromosome region of 50cM. We compared the results by using 50 SNPs (with d =1cM) in the region with those by using 100 SNPs (with d =0.5cM). Using 100 SNPs generated sharper and higher peaks (around the true QTL position 24.5cM) in the average log-likelihood test statistic curves.

A holistic approach to studying complex diseases using *Gentrepid*. *S. Ballouz[1,2], J.Y. Liu[1], M. Oti[3], B. Gaeta[2], D. Fatkin[4,5], M. Bahlo[6], M.A. Wouters[7].* 1) Structural and Computational Biology, The Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 2) School of Computer Science and Engineering, Faculty of Engineering, University of New South Wales, Kensington, NSW, Australia; 3) Centre for Molecular and Biomolecular Informatics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) School of Medical Sciences, University of New South Wales, Kensington, NSW, Australia; 5) Molecular Cardiology and Biophysics Division, The Victor Chang Cardiac Research Institute, Sydney, NSW, Australia; 6) Bioinformatics Division, The Walter and Eliza Hall Institute of Medical Research, Parkville, VIC, Australia; 7) School of Life and Environmental Sciences, Deakin University, Geelong, VIC, Australia.

Disease manifestation and presentation is a highly varied and complex phenomenon. The level of complexity of a disease is determined by multiple factors that include the allelic spectrum, genetic architecture and gene epistasis. These are further compounded with a multitude of regulatory and environmental effects. Monogenic and oligogenic diseases are much simpler to understand mechanistically, whilst polygenic diseases stretch the limits of our current knowledge of disease aetiology and of molecular interplay and regulation. In order to dissect the possible molecular mechanisms of complex disease, we have analysed genetic data obtained from genome-wide association studies. We looked at predicted candidate genes from our *Gentrepid* tool. Using what we know of protein pathways, protein-protein interactions and protein domains of the known disease genes to base the predictions (*seeded* approach), we then also took a blind approach (*ab initio*) that searches for enrichment of these annotations from multiple implicated genetic loci. Our results show that both the *seeded* and *ab initio* methods are capable of extracting known disease gene mechanisms. We also believe that novel implications from the *ab initio* approach are highly significant and require further molecular validation. In particular, our case study on coronary artery disease was able to extract novel LDL-like receptor proteins and cell-ECM adhesion factors. With the advent of whole exome and genome sequencing of disease and cancer genomes, even more data will be present to analyse. Therefore, it still remains highly important to be able to dissect the aetiology of diseases at a mechanistic level using current knowledge and more importantly a less biased and more holistic approach. *Gentrepid* is freely available as a webserver at https://www.gentrepid.org.

Genetic association studies with fetal hemoglobin levels and eight clinical complications in African-American sickle cell disease patients. *G. Galarneau[1], S. Coady[2], M. Pandey[2], B. Moore[2], N. Jeffries[2], D. Paltoo[2], A. Guasch[3], A. Kutlar[4], G. Lettre[1], G. Papanicolaou[2], The CARe Project.* 1) Montreal Heart Institute and Université de Montréal, Montréal, Québec, Canada; 2) National Heart, Lung and Blood Institute, Bethesda, MD, USA; 3) Emory University, Atlanta, GA, USA; 4) Medical College of Georgia, Augusta, GA, USA.

Sickle cell disease (SCD) is a monogenic disease caused by mutations in the) *-globin* gene, and results in many severe complications. Previous genetic studies carried out in SCD patients have so far focused on the regulation of fetal hemoglobin (HbF) because it is a strong modifier of morbidity and mortality in this population. However, few well-powered studies have attempted to identify genetic associations with the main clinical complications of SCD. As part of the NHLBI CARe Project, we genotyped 1,514 African Americans with SCD from the Cooperative Study of Sickle Cell Disease (CSSCD) on the IBC genotyping array, a gene-centric platform that contains 47,092 SNPs that cover genetic variation in ~2,100 genes relevant for heart, blood and lung diseases. Using imputation, we increased the total number of SNPs queried to 237,643. HbF levels were analyzed with linear regression. Pain crisis and acute chest syndrome were analyzed as quantitative traits using Poisson regression to account for the skewed distribution of the phenotypic data. Leg ulcer, priapism, osteonecrosis, renal failure, stroke and mortality were analyzed as dichotomous phenotypes using Cox proportional hazards regression models. Three loci had been previously identified as associated with HbF levels: *BCL11A* on chromosome 2, the *HBS1L-MYB* intergenic region on chromosome 6, and the) *-globin* locus on chromosome 11. As expected, we strongly validated the associations at *BCL11A* (rs1427407 ; P-value=2.1×10^{-41}) and the) *-globin* locus (rs3759074; P-value=6.2×10^{-9}). The *HBS1L-MYB* intergenic region was not covered by the IBC array. We did not identify SNPs that reach genome-wide significance level for any of the eight clinical complications tested, which is not surprising given our limited power. However, for these phenotypes, we observed a three- to eight- fold enrichment of SNPs with P-values less than 1×10^{-5} (2.4 expected by chance), suggesting an enrichment of true signals at the top of our results. We selected the most promising markers for replication in a panel of 315 independent African Americans with SCD. Replication results will be presented.

387F

GWAS follow-up mutation screen and expression analysis implicate *ARHGAP29* as a novel candidate gene for nonsyndromic cleft lip/palate. *E.J. Leslie[1], M.A. Mansilla[1], L.C. Biggs[1], K. Schuette[1], S. Bullard[2], T.X. Zhang[3], M. Cooper[4], M. Dunnwald[1], A.C. Lidral[2], D. FitzPatrick[5], M.L. Marazita[4], T.H. Beaty[3], J.C. Murray[1].* 1) Department of Pediatrics, University of Iowa, Iowa City, Iowa, USA; 2) Department of Orthodontics, University of Iowa, Iowa City, Iowa, USA; 3) Department of Epidemiology, School of Public Health, Johns Hopkins University, Baltimore, Maryland, USA; 4) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 5) Medical Research Council Human Genetics Unit, Western General Hospital, Edinburgh, UK.

Nonsyndromic cleft lip and/or cleft palate (NSCL/P) is a common birth defect with complex etiology reflecting the action of multiple genetic and/or environmental factors. Genome wide association studies have successfully identified novel loci associated with NSCL/P including a locus on 1p22.1. The peak association signals at this locus are near or in the *ABCA4* gene, mutations in which cause a range of retinal disorders. Neither expression analysis nor mutation screening support a role for ABCA4 in the etiology of NSCL/P, so we investigated an adjacent gene, *ARHGAP29*, encoding Rho GTPase activating protein 29. ARHGAP29 has preferential activity toward RhoA, which is involved in many functions related to cellular shape, movement, and proliferation, all critical for craniofacial development. Sequencing of *ARHGAP29* in 1064 individuals with NSCL/P and 357 unrelated controls from the Philippines and the United States (US) revealed one nonsense and eleven missense variants. The cumulative frequency of rare coding variants (defined by a minor allele frequency less than 0.5%) from both populations was greater for cases than controls (0.38% vs. 0.19%), but this difference is not statistically significant (p=0.29). Expression analysis using a mouse model demonstrated that *Arhgap29* is present in the epithelium and mesenchyme of the medial and lateral nasal processes and the mandibular processes at E10.5 as well as the oral and medial edge epithelia and palatal mesenchyme at E14.5. We tested the most associated SNP (rs560426) near *ABCA4* and *ARHGAP29* for genetic interaction with other candidate genes including *IRF6*, 8q24, and *MAFB*, identifying a possible interaction with IRF6 (rs2235371) (p=0.04), which is supported by reduced expression of Arhgap29 in the oral epithelium of a mouse deficient for *Irf6*. These data suggest a novel pathway for clefting involving the transcription factor *IRF6* interacting with the Rho pathway via *ARHGAP29*. The combination of genome wide association, rare coding sequence variants, craniofacial specific expression, and interactions with a known clefting gene, *IRF6*, support a role for *ARHGAP29* in NSCL/P. Additional sequencing of *ARHGAP29* and putative regulatory elements will be needed to identify other rare and common variants contributing to NSCL/P. Further study of the genetic and molecular interactions between *ARHGAP29*, *IRF6* and other candidate genes in model systems will further elucidate the role of *ARHGAP29* in craniofacial development.

Whole-genome sequencing and haplotype characterization of an extended multiplex kindred with inflammatory bowel disease. *A.P. Levine[1], L. Jostins[2], G.W. Sewell[1], P.J. Smith[1,3], L.B. Lovat[3], A.P. Walker[1], J.C. Barrett[2], A.W. Segal[1].* 1) Division of Medicine, University College London, London, WC1E 6JJ, United Kingdom; 2) Statistical and Computational Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, United Kingdom; 3) Department of Gastroenterology, University College London Hospitals NHS Foundation Trust, London, NW1 2BU, United Kingdom.

The study of large families with many affected individuals is a powerful method for identifying rare disease causing variants that might contribute to the “missing heritability”. To date, this approach has been of limited value in inflammatory bowel disease (IBD) owing to the moderate size of families described and the polygenic architecture of IBD. We have characterized an extended multiplex kindred of Ashkenazi Jewish descent comprising over 40 individuals with IBD spanning seven cities, from a total of over 800 individuals across four generations. This is far in excess of the 6 affected individuals expected given the prevalence of IBD of ~0.75% in this population. To assess the extent to which the increased prevalence is due to a high load of known IBD risk loci, we genotyped 160 family members for 38 previously associated variants. The family has a significant enrichment of known risk variants, but simulations show that this does not explain the large number of cases observed. We genotyped all affected and 60 unaffected family members for 300K SNPs. To cope with the size of the family, we implemented a novel parallel method that combines pairwise identity-by-descent calculation and haplotyping in selected overlapping subfamilies to reconstruct haplotype sharing over the entire pedigree. No genome-wide significant linkage was found, consistent with a complex disease. We therefore conducted a joint linkage and high-throughout sequencing experiment to identify rare moderate-to-high penetrance variants. We performed whole-exome sequencing in 6 affected individuals and used the haplotype sharing information within the family to identify genomic regions that could harbor causal variants. We filtered variants on microarray gene expression in monocyte-derived macrophages and rectal biopsies from patients, population frequency and functional prediction. We present a number of candidate variants and describe bioinformatic and experimental procedures for variant follow-up. As no candidate variant seemed to fully explain the heightened disease prevalence, whole-genome sequencing is being performed on an additional 8 selected individuals from a subfamily prioritized for the lowest *a priori* disease risk. This will allow full identification of coding and non-coding variants in all shared haplotypes. This family and its associated datasets provide an unprecedented resource for studying the profile and segregation of common and rare disease variants in IBD.

Exome sequencing in two families of Dutch origin segregating for celiac disease. *A.M. Szperl[1], I. Ricaño-Ponce[1], J.K. Li[2], P. Deelen[1], A. Kanterakis[1], V. Plagnol[3], F. van Dijk[1], HJ. Westra[1], G. Trynka[1], C.J Mulder[4], M. Swertz[1], H.Ch. Zheng[2], C. Wijmenga[1].* 1) Genetics, UMCG, Groningen, Groningen, Netherlands; 2) Department of BioMedical Research, Research & Cooperation Division, BGI-Shenzhen, Shenzhen, China; 3) UCL Genetics Institute, University College London, London, UK; 4) Department of Gastroenterology, VU Medical Center, Amsterdam, the Netherlands.

Celiac disease (CeD) is a complex genetic disorder triggered by the environmental factor gluten, in genetically susceptible individuals. HLA and associations to 39 non-HLA loci explain around 40% of the heritability of CeD. We hypothesized that part of the hidden heritability could be due to low-frequency and rare variants that influence expression of protein and which map to exons and splice sites. Such causal variants could be more prominent in multi-generation families in which private mutations may co-segregate with the disease. We performed a combined linkage analysis and exome sequencing approach in two Dutch families, one family covered three generations and the other four, containing 23 patients in total that show an autosomal dominant segregation of CeD. The families showed linkage to five different regions of the genome (4q32.3-4q33, 6q25.3, 8q24.13-8q24.21, 9p13 and 10q23.1-10q23.32). In both families we then selected two affected individuals separated by 4 or 5 meiotic steps for sequencing. We investigated the linkage regions and the remaining exome for causal nonsense variants. In the first family we identified 12 nonsense mutations with a low frequency (MAF < 10%) present in both individuals, but none mapped to the linkage regions. Two nonsense variants in the CSAG1 and KRT37 genes were found to be present in all affected individuals. We are currently validating all the candidate nonsense variants from the second family by Sanger sequencing. The variants co-segregating with CeD in both families will also be examined in our cohort of >10,000 CeD cases and controls.

Genetic association analysis of CIITA polymorphisms with nasal polyps pathogenesis in Korean asthma patients. *J.S. BAE[1], C.F.A Pasaje[1], C.-S. Park[3], H.D. Shin[1,2].* 1) Life Science, Sogang university, Seoul, Korea; 2) Department of Genetic Epidemiology, SNP Genetics, Inc., Seoul, Republic of Korea; 3) Division of Allergy and Respiratory Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea.

Nasal polyps are abnormal lesions arising mainly from the nasal mucosa and paranasal sinuses. By functioning as a positive regulator of MHC class II transcription, the human class II, major histocompatibility complex, transactivator (CIITA) gene is speculated to be involved in the presence of nasal polyps in asthma and aspirin-hypersensitive patients. To investigate the association between CIITA and nasal polyposis, 18 single nucleotide polymorphisms (SNPs) were genotyped in 467 asthmatics of Korean ancestry who were stratified further into 158 aspirin exacerbated respiratory disease (AERD) and 309 aspirin-tolerant asthma (ATA) subgroups. From pairwise comparison of the genotyped polymorphisms, 11 major haplotypes (frequency > 0.05) were inferred and selected for further association analysis. Differences in the frequency distribution of CIITA variations between polyp-positive cases and polyp-negative controls were determined using logistic analyses. Results reveal that five CIITA SNPs were significantly associated with the presence of nasal polyps in the overall asthma group (P = 0.006-0.05, OR = 0.53-2.35, using various modes of genetic inheritance). In addition, significant associations were also observed between the genetic variants tested for the presence of nasal polyps in AERD (P = 0.01-0.02, OR = 2.45-2.66) and ATA (P = 0.001-0.05, OR = 0.45-2.61) patients. The conclusions derived from the study are preliminary and may provide useful insights on the pathogenesis of nasal polyps. (This abstract will be submitted to a journal before the October meeting.).

Familial Autoimmune Disease among Children with MS in the Canadian Pediatric Demyelinating Disease Study. *L. Zahavich[1], M. McGowan[1], C. Guimond[2], I. Yee[2], D.L. Arnold[3,4], A. Bar-Or[3,4], R.A. Marrie[6], B. Banwell[1,5], A.D. Sadovnick[2].* 1) The Hospital for Sick Children, Toronto, Canada; 2) The University of British Columbia, Vancouver BC; 3) The Montreal Neurological Institute, Montreal QC; 4) McGill University, Montreal QC; 5) The University of Toronto, Toronto ON; 6) University of Manitoba, Winnipeg, MB.

Background: The etiology of Multiple Sclerosis (MS) is thought to involve a complex interaction between genetic and environmental factors. Associations have been shown between susceptibility to MS and immune-response genes. Between 25-40% of children with acute acquired demyelination (ADS) of the CNS will ultimately be diagnosed with MS. Objective: To explore whether family history of MS or other autoimmune disorders helps distinguish children destined for MS from those with a monophasic CNS illness. Methods: As part of a 23-site prospective, observational Canadian Pediatric Demyelinating Disease Study, genetic-epidemiology data was acquired by a genetic counsellor through standardized interviews of biological parents, legal guardians, and/or grandparents of children presenting with ADS. Data collected included prenatal factors and demographic and health (particularly autoimmune diseases including rheumatoid arthritis, juvenile diabetes, lupus erythematosus, IBD and thyroiditis) information on the proband, proband's parents and grandparents. Results: Of 302 enrolled children with confirmed demyelination, 216 (71.5%) have completed the genetic interview to date and 47 of these (21.8%) have been diagnosed with MS (conferred by second clinical demyelinating attack or by MRI confirmation of dissemination in time). Among children with monophasic ADS, 107 (63.7%) reported a family history of autoimmune disease (AID). This is lower than for those with MS, where 36 (76.6%) had a family history of AID (p=0.089). A family history of IBD was most associated with a diagnosis of MS (p=0.045) followed by rheumatoid arthritis (p=0.069). Of children with MS, 8 (17.0%) reported a family history of MS. This is similar to children with monophasic ADS where 26 (18.8%, p=0.79) described a family history of MS. Conclusions: Our previous work has described familial autoimmune disease in children with ADS, however this new data provides insight into the difference in familial AID between children with monphasic ADS and those with MS. Preliminary results suggest that children with MS have a higher familial rate of AID. Of note, the strongest association of AID for patients with MS was IBD. The increased frequency of IBD in families of children with MS suggests that despite the involvement of different organ systems, there is a shared genetic factor increasing one's risk for AID. Future studies are ongoing exploring possible susceptibility loci in children with IBD and MS.

The AcB61 and AcB60 recombinant congenic strains of inbred mice: susceptibility and resistance to a murine model of human Typhoid fever. *S.C. Beatty[1,2], M. Roy[3], J.C. Loredo-Osti[4], D. Malo[5].* 1) Complex Traits Group, McGill University, Montreal, QC; 2) Human Genetics, McGill University, Montreal, QC; 3) Department of Equine Internal Medicine, University of Calgary, Calgary, AB; 4) Department of Mathematics and Statistics, Memorial University, St. John's, NFLD; 5) Department of Medicine, McGill University, Montréal, QC.

Survival following acute infection with *Salmonella* Typhimurium, a systemic infection modelling human typhoid fever, is dependent upon a coordinated and genetically complex immune response. Previously our laboratory identified a locus, *Ity5* (chr2) in (AcB61x129S6)F2 mice, linked to a susceptibility to *Salmonella* infection of unknown aetiology.Using a fully informative F2 intercross we have validated the presence of the *Ity5* locus in (A/Jx129S6)F2 mice. In addition to *Ity5* we have a identified a second locus linked to resistance to Salmonella infection, *Ity8* (chr15) in (AcB60xDBA/2J)F2 mice. Using genome-wide transcription profiling and fine mapping, informed through the exploitation of bioinformatic resources, we have identified candidate genes underlying the *Ity5* and *Ity8* loci. Using both DNA and RNA sequencing, as well as analysis of gene expression (Q-PCR) we have characterized the impact of positional candidate genes for both *Ity5* and *Ity8* on the host-response to *Salmonella* infection. Through the characterization of the *Ity5* and *Ity8* susceptibility and resistance loci these results provide new insight into the pathogenesis of Salmonella infection and further illuminate the genetic elements of the host immune response to the murine model of Typhoid fever.

Deep sequencing and pooled association testing of 259 candidate genes reveals a role for rare variants associated with durable control of HIV-1 replication. *P.J. McLaren[1, 2], E.A. Stahl[1, 2], M. Rivas[2,3], F. Pereyra[4], N. Gupta[2], B.D. Walker[4], P.I.W. de Bakker[1,2,5], The International HIV Controllers Study.* 1) Department of Medicine, Harvard Medical School, Boston, MA; 2) Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Oxford Centre for Diabetes, Endocrinology & Metabolism, Oxford, UK; 4) Ragon Institute of MGH, MIT and Harvard, Charlestown, MA; 5) Department of Medical Genetics, Division of Biomedical Genetics, University Medical Center, Utrecht, Netherlands.

Background: Low-frequency variants are poorly interrogated by GWAS, though likely influence complex phenotypes. A recent GWAS of HIV control demonstrated a major role for common variants within the MHC and no significant associations elsewhere. Here we used pooled next-generation sequencing of select genes to test rare sequence variants for association to HIV control.

Methods: We sequenced the coding exons of 295 candidate genes known to impact the HIV life cycle, host response to HIV or with suggestive GWAS P-values in 499 HIV controllers (virus load <2,000 copies per mL) and 500 progressors (median virus load >50,000 copies per mL) of European ancestry. We used principal components from GWAS data to match cases to controls. We constructed 40 case pools and 40 control pools of 12 or 13 individuals each, captured their exons by in-solution hybridization and sequenced them on the Illumina HiSeq. Variants were called using the Syzygy algorithm and filtered based on several quality control heuristics. We used likelihood ratio tests to assess single variants, and permutation-based burden tests per-gene and across all genes to detect differences in variant frequencies between controllers and progressors.

Results: Sequence data was obtained for ~450 Kb of exon target with a median coverage of >250x. After variant calling and quality control, 2,005 SNPs were analyzed. No single variant reached study-wide significance using likelihood ratio tests ($P>1x10^{-4}$). Burden tests (including C-alpha and variable threshold tests) of variants across the entire gene set showed significant association (study-wide permutation P-values < 0.01) and an enrichment of variants occurring exclusively in HIV controllers ($P<0.05$). Three genes, *SOCS1*, *ACCN1* and *WWOX* (implicated in HIV replication by genome-wide transcriptional profiling, or with suggestive GWAS P-values) achieved significant burden test results after correcting for multiple comparisons ($P<3x10^{-4}$ for all).

Conclusions: Next-generation sequencing of candidate genes shows differential proportions of rare variants in HIV controllers compared to progressors. This analysis implicates novel non-MHC genetic factors in HIV control, highlighting a role for low-frequency variants not detected by GWAS. These encouraging preliminary findings are now being replicated.

Polymorphisms in *MC3R* promoter and *CTSZ* 3`UTR are associated with tuberculosis susceptibility. *M. Möller[1], L.A. Adams[1], A. Nebel[2], S. Schreiber[2], L. van der Merwe[3,4], P.D. van Helden[1], E.G. Hoal[1].* 1) DST/NRF Centre of Excellence for Biomedical Tuberculosis Research / MRC Centre of Molecular and Cellular Biology, Faculty of Health Sciences, Stellenbosch University, Western Cape, South Africa; 2) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 3) Biostatistics Unit, Medical Research Council, Tygerberg, South Africa; 4) Department of Statistics, University of Western Cape, South Africa.

We have validated the association of two genes on chromosome 20q13.31-33 with tuberculosis susceptibility. A previous genome-wide linkage study performed by Cooke *et al* identified the genes melanocortin-3-receptor (*MC3R*) and cathepsin Z (*CTSZ*) as possible candidates in tuberculosis susceptibility. MC3R has been implicated in obesity studies and is known to play a role in many biological systems including the regulation of energy homeostasis and fat metabolism. CTSZ has been detected in immune cells, such as macrophages and monocytes and it is hypothesized that the protein may play a role in the immune response. In our South African population, a case-control study confirmed the previously reported association with a SNP in *CTSZ* and found an association in *MC3R* with a SNP not previously implicated in tuberculosis susceptibility. Six single nucleotide polymorphisms (SNPs) in *MC3R* and eight in *CTSZ* were genotyped and haplotypes were inferred. SNP rs6127698 in the promoter region of *MC3R* (cases = 498, controls = 506) and rs34069356 in the 3`UTR of *CTSZ* (cases = 396, controls = 298) both showed significant association with tuberculosis susceptibility ($p = 0.0004$ and <0.0001, respectively) indicating that pathways involving these proteins, not previously researched in this disease, could yield novel therapies for tuberculosis.

Investigating single nucleotide polymorphisms and interactions of candidate genes involved in susceptibility to tuberculosis in a South African population. *C. Wagman, M. Möller, E.G. Hoal.* Division of Molecular Biology and Human Genetics, MRC Centre for Molecular and Cellular Biology and the DST/NRF Centre of Excellence for Biomedical TB Research, Faculty of Health Sciences, Stellenbosch University, Tygerberg 7505, South Africa.

Tuberculosis (TB) is an infectious disease, primarily caused by the bacterium *Mycobacterium tuberculosis*, which is estimated to have infected a third of the world's population and has resulted in a worldwide incidence of more than 8 million cases per year and a mortality rate of 2 million individuals each year. In developing countries, such as South Africa, TB has been a public health problem for a long time. According to the latest World Health Organisation report, South Africa is ranked 5th in the world with regards to TB incidence. Although a large portion of the population is infected with *M. tuberculosis*, only 10% of those infected will develop active disease while the majority of the population effectively control the bacterium. Many studies have shown that genetic factors are involved in the disease and numerous studies have identified host susceptibility genes in TB. The Macrophage Scavenger Receptor with Collagenous Structure (*MARCO*); Surfactant Protein D (*SP-D*); Toll-like Receptor 2 (*TLR2*) and *CD14* genes have been shown to play crucial roles in TB. We investigated the role of ten single nucleotide polymorphisms (SNPs) in the *MARCO* (rs6761637; rs1318645; rs3943679 and rs2119112) and *SP-D* (rs1923537; rs1923538; rs1923539; rs2243639; rs721917 and rs2255326) genes in susceptibility to TB in the South African Coloured population. This population is genetically diverse, as there is genetic input from several populations, and this makes it possible to evaluate the association of unique markers with TB in a single population. A case-control association study was done which included approximately 400 pulmonary TB patients and 400 healthy controls. Samples were genotyped with ARMS-PCR and TaqMan™ SNP genotyping assays and genotypes were confirmed by sequencing. Gene interaction analysis was performed with SNPs from *MARCO*, *SP-D*, *CD14* and *TLR2*. The R statistical program was used to analyse results, which were all adjusted for age and sex. We found that five SNPs (rs1923537; rs2255326; rs1318645; rs3943679; rs2119112) were associated with TB susceptibility in the Coloured population. A number of haplotypes occurred more frequently in cases than controls and there was an indication that SNPs from genes interacted with SNPs from the same gene as well as the other genes in question. These results suggest that variants in *MARCO* and *SP-D* and interactions between these genes and *CD14* and *TLR2* may affect susceptibility to TB in the South African population.

396F

QTL analysis, pathway analysis and consomic mapping show genetic variants of Tnni3k, Fpgt or H28 control susceptibility to viral myocarditis. *S. Wiltshire, G.A. Leiva-Torres, S.M. Vidal.* Human genetics, Mcgill University, Montreal, QC, Canada.

Coxsackievirus B3 (CVB3) infection is the most common cause of viral myocarditis. The pathogenesis of viral myocarditis is strongly controlled by host genetic factors. While certain indispensible components of immunity have been identified, the genes and pathways underlying natural variation between individuals remain unclear. Previously, we isolated the Viral Myocarditis Susceptibility 1 (Vms1) locus on chromosome 3, which influences pathogenesis. We hypothesized that confirmation and further study of Vms1 controlling CVB3-mediated pathology, combined with pathway analysis and consomic mapping approaches, would elucidate both pathological and protective mechanisms accounting for natural variation in response to CVB3 infection. Vms1 was originally mapped to chromosome 3 using a segregating cross between susceptible A/J and resistant B10.A mice. To validate Vms1, C57BL/6J-Chr 3A/NaJ (CSS3) were used to replicate susceptibility compared to resistant C57BL/6J (B6). A second segregating F2 cross was generated between these confirming both the localization and effects of Vms1. Microarray analysis of the four strains (A/J, B10.A, B6 and CSS3) illuminated a core program of response to CVB3 in all strains that is comprised mainly of interferon stimulated genes. Microarray analysis also revealed strain specific differential expression programs and genes that may be prognostic or diagnostic of susceptibility to CVB3 infection. A combination of analyses revealed very strong evidence for the existence and location of Vms1. Differentially expressed pathways were identified by microarray and candidate gene analysis revealed Fpgt, H28 and Tnni3k as likely candidates for Vms1. .

Genetic Analysis of a Rat Model of Aerobic Capacity and Aging. *Y. Ren[1], L.G. Koch[2], S.L. Britton[2], N. Qi[3], C.F. Burant[3], M.K. Treutelaar[3], J. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Anesthesiology, University of Michigan, Ann Arbor, MI; 3) Department of Internal Medicine, University of Michigan, Ann Arbor, MI.

We have established two outbred lines of rat for studying the biological basis of running capacity and metabolic traits. The two lines, high capacity runners (HCR) and low capacity runners (LCR), were developed by selectively breeding for high and low inborn endurance running capacity. HCRs and LCRs are maintained as heterogeneous cohorts using a rotational mating scheme to minimize inbreeding. After 27 generations, the two lines differed by 7-fold in running capacity, and diverged in many other physiological measures and health indicators, including metabolic syndrome, body weight, oxygen consumption, and life span. Our goal is to use HCR/LCR as a model system for dissecting the genetic and functional mechanisms of endurance, metabolism, and accelerated aging. We genotyped genomic DNA for 142 rats representing the breeding members of both lines at the 5th, 14th, and 26th generations by using the Affymetrix Rat Mapping 10K GeneChips that cover >10K SNPs. Principal Component Analysis (PCA) reveals an increase in genetic divergence between the two lines over the three generations analyzed. The clusters also became tighter over time, reflecting increasing levels of fixation. As expected, genomewide heterozygosity decreased over time in both lines, ranging from 0.37 to 0.34 in HCRs, and 0.37 to 0.36 in LCRs. The coefficient of inbreeding showed an increasing trend across generations. The heritability of running capacity was much higher in the HCR line for two possible reasons: (1) the low runner trait approaches its lower limit in early generations, reducing the effectiveness of selection; and (2) more genetic loci exist for high aerobic capacity and were progressively exposed to selection as “buffering” loci came to fixation. Haplotype structures showed significant differences between the HCR and LCR lines, supporting our hypothesis that different alleles are differentially enriched among the two divergent lines. Ongoing analysis will compare the patterns of genetic drift and selective sweep in both lines, and determine the heritability of related traits such as body weight and aging phenotypes, across 28 generations. An animal model such as HCR/LCR has the inherent advantage of a known genealogy, controlled environment, accessibility of multiple tissues for functional analyses, and has the potential to accelerate the understanding of polygenic human traits, including aging and late-life diseases.

Conditioning on associated alleles increases power to detect linkage and gene-gene interaction. *B. Corso[1,2], R.L. Subaran[2,3], D.A. Greenberg[2,3].* 1) Applied Health Science, University of Pavia, Pavia, Italy; 2) Division of Statistical Genetics - Biostatistics, Columbia University, Mailman School of Public Health; 3) Department of Psychiatric, New York State Psychiatric Institute Columbia - Presbyterian Medical Center.

Background Complex diseases are likely influenced by multiple interacting genes. However, proving that gene-gene interaction exists between loci is difficult. Many existing methods can be computationally intensive and are often underpowered. We tested whether interaction can be reliably established between two epistatically interacting loci (A & B) compared to two loci that independently produce the trait (heterogeneity). We hypothesized that observing only offspring that carry an allele strongly associated with the trait at locus A significantly increases power to detect linkage at locus B compared to analysis where all offspring are observed. Furthermore we predict that such a comparison can yield evidence of an interaction between the two loci. **Methods** We generated linkage data for a disease caused by two separate, epistatically-interacting loci and tested evidence for linkage. A marker allele near disease locus A was in strong linkage disequilibrium (LD) with the disease allele at A. There was no disease-marker association for locus B. We then removed (pruned) all offspring without the locus A-associated marker allele and reanalyzed the dataset for linkage, thus stratifying the data on the presence of the locus A disease allele. For comparison, we did the same two analyses on data simulated under a two locus heterogeneity model where each locus caused disease independently (i.e., no inter-locus interaction). **Results** Under epistasis, when the associated marker is in strong LD (D' > 0.8) with the disease allele at locus A, removal of all offspring not carrying the associated marker *increased* the Hlod score at locus B. Under heterogeneity, this stratification strategy *lowered* the Hlod score at locus B compared to analysis of the unpruned data. We show that if the Hlod score increases by 0.5 or more after pruning, this indicates epistasis with 93% sensitivity over multiple epistatic disease models (DD, DR, RD, RR). When heterogeneity was simulated, the Hlod for the pruned families is significantly lower than for the unpruned data and the average specificity across all disease models is 98%. Sensitivities: RR=100%; DD=82%; DR=91%; RD=96%. Specificities: RR=DD=RD=100%; DR=92%. **Conclusion** We propose that the stratification scheme we tested (1) can increases the power to detect epistatically interacting loci; (2) can, with good specificity and sensitivity, distinguish whether linkage signals are the result of gene-gene interaction or heterogeneity.

399F

Genome-wide meta-analysis of autosomal SNP differences between men and women. *V. Boraska[1,2], Autosomal sex differences meta-analysis group.* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) University of Split School of Medicine, Soltanska 2, 21000 Split, Croatia.

Introduction: The male-to-female sex ratio at birth is constant across world populations, ranging between 1.02-1.08 (102-108 male to 100 female live births), with an average of 1.06 for populations of European descent. Sex ratio is considered to be affected by numerous biological and environmental factors, and has been suggested to have a heritable component. The aim of the present study is to investigate the presence of common-allele modest effects at autosomal variants that could explain the observed sex ratio at birth. We also conducted a simulation study to assess the probability of observing significant allele frequency differences at autosomal markers between men and women. Methods: We conducted fixed and random-effects large-scale genome-wide scan (GWAS) meta-analysis across 51 studies, comprising overall 114,863 individuals (61,094 women and 53,769 men) of European ancestry. Allele frequencies were compared between men and women for directly-typed and imputed common (minor allele frequency >0.05) variants within each study. Forward-time simulations for unlinked neutral biallelic loci were performed under the demographic model for European populations. Results and Discussion: We did not detect any genome-wide significant ($p<5x10^{-8}$) autosomal common SNP differences between men and women in the meta-analysis. We also observed no frequency differences between men and women in our simulation of 1.3 million common loci in a cohort matching the study sample. Conclusion: This large-scale investigation across ~115,000 individuals shows no detectable contribution from common genetic variants to the observed skew in sex ratio. The absence of sex-specific differences is useful in guiding genetic association study design, for example when using mixed controls for sex-biased traits.

Additive genetic variation in risk to schizophrenia tagged by common SNPs in an admixed African American population. *T. de Candia[1, 2], S.H. Lee[3], J. Yang[3], P.M. Visscher[3], N.R. Wray[3], M.C. Keller[1, 2], P.V. Gejman[4], D.F. Levinson[5].* 1) Department of Psychology & Neuroscience, University of Colorado at Boulder, CO, USA; 2) Institute for Behavioral Genetics, University of Colorado at Boulder, CO, USA; 3) Queensland Institute of Medical Research, 300 Herston Road, Brisbane, Australia 4006; 4) Department of Psychiatry and Behavioural Sciences, Evanston Northwestern Healthcare Research Institute, Evanston, IL, USA; 5) Department of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, CA 94304-5797, USA.

Schizophrenia is a highly heritable disorder (~.7 to .8) with a prevalence rate of ~1%, but with prominent variation between populations (McGrath, 2006) . However, to date, few studies have specifically examined heritability in African American (AA) populations. We used a recently developed method to determine the proportion of additive genetic variance in liability to schizophrenia tagged by common SNPs in the AA (n=1286 cases and 973 controls) Molecular Genetics of Schizophrenia sample. We also undertook a number of additional analyses, including the exclusion of SNPs that predict African ancestry, to explore the impact, if any, of population stratification on these results. Using 760803 genome-wide SNPs that passed rigorous quality control procedures, we estimate the variation in liability to schizophrenia associated with these SNPs after controlling for potential confounds to be at least .25 (SE .13). These results are in line with previous studies using samples of European Ancestry (EA). Given that common SNPs capture a considerable proportion of heritability, this indicates that common causal variants are likely important factors in the etiology of schizophrenia. Multi-ethnic studies in complex disease: towards better insight in disease mechanisms. *E. Festen[1,2], J.Y. Fu[2], C. Wijmenga[2].* 1) Dept of Gastroenterology, UMCG, Groningen, Groningen, Netherlands; 2) Dept of Genetics, UMCG, Groningen, Groningen, Netherlands.

Genome-wide association studies (GWAS) have become a powerful tool to identify genetic variants underlying complex human traits and have greatly improved our understanding of complex disease. Although the history of GWAS is still short, the course of the development of GWAS seems to consist of four consecutive stages: 1) single GWAS performed per research institute with samples taken exclusively from Caucasian populations; 2) merging of multiple GWAS in meta-analyses by research institutes joining forces in international consortia; samples are still taken from Caucasian populations; 3) GWAS on non-Caucasian populations; 4) establishment of global consortia for GWAS on multi-ethnic groups simultaneously. Currently GWAS are heading from stage 1 and 2, to stage 3 and 4. Complex traits are characterized by marked genetic heterogeneity. This heterogeneity poses a major challenge in complex disease research, but also yields an opportunity for multi-ethnic mapping. The recent advance in GWAS on East Asian populations allows us to compare the genetic architecture of complex traits between Caucasians and East Asians. Based on this comparison we construct a proposal on analysis strategies for multi-ethnic GWAS. For this study we selected four traits for which we extracted the risk loci reported from Caucasian and East Asian GWAS from the GWAS database (www.genome.gov/gwastudies). We analyzed 34 susceptibility loci for type 2 diabetes, 21 loci for systemic lupus erythematosus, 47 loci for ulcerative colitis and 157 loci for height. For each trait we observed that 50%-100% of the susceptibility loci identified in East Asians were shared with Caucasians. However, we also observed that 25%-55.6% of the association signals at the shared loci were independent between populations (R2< 0.2 in each population). This suggests that diseases etiology is common between populations but risk variants can be population-specific. The population-specific variants could result from natural selection, genetic drift and from recent mutation after population immigration. When analyzing multi-ethnic GWAS population-specific variants will significantly reduce the power of the study. Therefore we propose gene-based meta-analysis to pool population-specific signals at the shared loci. Gene-based meta-analysis is a complementary approach to signal variant-based meta-analysis that is also targeted at shared association signals.

Weedon[13].* 1) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 2) Harvard Medical School, Department of Genetics, Boston, Massachusetts, United States of America; 3) Broad Institute, Cambridge, Massachusetts, United States of America; 4) Children's Hospital, Boston, Massachusetts, United States of America; 5) Department of Public Health and General Practice, Norwegian University of Science and Technology, Trondheim, Norway; 6) National Institute for Health and Welfare, Helsinki, Finland; 7) Department of Laboratory Medicine, Norwegian University of Science and Technology, Trondheim, Norway; 8) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 9) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, United States of America; 10) Estonian Genome Project, University of Tartu, Tartu, Estonia; 11) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 12) Department of Medical Genetics, University of Helsinki and University Central Hospital, Helsinki, Finland; 13) Genetics of Complex Traits, Peninsula Medical School, University of Exeter, Exeter, United Kingdom.

Common genetic variants have been shown to explain a fraction of the inherited variation for many common diseases and quantitative traits, including height, a classic polygenic trait. The extent to which common variation determines the phenotype of even highly heritable traits such as height is uncertain, as is the extent to which common variation is relevant to individuals with more extreme phenotypes. To address these questions, we genotyped SNPs at ~160 loci previously associated with height in 1,214 individuals from the top and bottom extremes of the height distribution (tallest and shortest ~1.5%), drawn from ~78,000 individuals from the HUNT and FINRISK cohorts. We found that common variants still influence height at the extremes of the distribution: more common variants were nominally associated with height in the expected direction than is consistent with chance ($p < 5 \times 10^{-28}$) and the odds ratios in the extreme samples were broadly consistent with the effects estimated previously in population-based data. To examine more closely whether the common variants have the expected effects, we calculated a weighted allele score (WAS), which is a weighted prediction of height for each individual based on the previously estimated effect sizes of the common variants in the overall population. The average WAS was consistent with expectations in the tall individuals, but was not as extreme as expected in the shortest individuals ($p<0.006$), indicating that some of the short stature is explained by factors other than common genetic variation. The discrepancy was more pronounced ($p<10^{-6}$) in the most extreme individuals (height <0.25 percentile). In additional simulations, we showed that the observed WAS was consistent with a number of different models incorporating rare genetic variants (or rare non-genetic factors) that decrease height. In conclusion, our data suggest that common genetic variants are associated with height at the extremes as well as across the population, but that additional factors start to predominate around the shorter 0.25% extreme.

A comprehensive assessment of the power to detect low-frequency risk alleles through imputation in genome-wide association studies of Northern European populations. *B. Howie[1], C. Fuchsberger[2], H.M. Kang[2], A. Mahajan[3], A. Morris[3], M. Stephens[1] on behalf of the 1,000 Genomes Project and the Genetics of Type 2 Diabetes (GoT2D) Consortium.* 1) Department of Human Genetics, University of Chicago, Chicago, IL, USA; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Through a combination of large disease cohorts and improvements in DNA sequencing and genotyping technologies, it is now possible to extend genome-wide association studies (GWAS) to variants that exist at low frequency (0.5-5%) in a population. One affordable way to test such variants is to sequence them in hundreds of samples, then use statistical imputation methods to extrapolate them to thousands of GWAS samples. A major challenge in designing and interpreting this kind of study is to know how much power is lost through imperfect imputation. Researchers have tried to address this question through cross-validation in existing GWAS datasets, but such comparisons are hard to generalize because of SNP ascertainment bias and limited sampling of the genome. Here, we use data from the GoT2D Consortium to overcome these limitations and provide the first comprehensive assessment of imputation power for low-frequency variants throughout the genome. GoT2D is investigating the genetic architecture of type 2 diabetes (T2D) through a combination of low-coverage shotgun sequencing, deep exome sequencing, and 2.5M SNP array genotyping of 1,325 cases and 1,325 controls of Northern European ancestry. We use this dataset to evaluate imputation accuracy by masking GoT2D genotypes and imputing them from a reference panel of 762 European haplotypes from the 1,000 Genomes Project (1kGP). We find that the 1kGP haplotypes, which were estimated statistically from low-coverage sequence data, are nearly as effective for imputation as high-quality haplotypes obtained from array genotypes and family transmission data for the same samples. We observe high imputation coverage among common SNPs and a nearly linear relationship between coverage and MAF at low-frequency SNPs, where imputation from a 2.5M array captures (at R^2>0.8 between true and imputed genotypes) 76% of SNPs with MAF=5% and 41% of SNPs with MAF=1%. For SNPs with MAF<1%, coverage drops sharply to 17%, which actually overestimates genome-wide coverage because SNP discovery is incomplete at low frequencies; we are actively working to quantify this effect. We also quantify the ascertainment bias of using GWAS SNP chips in cross-validations: relative to SNPs on a 2.5M array, the mean R^2 between true and imputed genotypes at non-chip SNPs drops by 0.03 for MAF>5%, 0.08 for MAF= 3%, and 0.25 for MAF<1%. These results provide valuable benchmarks that we will update as larger reference panels are generated by 1kGP and GoT2D.

Dissecting the genetic and disease heterogeneity in complex traits: Crohn's Disease as an example. *N. Maniatis[1], H. Elding[1], W. Lau[1], T. Andrew[2], D. Swallow[1].* 1) RESEARCH DEPARTMENT OF GENETICS, EVOLUTION AND ENVIRONMENT, UNIVERSITY COLLEGE LONDON, LONDON, United Kingdom; 2) Department of Twin Research & Genetic Epidemiology, Kings College London, London, United Kingdom.

The very small contribution of many genes that has been reported so far in GWA studies for complex diseases has led some to believe that GWA studies have been an expensive waste of time. However for many complex traits, it is very likely that different risk genes are involved in different patients. Dissecting this genetic heterogeneity is thus of utmost importance for the identification of all the genes involved. Here we report an approach to this problem and also demonstrate methodological progress and the importance of using high-resolution genetic maps in identifying disease loci. We employ a multimarker approach to analyse many SNPs simultaneously within a genomic window. This takes directly into account the underlying structure of Linkage Disequilibrium (LD) by using genetic distances from LD maps rather than physical locations, and provides an estimated location of the causal variant. In addition, we genetically and phenotypically stratify the data to demonstrate independent effects. Here we give as an example our work on Crohn's Disease (CD) and on chromosome 16q that harbours *NOD2* (the first gene that was identified for CD using family studies). Several GWA studies had only detected *NOD2* despite the fact that linkage is still observed on 16q for families who do not have the common *NOD2* mutations. Using the WTCCC1 data on CD, we show genetic heterogeneity within the *NOD2* region itself and demonstrate the independent involvement of the neighbouring gene *CYLD* which is replicated with striking precision using an independent GWA data. *CYLD* encodes a deubiquitinating enzyme known to be down-regulated in CD. We also report for the first time significant association with the *CDH1/CDH3* genes encoding cadherins, and the *IRF8* gene-region, genes also known to be involved in inflammation/immune dysregulation. These two signals are also powerfully replicated only when we sub-classify the disease phenotype and/or ancestry/ethnicity. We thus show that disease phenotype and ancestry sub-classification can help to dissect the genetics of complex inheritance, and we demonstrate its impact on association mapping. This demonstrates that addition of phenotypic and other data to DNA banks is much more important than increasing their sample size. These results and the striking replication not only bring to light new genes involved in CD but also show how the complexity of complex inheritance can be understood, showing a promising way forward in disease-gene mapping.

Genome-wide methylation profiling of Chronic Rhinosinusitis. *L. Mfuna Endam[1], A. Filali-Mouhim[1], C. Divoy[1], V. Tardif[1], M. Desrosiers[1,2].* 1) Department of Otolaryngology, Hôtel-Dieu Hospital, Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), Montreal, PQ, Canada; 2) Department of Otolaryngology-Head and Neck Surgery, Montreal General Hospital, McGill University, Montreal, PQ, Canada.

Background: Chronic Rhinosinusitis (CRS) is a common inflammatory disorder of the upper airway affecting 10% of Americans. The etiology of CRS remains unknown but is believed to result for deregulated responses to bacterial pathogens on the sinus mucosa. In support of this, our group has identified a marked hyporesponsiveness to bacterial pathogens in cultured primary epithelial cells isolated from CRS patients. (Divoy, 2011) This downregualtion is not present on PBMCS isolated from the same patients, suggesting that a localised effect, possibly from a bacterial toxin. That this effect remains present in cultured cells suggest a potential epigenetic modification in genes of the immune response. Objective: To wished to verify if epigenetic changes are present in cultured primary epithelial cells obtained from CRS subjects by evaluating the methylation status of whole genome in primary nasal epithelial cells isolated from patients with CRS. Methods: Primary nasal epithelial cells were isolated from 11 patients with CRS and 8 controls (CTL) and raised until differentiated in an air-liquid interface. DNA was extracted using QIAmp DNA Mini kit and genome-wide DNA methylation was performed using Illumina Infinium HumanMethylation450 BeadChip. The level of methylation for each CpG site was measured by a quantity (Beta) ranging from 0 (no cytosines methylated) to 1 (all cytosines methylated). To identify differentially methylated CpG sites between the CRS and CTL individuals we used a t test. DeltaBeta was calculated as the average of beta values for CRS group minus the average of beta values for CTL group. We selected loci with |DeltaBeta|>0.2 and t test p value <0.05. Results: In CRS, hypermethylation was detected at 344 loci, while in CTL, hypermethylation was obtained in 50 loci. Pathways analyses using Ingenuity software implicated networks in cell signalling and cell death. Implicated functions were immunological disease, endocrine disorders, cell morphology, cell development, and tissue development and nervous system development and function. Conclusions: Methylation of genes of immune function is present in epithelial cells isolated from CRS subjects and may be responsible for the hyporesponsiveness to bacteria identified in these subjects. Correlation with functional data from expression studies will help assess functional impact of these changes.

Finding all statistically significant genetic interactions in case-control datasets without using a supercomputer. *S. Prabhu, I. Pe'er.* Computer Sci, Columbia Univ, New York, NY.

The hundreds of genetic variants found by GWAS so far have told us very little about the genetic architecture of common diseases. These diseases are likely to possess a complex genetic etiology - harboring gene-gene interactions, among other possibilities. Yet, statistical and computational hurdles have limited the systematic characterization of interactions in genome-scale datasets. Existing approaches fall into 2 categories: either extremely time consuming (exhaustive tests) or incomplete (sub-genome scale). We present a powerful statistical technique - Probably complete and Approximately Correct (PAC) sampling - which overcomes the computational burden that has plagued interaction methodology so far. PAC sampling can exhaustively scan for interactions between millions of SNPs, without relying on incomplete information (like marginal association) to mitigate the search problem. Instead, we reduce our computational footprint by focusing only on those interactions which will pass the multiple-testing burden. In fact, our technique is several orders of magnitude faster than its contemporaries. For datasets of a million SNPs it is ~20X faster for all pairwise tests and ~200X faster for all 3-way tests, when compared to exhaustive search methods that are currently in use. To the best of our knowledge, ours is the only method that has the potential to comprehensively scan for 3-way interactions between millions of SNPs in feasible amounts of time. Most importantly, PAC sampling can provide guarantees of arbitrarily high power (e.g. 99% certain) that all statistically significant interactions in the dataset will be found. We have implemented our algorithm in java, and the software - SIXPAC - is available on our webpage (www.cs.columbia.edu/~snehitp). We ran SIXPAC on 7 common diseases (WTCCC data), scanning for interactions that cleared the Bonferroni significance threshold (1e-11). Our test statistics do not suffer from undue overinflation ($\lambda \sim 1.01$ to 1.06) on the 7 datasets. We observed a distinct landscape of interaction for each disease, and report finding (at least) 1 interaction in CAD, 1 in T1D, 2 in BD, 4 in T2D, 8 in RA, 4 in CD and 3 in HT. Crohns interactions have been validated, while others are as yet untested on other datasets. All interactions have been further confirmed using a regression based ANOVA test (interaction term pval <1e-9), verifying that the interaction effect cannot be attributed to marginal SNP associations.

Screening for pathogenic sequence variants in early-onset and familial Crohn's disease. *N.J. Prescott[1], B. Lehne[1], K. Harrison[1], J. Knight[1], M.A. Simpson[1], P. Green[1], J. Sanderson[2], J.C. Mansfield[3], C.M. Lewis[1], M.E. Weale[1], T. Schlitt[1], C.G. Mathew[1].* 1) Department of Medical and Molecular Genetics, King's College London School of Medicine, London, UK; 2) Department of Gastroenterology, Guy's & St Thomas' NHS Foundation Trust, St Thomas' Hospital, London, UK; 3) Department of Gastroenterology and Hepatology, University of Newcastle upon Tyne, Newcastle Upon Tyne, UK.

Genome-wide association studies (GWAS) have delivered significant discoveries of common genetic variants that increase susceptibility to Inflammatory Bowel Disease. However, much of the genetic contribution to Crohn's disease (CD) remains unaccounted for. A possible source for this is rare disease-causing variants undetectable by GWAS, but with stronger genetic effects. Here, we have used massively parallel sequencing to attempt to elucidate such rare causal variation. We identified 531 candidate genes either located in GWAS hit regions or identified by gene ontology and network-based analyses as interacting with these genes. CD patients were selected for early-onset disease and/or a family history to enrich for causal mutations of higher penetrance. DNA samples from 475 CD cases and 481 controls were pooled and pool size was optimised to 24 using known individual genotypes at 150 SNPs. Coding exons and proximal promoters (1.2Mb total) were enriched from genomic DNA using a custom liquid capture array and then sequenced on an Illumina GAIIx. Variants were called from sequence reads using stringent criteria: base quality >20 per pool, variant seen in 3 or more pools at 1/n of reads per locus per pool (n = pooled chromosome number). We identified 2561 variants, 316 of which were novel and included 118 missense changes and 4 nonsense mutations. We performed variant-level and gene-level analyses, in which allele counts for individual variants, or combined allele counts for all rare variants (control MAF<5%) in a gene, were compared in cases and controls. We replicated associations with known CD risk variants NOD2 p.R702W, IRGM p.L105L, and ATG16L1 pT300A, and observed 2 rare protective variants in IL23R, p.G149R and p.V362I recently reported in a Belgian cohort (Momozawa et al 2011). In the top 20 ranked hits, the ratio of risk:protective effects was high (20:0 in rare variants, 14:6 in genes), despite ratios overall being closer to 1:1 (691:536 in all rare variants, 222:200 in all genes). 6 rare variants, 5 common variants and 5 genes survived Bonferroni correction for multiple tests. In 4 genes the variants conferred increased risk and in one they were protective. Our analyses are consistent with a contribution of rare variants to influencing risk in Crohn's disease. Follow-up studies of candidate genes and variants in large case control samples will be required to further validate their role in pathogenesis.

408F

Joint Ancestry and Association Testing in Admixed Individuals. *D. Shriner, A. Adeyemo, C. Rotimi.* National Human Genome Research Institute, Bethesda, MD.

Population structure is detectable in essentially all human populations given sufficiently large samples and dense panels of genomic markers. In genome-wide association studies, many techniques exist to control for population stratification resulting from analysis of multiple, ancestrally homogenous samples. For admixed samples, it is possible to test for both ancestry effects via admixture mapping and genotypic effects via association mapping. Here, we describe a joint test of ancestry and association for a sample of unrelated, admixed individuals. We first perform high-density admixture mapping using local ancestry. We then perform association mapping using stratified regression, wherein for each marker genotypes are stratified by local ancestry. In both stages, we use generalized linear models providing the advantage that this test can be used with any phenotype distribution (*e.g.*, binary or quantitative traits) with an appropriate link function. To define the alternative densities for admixture mapping and association mapping, we describe a method based on autocorrelation to empirically estimate the testing burdens of admixture mapping and association mapping. We then describe a joint test that uses the posterior probabilities from admixture mapping as prior probabilities for association mapping, capitalizing on the reduced testing burden of admixture mapping relative to association mapping. The sample size required to reach genome-wide significance via association mapping is reduced by a minimum of 63.7% given genome-wide significance via admixture mapping. We illustrate the gain in power through analysis of fasting plasma glucose among 922 unrelated, non-diabetic, admixed African Americans from the Howard University Family Study. We detected loci at 1q24 and 6q26 as genome-wide significant via admixture mapping. Using the joint test, we resolved the 1q24 signal into two intergenic regions. One region, upstream of the gene *FAM78B*, contains three binding sites for the transcription factor PPARG and one binding site for HNF1A, both previously implicated in the pathology of type 2 diabetes. The fact that both loci were discovered via admixture mapping may provide novel insight into the genetic architecture of fasting plasma glucose in persons of African ancestry.

409F

Unveiling and detecting the hidden heritability of complex disease genes. *G. Thomson.* Dept Integrative Biol, Univ California, Berkeley, CA.

Confirmed GWAS SNP associations with complex diseases show weak effects and explain little of the disease heritability even when many disease predisposing genes have been identified. Explanations for this encompass: heritability is overestimated; overly stringent statistical requirements; unidentified structural and rare variants; and predisposing variants are not in sufficient linkage disequilibrium (LD) with the SNPs studied. While all are potentially contributing factors, the aim of this study was to investigate a simpler overriding solution: Does the multi-locus nature of complex diseases itself contribute to this phenomenon, and if so by how much, and how to take account of this? A spectrum of multi-locus models of disease susceptibility, specifying *within* and *between* locus effects, were analyzed. *Except for the case of multiplicative penetrance values between loci, all models show decreasing marginal single locus odds ratios (ORs) and heritability with increasing numbers of disease loci.* This follows since individuals *not* carrying the risk variant at a single locus under study have increased risk when they carry disease predisposing genotypes at other loci. In many cases the resulting marginal effects correspond to those in the range of validated, albeit weak, single SNP associations. For example, if one gene predisposes to disease (recessive with sporadics, allele frequency 0.5) and has an OR of 4; this exact same disease model will result in marginal ORs of 2.2, 1.4, and 1.2, for corresponding symmetric 3, 10, and 20 gene models (with a between gene additive penetrance model). Thus, measuring only single locus marginal effects, the true heritability may be well hidden. Unmasking of this effect is achieved by considering pairwise, and then progressively increasing, numbers of SNP genotypes simultaneously based on the strongest effects at each step: the ORs, chi-squares, and overall heritability progressively increase beyond the combined marginal effects, and significant heterogeneity is seen in marginal ORs based on the risk level averaged over the other disease predisposing loci. Concomitant study of significant effects of markers in LD with each other reduces the number of SNPs studied at each step. Thus, with appropriate increase in the numbers of SNPs analyzed simultaneously, including effects that do not reach marginal single locus genome wide significance, the heritability and penetrance values are much higher and closer to true values.

410F

An Assessment of the Individual and Collective Effects of Variants on Height Using Twins and a Developmentally-Informative Study Design. *S.I. Vrieze[1], M. McGue[1], M.B. Miller[1], L.N. Legrand[1], N.J. Schork[2], W.G. Iacono[1].* 1) University of Minnesota, Minneapolis, MN; 2) The Scripps Translational Science Institute The Scripps Research Institute 3344 North Torrey Pines Court, Room 306 La Jolla, CA 92037.

In a sample of 3187 twins and 3294 of their parents we sought to replicate association of both individual variants and a genotype-based height score involving 180 common genetic variants with adult height identified recently by the GIANT consortium. We also sought to extend this association in two important ways. First, longitudinal observations on height spanning pre-adolescence through adulthood in the twin sample allowed us to investigate the separate effects of the previously identified SNPs on pre-pubertal height and pubertal growth spurt. We show that the effect of the SNPs identified by the GIANT consortium is primarily on prepubertal height. Only one SNP, rs7759938 in LIN28B, was found to be significantly associated with pubertal growth. Second, we show how using the twin data to control statistically for environmental variance can provide insight into the ultimate magnitude of SNP effects and consequently the genetic architecture of a phenotype. Specifically, we computed a genetic score by weighting SNPs according to their effects as assessed via meta-analysis. This weighted score accounted for 9% of the phenotypic variance in prepubertal height, but 14% of the corresponding genetic variance. Longitudinal samples will be needed to understand the developmental context of common genetic variants identified through GWAS, while genetically informative designs will be helpful in accurately characterizing the extent to which these variants account for genetic, and not just phenotypic, variance.

Whole Exome Sequencing of 42 Crohn's Disease Patients and Identification of Rare Variants associated with Crohn's Disease. *D. Ellinghaus[1], T. Jiang[2,3], B. Stade[1], A. Keller[4], E. Ellinghaus[1], C. Sina[6], Y. Bromberg[5], X. Liu[2], Q. Liu[2], F. Jiang[2,3], P. Rosenstiel[1], S. Schreiber[1,6], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 2) BGI-Shenzhen, Shenzhen, China; 3) Genome Research Institute, Shenzhen University School of Medicine, Shenzhen, China; 4) Department of Human Genetics, Saarland University, Saarbrücken, Germany; 5) Department of Microbiology, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, New York, USA; 6) First Medical Department, University Clinic S.-H., Campus Kiel, Germany.

Crohn's disease (CD) is one of the most important subphenotypes of common idiopathic inflammatory bowel disease (IBD) with high relative risk of siblings to affected individuals (3s ~ 25-42). A recent meta-analysis of six distinct genome-wide association studies (GWAS) established 71 CD susceptibility loci as genome-wide significant. However, the 71 loci described so far account for only a limited amount (~ 23.2%) of CD heritability. This suggests that the more common (>5% allele frequency) GWAS tag SNPs are accompanied by many large effect low-frequency variants. High-throughput sequence capture methods coupled with next generation sequencing (NGS) technologies offer the opportunity to extract almost the complete variation in regions of interest which may help to elucidate the missing genetic contribution to disease susceptibility, in our case CD. We captured the exomes of 42 german CD patients, one HapMap trio and 3 german unrelated healthy control individuals by means of the NimbleGen 2.1M Human Exome Array, and subsequently sequenced on the Illumina Genome Analyzer (GA) platform. In total, 39,370 megabases (Mb) of mappable sequence was generated and was mapped to target region for our 48 individuals, with an average read depth on target of 24.77 per individual exome. On average, approximately 96.92% of targeted bases were successfully covered. We identified 117,957 SNPs in our 48 individuals, including 59,076 coding and splice site SNPs (cSNPs + ssSNPs). On the basis of existing filtering strategies that had been demonstrated to work well for monogenic disorders, we developed a strategy approach that incorporates association results from the recent CD meta-analysis in combination with previously developed in silico mutation effect prediction algorithms. Selected rare variants were then subjected to a replication phase using large and independent case-control collections. The replication results will be presented at the conference.

Is CADPS2 involved in autism and intellectual disability? *G. Tortora[1], P. Magini[1], S. Miccoli[1], E. Bacchelli[2], F. Minopoli[1], A. Battaglia[3], L. Mazzone[4], G. Romeo[1], E. Maestrini[2], E. Bonora[1], C. Graziano[1].* 1) U.O. Genetica Medica, Policlinico S Orsola-Malpighi, Università di Bologna, Bologna, Italy; 2) Dipartimento di Biologia Evoluzionistica Sperimentale, Università di Bologna, Bologna, Italy; 3) Stella Maris Istituto Scientifico per la Neuropsichiatria dell'Infanzia e dell'Adolescenza, Calambrone (Pisa), Italy; 4) U.O. Neuropsichiatria Infantile, Dipartimento di Pediatria, Università di Catania, Catania, Italy.

We describe a family where brother and sister show mild intellectual disability, behavior abnormalities and epilepsy, with normal brain imaging and no major dysmorphic features. Karyotype is normal, as well FMR1 analysis in the male patient. Their mother, who died of cancer at 48 years of age, and a maternal aunt are both reported to have behavioral abnormalities, mild intellectual disability, but no seizures. Two maternal uncles are healthy. In both patients, array-CGH analysis revealed a 250 kb deletion of chromosome 7q31.32 encompassing one single gene, CADPS2. The father does not carry the deletion, indicating likely maternal inheritance. The deletion was excluded in one of the maternal uncles. CADPS2 is a calcium binding protein that regulates the exocytosis of synaptic and dense-core vesicles in neurons and neuroendocrine cells. It is a candidate gene for autistic disorders, since it maps in the autism susceptibility region AUTS1 on chromosome 7q31.32, which also corresponds to a candidate region for mood disorders. Knockout mice show an autistic-like phenotype and some ASD (Autism Spectrum Disorders) patients show a possible defect in CADPS2 splicing. The identification of a cryptic deletion encompassing one single gene in 2 siblings affected by intellectual disability gives further evidence of CADPS2 involvement in brain development and function. We performed, therefore, a mutation screening in 2 cohorts of patients with ASD and with intellectual disability, who did not carry any genomic rearrangement as far as array-CGH analysis could detect. Detailed results will be presented concerning the identified single nucleotide variants.

Anthropometric traits have a strong genetic component with heritability estimates between 40-70% for body mass index (BMI) and 80-90% for height; however, established loci only account for a fraction (1-10%) of the phenotypic variance of these complex traits. It has been hypothesized that the extremes of the distributions for these traits are enriched for genetic loci and may have a distinct genetic architecture compared to the general population. To explore the genetic contribution of the extremes (defined as the upper and lower 5th percentile) of BMI, height, and waist-hip ratio and clinical classes of obesity (including overweight and obesity classes I, II, and III), we conducted meta-analyses of ~2.8 million SNPs from 49 genome-wide association studies of European ancestry totaling from 7,962 cases and 8,106 controls (extreme BMI) to 93,015 cases and 65,840 controls (overweight) for these traits. The most promising loci from each meta-analysis ($P < 5 \times 10^{-6}$) were taken forward for replication. Preliminary analyses of the combined stages identified 10 novel loci ($P < 5 \times 10^{-8}$), including two loci for extreme height (*H6PD, RSRC1*), three for obesity class II (*HS6ST3, AK5/ZZZ3, PCDH8P1*), three for obesity class I (*GNAT2, CACNA1D, MRPS33P4*), and two for overweight (*RPTOR, LOC644456/EIF3FP3*). Several loci for obesity were located near genes expressed primarily in the brain (e.g., *CACNA1D, AK5*), suggesting a neuronal influence, whereas the loci for overweight were near genes involved in other processes, such as mTOR signaling (e.g., *RPTOR*). All of the novel loci discovered for the extremes and obesity classes were nominally associated with the trait as a continuous measure in the general population (N = 123,865) but at a lesser significance level (P range: 0.003 - 1.4×10^{-5}). A polygenetic risk score including all independent SNPs associated with BMI (at different P-value thresholds) revealed that significantly more of the variance was explained for the extremes of BMI and obesity class II than for BMI as a continuous measure in the population (variance explained, 20%, 10% and 5%, respectively), suggesting a greater genetic influence on the extremes. Investigations are underway to evaluate haplotypes and additional signals at known BMI and height loci in the extreme samples to explore allelic heterogeneity. In conclusion, this study identifies additional loci and provides novel insights into the genetic architecture of the extremes of anthropometric traits.

Integrating linkage and association data through a weighted test statistic increases power to detect association. *A.L. Peljto, T.E. Fingerlin.* Epidemiology, University of Colorado Denver, Aurora, CO.

Genome-wide association studies often combine familial cases of disease from linkage studies with sporadic cases to achieve the large samples necessary for detecting low-penetrance alleles. Most such studies include only a single case from each family. Family-based association tests cannot be applied in this case and case-control association tests ignore family-specific allele-sharing information that may be available, which results in an inefficient use of resources and loss of power for this common study design. We propose a weighted test of association that increases power by integrating family-specific linkage information with association data across the genome. We have previously shown that including familial cases based on family-specific allele sharing can increase the disease allele frequency in the cases, even when there is no evidence for linkage. This indicates that there is valuable information in allele sharing scores genome-wide. Common strategies for combining linkage and association information either require significant evidence for linkage, or combine results in an ad-hoc manner by identifying regions with overlapping evidence. By contrast, our method directly combines family-specific linkage and association data by giving more weight to familial cases with evidence for excess allele sharing at the position of the variant being tested. To assess the performance of our method, we simulated genetic data for familial cases, singleton cases, and controls under various genetic models. We then compared our weighted test of association to the standard case-control test using case samples that included varying proportions of familial cases.

RESULTS: We show that our method has increased power compared to the standard method, and that power increases were greater when the proportion of familial cases was higher. Power increases were greatest for models with modest genetic effects where there was no evidence for linkage, as is the case for many complex traits. For example, in a dominant model with a genotype relative risk of 1.25, power increased by 1.6% - 6.2% in samples with 10% - 50% familial cases. Our method provides a framework for tests of association applicable to GWAS and resequencing studies that are more statistically efficient, while leveraging the tremendous resources that have been devoted to recruiting, describing, and genotyping familial linkage cohorts.

415F

A new whole-genome genotyping array of almost 4.5 million SNPs based on data from the 1000 Genomes Project. *M.A. Eberle, J. Stone, L. Galver, M. Hansen, C. Tsan, D. Segale.* Dept Bioinformatics, Illumina, Inc, San Diego, CA.

The 1000 Genomes Project is creating a comprehensive catalogue of human variation down to ~1% minor allele frequency. We now have progressed from the HapMap database which contained genotypes for ~3.5 million SNPs genotyped across 270 samples of European, African and Asian descent to the 1000 Genomes database which contains ~40 million SNPs and short indels categorized across almost 1200 samples. Data from the 1000 Genomes Project is being used to develop the next generation of arrays that will be used to search for disease associations in whole genome association studies. Compared to whole genome sequencing these arrays are limited to a significantly smaller portion of the total genome - e.g. the latest Illumina array (the Omni5) can simultaneously assay ~4.5 million markers per sample versus sequencing which assays almost 3 billion bases. Through careful design and because the majority of the genome is not polymorphic in a reasonable number of samples much of the total genomic information can still be included in a relatively small number of markers. The measure commonly used to quantify the amount of the total genomic SNP information contained by a particular array is commonly referred to as the genomic coverage and is the fraction of SNPs highly correlated ($r^2>0.8$) to the SNPs on the array. Genotypes from the 1000 Genomes Project can be used to assess the genome-wide coverage of these new arrays, but because the quality of the genotypes from low-depth sequencing is error prone coverage is systematically underestimated when calculated this way. For example, the OmniExpress genotyping chip which contains ~732k markers covers ~66% of the common variants in the YRI samples when LD is calculated using the HapMap genotypes. An identical calculation (e.g. coverage of the SNPs common in the HapMap samples) performed using the 1000 Genomes genotypes estimates the coverage at 58% - a reduction in the estimated coverage of ~13%. The drop in coverage for the JPT+CHB and CEU and samples is less significant - 2.5% and 5% respectively. We will calculate the coverage of the Omni5 based on the most recent data from the 1000 Genomes. Also, because this calculation will be an underestimate we will use the array genotypes to assess the LD biases overall and also as a function of both population and minor allele frequency.

416F

The first genetic animal model for idiopathic scoliosis. *K. Gorman[1], J. Parent[2], R. Amahadi[2], K. Pohl[2], F. Ali[2], K. Bandwait[2], R. Wallis[2], E. Jin[2], G. Handrigan[2], J. Christians[2], F. Breden[2], A. Moreau[1].* 1) Biochemistry, Université de Montréal;Viscogliosi Laboratory in Molecular Genetics of Musculoskeletal Dis, Montreal, Quebec, Canada; 2) Department of Biological Sciences, Simon Fraser University, Burnaby, British Columbia, Canada.

Idiopathic-type scoliosis (IS) accounts for 80% of all human spinal curvatures and affects on average 3%-4% of the pediatric population. The deformity imposes a substantial cost on the healthcare system through physician care, bracing treatments, and spinal fusion surgeries. The etiology remains unknown because of phenotypic variability, a curve pathogenesis that coincides with variable growth dynamics, and the lack of an animal model with a similar phenotype. Although there have been numerous genetic studies for IS, causative genes have not been confirmed. The proposed research uses model teleosts to study the basic biology of heritable idiopathic-type spinal curvature. Considering that humans and teleosts share many genes with similar tissue and temporal expression characteristics, we hypothesize that the basic biology is conserved between human and teleost heritable idiopathic-type spinal curvature syndromes. In order to test the feasibility of teleosts as models for human idiopathic-type spinal curvature, we characterized the non-induced guppy curveback phenotype using the same parameters that are used for IS. We demonstrated that as with the human IS syndrome, the curveback spine has no congenital abnormalities that explain curvature; has similar concave/convex biases such as vertebral thickening at the curve apex; has a female bias for severe curves; is associated with disproportionate allometric growth; and has a similar scope of phenotypic variability. Based on these and other phenotypic parallels, we propose curveback as the first genetic/developmental animal model for IS. To identify genes that are associated with curvature in curveback, and candidates for IS, we mapped a single major effect QTL explains 100% of the susceptibility for curvature and approximately 80% of the variation for curve magnitude. Identification of a major QTL for curvature is a first step in understanding the genetics of this type of deformity and will lead to the identification of important pathways associated with spinal integrity. We describe how the curveback model is being applied to help understand the genetic basis of IS as well as phenotypic complexity.

Disruption of imprinted regions in a mouse model of fetal alcohol spectrum disorders (FASD). *B. Laufer, E. Diehl, M. Kleiber, K. Janus, E. Wright, S. Singh.* Department of Biology, University of Western Ontario, London, ON.

Fetal Alcohol Spectrum Disorders (FASD) remain the leading cause of preventable birth defects and cognitive deficits in North America. We have developed a C57BL/6J mouse model of voluntary ethanol consumption in which pregnant mice show a 70% preference for 10% ethanol over water. The offspring of these mothers show developmental and behavioral abnormalities, including learning deficits as young adults (60 day old). Using this model, RNA and DNA from the whole brains of ethanol-exposed offspring (and matched controls) were used on mouse-specific arrays (gene expression, microRNA and DNA methylation) to assess alterations in genome-wide gene expression (including noncoding RNAs) and DNA methylation at early adulthood (postnatal day 70). Results show that exposure to alcohol during neurodevelopment has a long-lasting effect on neurometabolomics. There is a significant ($p<0.05$) up-regulation of noncoding RNA from both known mammalian clusters of small nucleolar RNA (snoRNA) encoding genes, *Snrpn* through *Ube3a* (Human 15q11-q13/Murine 7qC) and *Dlk1* through *Dio3* (Human 14q32.2/Murine 12qF1). These clusters are neuronally expressed, with the *Dlk1-Dio3* cluster containing an abundance of brain-specific microRNAs. The clusters are localized to imprinted loci and are associated with several neurodevelopmental disorders that exhibit developmental, behavioral and physical deficits similar to FASD. Furthermore, integral parts of the spliceosome (U6 and U2 splicesomal RNAs as well as *Prp2*) were significantly ($p<0.05$) up-regulated. Following confirmation by qPCR of select coding and non-coding RNAs and bisulfite sequencing of methylated regulatory regions, further research will evaluate the role of *Snrpn-Ube3a* cluster, which is known to play a unique role in the alternative splicing of the serotonin receptor *5htr2c*. These results suggest a novel relationship between imprinting, non-coding RNAs and alternative splicing in the etiology of FASD. Potentially, an epigenetic feedback loop may maintain these alterations in gene expression and splicing caused by prenatal alcohol exposure, providing a mechanism for long-term neural dysfunction leading to distinct and persistent FASD phenotypes.

Substance abuse and addiction measures in the PhenX Toolkit for use in genomic and epidemiologic studies. *K. Conway[1], D.B. Hancock[2], M. Scott[3], A. Agrawal[4], A. Hussong[5], W. Bickel[6], J. Bjork[1], P. Wakim[1], E. Augustson[7], T. Hendershot[2], D. Nettles[2], M. Phillips[2], J. Pratt[2], W. Huggins[2], T. Grant[2], D. Maiese[2], H.A. Junkins[8], L. Farrer[9], E.M. Ramos[8], L.C. Strader[2], C.M. Hamilton[2], K.J. Sher[9].* 1) National Institute on Drug Abuse, Bethesda, Maryland, MD; 2) RTI International, Research Triangle Park, NC; 3) National Institute on Alcohol Abuse and Alcoholism, Bethesda, Maryland, MD; 4) Washington University in St. Louis, St. Louis, MO; 5) University of North Carolina at Chapel Hill, Chapel Hill, NC; 6) Virginia Tech Carilion Research Institute, Roanoke, VA; 7) National Cancer Institute, Bethesda, MD; 8) National Human Genome Research Institute, Bethesda, MD; 9) University of Missouri, Columbia, MO.

The PhenX (consensus measures for **Phen**otypes and e**X**posures) Toolkit (https://www.phenxtoolkit.org/) offers 295 high-quality, well-established, standard measures of phenotypes and exposures for use in genome-wide association studies and other large-scale genomic and epidemiologic studies. Currently, the Toolkit addresses 21 research domains (fields of research), including an Alcohol, Tobacco and Other Substances domain with 14 measures related to substance abuse and addiction (SAA) (e.g., cigarettes per day). There was a recognized need for additional SAA measures in the Toolkit, so a project was launched in early 2011 to create six "Specialty" Collections and one "Core" Collection of SAA-related measures. These new Collections will provide SAA and other investigators with common measures, and thus make it easier to compare or combine studies. It is desirable to replicate association findings by comparing results from different studies or to combine studies to create larger sample sizes, increasing statistical power and the ability to detect more subtle and complex associations. To provide guidance, a SAA Scientific Panel (SSP) of 10 academic and federal governmental scientists was assembled to select and define the initial scope of six specialty areas using a consensus process. The six specialty areas are: (1) Assessment of substance use and substance use disorders, (2) Substance-specific intermediate phenotypes, (3) Substance use-related neurobehavioral and cognitive risk factors, (4) Substance use-related psychosocial risk factors, (5) Substance use- related community factors, and (6) Substance use-related co-morbidities and health-related outcomes. Each of three Working Groups (WGs) composed of academic and government experts will address two Specialty Areas. The WGs will recommend up to eight high-priority measures for each Specialty Area. The WGs will use a consensus-based process that includes input from the scientific community as they select the measures for inclusion in the PhenX Toolkit. Outreach results will be reviewed by the WGs and considered in their final deliberations. The WGs present their selections for review and approval by the SSP and the PhenX Steering Committee. We present the rationale, criteria, scope, and preliminary results from the SSP and the SAA Working Groups. It is expected that some 48 SAA measures will be added to the Toolkit by spring 2012. *Supported by NHGRI and NIDA grants 5U01HG004597 and 3U01HG004597-03S3.*.

419F

Mapping Phenotype Variables to Support Cross-study Data Integration Among Genomic Studies. *C.-N. Hsu[1,2], C.-J. Kuo[2], C. Cai[1], S.A. Pendergrass[3,4], T.C. Matise[5], M.D. Ritchie[3,4], J.L. Ambite[1].* 1) USC/Information Sciences Institute, Marina del Rey, CA; 2) Institute of Information Science, Academia Sinica, Taipei, Taiwan; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 5) Department of Genetics, Rutgers University, Piscataway, NJ.

A wealth of biomedical data is available in public and private repositories. These data from multiple sources can be integrated to improve statistical power for a variety of genetic analyses. Consider the National Center for Biotechnology Information (NCBI) genome-wide association studies (GWAS) database of Genotypes and Phenotypes (dbGaP). Due to the use of non-standardized phenotype labels by different studies, it can be difficult to find studies that have comparable phenotypic measures. Similarly, consider Phenome-Wide Association Studies (PheWAS), a novel study approach used by the Population Architecture Using Genomics and Epidemiology (PAGE) network that investigates the association between genetic variation and an extensive range of phenotypes. In order to compare PheWAS results across studies to seek replication for significant genotype/phenotype associations, an important step is matching and mapping phenotypes across studies. Herein we present a machine learning solution to solve this challenging phenotype mapping problem. We have developed a computational approach which determines whether two phenotypes are in the same class from a training set of the results of manual phenotype matching. The key innovations include the use of weighted Jaccard features and term augmentation by dictionary lookup. We started with a set of 774 phenotype variables from five participating studies in our PAGE PheWAS study to train and evaluate different possible approaches. These phenotypes were manually mapped together into 106 classes. When compared to string similarity metric-based features, our solution improves the F-score from 0.59 to 0.73. With augmentation, we had further improvement in F-score to 0.89. For terms not covered by the dictionary, we used transitive closure inference and reached an F-score of 0.91, close to a level sufficient for practical use. We have found that our approach generalizes well to phenotypes not used in our training dataset. When used to map an independent set of 275 phenotypes from four studies, our program initially obtained an F-score of 0.78, low because 161 phenotypes could not be classified into the 106 known classes. After counting those mapped to semantically related existing classes as true positives, the F-score became 0.92. The results show that our solution is promising to significantly reduce the phenotype-matching burden on researchers when integrating data from multiple studies.

Tackling the Challenges of Phenotyping Behavior for Genetic Epidemiological Studies. *R. Plaetke, V. Stegall.* Anthropology, University of Alaska, Fairbanks, AK.

A bottleneck in producing high-quality genetic epidemiological research is phenotyping. This aspect of genetic epidemiological research is re-visited for behavior genetics studies by discussing relevant literature & our study of positive affect in Alaskan Huskies as an example. To obtain measures with reduced bias, we apply the following guidelines: (1) Focus on phenotyping components of multidimensional (latent) behavioral traits. (2) Reduce subjectivity in data collection. (3) Aim for good phenotypic resolution. (4) Investigate reliability & validity of data. Ad (1): Based on the Big-Five Model, temperament is a multidimensional, latent trait. To investigate the evolutionary aspect of one dimension, extraversion, we first study positive affect, one of its components. We use an ethological approach & expose dogs to two tests measuring the effect of positive stimuli. To date, we have collected 3 continuous phenotypes & over 30 (qualitative) characteristics of dogs' behaviors from a total of 73 dogs (2 kennels). Ad (2): Data characterize dogs' body language & vocal expressions & are extracted from videos, allowing quality control & evaluation of subjectivity of observers. A Clever Hans Effect in one of the tests in which a tester interacts with the dogs could not be observed: Correlations between sum-of scores characterizing behaviors when the tester arrived in a kennel and scores derived from the test were high (r=0.91). Ad (3): Two continuous variables (dogs' intensity & speed: contacting the tester) continue to show variation & reconfirm an already observed heterogeneity in 2 kennels. Ad (4): We are currently revisiting one kennel of 17 dogs for two more times to test reliability of the tests. We will provide an overview about the concordance of these repeated measures. To test validity of both tests, we are in the process of interviewing 10 people, who will be asked to evaluate study-dogs' behaviors & describe their perception of positive affect. Often genetic studies of behavioral traits have been performed by interviewing owners, since these traits need repeated observations. To avoid owners' subjectivity in phenotyping, we consider an ethological approach as optimal. The joint evaluation of multiple behavioral tests & additional observations, as proposed in our study, may provide a solution for generating consistent, unbiased behavioral phenotypes & the need of a genetic epidemiological study for large sample sizes.

421F

Genome wide association studies in allergic disease - re-definition of endotypes helps identify true genetic associations. *A. Simpson[1], J.A. Curtin[1], J. Winn[2], C.M. Bishop[2], A. Custovic[1].* 1) The University of Manchester, Manchester Academic Health Science Centre, NIHR Translational Research Facility in Respiratory Medicine, University Hospital of South Manchester NHS Foundation Trust, Manchester, UK; 2) Microsoft Research Cambridge, Cambridge, United Kingdom.

Background: Much of the heritability of complex traits (e.g. atopy, asthma) remains unexplained by genome wide association studies (GWAS). One reason for this may be poor phenotype definition. Conventionally, atopy is defined as the presence of a positive skin test or specific IgE to any allergen. We propose that this diagnostic label encompasses a number of different endotypes. To test this, we applied machine learning approach to all available skin test and sIgE data collected from birth to age 8 years in an unselected birth cohort to cluster children into different atopy classes (Simpson et al. AJRCCM 2010;181:1200-6). Most atopic children clustered into 4 distinct classes, only one of which was associated with asthma (Multiple early sensitization class, comprising ~25% of children assigned as atopic using conventional criteria). We hypothesized that genetic associates of different endotypes will be characteristic; to test this, we compared the results of GWAS using “Conventional atopy” and “Multiple early sensitization class” as outcomes. **Methods:** DNA was genotyped using Illumina 610 quad chips. Following standard QC we imputed additional genotypes (IMPUTEv2.1.2) with 1000 genomes and Hapmap phase 3 as reference; we excluded SNPs with INFO <0.4 and MAF <0.05. GWAS was performed with probabilistic imputed genotypes (SNPTEST) with two different definitions of outcome: “Conventional atopy” (250 cases; 519 controls) and “Multiple early sensitization class” (105 cases; 513 controls). We defined genome wide significance as p<5X10-8. **Results:** Using the additive model, markedly different patterns of association were observed for the two outcomes. For “Conventional atopy” no SNP reached genome wide significance. In contrast, despite a lower number of cases, we observed significant association of 7 SNPs (5 regions) with “Multiple early sensitization class”: 2 SNPs on 3q25.2 (p<=1.84E-09) and 20p11.1-20q11.1 (p<=2.24E-09) and single SNPs on 6p12.1 (p=2.56E-08), 13q3 (p=4.70E-09) and 21q22.3 (p=2.24E-09). **Conclusions:** Atopy comprises multiple latent atopic vulnerabilities with different genetic risk factors. We identified 5 regions associated with precisely defined endotype of “Multiple early sensitization”, whereas no loci were associated with “conventional atopy”. Increasing the size of studied populations will not overcome the problem of phenotypic heterogeneity; better endotyping may help explain part of the “missing heritability” of complex diseases.

422F

Association of Polymorphisms in the ITPKC gene with Susceptibility to Kawasaki disease in Taiwanese children. *H. Chi[1,5,6], LY. Chang[2,5], FY. Huang[1,4], MR. Chen[1,6], NC. Chiu[1,6], HC. Lee[1,4], SP. Lin[1,3,6,7], WF. Chen[3], CL. Lin[3], HW. Chan[3], HF. Liu[3], LM. Huang[2,5], YJ. Lee[1,3,4].* 1) Pediatrics, Mackay Memorial Hosp, Taipei, Taiwan; 2) Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 3) Medical Research, Mackay Memorial Hospital, Tamshui, Taipei, Taiwan; 4) Pediatrics, Taipei Medical University, Taipei, Taiwan; 5) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 6) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 7) Infant and Child Care, National Taipei College of Nursing, Taipei, Taiwan.

Kawasaki disease (KD) is a systemic vasculitis caused by unknown infectious agents, host immune dysregulation, and genetic susceptibility in children. Coronary artery lesions (CALs) complicate 15%-25% of cases of untreated KD. Inositol 1,4,5-trisphosphate 3-kinase C (ITPKC) is a kinase of inositol 1,4,5-trisphosphate (IP3), which negatively regulates T-cell receptor signal transduction. The aim is to investigate the association between ITPKC gene polymorphisms and the susceptibility to KD or with CALs in Taiwanese children. All patients with KD were from the Department of Pediatrics at Mackay Memorial Hospital and National Taiwan University Hospital, Taipei, Taiwan. A total of 494 unrelated Taiwanese children (282 boys and 212 girls) with KD were included, 181 of whom had CALs. Mean age at diagnosis was 1.9 ± 1.7 (0.1 - 10.2) years. A group of 614 (339 boys and 275 girls) unrelated, healthy, Taiwanese subjects with age at 9.1 ± 4.3 (0.1 - 20.0) years served as a control group. We selected 7 tag SNPs (rs2561531, rs2561528, rs890934, rs2303723, rs10420685, rs2561536, and rs2290693) and 1 putative functional SNP (rs28493229) to be genotyped by using the TaqMan Allelic Discrimination Assay. The Hardy-Weinberg equilibrium was assessed for each SNP in both the control and study groups by chi square analysis. The frequencies of ITPKC haplotypes and linkage disequilibrium (LD) between paired SNPs in controls and children with KD were estimated using Haploview 4.1. Corrected P (Pc) values < 0.05 were considered statistically significant. The results showed a significant association between genotype GG+AG of SNP rs2290693 and the susceptibility of KD (OR = 1.46, 95%CI 1.13-1.90, P=0.0042, Pc=0.0327) and CALs (OR = 1.69, 95% CI 1.16-2.47, P=0.0064, Pc=0.0498). Besides, significant associations were obtained between genotype CC+CG of SNP rs2561536 and the susceptibility of KD (OR = 1.42, 95%CI 1.12-1.81, P=0.0039, Pc=0.0311) as well as between genotype GG+GT of SNP rs890934 and the susceptibility of CALs (OR = 2.00, 95% CI 1.23-3.25, P=0.0046, Pc=0.0359). No statistically significant differences were found in the distribution of haplotypes between the controls and children with in KD patients with and without CALs and controls. This extensive tag SNP of ITPKC gene study showed that SNP rs2561536 and rs2290693 polymorphisms are associated with KD susceptibility and SNP rs890934 and rs2290693 polymorphisms are associated with CALs in the Taiwanese population.

Common variant of the *TRIB2* influences central obesity. *K. Nakayama[1], A. Ogawa[1], Y. Ishizuka[1], Y. Yanagisawa[1], H. Miyashita[2], Y. Kagawa[3], S. Iwamoto[1].* 1) Jichi Medical University, Shimotsuke, Japan; 2) Jichi Medical University Hospital, Shimotsuke, Japan; 3) Kagawa Nutrition University, Sakado, Japan.

Human *TRIB1-3* encode the pseudokinase protein family that influence various biological processes including energy metabolism. Common variants of the *TRIB1* and the *TRIB3* were known to be associated with blood lipid profiles and insulin resistance, respectively. The *TRIB2* was reported to be involved in adipocyte differentiation and inflammatory responses in monocytes. However, for the *TRIB2*, there has been no report of variants that affect energy metabolism. We recruited 2,755 Japanese individuals from attendees of general health-checkups. Five tag SNPs in the *TRIB2* were tested for associations with BMI, waist circumstance (WC), BMI-adjusted WC, plasma triglycerides, LDL- and HDL-cholesterol, fasting blood glucose, and blood pressures. Another cohort consisted of 1,560 East Asians was used for replication analyses. Visceral and subcutaneous adipose tissues were obtained from 45 Japanese individuals and measured *TRIB2* expression level. 95 Japanese individuals were screened for sequence variants of *TRIB2* exons. Among tests of 5 SNPs for 8 traits, association of rs1057001, A to T transversion in the 3' UTR, and BMI-adjusted WC survived multiple testing corrections ($P < 0.0007$). Copy number of the minor T allele (allele frequency = 0.22) was associated with increased BMI-adjusted WC. The association of rs1057001 and BMI-adjusted WC was successfully replicated in the East Asian cohort ($P < 0.0019$). Moreover, rs1057001 was positively associated with BMI-adjusted waist-hip ratio ($P < 0.0082$) but not with hip circumstance ($P > 0.44$). rs1057001 showed genotypic differences of the *TRIB2* expression level in the adipose tissues, in which T/T homozygous individuals had higher expression levels ($P < 0.05$). We performed allele specific quantification of the *TRIB2* transcripts in 20 heterozygous individuals and confirmed the significant enrichment of the T allele in *TRIB2* transcripts. Moreover, the variant screening identified a proxy polymorphism ($r^2 = 1.0$) that was a TC indel near a poly adenylation signal of the *TRIB2*. The high expresser T allele was linked with TC insertion allele and this insertion type sequence was highly conserved among other mammalian homologues. The association between functional variant of the *TRIB2* and BMI-adjusted WC unveiled emerging roles of the *TRIB2* in abdominal specific adiposity. The *TRIB2* may confer risks of central obesity and metabolic syndrome in East Asians.

424F

CYP1A1(Ile462Val) genetic polymorphisms and uterine leiomyoma risk ina cohort of iranian women, a case- control study. *f. taghizade mortazaee, S. Miraj, E. farrokhi, N. shahinfard, M. Hashemzadeh, S. Ashori, K. Ghatre Samani.* , Cellular and Molecular Research Center, shahrekord, Select a Country.

Background: Uterine leiomyoma is benign solid tumors of smooth muscle and the most common type of gynecological tumor. it occurs in approximately 25%-30% of women over 30 years of age and the most common disorder leading to hysterectomy, therefore, has a significant effect upon health of women. Purpose: The aim of the study was to evaluate the association of CYP1A1(Ile462Val) polymorphisms with uterine leiomyoma in a cohort of women Charmahal va Bakhtiari province in southwest of iran . Methods: In this case - control study 156 women with clinically diagnosed uterine leiomyoma and 151 healthy normal subjects were investigated. The genetic distribution of CYP1A1 polymorphism at Ile462Val were analyzed by polymerase chain reaction - restriction fragment length polymorphism method. All the data were analyzed by SPSS.17 software, using chi squre test. Results: no significant differences was found in the frequency of Ile462Val (A>G) polymorphism between uterine leiomyoma patients and controls in Charmahal va Bakhtiari women (p>0.05). Conclusion: our findings suggest that the genotype of CYP1A1 Ile462Val was not associated with the increased risk of uterine leiomyomas in studied cases. Keywords: CYP1A1 . Uterine leiomyoma .polymorphism.

Allele-specific transcriptional activity at type 2 diabetes-associated SNPs in regions of pancreatic islet open chromatin. *M.P. Fogarty[1], T.M. Panhuis[1,2], S. Vadlamudi[1], M.L. Buchkovich[1], K.J. Gaulton[1,3], K.L. Mohlke[1].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Zoology, Ohio Wesleyan University, Delaware, OH; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

For many type 2 diabetes (T2D) susceptibility loci, the underlying functional variants and genes are unknown. As pancreatic islets are a critical tissue in T2D pathogenesis, we hypothesized that altered transcriptional regulation in islets could contribute to trait susceptibility at some loci. We used maps of predicted regulatory regions, including islet open chromatin, histone modifications and transcription factor ChIP-seq data, to distinguish potentially functional regulatory SNPs from marker SNPs in high linkage disequilibrium (LD). We selected variants in strong LD with GWA index SNPs (r^2>.8, CEU) at three T2D-associated loci (*JAZF1*, *TCF7L2*, *CDC123/CAMK1D*) for which an islet regulatory effect is plausible. Selected SNPs meeting these criteria and also present in an islet predicted regulatory region were tested for transcriptional activity using luciferase reporter assays in 832/13 insulinoma cells.

We successfully identified SNPs with allele-specific transcriptional enhancer activity for rs1635852 in intron 1 of *JAZF1* (*P*=7.8x10^{-5}), rs7903146 in intron 1 of *TCF7L2* (*P*=.005) and rs11257566 located between the *CDC123* and *CAMK1D* genes (*P*=.03). For rs1635852 and rs7903146, we confirmed differential luciferase activity in MIN6 insulinoma cells and identified allele-specific protein binding using gel shift assays. The specific DNA-binding proteins for both of these SNPs remain to be identified. At the *JAZF1* locus, the rs1635852 T2D protective allele (C) is associated with increased *JAZF1* transcript levels in eQTL analysis of adipose tissue (Voight et al, Nat Genet 42; 579), consistent with the direction of allele-specific enhancer activity. At the *CDC123/CAMK1D* locus, decreased luciferase activity with the rs11257655 T2D risk allele (C) is not consistent with the direction of eQTL's for both *CAMK1D* and *CDC123* in blood. Opposing directions may reflect cell-type specific regulatory mechanisms or indicate that other regulatory variants remain to be identified.

While further experiments are necessary to validate this initial evidence of functional variants associated with T2D, these results support epigenomic maps as a valuable resource to guide identification of variants with allelic differences in regulatory activity at complex trait loci.

Exome Sequencing in Severe COPD Cases and Resistant Smoking Controls from COPDGene. *M.H. Cho[1], M. Emond[2], R.A. Mathias[3], J. Hokanson[4], T.H. Beaty[6], N. Laird[5], C. Lange[5], K.C. Barnes[3], M. Bamshad[2], J.D. Crapo[7], E.K. Silverman[1] on behalf of the NHLBI Exome Sequencing Project.* 1) Channing Lab, Brigham & Women's Hosp, Boston, MA; 2) University of Washington, Seattle, WA; 3) Johns Hopkins School of Medicine, Baltimore, MD; 4) Colorado School of Public Health, University of Colorado Denver, Aurora, Colorado; 5) Harvard School of Public Health, Boston, MA; 6) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 7) National Jewish Medical and Research Center, Denver, Colorado.

Background: Chronic obstructive pulmonary disease (COPD), defined as airflow obstruction that is not fully reversible, is the third leading cause of mortality in the United States. In addition to common variants, rare protein-coding variants are also known to have a role in COPD susceptibility: alpha-1 antitrypsin deficiency, typically caused by a rare nonsynonymous SNP in SERPINA1, is a well-known Mendelian disorder characterized by severe COPD. We hypothesized that additional rare coding variants contribute to COPD susceptibility. Methods: We selected extremes of COPD susceptibility from among Non-Hispanic Whites from the multicenter COPDGene study: 132 cases of severe, early-onset COPD (age < 63.0, GOLD Stage 3-4 COPD) with emphysema on chest CT scan (>15% at -950 HU) and 127 resistant controls (age > 65.0, normal lung function) without emphysema (<5% at -950 HU) with similar cigarette smoking histories. Exome sequencing was performed using the Nimblegen SeqCap EZ V2.0 on the Illumina platform as part of the NHLBI Exome Sequencing Project LungGO. Sequences were aligned using BWA, and variants were called using the Genome Analysis Toolkit. Variant positions were annotated using Seattle-Seq and Polyphen2. Quality control checks included gender, missingness, and transition / transversion ratios. Case-control analysis was performed collapsing nonsynonymous and nonsense variants by gene using a fixed allele frequency threshold in cases and controls in a logistic regression framework, with secondary analyses using the variable threshold test and Polyphen2 weights. Results: After quality control, we identified a total of 162,757 SNPs (81,675 nonsynonymous or stop) with a TsTv of 3.11. Analysis of the most significant genes using a fixed cutoff included SUN2, PCDHA6, and RECQL; and using a variable threshold MGLL, C6ORF97, and RSPH6A. None of the genes were significantly associated after correction for multiple testing, and overlap of the most significant results between the analytical methods was modest. Conclusions: Analysis of exome sequencing in severe COPD and resistant smoking controls can identify novel candidate genes that may contain rare variants influencing COPD susceptibility. Sequencing of additional cases and controls and exploration of other rare variant analytical methods are underway.

427F

Admixture mapping in Puerto Rican and Mexican Latinos: Dense SNP genotype data identifies novel genetic risk factors for asthma. *L.A. Roth[1], D.G. Torgerson[1], C.R. Gignoux[1], J.M. Galanter[1], K. Drake[1], C. Eng[1], S. Huntsman[1], P. Avila[2], R. Chapela[3], J.G. Ford[4], J. Rodriguez-Santana[5], W. Rodriguez-Cintron[6], S. Sen[1], E.G. Burchard[1].* 1) University of California, San Francisco - San Francisco, CA; 2) Northwestern University - Chicago, IL; 3) INER - Mexico City, Mexico; 4) Johns Hopkins University - Baltimore, MD; 5) Centro de Neumologia Pediatrica - San Juan, Puerto Rico; 6) VA Medical Center - San Juan, Puerto Rico.

Asthma is a chronic respiratory disease that disproportionately affects certain racial and ethnic groups. In the United States the highest asthma incidence, morbidity, and mortality is in Puerto Ricans, and the lowest in Mexicans, highlighting heterogeneity within Latinos. The Genetics of Asthma in Latino Americans (GALA) study genotyped ~900,000 SNPs in 529 asthmatic children and 343 controls. All four subject grandparents had self-declared Mexican or Puerto Rican ancestry. Genomic ancestry estimated using clustering and PCA confirms that Puerto Ricans have a larger African ancestry proportions, whereas Mexicans have Native American ancestry proportions. Local genetic ancestry of European, African, and Native American origin estimated using LAMP exhibited considerable variation across loci and between individuals. We leveraged the genetic diversity between Puerto Rican and Mexican Latinos in GALA by performing genome-wide admixture mapping to identify novel asthma associated loci. We tested for differences in local ancestry between cases/controls rather than individual genotype, which presumably has more power over genotypic associations due to increased coverage from ancestry-LD, and may also identify regions more likely to contain population-specific rare variants. Our admixture mapping scan identified 62 candidate regions where differences in local ancestry were associated with asthma susceptibility at $p<10^{-3}$. Notably, we find that Native American ancestry is risk factor for asthma in Puerto Ricans at 1p13.2 ($p=5.1x10^{-4}$, OR=2.3), whereas African ancestry is a protective for asthma in Mexicans at 6q15 ($p=4.6x10^{-6}$, OR=0.56). To take advantage of the genetic variation produced by local ancestry and genotype, we performed a likelihood ratio test that examined their joint effect across the genome. We identified a locus associated with asthma (likelihood ratio test $p=4x10^{-7}$) at TCRA, the alpha chain of the T cell receptor, a commonly studied gene in asthma. Overall, our results suggest that the genetic architecture of asthma susceptibility may differ across genetically diverse Latino populations, and that incorporating estimates of local genetic ancestry enhances genetic association tests in admixed populations.

428F

Risk prediction for hypertension using gene-environment risk scores and a decision tree in a Korean genome-wide association study. *J.W. Park[1], I. Kim[1], S. Uhmn[2], J. Hwang[3], C. Shin[4], N.H. Cho[5], J.Y. Lee[3].* 1) Department of Medical Genetics, College of Medicine; 2) Department of Computer Engineering, College of Information and Electronic Engineering, Hallym University, Chuncheon; 3) Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, Korea University Ansan Hospital, Ansan; 4) Department of Preventive Medicine, Ajou University School of Medicine, Suwon; 5) Center for Genome Science, National Institute for Health, Seoul, Korea.

Hypertension is one of the most common diseases influenced by complex interplay of multiple genetic and environmental factors. Conventional methods of multiple regression, genotype scoring, and reclassification, may be of limited use in risk prediction for complex disease due to difficulties of estimating multilayer interactions of gene-gene and gene-environmental factors. We performed a genome-wide association study using 352,228 SNPs for hypertension by comparison of 1,878 cases and 3,811 controls that were obtained from two population-based cohorts developed in South Korea. The SNPs showing significant association in the initial study were reanalyzed in an independent study composed of 215 cases and 737 controls. We compared the prediction abilities of five risk scores combined genetic and/or non-genetic risk factors and a machine-learning approach (i.e. decision tree, DT). We found the evidence for association with the SNPs located in seven genes including TSNARE1 (rs6583607, 8q24.3, $p=1.04 \times 10^{-7}$ under a dominant model). These 7 SNPs (i.e. rs16844620, rs7142394, rs9861122, rs6026886, rs7125196, rs6583607, and rs2074356) were evaluated for their genotype risk score (GRS) and weighted GRS (WGRS). Additionally, non-GRS (NGRS), weighted non-GRS (WNGRS), and weighted genetic-nongenetic risk score (WGNRS) were calculated. Adding the effect of non-genetic risk factors to the GRS increased the area under the curve (AUC) slightly (from 0.57 to 0.63). In the DT analysis, a prediction model composed of 5 SNPs and 3 non-genetic factors (i.e. age, BMI, family history) increased the overall accuracy to 67.4. In conclusion, the machine learning approach improves the ability to predict risk of hypertension. To develop more accurate risk prediction model for a complex disease, not only genetic factors but also non-genetic factors must be evaluated under a goodness-of fit genetic model.

Variants of C-C motif chemokine 22 (*CCL22*) are associated with susceptibility to atopic dermatitis. *T. Hirota[1], H. Saeki[2], K. Tomita[1], K. Ebe[3], S. Doi[4], T. Enomoto[5], N. Hizawa[6], S. Takashi[7], T. Ebihara[7], M. Amagai[7], S. Takeuchi[8], M. Furue[8], N. Kamatani[9], M. Kubo[10], M. Tamari[1].* 1) Laboratory for Respiratory Diseases, CGM, RIKEN, Yokohama, Kanagawa, Japan; 2) Department of Dermatology, The Jikei University School of Medicine, Tokyo, Japan; 3) Takao Hospital, Kyoto, Japan; 4) Department of Pediatric Allergy, Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, Osaka, Japan; 5) Wakayama, Japan NPO Japan Health Promotion Supporting Network, Wakayama, Japan; 6) Division of Respiratory Medicine, Institute of Clinical Medicine, University of Tsukuba, Ibaraki, Japan; 7) Department of Dermatology, Keio University School of Medicine, Tokyo, Japan; 8) Department of Dermatology, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 9) CGM, RIKEN, Yokohama, Kanagawa, Japan; 10) Laboratory for Genotyping Development, CGM, RIKEN, Yokohama, Kanagawa, Japan.

Background: Atopic dermatitis (AD) is a pruritic and chronically relapsing inflammatory skin disease involving disturbed skin barrier functions, cutaneous inflammatory hypersensitivity and defects in the antimicrobial immune defense with a strong genetic background. CCL22 binds to CC-chemokine receptor 4 (CCR4), which is expressed by Th2 cells. CCL22 plays a crucial role in controlling the trafficking of Th2 cells into sites of allergic inflammation. But genetic influences of CCL22 on pathophysiology of AD are unclear. **Methods**: We searched for genetic variations in CCL22 region by PCR-directed sequencing. Seven tag SNPs were selected using the Tagger algorithm and genotyped by Taqman and invader methods. We performed association studies of CCL22 with two independent Japanese populations (919 AD patients and 1032 controls, and 1034 AD patients and 1004 controls, respectively) and combined the results using Mantel-Haenszel meta-analysis. We further conducted allele-specific transcript quantification (ASTQ) and electrophoretic mobility shift assay (EMSA) analyses of the susceptible SNPs. **Results**: We found that rs4359426 (Ala2Asp) SNP was associated with AD under an allelic model in the first population (P = .0070; OR, 1.29; 95% CI, 1.07-1.56) and the second population (P = .00034; OR, 1.40; 95% CI, 1.17-1.69). The direction of association of the SNP was similar in both of the populations. We combined the results using Mantel-Haenszel meta-analysis, and observed the association at rs4359426 (meta-analysis, P = .0000089; OR, 1.35; 95% CI, 1.18-1.54). The susceptible allele showed higher mRNA expression in ASTQ analysis. We also observed that the susceptible allele of rs223821 (in absolute LD with rs4359426) showed stronger signal intensity of the DNA-protein complex than non-susceptible allele in EMSA analysis. **Conclusion**: Polymorphisms of the CCL22 gene might be involved in AD in a gain of function manner.

Exome Data Analysis for a Complex Disease Using a Novel Filtering Tool Reveals a Candidate Mutation. *B.-S. Petersen[1], B. Stade[1], B.D. Juran[2], J.K. Laerdahl[3], J.R. Hov[4], A. ElSharawy[1], K.N. Lazaridis[2], T.H. Karlsen[4], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, Germany; 2) Division of Gastroenterology and Hepatology, Center for Basic Research in Digestive Diseases, Mayo Clinic College of Medicine, Rochester, Minnesota, USA; 3) Centre for Molecular Biology and Neuroscience (CMBN), Department of Microbiology, Oslo University Hospital Rikshospitalet, Oslo, Norway; 4) Norwegian PSC Research Center, Clinic for Specialized Surgery and Medicine, Oslo University Hospital Rikshospitalet, Oslo, Norway.

Exome sequencing is currently one of the most promising applications for next-generation sequencing in medical research. We have developed a pipeline for the filtering of variants from exome sequencing data for finding disease-relevant ones and here demonstrate its functionality using the example of a family with multiple individuals affected by a generally assumed polygenic disease. The familial clustering represents an opportunity to identify rare, high-penetrance polymorphisms that could shed light on the underlying pathogenic mechanisms. The family consisted of two affected sisters with an affected mother and unaffected father. Enrichment was performed using Agilent SureSelect v1 and sequencing was carried out on a SOLiD v4 sequencer. BioScope was used for alignment to the reference and SNPs were identified using two distinct algorithms. Further analyses were performed using our own tool snpActs which annotates the SNPs and displays predictions of various programs for the impact on protein structure and function as well as e.g. collecting information from dbSNP, the 1000 Genomes data, HGMD and calculating Grantham scores for a thorough overall picture. The average on-target coverage was 24.5x with ~19,000 genetic polymorphisms identified per exome. Using snpActs, it was possible to find a likely mutation segregating with the phenotype in the family. We filtered the data keeping non-synonymous/nonsense and splice-site SNPs present in all three affected individuals but not in the unaffected father, in dbSNP or any of the 200 available exomes of healthy controls (Ng et al. Nature 2009, Li et al. Nat. Genet. 2010) and a maximum frequency of 1% in the 1000 Genomes data. Comparing the remaining 84 SNPs with 10 predefined candidate genes revealed a nonsense SNP resulting in truncation of the protein involved in the same pathway as those of previously identified susceptibility genes. Functional and genetic follow-up studies are under way. This example shows that exome sequencing is not only applicable for monogenic diseases but also for cases of multiplex families of complex diseases. The main challenge is the filtering for finding those variants involved in disease manifestation. Our tool provides an ideal environment by bundling various sources of information in a single step and allowing their collective analysis. A user-friendly web-interface has been set up. At the conference, we will publicly release the tool and describe the pilot study in detail.

Syntropy and Personalized Medicine. *V.P. Puzyrev.* Research Institute for Medical Genetics, Tomsk, Russian Federation.

In the “unbounded” phenome separate diseases and their clinical courses are usually analyzed in respect to association with genetic variants (GAS or GWAS), although the phenomenon of co-morbidity is a very specific feature of human morbidity in modern society. Co-morbidity, or syntropy (the term introduced by German pathologists M. Pfaundler and L. von Seht, 1921) which is a natural generic phenomenon itself, is defined as non-random combination of two or more pathological conditions (nosologies or syndromes) in an individual and his/her closest relatives, which has an evolutionary and genetic bases. A set of functionally interacting genes spread throughout the entire space of human genome, co-regulated and involved in common metabolic pathways for a given syntropy, are the syntropic genes (Personalized Medicine. 2010, 7:359-370). In fact, the concept of syntropy, suggested 90 years ago, is the source of the modern “diseasome” conception. Personalized medicine should take into account that genetic testing is necessary not only for single diseases, but for a disease complexes (syntropies). Both science and medical practice are in the very beginning of this route. On the current stage of genetic testing for common diseases development we proposed the guidelines/paradigms which can be useful to promote successes of personalized medicine: while moral and “absolute” knowledge represent an ideal world, clinical practice is a real world; genetic testing is a way toward something which will never be identified perfectly and never be a simple area of application and a simple subject of study; a reconstruction of mutual expectations of doctors, researchers, and patients is a prerequisite of successful advancement of genetic testing; clinical practice has to lean on evidence-based medicine, but the latter is a process of everlasting improvement for the guarantee of high-quality healthcare; genetic testing, not instead, but together with phenotypic markers can be accounted for in personalized prognosis, always probable. In traditional medicine “nosology” concept is basic. However, shared susceptibility (resistance) genes for different diseases (nosologies) can be a proof of other “pathological panorama” of diseases in contemporary human populations. The genetic approach to human diseases systematics will lead to reassessment of their classification which makes a direction towards personalized medicine practice more precise.

432F

Genome-wide analysis of imputed genotypes identifies chemokine receptor-1 (*CCR1*) as a novel susceptibility locus in Behçet's disease. *E.F. Remmers[1], G. Bertsias[1, 2], Y. Kirino[1], M.J. Ombrello[1], D. Ustek[3], C. Satorius[1], J. Le[1], A. Gül[3], D.L. Kastner[1].* 1) Inflammatory Disease Section, Medical Genetics Branch/NHGRI, Bethesda, MD; 2) Rheumatology, Clinical Immunology, and Allergy, Department of Internal Medicine, Faculty of Medicine, University of Crete, 2208, Heraklion, Greece; 3) Istanbul Faculty of Medicine, Department of Internal Medicine, Division of Rheumatology, Istanbul University, Istanbul, Turkey.

Behçet's disease (BD) is a genetically complex disease characterized by recurrent inflammatory attacks affecting the orogenital mucosa, eyes, and skin. We have previously performed a genome-wide association study with 311,459 SNPs in 1,215 BD cases and 1,278 healthy controls from Turkey, and have identified independent associations with HLA-B*51, an additional MHC class I locus, *IL10*, and the *IL23R-IL12RB2* locus. In this study, we carried out whole-genome imputation, using as a reference, the genotypes of 96 of the Turkish healthy controls determined on Illumina HumanOmni1M-Quad SNP chips. SNPs were excluded for deviation from HWE ($p<5\times10^{-4}$), low call rate (<95%), and low MAF (<5%). Imputation was conducted using MACH v1.0.15 providing 814,474 SNPs for analysis in the 1,215 BD cases and 1,278 controls. Using a p-value cut-off of 1×10^{-5}, we identified 114 non-HLA gene SNPs suggestive of association with BD. One imputed SNP rs7616215 on chromosome 3, located ~38 kb from the 3' UTR of the chemokine receptor-1 gene (*CCR1*), (odds ratio [OR] = 0.71, $p=1.9\times10^{-8}$) exceeded genome-wide significance ($p<5\times10^{-8}$). Fine mapping of the *CCR1* region using Sequenom iPLEX assays confirmed the imputation results for rs7616215 and identified 2 additional SNPs in strong LD with rs7616215 that also exceeded genome-wide significance. The association of rs7616215 replicated in additional Turkish and Japanese BD cases and controls (in a meta-analysis of 2,007 cases and 2,187 controls, OR = 0.73, 95% CI 0.66-0.81, $p=3.1\times10^{-10}$). CCR1 belongs to the family of CC-motif chemokine receptors, is expressed on neutrophils, monocytes, and T lymphocytes, and binds several chemokine ligands, including CCL5/RANTES, CCL3/MIP-1(, and CCL4/MIP-1) . A role for CCR1 has been identified in several inflammatory conditions, such as rheumatoid arthritis, multiple sclerosis, and transplant rejection. ENCODE data indicate that rs7616215 resides in a putative regulatory genomic domain. Analysis of *CCR1* transcripts from the HapMap European (CEU), Chinese (CHB), and Japanese (JPT) subjects showed the disease-associated (T) allele correlated with significantly reduced *CCR1* expression ($p<0.03$). Similarly, we found reduced *CCR1* mRNA as a function of the number of rs7616215 risk alleles in purified peripheral blood CD14+ monocytes from healthy controls. We have identified *CCR1* as a novel susceptibility locus in BD, with potential implications for regulation of inflammatory responses in the context of disease.

433F

Experimental validation and search for polymorphism of insertions and deletions from comparisons of primates genomes. *D. Ferrer[1], A. Mazo-Vargas[1], C.T. Ruiz-Rodriguez[1], J.Cr Martínez-Cruzado[1], R.M. Stephens[2], C.A. Winkler[3], N. Volfovsky[2], T.K. Oleksyk[1], Ferrer.* 1) Biology Department, University of Puerto Rico-Mayaguez; 2) ABCC, SAIC-Frederick, NCI-Frederick, Frederick, MD; 3) Basic Science Program, SAIC-Frederick, NCI-Frederick, Frederick, MD 21702.

Comparisons between human and primate genomes are important to further understand the evolution of our own species. Indels, insertion or deletion fragments discovered by sequence alignments among closely related species or individuals are common in these comparisons. Preliminary pairwise comparison revealed 33,479 indels >10bp in reference genomes of human (Homo sapiens), and four primate species: chimpanzee (Pan troglodytes), gorilla (Gorilla gorilla), rhesus macaque (Macaca mulatta), and orangutan (Pongo abelii). The objective of this study was to validate the existence of indels found computationally either in the coding sequence or in the splice sites in vitro by PCR amplification and electrophoresis across all five species, as these have the largest potential impact on protein sequence. From 153 genes containing candidate indels, all have been tested in the laboratory. Of these, 30% have not been validated from human to chimpanzee and 15% from human to rhesus comparisons. Validation results suggest that computational analysis alone is not sufficient for the reliable discovery of insertions and deletions, and additional laboratory testing is required. We further tested HapMap populations for presence of ancestral/derived polymorphisms among the interrogated indels; polymorphic indels were further tested in the HGDP and maps were created of their worldwide distributions. Gene ontology analysis indicated that indels discovered in our study are overrepresented in genes involved in the nervous system, followed by the reproductive system. This is consistent with the current view of human evolution, in which selection operates more strongly on cognitive skills. Further analysis is required to understand the precise impact and differentiation of these genes. The discovered polymorphisms, due to their high impact, will serve as good candidates for the search for human disease associations.

434F

Recent accumulation of deleterious mutations in human populations. *E. Gazave[1], A.G. Clark[2], A. Keinan[1].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY, USA; 2) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, USA.

Since the emergence Out-of-Africa, the human population has grown exponentially at a moderate rate (0.4% per generation). In the last 100 generations, this rate has progressively increased: from around 10% per generation 2000 years ago, it has reached the dramatic figure of 37% in the last 100 years. One genetic consequence of the rapid increase of the human population is the accumulation of rare variants arising from very recent mutations, that are observed in large sequencing datasets, such as in Coventry et al. (2010). The present work is motivated by the need to understand the nature of the very low-frequency polymorphisms that are present in our current population, as it may help to answer the fundamental question of how recent demography affects the architecture of genetic risk of chronic disease. Based on simulated data, we studied the interplay of demography and natural selection comparing two model populations, one following a classical model of European demography (with two population bottlenecks), and the other also experiencing a strong recent exponential growth. Our results show a clear difference between the distribution of the number and fitness effect of mutations present in the two populations: with explosive growth, the number of mutations per individual is increased. Although natural selection is expected to be more efficient in a larger population, our simulations predict that the rapid and recent growth has led to an accumulation of deleterious mutations, which are retained longer in the population. Contrary to what is seen in the baseline model with no growth, we observed no significant increase in the proportion of alleles with positive fitness effect among the very few mutations that go to fixation. The proportion of SNPs lost at each generation increases logarithmically over time, reflecting a complex relationship between the diversity present in the population before the expansion, the number of new mutations introduced at each generation, and the extremely low frequency of these new variants that are likely to be lost before they can increase in frequency. Altogether, our results suggest that the recent rapid population growth has produced an increase of the mutation load in human populations today. We highlight the challenge of differentiating between the genetic signature of recent neutral variants from those of rare deleterious mutations in the face of explosive growth of the magnitude experienced in recent human evolution.

435F

Natural selection and the allele frequency spectrum for the APOL1 gene. *G. Genovese, D.J. Friedman, M.R. Pollak.* Nephrology, Beth Israel Deaconess Medical Center, Boston, MA.

Two distinct protein coding changes in the APOL1 gene have been associated with kidney disease in people of African descent. It is likely that these changes arose to high frequency within the last 10,000 years due to conferring resistance to Trypanosoma Brucei Rhodesiense, an African parasite causing sleeping sickness and transmitted by the tsetse fly, similar to transmission of malaria. While the exact infectious agent responsible for the selective pressure has not been yet identified, analysis of the allele frequency spectrum for APOL1 in different African populations shows patterns indicating that natural selective pressures are geographically localized. Data from the 1,000 Genomes project show the existence of haplotypes at high frequency with diversity falling well outside the haplotypic variation of African haplotypes, consistent with introgression of a divergent APOL1 allele in the ancestral non-African population. While it is now known that APOL1 plays a role in the innate immune system, the specific roles played by this gene remain yet to be determined.

436F

Allele-level HLA A~B~DRB1 global haplotype frequency maps. *L. Gragert, E. Williams, M. Maiers.* Bioinformatics, National Marrow Donor Program, Minneapolis, MN.

Integrating analysis of human leukocyte antigen (HLA) genes in genetic studies has many challenges due to extreme polymorphism, high population privacy of alleles and haplotypes, and the unique DNA typing methods required. This study provides population specific allele-level reference HLA frequencies useful in uncovering associations of specific HLA variants with disease and/or drug interactions, and in revealing the origins and movement of global human populations. We analyzed HLA genotypes provided by 78 international registries representing 41 countries, members of Bone Marrow Donors Worldwide (BMDW), which list nearly 18 million volunteer donors and cord blood units available for unrelated stem cell transplantation. Allele-level HLA A~B~DRB1 haplotype frequencies were estimated by country using the expectation-maximization (EM) algorithm to resolve allelic and phase ambiguity from HLA genotype data. Haplotype frequencies were plotted by country using ESRI ArcGIS 9.3 software to create global maps. Global maps of HLA haplotype frequency are available through the National Marrow Donor Program (NMDP) HaploStats web application (http://www.haplostats.org). When HLA A-B-DRB1 genotype information from individual subjects is input at any level of typing resolution, the application displays the most likely allele-level haplotype pairs in different population categories, with each haplotype linked to a global map. The global maps offer a visual depiction of the worldwide geographic variation of allele-level HLA haplotypes, available for the first time. We observed that the majority of HLA haplotypes have a wide range of variation in frequency in the geospatial dimension, including a number of haplotypes that were private to small regions of the world. The availability of global HLA haplotype maps in HaploStats has direct application in unrelated donor selection for stem cell transplantation therapies and can also be useful in other genetic association or anthropological studies. While Europe has especially good coverage, many regions of the world are unrepresented in these maps due to a lack of stem cell registries in associated countries. Integration of published results from HLA population studies could expand the global coverage. Collection of more detailed population and regional information from BMDW registries could provide refinements to existing maps.

Admixed human genomes reveal ancient and recent migration patterns. *S. Gravel, J.M. Kidd, J.K. Byrnes, A. Moreno-Estrada, S. Musharoff, F.M. De La Vega, C.D. Bustamante.* Genetics, Stanford University, Stanford, CA.

A substantial fraction of humans are admixed, having recent ancestry from distinct continental groups. We conduct a population genomic analysis of admixed individuals that combines local ancestry assignment with whole-genome sequencing data. We focus analysis on 50 individuals sequenced by Complete Genomics, including 4 Mexican-Americans, 4 African-Americans and 2 individuals from Puerto Rico. Combining these data with SNP genotype data from 130 additional samples, we employ a PCA-based method to infer the ancestral population of origin for each genomic location.

To study local ancestry patterns resulting from admixture, we developed a continuous Markov model approach where states include timing information of past migration events. This model remains tractable for a variety of time-dependent migratory models, and we develop an inference framework for parameter estimation and hypothesis testing within this model. We use this framework to infer the timing of admixture and to differentiate between punctual and continuous models of migration: using demographic models that are consistent with both historical records and genetic data, we find evidence for continuous migration patterns in both Mexican and African-American populations.

Whole genome sequence data further reveals that admixed populations contain an excess of low frequency variants compared to their less-admixed counterparts. This excess can be, for the most part, traced back to a simple, neutral sampling process, but affects the frequency distribution of functional variants. We further use our local ancestry assignments to evaluate times to the most recent common ancestors for different population pairs, and find that the results recapitulate the expansion of modern humans out of Africa. Taken together, whole genome sequencing and local ancestry assignment therefore permit inferences about long-term histories of unsampled ancestral populations and highlights recent historical demographic processes that altered patterns of variation observed in admixed populations.

Divergences among 21 Native American populations suggesting a rapid prehistorical dispersion in Central and South Americas. *Y. He[1], R.W. Wang[1], R. Li[1], S. Wang[2], L. Jin[1,3].* 1) Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China; 2) FAS Center for Systems Biology, Harvard University, 52 Oxford Street, Cambridge, MA 02138; 3) Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institute of Biomedical Sciences, Fudan University, Shanghai 200433, China.

Genetic divergence of Native American populations plays a critical role in understanding the initial entry and early dispersion of human being in New World. Although investigations for classic genetic coefficient have provided valuable clues for divergence of Native American populations, a linear correlation between the coefficient and divergence time is susceptible in scenarios involving multiple populations in significant size expansion. Based on a four-population model, a measure for genetic divergence of populations, i.e. `time unit' was proposed in this report. Computer simulation showed the measure of serial divergence events kept a good linear correlation with time of the serial divergence events in complicate multi-population scenarios. Utilizing the novel method and microsatellite data of 21 Native American populations, we investigated genetic divergences of the Native American populations. Results showed genetic divergences between North American populations are greater than that between Central or South American populations. None of the divergences, however, is great enough to be a concrete evidence to support the two-wave or multi-wave migration model for the initial entry of human being. Genetic affinity of the Native American populations suggested that the populations could be divided into 4 groups without damaging their geographic relationship. Divergence of the population groups implicated that early dispersion of human being in America was more likely to be a multi-step procedure. And the divergences supported that there was a rapid dispersion of Native Americans in Central and South Americas right after a long-time standstill in North America.

A coalescent model for genotype imputation. *L. Huang[1], E.O. Buzbas[2], N.A. Rosenberg[1,2].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor MI.

Empirical studies have identified population-genetic factors as important determinants of the properties of genotype-imputation accuracy in imputation-based disease association studies. Here, we develop a coalescent model of imputation that we use to explore the theoretical basis for the ways in which these factors influence genotype-imputation accuracy. Under a two-population demographic model in which two populations diverged at some time in the past, we derive the expectation and variance of imputation accuracy in a study sequence sampled from one of the two populations, using reference sequences sampled either from the same population as the study sequence or from the other population. We analytically show that under this model, imputation accuracy-as measured by the proportion of polymorphic sites that are imputed correctly in the study sequence-increases in expectation with the mutation rate, the proportion of the markers in a chromosomal region that are genotyped, and the time to divergence between the study and reference populations. Each of these effects derives largely from an increase in information available for determining the reference sequence that is genetically most similar to the sequence targeted for imputation. We analyze as a function of the divergence time the expected gain in imputation accuracy in the target using a reference sequence from the same population as the target rather than from the other population. Together with a growing body of empirical investigations of genotype imputation in diverse human populations, our population-genetic modeling framework lays a foundation for extending imputation-based association techniques to novel populations that have not yet been extensively examined.

440F

Out of Africa migrations determine the distribution of deleterious alleles in diverse human genomes. *J. Kidd[1], B. Henn[1], S. Musharoff[1], M.C. Yee[1], G. Euskirchen[1], H.M. Cann[2], M. Snyder[1], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Fondation Jean Dausset - Centre d'Étude du Polymorphisme Humain Paris, France.

The primary demographic signature in many human populations is an ancient bottleneck associated with the Out-of-Africa expansion 50,000 years ago. We expect this event to have a lasting effect on existing patterns of genetic variation, including altered proportions of deleterious alleles in populations that have undergone severe bottlenecks. To test this hypothesis, we have sequenced full genomes to 6x-15x coverage from over 50 individuals from 7 divergent human populations included in the HGDP-CEPH Diversity Panel. These populations complement the 1000 Genomes Project by establishing a picture of genomic diversity in geographically and ethnically distinct indigenous groups from Namibia, Congo, Algeria, Pakistan, Cambodia, Siberia and Mexico. We identify alleles inferred to be deleterious using the predicted impact for protein-coding changes as defined by the PolyPhen-2 algorithm. Using the analysis framework implemented in the program dadi we fit demographic models based on a numerical solution of the diffusion equation representation of the allele frequency spectrum. Using these data, we test the effect of the age and strength of bottlenecks on the distribution of deleterious alleles and quantify the distribution of selective effects for variants observed in each population. We conclude that ancient demographic history, in particular severe bottlenecks, contribute to significant differences between human populations in their mutational load.

Validating the authenticity of the pedigrees of Chinese Emperor CAO Cao of 1,800 years ago. *H. Li.* MOE Key Laboratory of Contemporary Anthropology, Fudan University School of Life Sciences, Shanghai, China.

Deep pedigrees are of great value for studying the Y chromosome evolution. However, the authenticity of the pedigree information requires careful validation. Here, we validated some deep pedigrees in China with full records of 70-100 generations spanning over 1,800 years by comparing their Y chromosomes. The present clans of these pedigrees claim to be descendants of Emperor CAO Cao (155AD-220AD). Haplogroup O2-M268 is the only one that is enriched significantly in the claimed clans ($P=9.323\times10^{-5}$, OR=12.72), and therefore, is most likely to be that of the Emperor. Moreover, our analysis showed that the Y chromosome haplogroup of the Emperor is different from that of his claimed ancestry of the earlier CAO aristocrats (Haplogroup O3-002611). This study offers a successful showcase of the utility of genetics in studying the ancient history.

442F

Using ancestry information and tests of natural selection to prioritize craniofacial candidate genes for admixture mapping. *D.K. Liberton[1], A.W. Bigham[2], X. Mao[3], B.P. McEvoy[4], M.D. Shriver[1].* 1) Anthropology, Pennsylvania State University, University Park, PA; 2) Department of Anthropology, University of Michigan, Ann Arbor, MI; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Queensland Institute of Medical Research, Brisbane, Australia.

When performing candidate gene studies, prioritizing the genes to assay leads to more efficient use of resources. A set of candidate genes known to be involved in Mendelian craniofacial dysmorphologies will be tested against quantitative measures of normal human facial variation in an admixture mapping study. To determine the list of candidate genes to test, ancestry information as well as tests of natural selection were used to prioritize the genes. First, a list of 199 potential candidate genes associated with craniofacial variation was determined by searching OMIM for the terms “facial” and “craniofacial.” However, only SNPs that exhibit large frequency differences (high deltas) between particular parental populations are informative for admixture mapping studies. Therefore, all SNPs in these 199 genes were pulled from HapMap and then tested for the presence of ancestry informative markers (AIMs) with a frequency difference of greater than 50% between West Africans and Europeans as the high-delta threshold. Of the 199 OMIM candidate genes, only 58 genes had AIMs with high deltas. To further refine the candidate genes, a 500kb window surrounding each of the 58 candidate genes was tested for signatures of natural selection in the HapMap populations using three standard statistics: Tajima's D, the log of the ratio of the heterozygosities (lnRH), and Locus Specific Branch Length (LSBL). A gene was considered to show evidence of natural selection if all three statistics had significant values or if Tajima's D and either lnRH or LSBL had significant values. Because these genes will be tested for phenotypic effects in an admixed population of West African and European descent, a significant value in either Europeans or West Africans was required for inclusion of the gene in the candidate gene list. After testing, 30 out of 58 genes containing AIMs were found to exhibit signatures of natural selection. Nine out of 30 genes demonstrated significant evidence of natural selection in West Africans and 17 in Europeans. Additionally, four genes yielded significant results in both populations, although the proportion of significant SNPs in each window varied between the populations. These methods provide a means of prioritizing candidate genes for tests for phenotypic association via admixture linkage. Ancestry informative SNPs in these 30 selection-nominated candidate genes will be then tested for an association with normal human facial variation.

443F

Signature of negative natural selection in the human genome on sites that are not conserved across species. *K. Lohmueller, R. Nielsen.* Integrative Biology, University of California, Berkeley, CA.

Comparative genomic studies indicate that approximately 5% of the human genome is conserved across distantly related species. Based on these analyses, it has been suggested that about 5% of the genome is directly affected by negative natural selection. The common assumption is that the remaining 95% of the genome is neutrally evolving, though, to date, this assumption has not been explicitly tested. Here we test this assumption. To do this, we developed a novel approach to detect negative natural selection at sites of the genome that are not conserved across species. We applied this test to six European genomes sequenced by Complete Genomics. First, we removed sites that are conserved across distantly related species. Under the null hypothesis, the remaining sites should be neutrally evolving. However, we found that in genic regions of the genome, minor allele frequency was positively correlated with human-chimp divergence. Such a correlation is unexpected under models including only neutrally evolving sites. Instead, this correlation can be explained by varying amounts of negative selection across the genome. Regions with more sites under negative selection will have reduced human-chimp divergence and reduced minor allele frequency. Regions with fewer sites under negative selection have higher levels of divergence and higher allele frequencies. Thus, this result suggests that there are non-conserved sites that are directly affected by negative natural selection and that these sites are located near genes. Conversely, in regions of the genome that do not overlap with genes, there is no correlation between human-chimp divergence and minor allele frequency, suggesting that non-conserved sites in these regions are neutrally evolving. Finally, we examined the site frequency spectrum of single nucleotide polymorphisms (SNPs) at sites of the genome that are not conserved across distantly related species. Nonsynonymous, 5' UTR, and 3' UTR SNPs showed an excess of low-frequency alleles, as compared to intergenic SNPs, suggesting that the former have been affected by negative selection. We will present estimates of the fraction of the genome that is negatively selected within human populations. In conclusion, we have shown that sites of the human genome that are not conserved across species are not all neutrally evolving.

444F

A SNP array for human population genetics studies. *Y. Lu[1], T. Genschoreck[1], S. Mallick[2,3], A. Ollmann[1], N. Patterson[3], Y. Zhan[1], T. Webster[1], D. Reich[2,3].* 1) Affymetrix, Inc. Santa Clara, CA 95051; 2) Harvard Medical School Department of Genetics, Boston, MA 02115; 3) Broad Institute of Harvard and MIT, Cambridge, MA 02142.

High-density arrays that simultaneously genotype hundreds of thousands of single nucleotide polymorphisms (SNPs) can be a powerful tool in theory for population genetics studies, whether for learning about human history or natural selection. However, SNP arrays designed for medical genetics have been limited in their utility for population genetics because the polymorphisms on the arrays were discovered and selected for inclusion in a complicated manner that is difficult to model. This “ascertainment bias” has severely limited the types of population genetic analyses that can be carried out with SNP arrays. Here we report the first SNP array developed specifically for human population genetics studies. A total of 1.81 million candidate SNPs, all from genome locations covered by sequencing reads from Neandertals, Denisovans, and chimpanzees, were ascertained using a simple SNP discovery procedure first described by Keinan et al., 2007. The most important ascertainment involved using whole-genome shotgun sequencing data to discover differences between the two chromosomes carried by individuals from 11 populations (San, Yoruba, Mbuti, French, Sardinian, Han, Cambodian, Mongolian, Karitiana, Papuan, and Bougainville). This resulted in 13 panels of SNPs ascertained in simple ways that are appropriate for population genetic analysis. An Axiom® genotyping screen was carried out for 1.35 million of the SNPs and about 600,000 were validated on the Axiom platform, producing genotypes that passed rigorous quality thresholds appropriate for inclusion in a commercial array design. To facilitate joint analysis with other data sets that have been collected on diverse populations, the final array contains an additional approximately 80,000 SNPs that overlap between the Affymetrix SNP Array 6.0 and Illumina 650Y array. We genotyped 952 unrelated samples from 53 populations in the CEPH-Human Genome Diversity Panel (Cann et al., 2002), and have made the data freely available in the CEPH-HGDP database. In addition, we report on the genotyping of approximately 500 samples from 70 other diverse worldwide populations. Preliminary analyses demonstrate the promise of this SNP array for population genetics. As examples, we use the data to provide a new line of evidence for gene flow from Neandertals into modern humans, and to learn about the history of ancient African population that was ancestral to Yoruba and San Bushmen.

Assigning Intra-European Ancestry to Identical-by-Descent Segments using a Large Database of Self-Reported Ancestry. *J.M. Macpherson, B.T. Naughton, C.B. Do, J.Y. Tung, J.L. Mountain.* 23andMe.com, Mountain View, CA.

For assignment of ancestry to a given genomic region, traditional autosomal ancestry analyses rely on probabilistic models of haplotype frequencies. This approach has been successful in assigning ancestry in individuals with ancestry from widely-separated geographic regions, for example in admixture mapping studies of African-American and Latino populations. However, this approach has difficulty in discriminating between haplotypes from more closely-related populations. Here we introduce a method for autosomal ancestry assignment using identical-by-descent (IBD) segments from a large database of individuals of European ancestry who have themselves provided information about their, their parents', and their grandparents' ancestry. The method is frequently able to identify the European countries of origin of segments in individuals of known ancestry correctly, which suggests its use in identifying the origin of segments in individuals of unknown ancestry. The method is based on the idea that, if an individual shares an IBD segment with an individual of uniform ancestry from a given country, the segment likely derives from that country. To guard against the possibility of erroneous or misleading ancestry information, we use a procedure based on principal components analysis to filter the dataset. We examined the concordance of the method's results with the individuals' own self-reported ancestry information; depending on the country of origin, the method correctly identifies European country of origin from 55% to 85% of the time, and correctly identifies European region of origin 65 to 100% of the time. We also explore the accuracy of the method in Ashkenazi Jewish individuals, finding 85% concordance in individuals with self-reported Ashkenazi Jewish ancestry. We conclude by analyzing how this method's coverage and accuracy depend on database size and mean population IBD sharing.

446F

Comparative population structure among three ethnic groups (Indian, Chinese, and Malay) from Malaysia and Singapore. *J.E. Molineros[1], K.H. Chua[2], A.J. Adler[1], K.M. Kaufman[1], S.K. Nath[1].* 1) Program of Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, 825 NE 13th Oklahoma City, OK 73104; 2) Dept of Molecular Medicine,Faculty of Medicine,University of Malaya,50605 Kuala Lumpur, Malaysia.

Malaysia is a multi-ethnic country with three main ethnic groups (Malay (54%),Chinese (25%) and Indians (9%)). Our objectives were to elucidate population structure of 3 ethnic groups in Malaysia, and compare admixture proportions between Malayans and Singapore natives. We genotyped 575 individuals from Malaysia from 3 different ethnic origins (Chinese N=363; Malay N=173; and Indian N=39). We selected 1265 ancestral informative markers. We used 268 samples from the Singapore Variation Project ($N_{Chinese}$=96; N_{Indian}=83; N_{Malay}=89), 944 HGDP samples and 993 HAPMAP samples as reference. We estimated 10 principal components and used them to determine the optimal model for clustering between populations. We estimated admixture proportions and compared them between countries of origin. We attributed origin to each cluster by admixture proportion of the reference population in each cluster. Differences between ethnic groups were tested by t-test. Using all population data, the best admixture model was identified as the 6 ancestral population model; optimal classification of principal components had 6 clusters. Among the 6 admixture populations we identified primarily Chinese-Japanese, African, Polynesian, Caucasian, Indian, and Native American ancestries. Malaysian and Singapore Chinese were only significantly different on their African ancestry ($P=4.2x10^{-3}$). Indians were significantly different in the Indian, Caucasian and Chinese-Japanese ancestries ($P_{Indian}=3.1x10^{-2}$, $P_{Caucasian}=1.1x10^{-5}$, $P_{China}=3.3x10^{-4}$). Malays were significantly different in the Indian, Chinese-Japanese, African and Polynesian ancestries ($P_{Indian}=5.7x10^{-10}$, $P_{China}=2.3x10^{-8}$, $P_{Africa}=1.6x10^{-4}$, $P_{Polynesia}=2.8x10^{-2}$). This was confirmed by clustering, where samples from Singapore remained within the same cluster, and Malaysian samples clustered in separate groups. Malaysian-Chinese were split into the Han-Chinese cluster and the cluster including Malays, Dai Chinese and Cambodians. Indians clustered together with Gujarati and Pakistani. Indians and Malay were significantly differently admixed with the major difference coming from the Chinese-Japanese cluster and the Caucasian cluster. Difference in Malay admixture was primarily due to differences in Indian ancestry. These results suggest a difference in the history of admixture between individuals from Malaysia and Singapore.

447F

Comparison of the X Chromosome to Autosomes of Diverse Human Genomes and the Analysis of Sex-Specific Processes. *S. Musharoff[1], S. Ramachandran[2], J.M. Kidd[1], B.M. Henn[1], M.C. Yee[1], H.M. Cann[3], G. Euskirchen[1], M. Snyder[1], C.D. Bustamante[1].* 1) Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Ecology and Evolutionary Biology, Brown University, Providence RI; 3) Fondation Jean Dausset - Centre d'Étude du Polymorphisme Humain Paris, France.

Analysis of the human X chromosome presents a unique opportunity to look at the effect of population genetic forces. Because the X chromosome is carried in two copies in females and in one copy in males, it has a smaller effective population size relative to that of the autosomes and is more affected by drift. Since males are effectively haploid on the X chromosome, there may be increased selection relative to the autosomes as has been previously shown in other organisms. The X chromosome is sensitive to sex-baised processes such as male-based migration or increased female reproductive success and comparison of the X chromosome to autosomes can reveal the information about demographic events that looking at either class of chromosomes alone cannot. To quantify the effect of sex-biased forces on patterns of genomic variation, we have sequenced full genomes to 6x-15x coverage from over 50 individuals from 7 divergent human populations included in the HGDP-CEPH Diversity Panel. Estimates of diversity, levels of heterozygosity, and TMRCA (time to most recent common ancestor) as well as the distribution of deleterious alleles compared between the X chromosome and autosomes reveal the effect of sex-biased forces. By inferring the demographic history of these populations, some of which have been isolated or have experienced a bottleneck, we seek to reconcile conflicting estimates of key population genetic parameters relating to the X chromosome including the effective population size of males and females. This is of fundamental importance to the reconstruction of human history and to analysis that depends on the estimate of human demographic parameters.

448F

PRDM9 binding targets occur within most human recombination hotspots. *N. Noor[1], J. Knight[1], A. Aricescu[3], G. McVean[1,2], S. Myers[1,2].* 1) Wellcome Trust Centre of Human Genetics, Oxford University, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford; 3) Division of Structural Biology, Wellcome Trust Centre for Human Genetics, University of Oxford.

In humans, meiotic recombination and crossing over is an essential process required for correct segregation of chromosomes. Recombination clusters within 1 to 2kb regions of the genome called “hotspots”, enriched for the presence of a 13-bp sequence motif, CCNCCNTNNCCNC. Recent work by several groups has shown PRDM9 binds to this motif, and so controls human recombination hotspot positioning. However, a close motif match occurs in only 40% of hotspots, while recent work shows that PRDM9 somehow controls hotspot activity even for hotspots lacking a close motif match. To address how this occurs, we used EMSAs to explore binding characteristics of human PRDM9. In each of five previously identified hotspots without a close motif match, we observe strong in vitro PRDM9 binding to more degenerate, but recognisably 13-bp motif like sequences near the hotspot centre, offering an explanation for hotspot activity in these cases. Although we also show PRDM9 binds DNA in a highly selective manner, with certain single base pair changes essentially abolishing binding, it is capable of binding considerably degenerate sequences, raising the question of why only a subset of in vitro binding targets correspond to recombination hotspots. A likely explanation is a role for nucleosome positioning and nucleosome modifications. We report the results of the first genome-wide survey revealing the role of these features in interacting with PRDM9 binding to shape the human recombination landscape.

449F

Length distributions of identity by descent reveal fine-scale demographic history. *P. Palamara, I. Pe'er.* Dept. of Computer Science, Columbia University, New York City, NY.

Data-driven studies of identity-by-descent (IBD) were recently enabled by high resolution genomic data and IBD detection algorithms that scale well for large, densely typed cohorts. However, haplotype sharing currently represents an underutilized source of information for population genetics research. We present a closed form relationship between a population's demographic history and IBD sharing. Based on the distributions for coalescent events and the length of co-inherited haplotypes, we express the expected fraction of genome spanned by IBD segments in specific length intervals as a function of a population's demographic history. We derive a least squares, closed form solution for population size inference in a Wright-Fisher model, and an efficient hill climbing approach for complex demographies. The reconstructed population size is within 3% of the true size in 95% of our simulations for Wright-Fisher populations. For exponentially expanding or contracting populations, the reconstructed size is within 10% of the true size for the past 100 generations. We applied our inference procedure to two densely typed datasets: 500 Ashkenazi Jewish (AJ) individuals and 56 Kenyan Masai individuals (HapMap 3 dataset). Analyzing the AJ cohort we reconstruct a mild population expansion (r _ .02) during the past two millennia, leading to an ancestral population of ~60,000 individuals in the 12th century A.D. Following a severe bottleneck, we reconstruct ~300 individuals rapidly (r _ .28) expanding to ~4,000,000 in the past 34 generations. This demographic profile is consistent with previous genetic analysis and historical accounts of AJ demographic history. In the Masai cohort high levels of cryptic relatedness are detected, in agreement with recent reports. The spectrum of IBD sharing favors a demographic explanation of this phenomenon over the effects of sampling procedures. When a single population model is used, our methodology suggests a population bottleneck (r _ -.14) during the past 30 generations. We show how this effect can be explained by an alternative demographic model, where several small-sized demes (“villages”) interact through high migration rates, resulting in a pattern of shared long-range haplotypes that is compatible with that observed in the Masai cohort. This mismatch between single-population models and historically structured demographies may explain the unexpected abundance of runs of homozygosity within several populations.

450F

A combined approach to identifying preterm birth risk genes: admixture mapping and signatures of selection. *L.N. Pearson[1], A.W. Bigham[2], X. Mao[3], J.P. Kusanovic[4], R. Romero[4], J.F. Strauss 3rd[5], M.D. Shriver[1].* 1) Department of Anthropology, The Pennsylvania State University, University Park, PA; 2) Department of Anthropology, University of Michigan, Ann Arbor, MI; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Perinatology Research Branch of the Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health in Bethesda, Maryland and Wayne State University, Detroit, MI; 5) School of Medicine, Virginia Commonwealth University, Richmond, VA.

Preterm birth is a complex phenotype that is a leading cause of infant mortality in the United States. Although there is a role for social and environmental factors in prematurity, it is increasingly understood that genes also contribute to risk. African-American women experience the greatest risk of preterm birth among U.S. populations, nearly twice that of European-American women. To prioritize a genotyping panel to test for association with preterm birth among African-American women, a combination of admixture mapping and selection screening, on both regions identified by admixture mapping and of candidate genes, was used. Admixture mapping analysis was conducted using a sample of 632 women of self-reported African-American ancestry recruited from Hutzel Hospital (Detroit), the Hospital of the University of Pennsylvania (Philadelphia) and Virginia Commonwealth University Medical Center (Richmond). Genotyping of cord blood or umbilical cords from the neonates of 371 women with confirmed preterm premature rupture of membranes (PPROM) and neonates from 261 women with normal term pregnancy outcomes was completed using a genome-wide panel of 1,509 ancestry informative markers (AIMs) designed for admixture mapping analysis in African-American populations. Using prior allele frequencies from three parental populations (West African, European and East Asian), Bayesian admixture mapping was conducted using the computer program ADMIXMAP. Regions on five chromosomes (2, 8, 11, 19 and 21) were identified as significantly contributing to risk of PPROM. Single nucleotide polymorphisms (SNPs) with significant allelic association within the chromosomal regions identified in the admixture mapping analysis were tested for signatures of selection using normalized Tajima's D, log of the ratio of heterozygosities (lnRH), and locus specific branch length (LSBL). Of the 26 SNPs analyzed, 6 show evidence for selection in West Africans. Additionally, preterm birth candidate genes identified from previous reports were assessed using the same tests of selection. Fourteen of the 85 candidate genes screened were found to show signatures of selection using all three tests. Combining admixture mapping with tests for signatures of selection is a useful method for identifying genes associated with phenotypes that vary among populations, like preterm birth.

Increased Genetic Diversity observed among Inupiat Populations from the North Alaskan Slope. *J.A. Raff[1, 2], M. Rzhetskaya[1], L. Armstrong[1], M.G. Hayes[1, 3, 4].* 1) Division of Endocrinology, Metabolism, and Molecular Medicine, Department of Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 2) Department of Anthropology, University of Utah, Salt Lake City, UT; 3) Center for Genetic Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 4) Department of Anthropology, Northwestern University, Evanston, IL.

Inupiaq speaking populations of the North American Arctic are characterized mitochondrially as possessing very little genetic diversity, often postulated to be due to a very recent, rapid migration of small, isolated groups, taking perhaps only 100-200 years to reach Greenland from the North Slope of Alaska. The Inupiaq speaking populations of Canada and Greenland investigated to date are virtually monomorphic for mitochondrial haplogroup A (the remainder are D [<3%]). However, very little is known genetically of the North Alaskan Inupiat populations, currently inhabiting the hypothesized source region for the migration eastward into Canada and Greenland. We investigated the mtDNA haplotype frequencies of Inupiat populations from the Alaskan North Slope, and discuss the placement of this population in the geographical and temporal context of North American Arctic Prehistory. Using standard methods, HVS1 of the mtDNA genome was sequenced using DNA extracted from saliva samples of 178 consenting adults residing in all eight communities that span the Alaskan North Slope. There is considerable variation in the pattern and frequencies of mtDNA haplogroups among the eight communities investigated although they hold the general North American Arctic pattern of haplogroup A being most common followed by haplogroup D. Most interestingly, the frequency of haplogroup D (10.7%) among the aggregate North Slope population is the highest observed among Inupiaq speakers in the North American Arctic. We also observed two instances (1.1%) of participants belonging to haplogroup C, which has never been reported for this region of the world. When compared to the haplotypes of their neighbors, the frequencies of A2a (52.8%) and A2b (32.4%) are most similar to the Siberian Eskimos. Haplogroup D3 (7.3%), which is found in among Greenland and Canada inhabitants, is also found in North Slope populations, as is D2 (3.4%), which is found among Aleut and Siberian Eskimos and ancient (Paleo-)Eskimos from the eastern Arctic. All modern and ancient Eastern Arctic haplotypes are present among modern North Slope populations, suggesting that the North Slope is a good source for Inuit populations further east. This study was funded by the National Science Foundation, grant number OPP- 0732857.

Population genetics of Finland revisited - looking Eastwards. *K. Rehnström[1,2], K. Palin[1], T. Esko[3,4,5], E. Salmela[2,6], O. Kallioniemi[2], J. Kere[6,7], S. Limborska[8], B. Melegh[9], J. Klovins[10], A. Metspalu[3,4,5], V. Salomaa[11], A. Palotie[1,2,12], P. Lahermo[2], R. Durbin[1], S. Ripatti[2].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 3) Department of Biotechnology, Institute of Molecular and Cell Biology, Faculty of Science and Technology, University of Tartu, Tartu, Estonia; 4) Estonian Genome Centre of University of Tartu, Tartu, Estonia; 5) Estonian Biocentre, Tartu, Estonia; 6) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 7) Department of Biosciences and Nutrition, and Science for Life Laboratory, Karolinska Institutet, Stockholm, Sweden; 8) Institute of Molecular Genetics, Russian Academy of Science, Moscow, Russia; 9) Department of Medical Genetics and Child Development, University of Pécs, Pécs, Hungary; 10) Latvian Biomedical Research and Study Center, Riga, Latvia; 11) National Institute for Health and Welfare, Helsinki, Finland; 12) The Broad Institute, Cambridge, Massachusetts, United States of America.

We have previously reported that the genetic structure within Finland correlates well both with geography and known population history. While these studies have quantified the genetic distances between Finland and European neighbours to the south and the west, the influence of the Eastern and the Northern populations have not been described using genome-wide tools. Here we investigated the degree of Asian ancestry in Northern Europe. We also studied the genetic ancestry of geographic and linguistic neighbours of Finns, using genome-wide SNP data in a dataset comprising over 2200 individuals. First we quantied the proportions of European (represented by HapMap CEU) and Asian (HapMap CHB/JPT) genetic ancestry. Within Finland, the average Asian ancestry proportion varied from 2.5% in the Swedish speaking Finns to 5.1% in Northern Finland. The Saami population, being the indigenous inhabitants of Northern Finland, showed a surprisingly high proportion of Asian genetic ancestry (17.5%). We therefore hypothesize that, as genetic sharing between individuals in Northern Finland and Saami are higher than in other parts of the country, the Asian genetic ancestry in Finland could partly be through admixture with the Saami. Using a model-based estimation of individual ancestry, three ancestral populations provided a best fit for the combined Finnish and Saami dataset. Particularly, one of these ancestral populations was predominant in the Saami (average 78%), and higher in Northern Finland (average 14%) compared to the rest of the country (average 4%). Despite the fact that Finns are the closest relatives of the Saami of all populations included in this study, in general, our results show that language and genetics are only weakly related. The Finns are more closely related to most Indo-European speaking populations than to linguistically related populations such as the Saami. These analyses are currently being extended to sequence level variation using genome-wide sequence data for 100 Finns as part of the 1000 Genomes project, and 200 further individuals from the North-Eastern Finnish subisolate of Kuusamo. These 200 individuals provide good power to identify founder haplotypes within this isolate. Next, we aim to investigate the power to extend the imputation of haplotypes to the rest of Northern Finland as well as to the rest of the country.

Coal: A Coalescent Simulator Capable of Modeling Faster than Exponential Population Growth. *M. Reppell, S. Zoellner.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Recent human sequencing projects with greater than 10,000 samples have discovered an extensive amount of very rare genetic variation with frequencies $<10^{-4}$. The estimated number of singleton and doubleton variants in these studies significantly exceed the predictions of a both a neutral Wright-Fisher and a model of exponential population growth. After sequencing 2 genes in 13,715 individuals, Coventry et al. estimated an expected number of singleton sites ~5 times greater and doubleton sites ~4 times greater than predicted under a neutral Wright-Fisher model at sites free from selection. Theory suggests a sample from a population growing at an explosive, faster than exponential rate, may display the quantity of rare variation seen, because the majority of mutation events in a sample from such a lineage would occur after the sample's pairwise MRCAs. Very rare variants are likely candidates for functional alleles as they are least affected by purifying selection. Development and refinement of new statistical tools aimed at uncovering the role of very rare genetic variants in trait and disease etiology depends on the ability to simulate data with an accurate distribution of rare variants. Current programs used to simulate human genetic data perform well when simulating common variation in humans. However these programs cannot accurately simulate the excess of rare variation present in human sequence data. Here we present a coalescent model of explosive, faster than exponential growth which generates the number of rare variants presently seen in human samples. By expressing the rate of change in a population's size as a function of its current size we are able to model samples from a population growing at a faster than exponential rate. We have implemented this model in a coalescent simulation program which generates haplotypes sampled from a population which has undergone such explosive growth. By comparing the site frequency spectrum and linkage disequilibrium patterns in simulated haplotypes to patterns in real sequence data we evaluate how well our program generates realistic data. Additionally, the model parameters which allow us to simulate human sequence data provide estimates of the growth rates responsible for the quantity of rare variation seen. In summary, we provide an easy to use tool which can rapidly produce realistic simulated human sequence data and answer questions about the impact of faster than exponential growth on a population.

Exome Sequencing in a Diverse Set of Individuals Identifies Potentially Deleterious Alleles at Unexpected Frequency in Qatar, the Migration Crossroads of Arabia. *J.L. Rodriguez-Flores[1], J. Fuller[1], N. Hackett[1], J. Salit[1], J.A. Malek[2], M.A. Ziki[2], G. Hoffman[3], L. Omberg[3], A. Jayoussi[4], M. Zirie[4], R.G. Crystal[1], J.G. Mezey[1,3].* 1) Department of Genetic Medicine, Weill Cornell Medical College, New York, NY; 2) Department of Genetic Medicine, Weill Cornell Medical College in Qatar, Doha, Qatar; 3) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 4) Hamad Medical Corporation, Doha, Qatar.

The allelic variation that distinguishes populations in the Arabian peninsula has not been studied in any depth. Qatar is a nation situated at the crossroads of Africa and Eurasia with a diverse population representative of ancient and recent migration in the region, hence it is ideal for sampling the spectrum of allelic variation in Arabia. Here, we used deep exome sequencing of Qatari individuals to identify potentially deleterious alleles at unexpected frequency when compared to European, Asian, and African populations sampled by the 1000 Genomes Project (1000G). Our strategy was to select Qatari individuals of primarily Arabian, Persian, or African ancestry, a diverse sample representing three major migrations in the region. Our analysis identified SNPs and other allelic variants that are either novel or at unexpected frequency in Qatar when compared to one, two or three neighboring continents (Europe, Asia, Africa). Where possible, we imputed local haplotypes around the exons using 1000G individuals as a reference panel, and determined the most likely continental origin of haplotypes flanking the enriched SNPs. Using a combination of disease and drug metabolism databases, including HuGE, OMIM, HGMD, PharmGKB and prediction tools, including SIFT and PolyPhen-2, we identified the subset of these alleles that show evidence for being potentially deleterious or that have been previously associated with disease. A number of these cases were consistent with the epidemiological profile of Qatar and reflect the rich migration history of Arabia. Among others, this included a SNP previously associated with type 2 diabetes in Asian populations that has an extreme frequency in Qatar with a 1.4x odds ratio for the risk allele in the Qatari individuals of Arabian and Persian ancestry, a result consistent with the high incidence of diabetes among the Qatari people. Our study demonstrates that next-generation exome data collected for a small sample of individuals can be used to reveal haplotypes of possible medical importance in populations understudied by genome sequencing efforts, providing an empowerment mechanism for building internal genomic health initiatives based on samples of diverse populations.

455F

Survey of 20,000 human Y chromosomes shows that the population genetic characteristics of deletions involving AZFc and the rates at which they arise by new mutations are surprisingly diverse. *S. Rozen[1,2], J.D. Marszalek[1,3,4], K. Irenze[5], L. Brown[1,3,4], H. Skaletsky[1,3,4], K. Ardlie[5,6], D.C. Page[1,3,4].* 1) Whitehead Institute, Cambridge, MA; 2) Duke-NUS Graduate Medical School, Singapore; 3) Howard Hughes Medical Institute; 4) Department of Biology; Massachusetts Institute of Technology, Cambridge, MA; 5) Genomics Collaborative, SeraCare Life Sciences, Cambridge, MA; 6) Broad Institute, Cambridge, MA.

The Y-chromosome's AZFc region is subject to four types of recurrent deletion. One of these, the b2/b4 deletion, removes most of the region and always severely impairs spermatogenesis. Three others, the “partial AZFc deletions" affect less of the Y chromosome, and many studies have focused on their influence on spermatogenesis. To better understand the population genetics of deletions involving AZFc, we assessed their prevalence in five populations and a total of 20,884 men unselected for sperm count or fertility. These results provide new insights into the relationships between the prevalence of the deletions, the rates at which they arise by new mutations, and natural selection. The prevalence of b2/b4 deletions across the five populations, 0.04%, is the lowest of four types of deletions. As b2/b4 deletions are almost never transmitted without assisted reproduction, their prevalence approximates the rate at which they arise by new mutation. The gr/gr deletions are the most common in our sample, with a prevalence of 2.4%. Based on this prevalence and the risk of severely impaired spermatogenesis in men with gr/gr deletions, we infer that they arise at a rate similar to new b2/b4 deletions. Deletions in a third group, the b1/b3 deletions, are almost are rare as b2/b4 deletions, 0.1%. Our analysis suggests that these deletions arise by new mutation < 1/10th as often as b2/b4 deletions. Further analysis suggests that deletions in a fourth group, the b2/b3 deletions, also arise very infrequently by new mutation. The population genetic characteristics of deletions involving AZFc and the rates at which they arise by new mutations are surprisingly diverse.

Ancient exome sequencing of human remains from Teopancazco, a neighborhood of the Teotihuacan Mesoamerican city. *K. Sandoval[1], B.A. Áglvarez-Sandoval[2], A. Moreno-Estrada[1], F.M. De La Vega[1], L.R. Manzanilla[3], T. Harkings[4], C.D. Bustamante[1], R. Montiel[2].* 1) Genetics, Stanford, Stanford, CA; 2) Laboratorio Nacional de Genómica para la Biodiversidad, CINVESTAV-IPN. Km. 9.6 Libramiento Norte Carretera Irapuato - León. Irapuato, Guanajuato, Mexico; 3) Instituto de Investigaciones Antropológicas, Universidad Nacional Autónoma de México, Mexico City, Mexico 04510; 4) Genetic Systems, Life Technologies, Beverly, MA 01915.

Mesoamerica is the cradle of some of the most complex and advanced civilizations of the New World. Its geographic location has been a key factor for acting as a natural corridor between North and Central-South America, thus becoming home not only of the initial and subsequent human migration waves into the continent but also of the many cultures that flourished later on. Today, this large geographical area continues to exhibit one of the highest cultural, linguistic, genetic and archeological diversity in the Americas. Of particular interest is the archeological site of Teotihuacan as it was the largest city in the pre-Columbian Americas. Around 500 CE, it may have had more than 125,000 inhabitants, placing it among the largest cities of the world in this period. The ethnicity of the inhabitants of Teotihuacan is a subject of debate. Possible candidates are the Nahua, Otomi or Totonac ethnic groups, but it has also been suggested that Teotihuacan was a multiethnic city. In order to shed light on their population history reconstruction, and as part of the multidisciplinary project Teotihuacan: elite and government, directed by Linda R. Manzanilla, we have collected 100 samples from human remains from the Teotihuacan neighborhood of Teopancazco and succesfully exctracted genomic DNA for 20 samples derived from bone and tooth. These samples are used to prepare whole-genome sequencing libraries to obtain mitochondrial variants and exon capture libraries for high-coverage human-specific sequence. The objective is to reconstruct the genetic variability of an ancient Native American population. By collecting genome-wide sequencing data of a pre-Columbian population we will be able to provide a non-biased reference panel of the Native American gene pool present in the Americas prior to the European contact. Comparison of these variants with contemporary genomic data from putatively related populations will be valuable to reveal important historic and genomic processes shaping the genome of extant Native Americans and to evaluate the proportional contribution of pre-Columbian diversity into present day ethnic groups and admixed Latino populations; as well as to discover functionally relevant and disease-related variants that were specific to Native Americans prior to the European contact. Given the scale of this effort, our project represents unparalleled challenges in the field but is paving the path on genome-wide ancient DNA studies in the Americas.

457F

A simple test for historical gene flow between populations based on shared genotype data for two individuals. *A. Scally, B. Yngvadottir, Y. Xue, Q. Ayub, C. Tyler-Smith, R.M. Durbin.* Wellcome Trust Sanger Institute, Hinxton, CB10 1SA, United Kingdom.

The increasing accessibility of genome sequence data means we are now able to sample genome-wide sequence diversity in many human and non-human primate populations throughout the world. Genetic analyses have shown that while divergence and separation are common features in the evolutionary history of these populations, so too are subsequent migration and gene flow between them. However, the inference of gene flow is often complicated by the use of a numerical demographic model in which the null hypothesis is overspecified. Here we derive a simple test for historical gene flow based on the sharing of heterozygous sites between two individuals from different populations, making a minimal set of assumptions about the demographic history of the two populations. In particular we make no assumptions about the time of separation or the size of either population since separation. The test uses genotypes called in each individual relative to an outgroup (e.g. chimpanzee for human data), and does not require phase information. We demonstrate this test and assess its robustness using coalescent simulations, and we apply it to publicly available data collected from individuals from modern human populations in Europe, Africa and Asia. We also apply it to data from two species of Gorilla, showing evidence for gene flow between the subspecies since separation, even though they are now morphologically distinct and separated by 1000 km in central Africa.

458F

Variants in SNAP25 are targets of natural selection and influence verbal performances in women. *M. Sironi[1], R. Cagliani[1], S. Riva[1], C. Marino[1], M. Fumagalli[1], M.G. D'Angelo[1], V. Riva[2], G.P. Comi[3], U. Pozzoli[1], D. Forni[1], M. Caceres[4,5], N. Bresolin[1,3], M. Clerici[6,7].* 1) Bioinformatics, IRCCS Eugenio Medea - Associaz, Bosisio Parini, Italy; 2) The Academic Centre for the study of Behavioural Plasticity, Vita-Salute San Raffaele University, Milan, Italy; 3) Dino Ferrari Centre, Department of Neurological Sciences, University of Milan, Fondazione Ca' Granda IRCCS Ospedale Maggiore Policlinico, 20122 Milan, Italy; 4) Institut de Biotecnologia i de Biomedicina, Universitat Autònoma de Barcelona, 08193 Bellaterra, Spain; 5) Institució Catalana de Recerca i Estudis Avançats (ICREA), 08010 Barcelona, Spain; 6) Chair of Immunology, Department of Biomedical Sciences and Technologies LITA Segrate, University of Milan, 20090 Milano, Italy; 7) Fondazione Don C. Gnocchi, IRCCS, 20148 Milano, Italy.

Descriptions of genes that are adaptively evolving in humans and that carry polymorphisms with an effect on cognitive performances have been virtually absent. SNAP25 encodes a presynaptic protein with a role in regulation of neurotransmitter release. We analysed the intra-specific diversity along SNAP25 and identified a region in intron 1 that shows signatures of balancing selection in humans. The estimated TMRCA (time to the most recent common ancestor) of the SNAP25 haplotype phylogeny amounted to 2.08 million years. The balancing selection signature is not secondary to demographic events or to biased gene conversion, and encompasses rs363039. This SNP has previously been associated to cognitive performances with contrasting results in different populations. We analysed this variant in two Italian cohorts in different age ranges and observed a significant genotype effect for rs363039 on verbal performances in females alone. Post hoc analysis revealed that the effect is driven by differences between heterozygotes and both homozygous genotypes. Thus, heterozygote females for rs363039 display higher verbal performances compared to both homozygotes. This finding was replicated in a cohort of Italian subjects suffering from neuromuscular diseases that do not affect cognition. Heterozygote advantage is one of the possible reasons underlying the maintenance of genetic diversity in natural populations. The observation that heterozygotes for rs363039 display higher verbal abilities compared to homozygotes perfectly fits the underlying balancing selection model. Although caution should be used in inferring selective pressures from observed signatures, SNAP25 might represent the first description of an adaptively evolving gene with a role in cognition.

Phylogeography of R1a1 Y-chromosomal haplogroup and genetic history of Indo-Europeans. *V.A. Stepanov, V.N. Kharkov.* Institute for Medical Genetics, Tomsk, Russian Federation.

Recent discussion of the prehistoric spreading of the Indo-European language group has generally concentrated on two alternative hypotheses: so-called “Kurgan Culture” hypothesis, which places the homeland of proto-Indo-Europeans to the Steppe of Eastern Europe, and alternative hypothesis of the spread of farmers from the Near East (Anatolia) to Europe in the Neolithic times. Y-chromosomal haplogroup R1a1, lineage is thought to have originated in the Eurasian Steppes north of the Black and Caspian Seas, seems to be associated with the Kurgan culture. Three geographic areas with the highest frequency of R1a1 haplogroup were revealed: Eastern Europe; Southern Siberia and Hindustan where the highest diversity of microsatellite haplotypes was observed. Phylogenetic analysis of microsatellite haplotypes demonstrates the presence of three corresponding major clusters with the age of the generation of haplotytic diversity of 7.2-12.5 ky. The highest diversity in Hindustani is related to the presence of haplotypes of Indo-Pakistani and Southern Siberian clusters in the population from India and Pakistan, probably due to relatively recent migrations from Central Asia. The age of the cluster admittedly brought to Hindustan from Central Asia / Southern Siberia is 3,9 +/- 1,3 ky. Probably, the primary center of the generation of diversity and expansion of R1a1a was the territory of the Eastern European Steppe. With the spread of of R1a1 carriers, secondary centers of genetic diversity and population expansions were formed in the Southern Siberia and Hindustan.

A Genetic Simulation Approach to Prehistoric Population Events in Finland. *T. Sundell[1,2], J. Kammonen[1], M. Heger[1], J. Palo[3], P. Onkamo[1].* 1) Department of Biosciences, University of Helsinki, Finland; 2) Department of Philosophy, History, Culture and Art Studies, Archaeology, University of Helsinki, Finland; 3) Hjelt Institute, Department of Forensic Medicine, University of Helsinki, Finland.

Due to Finland's geographical location and settlement history, the country has been a genetic isolate. Contemporary studies show that there is still a slightly reduced genetic diversity among the Finnish population. This diversity reduction and the specific `Finnish Disease Heritage' could be explained by founder effects and bottlenecks. Archaeologically, there is evidence for fluctuation of population size, including bottlenecks at 4100-3800 BP and 1500-1300 BP.

Together with population size estimates based on archaeological data, we use methods and ideas from genetics in order to assess the existence and size of possible prehistoric population bottlenecks. Well-preserved ancient organic remains entailing aDNA are practically non-existent in Finland due to the naturally acidic soil. Thus, we employ population simulations to follow genetic changes over hundreds of generations and evaluate the effects of Neolithic population bottleneck on the assumed Finnish gene pool. Here, in continuation of our previous research, we apply both forward and coalescent simulations with mtDNA and Y chromosomal haplotypes to trace back the possible population history behind the present day genetic diversity in Finland.

Our new model simulation begins at 11,000 BP and the prehistoric Finnish population is simulated with two archaeologically justified bottlenecks. We split the population into geographic sub-populations, added gender-specific migration as well as migration waves from neighbouring populations, compatible with archaeological phenomena. To follow the assumed demographic events as realistically as possible, we added minor constant gene flow from three background populations: Archaic European, Archaic Scandinavian and Saami. We have obtained actual ancient mtDNA haplotype frequencies from published aDNA studies of prehistoric European populations and used them as a proxy. According to recent studies, there are considerable differences in haplotype distributions of hunter-gatherers and early farmers.

The preliminary results indicate that bottlenecks substantially reduce genetic diversity, at least in the narrowest models and a surprisingly small constant gene flow from background populations clearly outweigh the effects of larger, short-term migration waves.

461F

Molecular analysis of an ancient Thule population at Point Barrow, Alaska. *J.C. Tackney[1], J.A. Raff[1,2], J.B. Coltrain[1], A.M. Jensen[3], D.H. O'Rourke[1].* 1) Department of Anthropology, University of Utah, Salt Lake City, UT; 2) Division of Endocrinology, Metabolism, and Molecular Medicine, Department of Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) UIC Science LLC, Barrow, AK.

Nuvuk was an Iñupiat village at Point Barrow, Alaska. It was continuously inhabited for at least 1300 years until it was lost to coastal erosion in the last century. Archaeologically recovered burials from Nuvuk have calibrated radiocarbon ages between 1187 and 1579AD. Molecular samples were collected in situ by genetic analysts prior to full burial exposure by archaeologists. mtDNA hypervariable segment I sequences indicate that the ancient Nuvuk individuals belong predominantly, but not exclusively, to mtDNA haplogroup A2. All ancient Nuvuk sequences reported here have been replicated from independent extracts in our laboratory.

Contemporary Iñupiat/Inuit populations and ancient Thule studied to date are nearly monomorphic for mtDNA haplogroup A2, although lineage heterogeneity exists. Individuals from Nuvuk can be confidently assigned to multiple sublineages of haplotypes A2b and A2a, as well as to haplotypes A2-root and D3. This is consistent with the standard view of the ancestral/descendant relationship between the prehistoric Thule and modern Iñupiat/Inuit populations. However, the mitochondrial sequence diversity at Nuvuk is noticeably lower than that observed in comparably aged ancient samples we have also sequenced from the Alaska Peninsula and Eastern Aleutians.

These results confirm that a subset of Beringian-specific mtDNA haplotypes were carried by the early Thule prior to their dispersal across the North American arctic, in what was likely the final major event in an extended period of later Holocene circumarctic migrations/gene flow between Asia and North America. The uniquely late expansion and limited dispersal of these mtDNA haplotypes in the Americas emphasizes the need to assay the full mtDNA genome, the Y chromosome, and various autosomal markers in these ancient samples. Next generation technologies will permit access to a richer genetic record of prehistoric arctic populations.

This research was supported by NSF grants OPP-0732846 AND OPP-0637246 to DHO'R, OPP-0820790 to JBC, and ARC-0726253 to AMJ.

Synthesis of autosomal and gender-specific genetic structures of the Uralic-speaking populations. *K. Tambets[1], S. Rootsi[1], M. Metspalu[1], B. Yunusbayev[1,2], E. Metspalu[1], A.M. Ilumäe[1], M. Reidla[1], K. Dibirova[3], O. Balanovsky[3], I. Evseeva[3], L. Osipova[4], E. Khusnutdinova[2], R. Villems[1].* 1) Evolutionary Gen, Estonian Biocentre, Tartu, Estonia; 2) Institute of Biochemistry and Genetics, Ufa Research Centre, Russian Academy of Sciences, Ufa, Russia; 3) Research Centre of Medical Genetics of Moscow, Laboratory of Human Population Genetics, Moscow, Russia; 4) Institute of Cytology and Genetics, Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russia.

The variation of uniparentally inherited genetic markers - mitochondrial DNA (mtDNA) and non-recombining part of Y chromosome (NRY) - has suggested somewhat different demographic scenarios for the spread of maternal and paternal lineages of North Eurasians, in particular those speaking Uralic languages. The west-east-directed geographical component has evidently been the most important factor that has influenced the proportion of western and eastern Eurasian mtDNA types among Uralic-speakers. The palette of maternal lineages of Uralic-speakers resemble that of geographically close to them European or Western Siberian Indo-European and Altaic-speaking neighbours. However, the most frequent in North Eurasia NRY type N1c, that is a common patrilineal link between almost all Uralic-speakers of eastern and western side of the Ural Mountains, is rare among Indo-European-speakers, with a notable exception of Latvians, Lithuanians and North Russians. In this study the information of genetic variation of uniparentally inherited markers in Uralic-speaking populations from 13 Finno-Ugric and 3 Samoyedic speakers is combined with the results of their genome-wide analysis of 650 000 SNPs (Illumina Inc.) to assign their place in a landscape of autosomal variation of North Eurasian populations and globally. The genome-wide analysis of the genetic profiles of studied populations showed that the proportion between western and eastern ancestry components of Uralic-speakers is concordant with their mtDNA data and is determined mostly by geographical factors. Interestingly, among the Saami - the population which is often considered as a genetic outlier in Europe - the dominant western component is accompanied by about one third of the eastern component, making the Saami genetically more similar to Volga-Finnic populations than to their closest Fennoscandian-East Baltic neighbors. The high frequency of pan-northern-Eurasian paternal lineage N1c among Saami cannot explain this phenomenon alone - genetic ancestry profiles of autosomes of other Finnic- and Baltic-speaking populations, who share the high N1c with the Saami, do not show a considerable eastern Asian contribution to their genetic makeup.

463F

Novel coding variation at TYRP1 explains a large proportion of variance in the hair colour of Solomon Islanders. *N.J. Timpson[1], E. Kenny[2], M. Sikora[2], A.M. Estrada[2], C. Eng[3], S. Huntsman[3], E.G. Burchard[3], M. Stoneking[4], C.D. Bustamante[2], S. Myles[2,5], The Solomon Islands Pigmentation Collection.* 1) MRC CAiTE Ctr/SSCM, Bristol Univ, Bristol, United Kingdom; 2) Department of Genetics, School of Medicine, Stanford University, Stanford, USA; 3) Department of Medicine, University of California, San Francisco, USA; 4) Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany; 5) Nova Scotia Agricultural College, Truro, Nova Scotia, Canada.

The Solomon archipelago comprises over 1,000 islands located east of Papua New Guinea and has a population noted for wide variation in hair pigmentation. 1200 samples were collected from 16 centres and hair colour measured in donors by spectrophotometer. Analysis of 589,241 single nucleotide polymorphisms across a subset of 42 dark haired and 43 blond haired individuals revealed a signal for pigmentation driven by 27 markers on 9p23 at the TYRP1 gene (rs13289810; OR=29.5, p=1.11e-19, lambda=1.03). There were no systematic differences in ancestry between dark and blond haired participants indicating that this variation is unlikely to be due to recent introgression from other populations. Sequencing of TRYP1 showed complete conservation of this locus bar nucleotide 5,888(NG_011750), which was homozygous C in dark haired individuals and T in blonds. The resulting CGC->TGC missense mutation changes the 93 amino acid in exon 2 from an Arginine to a Cystine. Genotyping of TYRP1(93C/T) in all samples and analysis showed that in a recessive model including sex, age and local geography, there was a -1.67(-1.76, -1.50) standard deviation difference in hair colour by genotype groups (p=3.5e-106) equating to ~40% variance in this trait. Genotyping in the Human Gene Diversity Panel showed TYRP1(93C/T) to be essentially private to the Solomon Islanders. TYRP1(93C/T) shows similarity to a Tyrp1 allele in the brown^light laboratory mouse where progressively lightened hair with age is due to premature melanocyte death. It is coincidental to observe another Arg to Cys substitution in humans and whilst in a different location, one would predict that a missense change creating a new Cys residue in the amino-terminal region of the protein would yield a similar phenotype. In humans, complete loss of function for Tyrp1 is known to cause rufous albinism. This is one of the only examples of a genomewide association study implicating causal variation directly, of a common local variant of functional effect being absent in other human populations and is one of the largest phenotypic effects attributable to a common polymorphism. Reasons for the maintenance of this variation are unclear, however this finding prompts the notion that we may find other large (disease causing) effect variants that are population specific and that our results are a call to arms to expand medical genomics to underrepresented populations.

464F

Estimation of Population Histories Incorporating Admixture using Genome-Wide Variation Data. *M. Tsai[1], G. Belloch[2], R. Ravi[3], R. Schwartz[4].* 1) CMU-Pitt Ph.D. Program in Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Computer Science, Carnegie Mellon University, Pittsburgh, PA; 3) Tepper School of Business, Carnegie Mellon University, Pittsburgh, PA; 4) Department of Biological Science, Carnegie Mellon University, Pittsburgh, PA.

Learning how modern human populations have arisen, dispersed, and intermixed since we emerged as a species is one of the central questions in anthropology and human genetics. Past models for learning divergence times and ancient admixture proportions have often been limited to a few loci and perform poorly when applied to genome-wide genetic variation data. With the advent of large-scale genome variation studies, methods able to take advantage of large numbers of variations are needed. We previously developed a method to infer an overall tree of population history that has maximum consensus with a large number of genomic variants, using information theoretic techniques to automatically adjust the complexity of the tree based on the amount and quality of data available. Here, we describe a novel two-step inference model designed to extend that prior work to incorporate admixture and other sources of reticulate evolution. Rather than inferring the parameters directly from the molecular data, we first learn a model of population divergence using our prior consensus tree algorithm and use that model to categorize the timing of variations with respect to potential admixture events. We then apply a coalescence-based Metropolis-Hastings sampler to learn divergence times and admixture proportions around the putative association events. To evaluate the algorithm, we generated simulated data consisting of a two parental and one admixed population model where individuals from two parental populations P_1 and P_2 migrated to form admixed population at time t(generations with (admixture fraction and the two parental populations diverged from an ancestral population t_d generations ago. Empirical evaluation of our method using simulated data with different t(, t_d, and (parameters shows good performance of the method at inferring the correct parameters from realistic data set sizes. Comparison of our method with alternatives in the literature shows improved accuracy in admixture estimation. Results from the analysis of the HapMap Phase II dataset are shown consistency with prior literature on human population dynamics. While these are relatively simple scenarios, they nonetheless provide promising evidence that our method will provide a viable strategy for learning more detailed and accurate histories of admixed population groups from large genetic variation data sets.

An automated method for deriving mitochondrial DNA (mtDNA) haplogroups based on changes within the Hypervariable Regions. *V.L. Vance, J.J. Bryan, M.R. Szczepanski, A.B. Carter, C.L. Mouritsen.* Research and Development, Sorenson Genomics, Salt Lake City, UT.

In 2009, van Oven and Kayser described a comprehensive phylogenetic tree of human mtDNA variation which has been made accessible at www.Phylotree.org. This phylogenetic tree is based on both coding and control (hypervariable) regions. Van Oven and Kayser identified the variances from the revised Cambridge Reference Sequence (rCRS) which define an individuals' haplotype and corresponding mtDNA haplogroup. A new computer-based method has been developed for assigning mtDNA haplogroups using the variances and haplogroup nomenclature described by van Oven and Kayser. This new method makes use of Structured Query Language (SQL) and a mathematical algorithm that allows for the reliable determination of one's haplogroup based solely on mtDNA sequence from the Hypervariable Regions (HVR). The SQL-based algorithm combines a database search process with a method that walks stepwise through the phylogenetic tree, which is rooted with rCRS at the first position. Using a novel scoring method to account for the number and stability of the markers that define each haplogroup, an individual's HVR differences from rCRS are compared with the haplogroup designations defined in the mtDNA Phylotree. The algorithm has a high degree of reliability even when potential “back-mutations” and/or recent mutations are observed at key haplogroup defining positions, in which case a haplogroup is assigned based on likelihood and match criteria thresholds defined within the algorithm. In instances of ambiguous calls, the algorithm has the ability to select the nearest parental haplogroup in the tree. This new method was validated by comparing the haplogroups assigned by our method to the haplogroups assigned by van Oven and Kayser for samples with mtDNA haplotypes published in Phylotree. This comparison showed concordance of our method to be greater than 95%. Use of our system can accurately and quickly estimate over 800 different mtDNA haplogroups across the mtDNA tree using only rCRS differences within Hypervariable Region 1, over 1000 haplogroups using Hypervariable Regions 1 and 2, and nearly 1100 haplogroups using Hypervariable regions 1, 2 and 3. Since Phylotree is continually being updated as new data are published, we have incorporated a parsing tool that allows the program to be updated as the science progresses.

Height-associated loci contribute to genetic differences between African Pygmies and their non-Pygmy neighbors. *P. Verdu[1], T.J. Pemberton[1], N.S.A. Becker[2], A. Froment[3], B.S. Hewlett[4], S. LeBomin[2], C. Willer[5], N.A. Rosenberg[1,6,7], E. Heyer[2].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, USA; 2) CNRS-MNHN-Université Paris7, UMR 7206 Ecoanthropology and Ethnobiology, Paris, France; 3) IRD-MNHN, UMR 208 Patrimoines locaux, Paris, France; 4) Department of Anthropology, Washington State University, Vancouver, Washington, USA; 5) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, USA; 6) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, Michigan, USA; 7) The Life Sciences Institute, University of Michigan, Ann Arbor, Michigan, USA.

African Pygmy populations have the shortest average adult height among worldwide human populations. These hunter-gatherer populations live in close socioeconomic association with nearby non-Pygmy agricultural populations that have noticeably greater average adult height. In search of genetic loci associated with height differences between Pygmies and non-Pygmies, we genotyped 358 individuals from 13 Central African Pygmy populations and 169 individuals from 7 neighboring non-Pygmy populations for ~200,000 SNP markers on the Illumina Cardio-Metabo BeadChip, which incorporates a large number of height-associated SNPs originally identified in populations of European descent. In an admixture analysis, we find that estimated non-Pygmy admixture in Pygmy individuals is positively correlated with individual height in males (r=0.350, P=0.002) and in females (r=0.451, P=0.003). A combined test of SNP-by-SNP P-values for allele frequency difference between Pygmies and non-Pygmies finds that the collection of 949 known height-associated SNPs on the chip has a greater difference between Pygmies and non-Pygmies (P=8.94×10^{-13}). This set of height-associated SNPs also has a greater allele frequency difference between Pygmies and non-Pygmies than do any of 10,000 frequency-matched SNP sets from the full SNP dataset (P<10^{-4}). These results provide evidence that some of the loci contributing to the difference between African Pygmies and non-Pygmies are among those loci previously identified as height-associated in Europeans.

Methods for demographic inference using the transition matrix of allelic types from diploid genomic sequences. *y. wang, k. lohmueller, r. nielsen.* University of California at Berkeley, Berkeley, CA.

We developed a novel population genetic method for inferring demographic parameters from pairs of diploid genomes. Our method uses information from both linkage disequilibrium (LD) patterns and differences in allele frequency between populations. We summarized the genomic information by numbers of different transitions between allelic types. Starting from the fact that there are three possible genotypes (homozygous ancestral, heterozygous and homozygous derived) at each site for one genome, we defined seven pair-wise allelic types at polymorphic sites, for a pair of diploid genomes. These allelic types contain information about the extent of population differentiation between the two genomes. For example, using genomes from highly differentiated populations, there would be many sites where the two individual genomes were homozygous for different alleles. The transition pattern from one allelic type to another allelic type moving along a chromosome is a measure of LD across the genome. Transitions between very different allelic types indicate that there is little LD in the genomic region. We tabulated the number of the 49 different possible transitions from a pair of genomes and applied standard coalescent simulation to estimate demographic parameters. Our method explicitly models variation in recombination rates including recombination hotspots, and further takes sequencing errors into account. We evaluated the method by simulations and by applying it to whole-genome sequences of seven Asian, European and African individuals.

468F

Validation of ancestry informative markers in Brazilian Amerindians and ancestry estimates in quilombo remnant communities. *C.E.V. Wiezel[1], M.R. Luizon[2], S.M.B. Sousa[3], K. Abe-Sandes[4], I.R. Souza[5], Y.C.N. Muniz[5], C.T. Mendes-Junior[6], A.L. Simões[1].* 1) Department of Genetics, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, São Paulo, Brazi.l; 2) Department of Pharmacology, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, São Paulo, Brazil; 3) State University of Santa Cruz, Ilhéus, Bahia, Brazil; 4) Departament of Genetic, State University of Bahia, Salvador, Brazil; 5) Departament of Cell Biology, Embryology and Genetic, Federal University of Santa Catarina, Florianópolis, Brazil; 6) Departamento de Química, Faculdade de Filosofia Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Brasil.

Brazilian quilombo remants are Afro-derived communities founded mainly by fugitive slaves between the 16th and 19th centuries. Each community has its own cultural and ancestral characteristics, including heterogeneous contribution of non-African people. Ancestry Informative Markers (AIMs) exhibit high allele frequency differences between ancestral populations, and can be useful to characterize populations that vary in degree of admixture and to estimate individual and population ancestry estimates. However, it is important to consider the most suitable ancestral population frequencies when generating admixture estimates. Then our goal was to characterize the frequencies for 12 AIMs (FY, RB, LPL, AT3, Sb19.3, APO, PV92, CKMM, DRD2, MID93, MID52 e MID575) in Amerindians from Brazilian Amazon in order to generate proper population and individual ancestry estimates in six quilombo remnants characterized by distinct demographic histories of formation: Mimbó, Sítio Velho, Gaucinha, Barra, São Gonçalo and Valongo; and five urban population samples: Teresina, Jequié, Pernambuco, São Paulo and Florianópolis. African and European genotypes were kindly provided by Dr. Mark Shriver from PSU. Genotyping was performed by PCR and PCR-RFLP and fragments analyzed by PAGE and silver staining. African Ancestry Indexes (AAI) was obtained by dividing the African component by the sum of the European and Amerindian components, obtained from STRUCTURE software. The comparison of AAI medians were performed by non-parametric tests using GraphPad. Ancestry estimates were performed using ADMIX software and Principal Component Analysis (PCAs) using MVSP software. The 12 AIMs were sufficient for an adequate discrimination among the considered ancestral populations. Three totally divergent clusters that correspond to the European, African and Amerindian populations were obtained without any overlap, each group clustered in one of the vertices of the STRUCTURE triangular plot. PCAs indicated that the first component groups the African population and the quilombo remnants. Although there is a clear AAI heterogeneity within and between groups, the AAI medians were not different among quilombo remnants. All ancestry estimates were trihybrid except for São Gonçalo. African estimates ranged from 51% in Valongo to 92% in Barra, and from 0.9% in Florianópolis to 46% in Jequié for urban populations. These estimates were more accurate than those obtained by autosomal STRs. Support: FAEPA, CNPq.

Remarkably little homozygosity in first generation mixed race individuals. *J. Wilson[1,2], C. O'Dushlaine[3,4], R. Fraser[1], R. McQuillan[1].* 1) Centre for Population Health Sciences, Univ Edinburgh, Edinburgh, United Kingdom; 2) EthnoAncestry Ltd, Howden St, Edinburgh, United Kingdom; 3) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) Stanley Center for Psychiatric Research, The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA.

Long runs of homozygosity (ROH) are ubiquitous features of human genomes. There is, however, wide variation in the number and length of ROH across individuals and populations due to their diverse demographic histories: sub-Saharan African populations are the least homozygous and Native South Americans the most. Using genomic analysis we here demonstrate the remarkable lack of homozygosity in mixed race individuals: first generation (F1) West African x European individuals are the least homozygous of all, with an order of magnitude fewer ROH than commonly observed in other populations. Their parents may not share ancestors after the Out of Africa movement, ~70,000 years ago. Populations may be ranked by increasing mean number of ROH: (1) F1 West African x European; (2) F1 Afro-Caribbean x European; (3) Afro-Caribbean; (4) sub-Saharan African (excluding hunter-gatherers), F1 European x East African, F1 European x East Asian, Mauritian and Seychellois; (5) F1 European x South Asian; (6) “Backcross” Eurasian mixed race individuals; (7) other Eurasians; and (8) Native North Americans. Afro-Caribbeans have on average ~20% European ancestry, and these haplotypes generate ROH in offspring with Europeans. F1 European x East Asian individuals carry a similar complement of ROH to sub-Saharan Africans, emphasising the great genetic diversity in Africa. The variance in the number of ROH was highest for Native North Americans: NROH was strongly inversely correlated with the large and variable genomic estimates of European admixture. The reduction in genome-wide homozygosity in mixed race individuals will reduce their risk for diseases with a recessive genetic component.

Genetic relationship among ethnic minority groups in South America from the viewpoint of autosomal and Y chromosomal STRs. *T. Yamamoto[1], T. Ito[1], T. Gomyoda[1], K. Saijo[2], I. Danjoh[2], Y. Nakamura[2].* 1) Dept. of Legal Med. & Bioethics , Nagoya University, Nagoya, Aichi, Japan; 2) Cell Engineering Div., RIKEN BRC, Tsukuba, Ibaraki, Japan.

RIKEN RBC, a public cell bank in Japan, preserves a valuable cell collection called “the Sonoda-Tajima Cell Collection” where cell samples collected from a variety of ethnic minority groups across the world especially from South America. A part of the samples were immortalized with Epstein-Barr virus, and the B-lymphoblastoid cell lines (B-LCLs) were established and provided to researchers. Alternatively, it is important to investigate the genetic relationship and structure among the present ethnic groups in South America to obtain the information about the peopling of the Americas. It is also valuable to investigate the origin of and the degree of admixture of male-linage to analyze the markers on Y chromosome (Y-chr). Here, DNA extracted from the 431 B-LCLs originated from the 32 ethnic groups were genotyped for 21 autosomal short tandem repeat (STR) loci using 2 multiplex typing systems. Based on the Fst genetic dictance, we constructed a Neighbor-Joining tree, and the topology was concordant with the geographical distribution, and in particular, Sanuma and Ye'kuana tribes in Venezela, Ticuna, Chipaya and Quechua tribes, Lengua and Nivacle tribes in Chaco Province in Paraguay formed each cluster, respectively. Genetic structural analysis revealed very isolated ethnic groups such as Sanuma, Ye'kuana, Ticuna, Chipaya tribes, and Chaco-Lengua and Nivacle tribes. Alternatively, 184 male DNA out of 431 were haplotyped for 17 Y-chr STRs (Y-STRs) using a commercially released kit. 160 haplotype(HT)s were observed, and all of them were searched through a web worldwide database (db) (YHRD; Y-STR haplotype reference database) including about 32000 HTs for 17 Y-STRs. As a result, totally 12 HTs matched and about 50 neighbor HTs were observed in the db, and one HT originated from Canar tribe in Ecuador and another HT from an unknown tribe in Ecuador were matched to one from Germany and Korea respectively, which suggests different population histories through the Beringia from East Asia and through the northeast America from the European Continent. The other HTs, however, were observed in African, Hispanic, native American and admixed populations in South America. Further examination would be necessary.

Evaluation of *ATOH7* and *RFTN1* in Primary Open Angle Glaucoma. *M. Zhang[1], J.H. Chen[1,2], D. Wang[1], Y. Zheng[1], H. Chen[1,2], L. Chen[2], C.P. Pang[2].* 1) Joint Shantou International Eye Center, Shantou, Guangdong, China; 2) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong, China.

Purpose: The atonal homolog 7 (*ATOH7*) and raftlin, lipid raft linker 1 (*RFTN1*) genes have recently been identified by genome-wide association studies to be associated with glaucoma-related parameters of optic nerve area and vertical cup-to-disc ratio (VCDR). Their link with the occurrence has not been reported. We investigated *ATOH7* and *RFTN1* sequence variations in primary open angle glaucoma (POAG). **Methods:** The study cohort contained 171 POAG patients and 200 controls recruited in Shantou, a city in southeast China. *ATOH7* sequence variations were screened by direct DNA sequencing of polymerase chain reaction-amplified UTRs, exons and splice regions. Logistic regression implemented by the R statistical language was performed for detected SNP. In silico tools were used for predicting the impact of any missense variant. **Results:** No coding mutations were detected in both patients and controls in *ATOH7* although 5 SNPs were detected, including 4 SNPs in *ATOH7* and 1 SNP in *RFTN1*. None of them deviated from Hardy Weinberg Equilibrium ($P > 0.05$). They did not show association with POAG statistical significance ($P > 0.05$). However, the *ATOH7* SNP rs7916697 showed strong interaction with the *RFTN1* SNP ($P = 0.007$, sex-adjusted $P = 0.020$). The combination of rs7916697 CC genotype and rs690037 AA genotype exhibited a strong protective effects (OR = 0.28, 95%CI: 0.11-0.71; sex-adjusted OR = 0.31, 95%CI: 0.12-0.83). **Conclusions:** No coding variants have been detected in *ATOH7*. However, the strong protective effect exerted by the interaction between the two VCDR-related genes but not by single SNP indicated multi-factorial effect in the complex genetics of glaucoma.

A Computationally Fast Bayesian Semi-parametric Algorithm For Inferring Population Structure And Adjusting For Case-control Association Tests. *S. Ghosh[1], A. Majumdar[1], S. Bhattacharya[2], A. Basu[3].* 1) Human Genetics Unit, Indian Statistical Institute, Kolkata, India; 2) Bayesian and Interdisciplinary Research Unit, Indian Statistical Institute, Kolkata, India; 3) National Institute of Biomedical Genomics, Kalyani, India.

Genome-wide case-control association studies have been successful in identifying novel variants involved in the pathogenesis of complex disorders. However, the problem of population stratification remains a major limitation of such studies. While methods have been developed (e.g., Genomic Controls, STRUCTURE along with STRAT, EIGENSTRAAT) to infer on population structure and correct for stratification in the tests for association, the estimation of the number of underlying subpopulations (K), which is of additional interest from an evolutionary perspective, has not been adequately addressed, except in STRUCTURE. In order to circumvent the problem of estimation of parameters in high dimensional spaces, STRUCTURE adopts an ad hoc approach of Bayesian deviance that tends to overestimate K and may lead to reduced power in detecting association. We have developed a Bayesian semi-parametric approach in the lines of Bhattacharya (2008) to estimate population structure under the assumption that K is random. The model is complemented by a summarization of the clustering data generated by the MCMC based on an elegant “Central Clustering” approach developed by Mukhopadhyay et al. (2011). Our approach has several advantages over STRUCTURE, the most prominent being a substantial reduction in computational time. Based on extensive simulations under a set-up of no admixture and an unlinked set of markers, we find that our method not only provides more accurate estimates of K compared to STRUCTURE, but also never overestimates the parameter. The test for association using STRAT is marginally more powerful for our clustering method compared to STRUCTURE after controlling for the overall false positive rate. We analyzed the Human Genome Diversity Panel data using our model and obtained very good clustering of the individuals in the panel. In the presence of admixture, the method can be modified by efficient designing of the Hierarchical Dirichlet Process.

Population Structure and Genetic Diversity Revealed by DNA Microsatellites of Han Population Through a Comparison with Populations Worldwide. *F. Guan[1,2,3], S. Li[1,2,3], S. Wei[1,3], H. Zhang[1,2], J. Feng[1,2], X. Gong[1,2], R. Su[1,2].* 1) Key Laboratory of National Ministry of Health for Forensic Sciences, College of Medicine, Xi'an Jiaotong University, Xi'an, China, 710061; 2) Key Laboratory of Environment and Genes Related to Diseases, Ministry of Education, Xi'an, China, 710061; 3) Institute of Human Genomics and Forensic Sciences, Xi'an, China, 710061.

This study examined genetic diversity and population structure of Han population including 33997 individuals from 31 Han subpopulations. Each of sampled individual was genotyped for 13 microsatellites spread across most autosomes, which are core loci for the Combined DNA Index System (CODIS). To detect the relationship between Han population and world's populations, we analyzed these date jointly with similar data of 12 other populations worldwide, available from Allele Frequency Database (ALFRED), including Japanese, Pakistani, Turks, Colombian, Brazilian, Russians, Australian Aborigines, European Americans, Tunisian, Navajo, African Americans and Equatorial Guinean. Through a series of analyses, including principal components analysis, structure analysis and analysis of molecular variance, our results clearly shown that there is a continuous gradient feature in the structure of two-dimensional West and East groups, which is different from the previous studies, and based on the percentage (9.251%) of genetic diversity among different subpopulations and the percentage (19.135%) of genetic variation between West and East groups, it is believed that there is a certain degree of genetic similarities among subpopulations in the Han gene pool, and there is obvious difference between West and East groups, which means that it's well supported by DNA molecular genetics to divide Han population into West and East groups. In addition, through comparing the autosomal gene bank of Han population with that of different reference populations worldwide, the results of neighbour-joining tree show that there is the grouping of Han population in one cluster, while such a cluster in the genetic variation of other populations worldwide is independent of and different from the Han population. The reason might be that these Han subpopulations have experienced the gene flow of certain extent in the history, which coincides with the facts that there are several large-scale migrations in history. Actually, it should be more cautious to perform population deduction based on the data of several loci which don't cover the whole genome, because too few loci may result in a statistically significant, but incorrect clustering. Anyway, we provided a large amount of forensic genetic data and it's very useful in relevant population genetics and forensic studies.

474F

Population Substructure in the Sea Island Gullah African Americans. *Y. Huang[1], WM. Chen[1], X. Hou[1], U. Nayak[1], J.C. Mychaleckyj[1], F. Chen[1], K.L. Keene[1], K.H. Lok[3], D.L. Kamen[2], K.J. Hunt[2], I.J. Spruill[2], J.K. Fernandes[2], W.T. Garvey[3], M.M. Sale[1].* 1) University of Virginia, Charlottesville, VA; 2) Medical University of South Carolina,Charleston,SC; 3) University of Alabama at Birmingham,Birmingham,AL.

African populations are the most ancient and diverse on Earth, with a complex genetic substructure due to a long history of migration and admixture. African Americans (AA) are the admixed descents of African and European ancestors and are more genetically susceptible than European Americans to certain prevalent complex diseases. This renders an understanding of African ancestry critical not only in terms of evolution but also for disease based analyses. We used Multidimensional Scaling (MDS) and Principal Component Analysis (PCA) to analyze the population substructure in 384 unrelated Sierra Leone Africans and 877 unrelated Gullah AAs from Sea Island Genetic African American Family Registry (SuGAR), the Center of Biomedical Research Excellence (COBRE) for Oral Health at MUSC and the Systemic Lupus Erythematosus in Gullah Health (SLEIGH) Study. In total, 103731 LD-pruned GWAS SNPs that are also present in 130 Stanford-HGDP and 592 Hapmap III founders were included in the analysis. Four distinct linguistic and lifestyle groups were found. They include West Africans (Sierra Leone populations, Yoruba (YRI) and Mendenka), 3 distinct populations in the South and Southwest (Biaka Pygmies, Mbuti Pygmies and San), Khoisans in the East (Luhya in Webuye(LWK), Maasai in Kinyawa(MKK) and North East Bantu in Kenya) and North Africans in the Northwest (Mozabite). Substructure was also observed within Sierra Leone samples with the three largest subgroups being Mende, Temne and Creole. In addition, the Mendenka samples from Senegal were found to distinct from all other African populations in MDS analysis. Consistent with migratory and residential history, the Gullah AA samples from SuGAR, COBRE and SLEIGH exhibit similar ancestry, and all carry higher (~89%) global African ancestry than what is typically reported for AA (~80%). Compared to YRI and Sierra Leone African samples, the African ancestry of Gullah AAs is closest to Creole in Sierra Leone Africans, while genetically in-between all other Sierra Leone Africans and YRI. These findings may contribute to further understanding of the Sea Islands Gullah population's ancestral origins. Similar finding were also obtained using model-based ancestry estimation software ADMIXTURE.

People of the British Isles: An analysis of fine-scale population structure in a UK control population. *S. Leslie[1], B. Winney[1], G. Hellenthal[2], S. Myers[2], A. Boumertit[1], T. Day[1], K. Hutnik[1], E. Royrvik[1], D. Lawson[3], D. Falush[4], P. Donnelly[2], W. Bodmer[1].* 1) Department of Oncology, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Department of Mathematics, University of Bristol, Bristol, United Kingdom; 4) Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany.

There is a great deal of interest in fine scale population structure in the UK, both as a signature of historical immigration events and because of the effect population structure may have on disease association studies. Although population structure appears to have a minor impact on the current generation of genome-wide association studies, it is likely to play a significant part in the next generation of studies designed to search for rare variants. A powerful means of detecting such structure is to control and document carefully the provenance of the samples involved. Here we describe the collection of a cohort of rural UK samples (The People of the British Isles), aimed at providing a well-characterised UK control population that can be used as a resource by the research community as well as providing fine scale genetic information on the British population. So far, some 4000 samples have been collected, the majority of which fit the criteria of coming from a rural area and having all four grandparents from approximately the same area. Three thousand samples were genotyped on the Illumina 1.2M and Affymetrix v6.0 platforms as part of WTCCC2. Using a novel clustering algorithm that takes into account linkage disequilibrium structure, approximately 3000 of the samples were clustered, using these comprehensive genotyping data, into more than 50 groups purely as a function of their genetic similarities without any reference to their know locations. When the appropriate geographical position of each individual within a cluster is plotted on a map of the UK, there is a striking association between clusters and geography, which reflects to a major extent the known history of the British peoples. Thus, for example, even individuals from Cornwall and Devon, the two adjacent counties in the southwestern tip of Britain, fall into different, but coherent clusters. Further details of this comprehensive analysis of the genetic structure of the People of the British Isles, together with a description of the provenance of the samples, will be give in the presentation. We believe that this is the first time that such a detailed fine scale genetic structure of a population of generally very similar individuals has been possible. This has been achieved through, on the one hand, a careful geographically structured collection of samples and, on the other hand, an approach to analysis that takes into account fully the linkage disequilibrium structure of the population.

476F

Nine forensic STRs are sufficient to determine genetic ancestries of Chinese populations. *S. Li[1,2], F. Guan[1,2], F. Gao[1,4], H. Gui[1,2], J. Wang[3], T. Doetschman[4], P. Stambrook[5].* 1) The Key Laboratory of National Ministry of Health for Forensic Sciences, College of Medicine, Xi'an Jiaotong University, Shaaxi 710061, China; 2) The Key Laboratory of Environment and Gene Related to Disease of Ministry of Education, College of Medicine, Xi'an Jiaotong University, Shaaxi 710061, China; 3) Department of immunobiology, University of Arizona, AZ 85724,USA; 4) BIO5 Institute and Dept of Cell Biology & Anatomy, University of Arizona, Tucson, AZ 85724,USA; 5) Department of Molecular Genetics, College of Medicine, University of Cincinnati, Cincinnati, Ohio 45267, USA.

Several indigenous ethnic populations in the Northwest region of China display clear differences in their cultures and social customs, perhaps as a result of geographic isolation and different linguistic traditions. Extensive trade and other interactions between these populations over the last two millennia probably also facilitated the admixture of different gene pools. Forensic identification of these populations often involves the genotyping of 16 STR loci (D3S1358, TH01, D21S11, D18S51, PentaE, D5S818, D13S317, D7S820, D16S539, CSF1PO, PentaD, vWA, D8S1179, TPOX, FGA, and AMEL). Since allele frequency distributions differ between these populations, however, it would be desirable to optimize the most effective set of genetic markers for genotyping. To further explore the evolutionary relationship between 13 ethnic populations residing in northwest China, and to reveal the features of population admixture, 9 most-commonly employed CODIS loci (D3S1358, TH01, D5S818, D13S317, D7S820, CSF1PO, vWA, TPOX, FGA) were selected for genotyping and further analysis. Multiple statistic methods were employed to explain the differentiation among populations and to explore the potential gene flow. The results suggest that populations living in Xinjiang Province typically show significant difference ($p<0.05$) from those residing in other provinces, while another five ethnic populations residing in Gansu and Qinghai Provinces show no significant difference from major populations such as Han, Hui and Mongolian. These data support the existence of high-level gene flows and population admixture in Gansu and Qinghai Provinces but not in Xingjiang Province . The Mantel test suggested that geographic factors contributed more significantly than linguistic differences ($p<0.05$), which explains the total variance of 21.58%.

Genome-wide patterns of admixture among US Hispanic/Latino populations of Caribbean-descent. *A. Moreno Estrada[1], P. Ortiz Tello[1], M.L. Cuccaro[2], S. Gravel[1], R.J. Martinez[2], J.L. McCauley[2], D.J. Hedges[2], R.W. Morris[2], J.K. Byrnes[1], F. Zakharia[1], S. Acevedo[3], P.J. Norman[4], Z. Layrisse[5], P. Parham[4], C.D. Bustamante[1], E.R. Martin[2].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Center for Genetic Epidemiology and Statistical Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Biology, University of Puerto Rico, Mayaguez, PR; 4) Department of Structural Biology, Stanford University, Stanford, CA; 5) Center of Experimental Medicine “Miguel Layrisse”, Venezuelan Research Institute (IVIC), Caracas, Venezuela.

Cryptic population structure and admixture are common confounders in genome-wide association and medical resequencing studies. Accounting for differences in ancestry, especially in case/control designs, is critical for proper analysis and interpretation of studies with multi- and trans-ethnic samples. Genomic studies of Hispanics/Latinos reveal that they are a highly genetically heterogeneous admixed group with strong variation in the proportions of African, European, and Native American ancestry. While Mexican populations have been characterized genomically to some extent, genetic studies of populations from the Caribbean and South America have been largely underrepresented. To that end, we have densely genotyped 252 samples from parent-offspring triads of Caribbean-descent sampled in South Florida, US, including Puerto Ricans, Cubans, Dominicans, Haitians, Hondurans and Colombians. We combined these SNP data with other publically available genomic resources, including HapMap and 1000 Genomes data, as well as Native American SNP data from putatively ancestral populations. Global ancestry proportions, estimated using the ADMIXTURE clustering algorithm, revealed substantial variation in admixture proportions among and within Caribbean populations. To assign local, ancestry-specific haplotypes across the genome, we implemented a novel PCA-based admixture deconvolution approach (PCADMIX) for three ancestral populations. Given the optimal accuracy obtained from trio phasing, we were able to determine exact posterior probabilities along each chromosome and measure the length of tracts attributable to distinct ancestries. We observed patterns consistent with continuous influx of African ancestry across the islands and a pulse migration across populations in contact with the continental landmass. By contrast, we find less evidence for continuous flow of Native American ancestry (characterized by shorter ancestry tracts), compatible with a single migration event between 15-20 generations ago and no further contribution of Native Americans into the Caribbean. We have also used local ancestry estimates to scan the genome for ancestry-specific enriched regions potentially indicative of natural selection. Insights gained from the application of new statistical methods for admixture deconvolution will improve the design and genetic analysis of medical genomic studies in Hispanics/Latinos and other complex admixed groups.

478F

Population Structure of Native Hawaiians in the Multiethnic Cohort Study. *R. Saxena[1], SK. Kim[2], CR. Gignoux[2], A. Lum-Jones[3], H. Wang[3], CA. Haiman[4], BE. Henderson[4], LN. Kolonel[3], L. Le Marchand[3], DO. Stram[4], I. Cheng[3].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Epidemiology Program, University of Hawai`i Cancer Center, Honolulu, HI; 4) Department of Preventive Medicine, Norris Comprehensive Cancer Center, Keck School of Medicine, University of Southern California, Los Angeles, CA.

The patterns of population structure and admixture in Native Hawaiians are understudied and quantification of their underlying population structure is imperative for providing a proper framework when conducting genome-wide association studies in this population. Unlike previous studies which have focused on ancestry informative markers (AIMs), we utilized high resolution genome-wide SNP array data and/or mitochondrial genomes to complement AIMs data when characterizing 403 self-reported Native Hawaiians with varying degrees of Native Hawaiian heritage. To calculate each individual's proportion of genetic ancestry, we conducted an unsupervised analysis of population structure by implementing ADMIXTURE. For genome-wide SNP array data, we detected 78% Native Hawaiian, 11.5% Caucasian, and 7.8% Asian origins for individuals who reported full Native Hawaiian heritage. For individuals who reported 75% and 50% Native Hawaiian heritage, we estimated a mean Caucasian ancestral proportion of 20.3% and 50.1% and Asian ancestral proportion of 22.3% and 43.6%, respectively. For whole mitochondrial genome data, we characterized each individual's haplogroup and found 99% of Native Hawaiians belonging to the B4 lineage and one Native Hawaiian of the Q1 haplogroup among those who reported full Native Hawaiian heritage. Our findings here represent the most comprehensive study of the genetic ancestry of Native Hawaiians to date.

479F

A Major Semitic Genetic Contribution to the Brazilian Population. *D. Schlesinger[1,2], L. Kimura[2], M. Naslavsky[2], L. Grinberg[3,4], R. Mingroni-Netto[2], M. Zatz[2], Brazilian Aging Brain Study Group.* 1) Brain Institute, Albert Einstein Jewish Hospital, Sao Paulo, Brazil; 2) Human Genome Research Center, University of São Paulo, Brazil; 3) Brazilian Aging Brain Study Group (LIM22), University of São Paulo Medical School; 4) Memory and Aging Center, Department of Neurology, UCSF.

We have genotyped 547 inhabitants of São Paulo, Brazil, for 90 ancestry-informative markers (analyzed using Structure 2.3.3) that have previously been shown to distinguish individuals with Semitic and European ancestry. Estimated Central-South Asian (CSA) ancestry corresponded to 29%, larger than the African cluster (19%). The percentage of CSA ancestry within the Caucasian cluster (44%) was comparable to Semitic groups (Israelis, Druze, Palestinians) of the Human Genome Diversity Project. CSA ancestry was also more frequent in Brazilian subjects with higher African and Amerindian ancestry (colonial/pre-colonial populations) ($p<0.001$ for each). We then genotyped 35 relatively isolated descendants of African slaves, the Quilombolas. The quilombo population had higher CSA/Caucasian ratios compared to the São Paulo urban population (66% vs. 42%, $p<0.001$). These results suggest, in agreeance with historical evidence, that the likely Semitic ancestry arrived in Brazil during the colonial (1500-1822) period rather than the recent European immigration wave (1822-today). Further studies should elucidate whether this ancestry in São Paulo is derived from Portuguese “New Christians” fleeing persecution by the Inquisition or a Moor genetic component of the Portuguese population.

480F

Improved inference of relationships and consanguinity in CEPH pedigrees using identity-by-state combined with identity-by-descent. *E. Stevens[1], G. Heckenberg[2], J. Baugher[3], T. Downey[2], J. Pevsner[4,5].* 1) Program in Human Genetics, Johns Hopkins School of Medicine, Baltimore, Maryland, 21205, USA; 2) Partek Inc., St. Louis, Missouri, 63141, USA; 3) Program in Biochemistry, Cellular, and Molecular Biology, Johns Hopkins School of Medicine, Baltimore, Maryland, 21205, USA; 4) Department of Neurology, Hugo Moser Institute at the Kennedy Krieger Institute, Baltimore, Maryland, 21205, USA; 5) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, Maryland, 21205, USA.

It is essential that specified relationships in large, population-based datasets are correctly annotated as related or unrelated. While many methods exist to assess genetic relatedness between two individuals, we developed a novel approach to infer identity-by-descent (IBD) and combined it with an existing identity-by-state (IBS) approach. This combined method also elicits information about the population structure. We estimated IBD based on the observed IBS values across all chromosomes using a windowed approach. We validated our approach against the methods of PLINK, RELPAIR, and PREST using a set of 186 Centre d'Étude du Polymorphisme Humain (CEPH) individuals in 14 families. An explicit feature of the CEPH collection is that these multigenerational families represent reference panels of known relatedness, consisting mostly of three-generation pedigrees. We identified unexpected relatedness between nominally unrelated grandparents both within and between pedigrees. In some cases, the estimated Cotterman's coefficient of relatedness K1 (IBD1) exceeded 0.1 indicating recent ancestry (consistent with one-sixteenth sharing) between either grandparents or parents. In several cases, significant K2 (IBD2) values in parent-child and second-degree relationships also indicated potential consanguinity within the pedigrees. Consistent with an interpretation of inbreeding, we identified corresponding regions of homozygosity in the offspring of related or consanguineous parents. Our findings support a 1999 report, by Broman et al., that several CEPH families had regions of homozygosity consistent with autozygosity. We found additional intrapedigree sharing among four CEPH/Utah families and interpedigree sharing within two other CEPH/Utah families. Our IBD method has the capacity to analyze datasets with thousands of samples, and improves IBD estimation compared to similar programs without the need for a priori information about haplotypes or relatedness between individuals. When combined with IBS we provide an intuitive and practical graphical approach. The application of this approach could improve genome-wide association, linkage, heterozygosity, and other population genomics studies that rely on SNP genotype data.

Barriers to Neutral Introgression Generated by Local Adaptation and Sex-Specific Incompatibility. *M.K. Uyenoyama[1], D. Fusco[2].* 1) Dept Biol, Duke Univ, Durham, NC; 2) Computational Biology and Bioinformatics, Duke Univ, Durham, NC.

Adaptation to local conditions within subpopulations balanced by migration can maintain polymorphisms for variants that affect fitness in certain ecological contexts. We addressed the effects of such polymorphisms on the rate of introgression of neutral marker genes, possibly genetically linked to targets of selection. This analysis serves as the basis for the development of a method designed to use the pattern of neutral variation throughout the genome to infer the location and characteristics of targets of local selection. We proposed a scaling of backward migration rates that explicitly incorporates linkage and selection for local adaptation and show that it accurately determines the waiting time between migration events at neutral sites traced back in time along randomly sampled lineages. We studied two major types of selection regimes: those that promote local monomorphism (purifying or disruptive selection) and those that promote local polymorphism (overdominance or purifying selection balanced by meiotic drive). In agreement with previous work by Barton and Bengtsson and others, we found that the former type generates barriers to neutral introgression that increase with linkage to targets of selection. However, the latter type generates only weak barriers, and in fact meiotic drive can enhance transmission of genes borne by migrants beyond residents. Viewing interspecific hybrid incompatibility as an extreme form of local selection, we explored the effects on neutral introgression of sex-specificity in crossover rates, expression of incompatibility, or transmission. The magnitude of the reproductive barrier differs among genomic regions, even in the absence of physical linkage of neutral markers to targets of selection or of functional epistasis among incompatibility factors. Our partitioning of variation in relative reproductive rate showed associations between sex and incompatibility and between sex and neutral markers. Concordant sex-specific incompatibility (e.g., greater impairment of male hybrids or longer map lengths in females) permits higher rates of introgression and discordant incompatibility lower barriers.

482F

A quantitative comparison of the similarity between genes and geography in worldwide human populations. *C. Wang[1], N.A. Rosenberg[1,2,3].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Life Science Institute, University of Michigan, Ann Arbor, MI.

Multivariate statistical techniques such as principal components analysis (PCA) and multidimensional scaling (MDS) have been widely used to summarize the structure of human genetic variation, often in easily visualized two-dimensional maps. Many recent studies have reported a visual similarity between geographic maps of individual or population locations and MDS or PCA maps of genetic variation inferred from single-nucleotide polymorphisms (SNPs). However, this similarity has primarily been evident only in a qualitative sense, and because different multivariate techniques and marker sets have been used in different studies, it has not been possible to formally compare datasets in terms of the levels of similarity with geography of MDS or PCA plots of genetic variation. In this study, we perform a systematic analysis to quantitatively evaluate the similarity of genes and geography in different geographic regions. We have therefore integrated genome-wide SNP data from over 100 populations worldwide, identifying a shared set of markers and employing the same multivariate analysis techniques to analyze datasets from different geographic regions. For each of a series of geographic regions, a Procrustes analysis approach is used to find an optimal transformation that maximizes the similarity between PCA maps of genetic variation and geographic maps of sampling locations. We consider examples consisting of populations from Africa, Asia, China, Europe, and a worldwide sample. We find that significant similarity between genes and geography exists in general at different geographic levels. Further, we find that the similarity is highest in our examples from Asia, and once isolated populations have been removed, Africa. Our results provide a broad picture of the geographic structure of human genetic variation across the world, supporting the view that geography plays a strong role in giving rise to human population structure.

483F

Epistatic selection between coding and regulatory variation in human evolution and disease. *T. Lappalainen, S.B. Montgomery, A.C. Nica, E.T. Dermitzakis.* Department of Genetic Medicine and Development, University of Geneva Medical School, Geneve, Geneve, Switzerland.

Interaction (non-additive effects) between genetic variants has been highlighted as an important mechanism underlying phenotypic variation, but the discovery of genetic interactions in humans has proved difficult. In this study, we show that the spectrum of variation in the human genome has been shaped by modifier effects that cis regulatory variation has on the functional impact of putatively deleterious protein-coding variants. We analyzed 1000 Genomes population-scale resequencing data from Europe (CEU) and Africa (YRI) together with gene expression data from arrays and RNA-sequencing for the same samples, as well as eQTL data based on RNA sequencing of B-cells, T-cells and fibroblasts of 55 individuals. We observed an underrepresentation of derived putatively functional coding variation on the higher expressed regulatory haplotype, which suggests stronger purifying selection against deleterious coding variants that have increased penetrance due to their regulatory background. Furthermore, the frequency spectrum and impact size distribution of common regulatory polymorphisms (eQTLs) appear to be shaped in order to minimize the selective disadvantage of accumulation of deleterious coding mutations on the higher expressed haplotype. We also describe how tissue-specific eQTLs leading to strong allelic imbalance of coding variants lead to differences in protein structure between the tissues of an individual. Interestingly, eQTLs explaining common disease GWAS signals showed an enrichment of putative epistatic effects, suggesting that some disease associations may arise from interactions increasing the penetrance of rare coding variants. Altogether, our results indicate that regulatory variation not only changes gene expression levels but also affects the penetrance of coding variants, which also implies that knowing the regulatory context is important for predicting the functional impact of coding variants. The specific type of genetic interaction described in this study is detectable from sequencing data in a genome-wide manner, and characterizing these joint effects may help to understand functional mechanisms behind genetic associations to human phenotypes - including both Mendelian and common disease.

Genotype-based test in mapping cis-regulatory variants from allele-specific expression data. *J.-F. Lefebvre[1], E. Vello[1], B. Ge[2], S.B. Montgomery[3,4], E.T Dermitzakis[3,4], T. Pastinen[2,5,6], D. Labuda[1,7].* 1) Centre de Recherche du CHU Sainte-Justine, Université de Montréal, Montréal, Québec, Canada; 2) McGill University and Genome Québec Innovation Centre, Montréal, Québec, Canada; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, 1211 Switzerland; 4) Wellcome Trust Sanger Institute, Cambridge CB10 1HH, UK; 5) Department of Human Genetics, McGill University Health Centre, McGill University, Montréal, Québec, Canada; 6) Department of Medical Genetics, McGill University Health Centre, McGill University, Montréal, Québec, Canada; 7) Département de Pédiatrie, Université de Montréal, Montréal, Québec, Canada.

Understanding the impact of regulatory variation in gene expression is of particular interest in evolutionary genetics and genetic epidemiology. Regulatory variation in cis is readily detected in individuals showing uneven expression of a transcript from its two allelic copies, usually referred to as allelic imbalance (AI). Identifying individuals exhibiting AI permits mapping regulatory DNA regions and the underlying genetic variants. However, the existing mapping protocols require knowledge of the haplotypes and are therefore sensitive to phasing errors, which may hamper identifying cis-regulatory variants located far away from the regulated transcript. We introduce genotype-based mapping test that does not require haplotype-phase inference. It relies on partitioning individuals exhibiting AI phenotype and non-AI regulatory homozygotes in a 2x3 contingency table comparing three possible bi-allelic genotypes of all SNPs along the chromosome that expresses the transcript of interest. Its performance to detect linkage disequilibrium (LD) between a purported regulatory site and the genotyped SNPs locating this region was examined by analyzing both simulated and empirical AI data. In simulation experiments the genotype-based test outperforms the haplotype-based tests with increasing genetic distance separating the regulatory region from its regulated transcript. The haplotype based tests compared include the linear regression and the binomial test partitioning SNPs between the down and up regulated chromosomes in AI individuals. The genotype-based test performed equally well with the experimental AI data, from genome-wide cDNA hybridization arrays and from RNA sequencing, pinpointing candidate regulatory regions that are either close or away from the examined transcript. Circumventing the need of haplotype inference, the genotype-based test will suit AI analyses in population samples of unknown haplotype structure and will facilitate tracing cis-regulatory variants that are located far away from the regulated transcript.

Genome-wide identification of neuronal targets for PTBP2 using RIP-seq. *P. Cormican, E.M Quinn, E.M Kenny, A.P Corvin, M. Gill, D.W Morris.* Neuropsychiatric Genetics Research Group, Dept. of Psychiatry and Institute of Molecular Medicine, Trinity College Dublin, Ireland.

RNA-binding proteins play a significant role in the regulation of mRNAs transcripts and facilitate differential gene expression patterns in a post-transcriptional context. One such RNA-binding protein, Polypyrimidine Tract Binding Protein 2 (PTBP2) is located in a strongly associatied region identified by the 2009 International Schizophrenia Consortium case-control study. PTBP2 is primarily a neuronal expressed gene and is involved in a range of cellular functions, including splicing, translational regulation, mRNA stability and transcription but as yet a comprehensive list of associated RNAs is not available. In this study we identify these associated mRNAs that co-precipitate with PTBP2 using RNA-immunoprecipitation and subsequent sequencing on an Illumina GAII. We employ two complementary tagging methods, His-Tag and anti-PTBP2 antibody to pull-down the protein-RNA interactors from a neuronal cell-line preparation. Examination of the overlap of enriched trancripts between these methods identifies ~1300 genes that comprise the PTBP2 associated transcriptome. Identification and classification of these associated mRNAs represents the next step in understanding the functional role of PTBP2 in neuronal cells and may potentially provide an insight into PTBP2s contribution to the pathogenesis of schizophrenia.

Comparative study of the Y chromosome diversity in some ethnic groups living in Iran and populations of the Middle East. *L. Andonian[1], S. Rezaie[2], A. Margaryan[3], D.D. Farhud[4], K. Mohammad[1], K. Holakouie Naieni[1,5], M.R. Khorramizadeh[6], K. Nourijelyani[1], M.H. Sanati[7], M. Jamali[8], A. Berahmeh[6], N. Aalizadeh[9], L. Yepiskoposyan[3].* 1) Dept. of Epidemiology and Biostatistics, School of Public Health, Tehran University of Medical Sciences, Tehran Iran; 2) Division of Molecular Biology, Dept. of Medical Parasitology and Mycology, School of Public Health, Tehran University of Medical Sciences, Tehran Iran; 3) Human Genetics Group, Institute of Molecular Biology, National Academy of Sciences, Yerevan Armenia; 4) School of Public Health, Tehran University of Medical Sciences, Tehran Iran; 5) Iranian Epidemiological Association; 6) Dept. of Medical Biotechnology, School of Advanced Medical Technologies, Tehran University of Medical Sciences, Tehran Iran; 7) National Institute for Genetic Engineering and Biotechnology, Pajoohesh Blvd., 17 Km Karaj HWY, Tehran Iran; 8) Academic Member of Ministry of Health and Education, Tehran Iran; 9) Hormozgan University of Medical Sciences, Bandar Abbas Iran.

Background: The main goal of this study is to conduct a population genetic study of: a) Armenians living in Iran, in the context of general Armenian population; and b) Iranian Azeris, one of the biggest ethno-linguistic communities, in comparison with other Turkic-speaking populations of the Middle East (from eastern Turkey, Azerbaijan Republic and Turkmenistan). Methods: Buccal cells of 89 Armenian males from central Iran, the descendants of Armenians forcibly moved to Iran in the beginning of 17th century CE, and 105 Turkic-speaking Azeri males from north-west Iran (Tabriz) were collected by mouth swabs. The samples were screened for 12 Single Nucleotide (SNP) and 6 microsatellite markers on the non-recombining portion of the Y chromosome. The results of genetic typing were statistically analyzed using Arlequin software. Results: Iranian Armenians display a moderate level of genetic variation and are genetically closer to Western Armenians which is in agreement with historical records. Iranian Azeris demonstrate much weaker genetic resemblance with Turkmens (as putative source population) than with their geographic neighbors. Conclusion: Political, religious and geographic isolation had moderate influence on the genetic structure of modern Iranian Armenians during the last four centuries, which is expressed in lower diversity of their patrilineal genetic legacy. The imposition of Turkic language to the populations of north-west Iran was realized predominantly by the process of elite dominance,i.e. by the limited number of invaders who left weak traces in the patrilineal genetic history of Iranian Azeris.

Refining the genetic effects of obesity-, dyslipidemia-, blood pressure-, hematology-associated variants on abdominal anthropometric measurements by constitution types. *S. Cha, H. Yu, S. Yu, J.Y. Kim.* Constitutional Med Res, Korea Institute of Oriental Medicine, Daejeon, Korea.

A Korea traditional tailored medicine, Sasang constitutional medicine, categorizes human beings into four types depending on states of physiological imbalances and responsiveness to herbal medicine; it has been also considered that each type may have different susceptibilities to metabolic disorders. Tae-eumin type, for instance, seems to be more susceptible to metabolic disorder like cardiovascular disease than other types, as it has been known for being sensitive to energy intake due to an imbalance toward preserving energy. One of main features for physiological imbalances developing metabolic disorder is the fat accumulation in abdomen. Therefore, the genetic variants associated with metabolic disorder could manifest different effects on the abdominal measurements according to the constitution types. Here, we examined the relationships between obesity-, dyslipidemia-, blood pressure, or hematology-associated polymorphisms and abdominal body mass in each Sasang constitution type. After the variants which had been reported in previous genome-wide association studies with the above disorders were genotyped with 2,328 Koreans, we estimated the effects of the variants on abdominal anthropometric measurements such as circumference and width as well as the respective ratio via multiple linear regression analyses in each consititution subgroup. The sets of polymorphisms affecting abdominal body mass were different between constitution types so that the variants significantly associated with abdominal increase in one type almost had no effects on the abdominal increase in the other types. The constitutional discrepancy for the association of genetic variants with accumulation in abdominal mass appeared to reflect the physique differences between constitution types, for example big Tae-eumin type and thin Soeumin type, as the major alleles of Tae-eumin type-associated variants showed the effects largely on the increases of abdominal phenotypes, whereas the variants associated in Soeumin type manifested the decreased effects on abdominal phenotypes. Our findings demonstrate that the genetic effects of certain polymorphisms involved in obesity, dyslipidemia, hypertension, or hematological disorder could be exerted in different manners for abdominal accumulation depending on constitution type. Therefore, classification of individuals based on Sasang constitution types would offer an effective assessing system for the risk of metabolic disorders.

Searching for adaptive introgression of favorable alleles in Yemeni populations. *J.A. Hodgson[1,2], R.L. Raaum[2,3], A.M. Al-Meeri[4], C.J. Mulligan[5].* 1) Center for the Study of Human Origins, Department of Anthropology, New York University, New York, NY; 2) New York Consortium in Evolutionary Primatology, New York, NY; 3) Department of Anthropology, Lehman College and The Graduate Center, City University of New York, New York, NY; 4) Department of Biochemistry, Faculty of Medicine, Sana'a University, Sana'a, Yemen; 5) Department of Anthropology, University of Florida, Gainesville, FL.

Adaptive introgression may be an important source of evolutionary novelty in geographically dispersed taxa such as humans, though the extent of its role in recent human evolution remains poorly understood. Adaptive introgression occurs when beneficial alleles previously unique to one population enter into a new population and are selected to a frequency above the background admixture rate. In order to better understand the possible extent of adaptive introgression in recent human evolution, we performed a genome-wide study of admixture between two divergent modern human populations. Populations on the southern Arabian Peninsula are located at the nexus of trade between East Africa and Eurasia and have a long history of known admixture. For example, in Yemeni populations approximately 30% of mitochondrial lineages and 15% of nuclear lineages are of African origin. We collected high-resolution SNP genotype data from 62 unrelated Yemeni sampled across the country. The ancestry of chromosomal segments in this sample was estimated using a haplotype-based method (HAPMIX) with the HapMap Masaai (MKK) and Northern and Western Europeans (CEU) as source populations. We have previously shown the HapMap Masaai (MKK) to be the best available proxy for the source population of African ancestry in Yemen. We applied a hierarchical Bayesian model to evaluate the extent of adaptive introgression from African populations into the Yemeni sample. The pattern of introgression varied across the genome, with regions showing significantly higher and lower than expected introgression relative to genome-wide admixture. The possible functional complexes associated with these outlier regions of introgression may provide insight into expectations for earlier episodes of introgression in human evolution. For example, it has been suggested that admixture with Archaic human groups such as Neanderthals has played an important role in human evolution. However, no clear examples of adaptive introgression from archaic populations have yet been found in living humans. Our study of the genetic consequences of historical admixture on the Arabian Peninsula provides a modern analogue for earlier admixture events in human evolution.

489F

Association of PCSK1 rs6235 with Cardiovascular Disease Risks in Relation to Neck Circumference in Koreans. *H. Yu, J.Y. Kim, S. Yu, S. Cha.* Korea Institute of Oriental Medicine, Daejeon, Korea.

Common nonsynonymous variants in proprotein convertase subtilisin/kexin type 1 (PCSK1) converting prohormones into active-form hormones have been associated with obesity in European ancestry. In subsequent studies with Chinese populations, the gene variants have been associated with obesity as well as cardiovascular disease risk factors, which are known to be correlated with neck circumference. Here, we studied the association between a nonsynonymous variant and the cardiovascular disease risk in relation to neck circumference in Koreans. The genotype of rs6235 polymorphism was determined with 2,328 Koreans, and the genetic effects on phenotypes and diseases related with cardiovascular disease risk were statistically analyzed via regression analyses in two subgroups divided by the neck circumference cut-off points (39 cm for men; 34 cm for women) for overweight status (body mass index／ 25 kg/m2) using a receiver operating characteristics curve analysis. While we failed to replicate an association with obesity and related traits, we found the association of a minor allele of rs6235 with decreases in the prevalence of stroke (OR = 0.42, P = 0.038), ischemic heart disease (OR = 0.63, P = 0.015), and diabetes (OR = 0.57, P = 0.025) especially in the subjects with neck circumference values under the cut-off points. We newly researched the genetic effects of PCSK1 in relation with neck circumference. The results suggested that rs6235 polymorphism in PCSK1 may affect cardiovascular disease risk through the mediation of neck circumference, although this remains to be confirmed with other large populations.

490F

Association of TNF-(gene with Neurological manifestations of dengue in the Rondonia Population. *D. Delani[1], A. Andrade-Casseb[1], L. Cantanhede[1], A. Krauze[1], A. Simões[2], M. Guimarães[1], J. Farias[1].* 1) Universidade Federal de Rondônia, Porto Velho, Brazil; 2) Faculty of Medicine of Ribeirao Preto, University of São Paulo, Brazil.

TNF gene showed a significant association with severe forms of infection caused by Dengue virus (Sierra 2010). By an extensive variability of SNPs, it has become essential tool for genetic linkage studies or association in composition and frequency within and between different ethnic groups (Vejbaesya, 2009). Aiming to genotype the SNPs -238 and -308 located in the promoter region of this gene and the genetic association observed between individuals infected with dengue, we collected blood samples from 108 individuals living in Cacoal and Jaru, Rondonia's State. DNA extraction was performed using the protocol described by Higuchi and analysis of samples was by PCR and RFLP, followed by electrophoresis on PAGE 6%. Statistical data were obtained using the program GENEPOP (Version 4.0). The allele frequency was 0.936 for -238G, and 0.0640 for -238A, corresponding to that observed in European populations (0.068 and 0.932 respectively, NCBI, 2010). In dengue patients the presence of this mutant allele-238A is associated with protection (Oliveira 2004). In this study, no association was found (p> 0.05). -308G allele had a frequency of 0.878 and -308A of 0.122, similar to described for African-American (0.123 and 0.877 respectively, NCBI, 2010), confirming the ethnic heterogeneity of the study population. Unable to establish a biological basis of susceptibility and resistance in relation to TNF, even though there is data in the literature (Fernández, 2004). New molecular approaches and statistics will be performed for the association dengue / TNF can be analyzed in order to confirm whether or not the literature.

491F

The paternal and grand-paternal age effects on blood telomere length in Cebu, Philippines. *D.T.A. Eisenberg[1,2], J.B. Borja[3], C.W. Kuzawa[1,2], M.G. Hayes[1,4,5].* 1) Department of Anthropology, Northwestern University, Evanston, IL; 2) Cells 2 Society: the Center for Social Disparities and Health, Institute for Policy Research, Northwestern University, Evanston, IL; 3) Office of Population Studies Foundation, University of San Carlos, Talamban, Cebu City 6000, Philippines; 4) Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Northwestern University Medical School, Chicago, Illinois; 5) Center for Genetic Medicine, Northwestern University, Chicago, Illinois.

Telomeres are repetitive DNA sequences (5'-TTAGGG in vertebrates) found at the ends of chromosomes. Telomere lengths (TL) shorten with age in proliferating human tissues due to the `end-replication problem' and oxidative stress. This shortening is implicated in senescence, with previous work suggesting that shorter TL impairs immune and cardiovascular function and results in increased mortality. Contrary to the TL shortening which occurs with age in human blood cells, several studies report that the TL in sperm of older men tend to be longer than that in younger men and, correspondingly, that offspring of older men inherit longer TL. We recently hypothesized that this paternal age effect on offspring TL is a mechanism for transmitting information about environmental experiences (age at reproduction) in recent generations to adaptively adjust offspring physiology. For the paternal age effect on TL to convey reliable information about past environments, it was predicted that the paternal age effect would exhibit a multi-generational character, providing integrated and thus more reliable information. This model leads to the prediction that grandfather age at the birth of the parent will be associated with longer TL in the grandchild (independent of any effects of paternal age). To test this hypothesis, TL from young men and women from Cebu, Philippines were measured from DNA extracts of blood using a qPCR method. Consistent with findings in European populations, having an older father was associated with longer TL in this population (n=799, p=0.02). Only a non-significant trend towards paternal grandfathers having grandchildren with longer TL was observed (n=122, p= 0.12). In analyses stratified by gender of the grandchild, older paternal grandfathers had grandsons with longer TL (n=69, p=0.03). No effect of maternal grandfather's age on grandchildren's TL was observed, which might be explained by past findings of reduced heritability of TL from mother to offspring when compared to paternal-offspring heritability. The effect sizes of the associations with paternal and grand-paternal ages suggest potentially biologically important magnitudes of effect. These findings provide the first evidence that grand-paternal age at conception of father might influence grandson's TL. This work was supported by NSF and Wenner Gren Foundation grants. DTAE is supported by a NSF GRF. DNA extracts generously provided by Karen Mohlke.

The mobilome of *Callithrix jacchus* (the common marmoset). *M.K. Konkel[1], J.A. Walker[1], B. Ullmer[2], Q. Wang[1], R. Hubley[3], A.F.A. Smit[3], M.A. Batzer[1] for the Marmoset Genome Sequencing and Analysis Consortium.* 1) Louisiana State University, Department of Biological Sciences, 202 Life Sciences Building, Baton Rouge, LA 70803; 2) Louisiana State University, Department of Computer Science, Center for Computation and Technology (CCT), 216 Johnston Hall, Baton Rouge, LA 70803; 3) Institute for Systems Biology, Computational Biology, 1441 North 34th Street, Seattle, WA 98103.

The availability of the common marmoset (*Callithrix jacchus*) genome provides the first sequenced New World monkey (NWM) genome. The purpose of this study was to investigate the propagation and evolution of mobile elements in the NWM lineage through the lens of the common marmoset. In addition, our objective was to investigate the population genetic composition of common marmosets using polymorphic retrotransposon markers to determine the diversity of common marmoset colonies of three U.S. Primate Centers (New England, Southwest, Wisconsin). Our analysis of the *C. jacchus* draft genome assembly [CalJac 3.2] revealed that the common marmoset has an overall repeat composition similar to other sequenced and analyzed primate genomes (e.g. human, chimpanzee, orangutan, and rhesus macaque). In the lineage leading to the common marmoset, two primary non-LTR (long terminal repeat) retrotransposon families, long interspersed elements (LINE1, L1) and short interspersed elements (SINEs) contribute the bulk of lineage-specific insertions. The NWM-specific L1 lineage intersects with the human-derived L1 tree between L1PA6f and L1PA7, and evolved in a mostly linear manner. Using the CalJac 3.2 assembly, we reconstructed the *Alu* subfamily evolution in the NWM lineage leading to the common marmoset. The youngest *Alu* subfamilies are derivatives of *Alu*Ta15, a previously identified NWM-specific subfamily. Moreover, about half of the NWM-specific *Alu* elements appear to be derived from *Alu*Ta15 or its derivatives, indicating that a small burst of *Alu* retrotransposition coincided with the rise of *Alu*Ta15 and its derived subfamilies. *Alu* activity seems to have declined somewhat thereafter, causing the most recent *Alu* retrotransposition rate in common marmosets to appear slower than in humans and rhesus macaques. Our population genetic analysis with polymorphic *Alu* markers using the Structure software indicates the presence of population structure with at least two different clusters, indicating diversity among common marmosets. In addition, we investigated the evolution of *Alu* subfamilies with respect to the radiation of NWMs through the lens of the common marmoset. This study provides insights into the evolution of mobile elements in the lineage leading to the common marmoset and represents the first comprehensive analysis of the mobilome of a NWM species.

***PDE4B* is a high myopia susceptibility gene likely by down regulating collagen synthesis in sclera.** *W. Chen[1], X. Zhou[2], C. Li[1], J. Qu[2], C. Zeng[1].* 1) The Laboratory of Disease Genomics and Individualized Medicine, Beijing Institute of Genomics, Chinese Academy of Sciences; 2) Wenzhou Medical College.

High myopia (HM) or `pathologic' myopia refers to short vision with refraction error less than -6.00 diopters or axial length higher than 26 mm. Previous pedigree and association analysis had identified several susceptible loci for HM. However, with its high heterogeneity and lacking of functional assays, the genetic mechanism underlying HM still remains uncertain.

In order to identify loci contributing to HM susceptibility in Han population, we conducted a two-stage study including whole genome association (GWA) analysis and functional assays. In attempt to have both large samples size and high SNP density in GWA analysis, we took a strategy of using pooled samples. Briefly, two batches of case pools (331 and 176 subjects) and control pools (144 and 150 subjects) were constructed by mixing equal amount of DNA in each group. Genotyping was then performed using Illumina 1M duo chip with 3 replicate arrays for each pool to reduce experimental bias. Candidate SNPs obtained from association analysis were then verified by individual genotyping with Sequenom MASSARRAY. In total, 9 loci associated with HM were obtained. We chose rs10889602 (pooling $p=1.38\times10^{-6}$; individual verification p=0.0198), which locates in the third intron of cAMP-specific phosphodiesterase 4B (*PDE4B*), for further replication study in consideration of the possible role of PDE4B in collagen synthesis. rs10889602 appeared to be truly correlate to HM in Han Chinese by association analysis using 1,606 cases and 1,509 controls in total from two Han cohorts ($p_{meta}=3.72\times10^{-3}$).

Next we explored if PDE4B is functionally involved in myopia formation. *PDE4B* expression in form-deprived myopic sclera of guinea pig was decreased compared to those in fellow eyes, whereas there was no reduced expression for other *PDE4* family members. The inhibition of PDE4B by subconjunctival injection of rolipram, a PDE4 inhibitor, induced myopia in normal eyes and exacerbated myopia in form-deprived eyes. Moreover, thinner scleral collagen fibrils were observed in form-deprived eyes treated with rolipram. PDE4B inhibition by rolipram down-regulated transcription of collagen I, III, and V as well as decreased collagen secretion in cultured human scleral fibroblasts. Our findings suggest that *PDE4B* is a susceptibility gene for high myopia and the inhibition of PDE4B contributes to myopia development by down-regulating scleral collagen synthesis.

Mutation analysis of Parkin, PINK1 and DJ-1 and LRRK2 G2019S in European and North African families with parkinsonism. *S. Lesage[1,2,3], A. Honoré[1,2,3], C. Condroyer[1,2,3], M. Anheim[1,2,3], S. Klebe[1,2,3,4], E. Lohmann[1,2,3], C. Cazeneuve[3], A. Dürr[1,2,3], A. Brice[1,2,3], The French Parkinson's Disease Genetics Study Group.* 1) INSERM, UMR_S975 (Formerly UMR_S679), and Université Pierre et Marie Curie-Paris, Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, Paris, France; 2) CNRS, UMR 7225, Paris, France; 3) AP-HP, Pitié-Salpêtrière Hospital, Department of Genetics and Cytogenetics, Paris, France; 4) INSERM CIC-9503, Hôpital Pitié-Salpêtrière, Paris, France.

BACKGROUND: Parkinson disease (PD) is a frequent neurodegenerative disorder caused by loss of dopaminergic neurons in the substantia nigra. Three genes are responsible for autosomal recessive early-onset parkinsonism: Parkin, PINK1 and DJ-1. Although the common LRRK2 G2019S mutation was initially associated with dominant forms of PD, it is also found in a significant proportion of apparently autosomal recessive and sporadic patients. **AIM**: To assess the frequency of Parkin, PINK1, DJ-1 and the LRRK2 G2019S mutations in a large series of 880 families with parkinsonism. **PATIENTS AND METHODS**: We studied a series of 380 probands with familial and 500 with isolated PD. The families were of European descent (n=733), North African (n=117) and of diverse or unknown origins (n=30). All probands were screened for mutations in Parkin, PINK1, DJ-1 and the LRRK2 exon 41 using direct sequencing and semi-quantitative multiplex PCR or Multiplex Ligation-dependent Probe Amplification (MLPA) kits. In this study, we focused on probands with two mutations in recessive genes, except for the LRRK2 G2019S mutation. Segregation of the identified mutations was determined by analyzing all available DNA from affected and non-affected family members. The proportions of patients with Parkin mutations in function of the age at onset were examined in a total of 960 PD patients. **RESULTS**: We found 94 PD families with two Parkin mutations, representing a total of 11% (17% in familial forms and 6% in isolated cases). The proportion of patients with two Parkin mutations from PD families and from isolated cases decreased significantly with increasing age at onset, ranging from 53% and 28% before age 20 to 8% and 2% between 46 and 55 years, respectively. PINK1 mutations were identified in 9 families (1%) whereas no mutation in DJ-1 was found. In contrast, the LRRK2 G2019S mutation accounts for 5% of familial and 3% of isolated forms of PD. **CONCLUSION**: Parkin mutations are the most common genetic cause of parkinsonism in Europe and North Africa, particularly in early-onset familial PD. Although LRRK2 is known as a dominant gene, it plays a significant role in autosomal recessive forms of PD. In contrast, PINK1 and DJ-1 are more rarely implicated. This comprehensive mutation analysis of recessive genes and the LRRK2 G2019S in a large series of familial and isolated cases will be of major importance for molecular diagnosis to prioritize testing of the most common disease-causing genes.

495F

Prioritizing novel variants through whole-exome sequencing and pathway discovery in Alzheimer's Disease. *M.W. Logue[1,6], M. Schu[1], B.N. Vardarajan[1], J. Farrell[1], C.T. Baldwin[1,7], L.A. Farrer[1,2,3,4,5,6].* 1) Biomedical Genetics, Boston Univ Sch Med, Boston, MA; 2) Neurology, Boston Univ Sch Med, Boston, MA; 3) Ophthalmology, Boston Univ Sch Med, Boston, MA; 4) Genetics & Genomics, Boston Univ Sch Med, Boston, MA; 5) Epidemiology, Boston Univ Sch Public Health, Boston, MA; 6) Biostatistics, Boston Univ Sch Public Health, Boston, MA; 7) Center for Human Genetics, Boston Univ Sch Med, Boston, MA.

There is growing consensus that, apart from *APOE* isoforms, late-onset Alzheimer (AD) risk conferred by common mutations is likely to be small. However, next-generation sequencing methodologies may enable the identification of rare or private risk variants of moderate to high effect. In this study we sequenced whole-exomes of 7 African American AD patients from the MIRAGE study including two affected sib-pairs with additional family history of AD and three singleton AD patients. Whole exome capture was performed using the Agilent SureSelect Human All Exon kit. Sequencing was performed using the Illumina GA IIx platform. The 80 bp single end reads were aligned with the Burrows-Wheeler Aligner (BWA) program. Sequencing was completed with a 96% read alignment and 17.5x coverage within target regions. The variant calling of the aligned sequencing data was completed using a pipeline based on the Genome Analysis Toolkit. The variant calls were further filtered for mapping quality, sequence depth, and extent of homozygosity in the region. To ensure that called variants were real and to prioritize those more likely to be pathogenic, we focused on the novel 1,746 variants in 1,364 genes found in 2 or more subjects. Two of these genes, *ABCA7* and *CD33*, were previously implicated in GWAS studies of AD (the reported variants were 4 and 15 kb away from the sequenced novel SNPs respectively). Ingenuity pathway analysis (IPA) was able to create several densely connected gene pathways based on our list of 1,364 genes. One of the most interesting and heavily weighted pathways (28 of 35 pathway genes from the target list) links *CD33* and genes involved in Lipid Metabolism, Molecular Transport, and Small Molecule Biochemistry. As a next step to determine whether or not these new variants are involved in AD risk, we are currently genotyping and testing association with SNPs from these pathways in a large group of African American and Caucasian AD cases and controls.

496F

Lipid droplets and the pathogenesis of axonopathies caused by dominant mutations in *BSCL2*. *G. Mancuso[1], T. Rizo[2], E.I. Rugarli[1,2,3].* 1) Institute of Zoology, University of Cologne, Cologne, Germany; 2) Center for Molecular Medicine (CMMC), University of Cologne, Cologne, Germany; 3) Cologne Excellence Cluster on Cellular Stress Responses in Aging Associated Diseases (CECAD), University of Cologne, Cologne, Germany.

Long axons of central and/or peripheral motor neurons degenerate in several inherited neurological conditions, such as hereditary spastic paraplegia and Charcot Marie Tooth disease. With the identification of many causative genes for these conditions, we now appreciate that a considerable overlap can exist in term of genetic causes and involved cell pathways. Dominant mutations in *BSCL2* are responsible for a variety of axonopathies, which clinically manifest as Silver syndrome/spastic paraplegia 17, distal hereditary motor neuropathy type V, and Charcot-Marie-Tooth disease type 2 with predominant hand involvement. *BSCL2* encodes for seipin, an integral membrane protein of the endoplasmic reticulum involved in lipid droplet biogenesis. Loss-of-function recessive mutations of *BSCL2* cause Berardinelli-Seip syndrome, a severe form of lipodystrophy, and deletion of the orthologous gene in yeast causes a defect in lipid droplet formation. The neurological diseases associated with *BSCL2* are dominantly inherited and due to missense mutations (N88S and S90L) affecting two residues within a glycosylation motif. The current hypothesis is that glycosylation defect of seipin leads to protein misfolding, endoplasmic reticulum (ER) stress, and subsequent cell death by apoptosis. A gain-of-function pathogenic mechanism is also supported by the fact that seipin-N88S and seipin-S90L can complement a deleted yeast strain to the same extent as the wild-type human protein. We now provide evidence that seipin-N88S and seipin-S90L mutants decorate cup-shaped ER subcompartments in close contacts with lipid droplets. Live-imaging experiments suggest that these ER structures closely follow lipid droplet movements. Experiments are in progress to understand the functional significance of these cup-like structures and the effect of mutant seipin on cellular lipid metabolism. We propose that seipin-N88S and seipin-S90L mutations display a gain-of-function effect on some aspect of lipid droplet biogenesis, thus linking *BSCL2* axonopathies to dysfunction in lipid metabolism.

497F

Genetic interactions in diversified biological pathways predict hippocampal and entorhinal atrophy in Alzheimer Disease. *S.A. Meda[1,2], M.E. Koran[2,3,4], N.A. Restrepo[2,4], T.A. Thornton-Wells[1,2].* 1) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics & Research, Vanderbilt University, Nashville, TN; 3) Vanderbilt Medical Scientist Training Program, Vanderbilt University, Nashville, TN; 4) Human Genetics Ph.D. Program, Vanderbilt University, Nashville, TN.

Background: The complex genetic etiology of late onset Alzheimer disease (LOAD) is still largely unknown. A large portion of the missing heritability can be attributed to heterogeneity in clinical disease status and to the lack of statistical analyses exploring genetic interactions. We attempt to address the above issues by using quantitative intermediate phenotypes derived from MRI data, which capture a larger portion of the underlying trait variation, and by testing for gene-gene interactions (GxG) within known biological KEGG pathways. **Materials and Methods:** This study included 156 control, 281 MCI and 140 LOAD Caucasian subjects derived from the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort. Brain volumes for hippocampus (HIP) and entorhinal cortex (ER) were derived using Freesurfer for their baseline and 12 month annual visits. Annual percent change for each region was used as a quantitative trait (QT), and 556,045 SNPs passed QC for further analysis. We tested all two-locus GxG within 212 KEGG pathways for association with both QTs using linear regression implemented in INTERSNP. This resulted in 151 million pairwise GxG models for each QT. Gender, APOE E4 and clinical status were included as covariates. **Results:** Atrophy rates for HIP ($p<1e-4$) and ER ($p<0.003$) were significantly different across groups and followed the expected direction (LOAD>MCI>controls). Results identified several significant (Bonf-corr (=0.05) two-locus associations with R HIP and R ER atrophy. A total of 143 GxG interactions in 34 KEGG pathways were associated with R HIP atrophy. Top pathways (with >=10 significant GxG) included calcium signaling (16), neuroactive ligand-receptor (12), long-term hippocampal potentiation (10), regulation of actin cytoskeleton (10) and gap junction (10). Similarly, 326 GxG in 41 KEGG pathways were significantly associated with R ER atrophy. Top associated pathways were calcium signaling (47), neuroactive ligand-receptor (41), axon guidance (20), glycan structure biosynthesis (23), purine metabolism (19), cell adhesion biosynthesis (15), prostrate-cancer (14) and focal adhesion (10). **Conclusion:** To our knowledge, this is the first study to explore association of pathway-based GxG interactions with cortical atrophy rates in LOAD. Findings support the interplay of specific biological networks (both known and novel in the context of LOAD) that contribute to atrophy rates in brain regions affected earliest in the disease process.

498F

The genetic contribution of dementia and Parkinson genes to Dementia with Lewy Bodies and Parkinson Disease with Dementia. *B. Meeus[1,2], A. Verstraeten[1,2], D. Crosiers[1,2,3], S. Engelborghs[2,4], M. Van den Broeck[1,2], M. Mattheijssens[1,2], K. Peeters[1,2], E. Corsmit[1,2], E. Elinck[1,2], B. Pickut[3], R. Vandenberghe[5], P. Cras[2,3], P.P. De Deyn[2,4], C. Van Broeckhoven[1,2], J. Theuns[1,2].* 1) Neurodegenerative Brain Diseases Group, Department of Molecular Genetics, VIB, Antwerpen, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerpen, Belgium; 3) Department of Neurology, University Hospital Antwerp, Antwerpen, Belgium; 4) Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerpen, Belgium; 5) Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium.

Dementia with Lewy bodies (DLB) and Parkinson Disease with Dementia (PDD) represent neurodegenerative dementias characterized by clinicopathological features that overlap with those of Alzheimer dementia (AD) and Parkinson disease (PD). Therefore, genetic commonalities between these disorders can be anticipated. Genetic research in a limited number of mostly isolated patients already supported a potential role for genes that are known to be implicated in classic forms of either AD or PD in the development of DLB and PDD. Despite strong hints for a genetic component in the etiology of both diseases a comprehensive mutation analysis of all major dementia and PD related genes in larger DLB and PDD cohorts is still missing. The prior aim of this study was to determine whether mutations in dementia and PD genes play a role in DLB and PDD.

Therefore, we systematically screened all major dementia and Parkinson disease genes in 99 DLB and 75 PDD patients for simple mutations in coding exons and regulatory regions previously reported to contain pathogenic mutations in AD, frontotemporal lobar degeneration (FTLD) or PD patients. In addition, copy number variations in *APP*, *SNCA* and *PARK2*, important dosage sensitive genes in AD and PD, were determined.

In the AD genes, we detected proven pathogenic missense mutations in *PSEN1* (A79V) and *PSEN2* (R71W) and two novel missense variants in *PSEN2* (V191E) and *MAPT* (R221Q). We identified one duplication mutation in *SNCA*, the *LRRK2* R1441C founder mutation and four novel heterozygous missense variants of which two in *PARK2* (A46S and R275W) and two in *PINK1* (P138L and S499C), with unknown pathogenicity.

It is not yet fully clear to which extent these genetic variants contribute to the pathogenesis of both disorders, but our data indicate a potential contribution to the genetic etiology of DLB and PDD though limited. Out results, however do support the hypothesis of a potential genetic overlap between diseases belonging to the Lewy body disease spectrum.

Identification of the causative gene for SPG27 by Exome capture. *A. Noreau[1], S.L. Girard[1], A. Szuto[1], I.A. Meijer[1], P. Cossette[1], P.A. Dion[1,2], G.A. Rouleau[1,3,4].* 1) The Centre of Excellence in Neuroscience, CRCHUM, Montreal, Quebec, Canada; 2) Université de Montréal, Department of pathology and cellular biology, Montreal, Quebec, Canada, H3T 1J4; 3) University of Montreal, Faculty of Medicine, Department of Medicine, Montreal, Quebec, Canada, H3C 3J7; 4) Research Center, CHU Sainte-Justine, Montreal, Quebec, Canada, H3T 1C5.

Hereditary spastic paraplegia (HSP) is a motor neuron disease for which the key symptoms are lower limb spasticity and weakness because of progressive neurodegeneration events. The group of HSP is particularly heterogeneous because different modes of inheritance were observed (dominant, recessive and X-linked) as well as various levels of symptoms complexity; pure and complicated forms were described. To date, over 45 spastic paraplegia locus were identified and 21 genes identified. A previous linkage analysis on an autosomal recessive pure HSP family identified a new locus (SPG27) on the 10q22.1-10q24.1 region; a locus partially overlapping the SPG9 locus. We proposed to perform use an exome capture approach with the Agilent Technology SureSelect Human All Exon Kit (50MB) and proceed to resequencing with ABI SOLID4 DNA sequencer. Four affected individuals, the unaffected-carrier father and another unaffected sibling carrying the same disease-allele as the father will be used. As we may be looking for compound-heterozygote mutations, we will develop an algorithm to determine the parental origin of variants and the more promising mutations will be validated through Sanger sequencing. By this method, it will be possible to cover the 40 genes, find the causative mutation and maybe solve the SPG9 clue.

500F

Identification and Confirmation of an Exonic Splicing Enhancer Variation in Exon 5 of the Alzheimer Disease Associated PICALM Gene. *N.C. Schnetz-Boutaud[1], J. Hoffman[1], D.G. Murdock[1], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research and Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN; 2) The Hussman Institute for Human Genomics at the Miller School of Medicine, University of Miami, Miami, FL.

Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by memory and cognitive impairment and is the leading cause of dementia in the elderly. A growing number of genome wide association studies and subsequent replication studies have been recently published on late onset AD (LOAD), these studies identified several new susceptibility genes including phosphatidylinositol-binding clathrin assembly protein (PICALM) on chromosome 11. The aim of this study was to examine the entire coding sequence of PICALM to determine if the association could be explained by any previously undetected sequence variation. Such variation might explain, in whole or in part, the observed association. Therefore, we sequenced 48 cases and 48 controls homozygote for the risk allele for rs3851179 and of mixed APOE status. In this dataset, we did not find any new polymorphisms. However, rs592297 a known coding SNP that is part of an exonic splice enhancer region in exon 5 is in strong linkage disequilibrium with rs3851179. This SNP has altered heterozygosity and likely requires further study.

501F

Whole-exome sequencing confirms locus heterogeneity underlying Parkinson disease in an extended Amish family. *W.K. Scott[1,2], K. Nuytemans[1,2], G. Bademci[1,2], Y.J.K. Edwards[1,2], G.W. Beecham[1,2], M.F. Davis[3], A.C. Cummings[3], C.A. Jauregui[1,2], S.L. Lee[4], M.A. Pericak-Vance[1,2], J.L. Haines[3], J.M. Vance[1,2].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Neurology, Dartmouth Medical School, Lebanon, NH.

We studied 19 individuals with Parkinson disease (PD) and 2 with progressive supranuclear palsy (PSP) in a large Amish kindred from Indiana and Ohio. Two-point linkage analysis for PD across 13 subpedigrees generated LOD scores > 3 for 7 regions on 6 chromosomes. We next performed whole-exome sequencing (WES) to identify candidate genes in these regions of interest. WES is an economical strategy that addresses the possibility of locus heterogeneity suggested by the multiple significant linkage regions. Relationships among individuals with PD vary from siblings to more distant than 2nd cousins. We captured exomes using the Agilent SureSelect Human All Exon 50Mb Kit. Paired-end sequencing on the Illumina HiSeq2000 platform was performed on the captured DNA. Illumina analysis pipeline v1.7 and MAQ software v0.7.1 were used for analyzing the sequencing data. No single rare variant (RV; allele frequency < 5%) was shared by all individuals (19 PD & 2 PSP) or by all 19 PD patients, affirming the apparent locus heterogeneity suggested by linkage results. Further, no single functional variant was shared by all PD patients in the 1-LOD-unit down support interval surrounding the most significant multipoint LOD score peak for PD (a 12 Mb region of chromosome 9). Fourteen of the 17 genes in the region contained RVs in at least one individual. Taken together, these results indicate that finding the PD-associated RVs will require detailed examination of segregation in subpedigrees linked to each locus. Next-generation sequencing technologies provide new opportunities for rapid interrogation of large numbers of candidate genes in multiple linkage regions, such as those detected in this Amish kindred. The initial results here suggest that the familial aggregation of PD observed in this family is not due to the sharing of a single causal variant, but is due to multiple loci segregating in subsets of the pedigree. While the isolation of the Amish population (estimated inbreeding coefficient 0.015) likely reduces the number of PD-associated genetic variants, enough locus heterogeneity persists to render this pedigree a good model for PD in the general population.

502F

Duchenne/Becher like phenotype and L276I mutation in FKRP gene. *P. Spadafora, V. Andreoli, R. Cittadella, F. Trecroci, L. Maria.* Inst Neurological Sci, National Research Council, Mangone (CS), Italy.

Background and Objective. Mutations in the FKRP gene encoding for the fukutin-related protein are responsible for either a severe form of congenital muscular dystrophy (MDCIC) and the Limb girdle Muscular Dystrophy type 2I (LGMD2I). IperCKmia, cardiomyopathy, proximal muscles weakness and atrophy, calf hypertrophy, respiratory failure are common clinical features in the LGMD2I as well in the dystrophinopathies. The majority of LGMD2I patients follow a mild Becher-like course without showing severe gait impairment until late in their adulthood. Especially in western and northern Europe, the most frequent mutation identified in LGMD2I patients is 826C>A (L276I) located in FKRP gene. Homozygosity for L276I variant seems to confer a mild clinical phenotype, while compound heterozygosity for this mutation has been reported associated with a more severe clinical phenotype. On these grounds, we decided to perform a L276I mutation screening in patients from southern Italy who originally referred to our diagnostic laboratory with a suspect of Duchenne (DMD)/Becher (BMD) syndromes. Materials and methods. The study was performed on 106 sporadic cases resulted negative for exonic deletion/duplication of the DMD gene. The molecular analysis consisted of PCR amplification of the FKRP gene coding region containing the L276I variant followed by Bfa1 restriction enzyme digestion. The L276I mutation was confirmed by direct sequencing. Results. The selected FKRP mutation screening revealed one patient homozygous for L276I and two patients heterozygous for the same mutation. A full sequencing of exon 4 did not reveal further genetic mutations. Discussion and conclusions. The spectrum of clinical variability reported associated with LGMD2I ranges from severe early onset Duchenne-like muscular dystrophy to mild late onset Becher-like muscular Muscolar distrophy and existence of a frequent mutation (L276I) in Caucasian patients with LGMD2I, led us to analyze this mutation in 106 DMD/BMD sporadic patients with no rearrangement of the dystrophin gene. We identified the L276I mutation in three subjects (2,8%). This finding indicates the importance of screening for the L276I mutation also patients with clinical presentation of DMD/BMD muscular dystrophy.

Alzheimer's disease: Novel Mutations in Genes Comprising the Gamma Secretase Complex. *P. St Jean[1], L. Li[1], J. Shen[1], M. Nelson[1], M. Ehm[1], J. Whittaker[2], A. Yeo[2], V. Mooser[3], J. Rubio[2].* 1) Genetics, GlaxoSmithKline, Inc, Res Triangle Park, NC; 2) Genetics, GlaxoSmithKline Inc, Stevenage, UK; 3) Genetics, GlaxoSmithKline Inc, Upper Merion, PA.

We sequenced the exons of 202 genes encoding known or potential drug targets in over 14,000 individuals identifying over 38,000 variants. Subjects were consented for the study of common diseases and medically-relevant traits including 679 Alzheimer's disease (AD) cases and 673 AD controls. AD cases had a mean age at onset of 72.9 years. To increase power, 6424 additional non-AD reference controls were selected from among the 14,000+ individuals using principal components to minimize the genetic distance between controls and cases. The focus of this abstract is the identification of rare functional variants in four genes (PSEN1, PSEN2, PSENEN and APP) that are involved in the gamma secretase complex taking advantage of the largest data set sequenced to date for these genes. Several analytical methods were used to investigate the effect of rare variants on disease endpoints including a binary collapsing method, SKAT and a variable allele frequency threshold method. Our primary endpoint was AD status. Within AD cases other endpoints were assessed including age at onset, Parkinsonism, psychosis and depression. Our most significant association with AD risk was PSENEN (p=2.66E-06). Of the 3 variants, R82Q, was present in 2 of 679 AD cases and 0 of 7097 controls. Both cases had onset at 65 years. This variant is predicted to be functionally damaging by both SIFT and Polyphen and has not been previously identified as an AD mutation. The other 2 variants, I80T and L29I, were each present in a single control. PSEN1 was our strongest association with age at onset (p=4.54E-10), underpinned by 4 variants (A79V, H163R, I213L, S365A) previously linked to Mendelian forms of AD. PSEN1 163R had been reported in early onset AD in French Canadian families, and in this study all 3 AD carriers were French Canadian with onset 40-44 years of age. PSEN1 213L was discovered in an early onset Polish AD family and our sole AD subject with this mutation was also of Polish/German ancestry with an onset of 40 years. A novel APP mutation predicted to be benign, V431L, and a novel PSEN2 mutation predicted to be damaging, S30F, were each present in a single AD case but no controls. Neither mutation was associated with any endpoints tested. The age at onset was 70 and 67 for subjects harboring APP 431L and PSEN2 30F, respectively. Our work adds to the body of knowledge of AD mutations present in genes in the gamma secretase complex, a target for the development of novel AD drugs.

504F

ROLE OF THE PPCS, PPCDC, PPAT, AND DPCK GENES IN THE PATHOGENESIS OF THE PANTOTHENATE KINASE-ASSOCIATED NEURODEGENERATION. *P. Tarantino[1], E.V. De Marco[1], D. Civitelli[1], F. Annesi[1], F. Cavalcanti[1], M. Gagliardi[1,2], A. Quattrone[3,4], A. Gambardella[1,3], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone (CS), Italy; 2) University of Magna Graecia, Catanzaro (CZ), Italy; 3) Institute of Neurology, Department of Medical Sciences, University of Magna Graecia, Catanzaro (CZ), Italy; 4) Neuroimaging Research Unit, Institute of Neurological Sciences, National Research Council, Catanzaro (CZ), Italy.

Mutations in the PANK2 gene, coding for an enzyme involved in the biosynthesis of coenzyme A (CoA), cause a rare autosomal recessive disorder known as PKAN (Pantothenate Kinase-Associated Neurodegeneration), characterized by progressive dystonia and iron accumulation in the brain. A small number of cases may be due to mutations in the PLA2G6 gene. In a recent study performed on the CoA pathway in Drosophila melanogaster, it has been shown that mutations in the PPCS, PPCDC, PPAT, and DPCK genes, orthologs of the corresponding human genes, cause a phenotype related to phenomena of neurodegeneration similar to those observed in patients with PKAN. On this basis, we performed a sequence analysis of these four genes in patients with PKAN to assess their role in the development of the disease. We analyzed 8 patients (6 females, 2 males) including 5 with the classic form (earlier onset and more rapid progression) and 3 with the atypical form, coming from Italy and France. In these patients was previously excluded the presence of PANK2 and PLA2G6 mutations, including exonic rearrangements. Molecular analysis of the PPCS, PPCDC, PPAT, and DPCK genes was performed by direct sequencing of the PCR products of all the exons. We did not find any pathogenic mutation in the PPCS, PPCDC, PPAT, and DPCK genes in the patients with classical and atypical PKAN analyzed. No polymorphic variations were found in the PPCS gene. One polymorphism was identified in the PPCDC gene, whereas many polymorphic variations were identified in the PPAT and DPCK genes. Recently, an increase in reactive oxygen species as well as in sensitivity to DNA damage was detected in a model of mutant Drosophila, together with lipid homeostasis alteration and formation of vacuoles in the brain, resulting in damage of the motor function. These results prompted us to verify the role played by the PPCS, PPCDC, PPAT, and DPCK genes in PKAN. Our results indicate that mutations in these genes do not cause PKAN in our patients. It would also be important to search for new genes, responsible for the cases not linked to PANK2 and PLA2G6. However, due to the small number of patients analyzed, the involvement of the genes studied cannot be definitely excluded. Further studies carried on a more extended number of patients and in other populations are required to confirm our data. This work was granted by AISNAF ONLUS.

***BIN1* and *PICALM* association with Alzheimer disease risk and CSF tau levels in a Flanders-Belgian cohort.** *C. Van Cauwenberghe[1,2], N. Brouwers[1,2], K. Bettens[1,2], S. Engelborghs[2,3], N. Le Bastard[2], R. Vandenberghe[4], P.P. De Deyn[2,3], C. Van Broeckhoven[1,2], K. Sleegers[1,2].* 1) Neurodegenerative Brain Diseases Group, Department of Molecular Genetics, VIB, Antwerpen, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerpen, Belgium; 3) Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerpen, Belgium; 4) Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium.

Recent genome-wide association studies (GWA) studies have led to the identification of putative novel risk factors for Alzheimer disease (AD). Genome-wide significant association was obtained with single nucleotide polymorphisms (SNPs) located 5' upstream of bridging integrator 1 (*BIN1*) and the phosphatidylinositol-binding clathrin assembly protein gene (*PICALM*). Both genes appear to be implicated in clathrin-mediated endocytosis (CME), a process responsible for the intracellular trafficking of proteins and endocytosis of synaptic vesicles in neurons. The aim of this project was to fine-map the *BIN1* and *PICALM* association signal in a Flanders-Belgian AD cohort (N = 1905). Further, the effect of SNP genotypes on cerebrospinal fluid (CSF) biomarker profiles was analyzed. We genotyped 1047 patients and 858 healthy control individuals for 24 SNPs in the *BIN1* and 19 in the *PICALM* locus and up- and downstream regions. CSF level of) -amyloid peptide (A) $_{1-42}$), total tau protein (T-tau) and tau phosphorylated at threonine 181 (P-tau$_{181P}$) were available for 342 of the patients. We observed significant genotypic associations for 6 *BIN1* SNPs (p-values ranging from 0.004 to 0.042) of which 2 are located 5' of the gene. Interestingly, 5 *BIN1* variants associated with T-tau levels in CSF of AD patients (p-values ranging from 0.008 to 0.044, of which 3 are located 5' of *BIN1*). No association for *BIN1* was found with A) $_{1-42}$ and P-tau$_{181P}$ CSF levels. One *PICALM* SNP, located 5' of the gene, showed nominal association with AD. 2 SNPs of *PICALM* were significantly associated with T-tau (p-values 0.014 and 0.038) and an association with P-tau$_{181P}$ was found for 2 variants. No association was identified with A) $_{1-42}$. In this study we were able to fine-map the reported *BIN1* and *PICALM* association signals in a Flanders-Belgian cohort. This lends further support to the notion of genetic variations in *BIN1/PICALM* affecting the susceptibility of late-onset AD and representing genuine AD susceptibility factors. Our study extends this genetic association by showing a correlation with tau levels in CSF, suggesting that *BIN1* and *PICALM* might affect AD risk through an effect on tau biology.

Pursuit of the biological variant underlying the association of TMEM106B with frontotemporal lobar degeneration. *J. van der Zee[1,2], S. Engelborghs[2,3], R. Vandenberghe[4], P.P. De Deyn[2,3], M. Cruts[1,2], C. Van Broeckhoven[1,2].* 1) Neurodegenerative Brain Diseases Group, Department of Molecular Genetics, VIB, Antwerpen, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerpen, Belgium; 3) Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerpen, Belgium; 4) Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium.

Background: The first genome-wide association (GWA) study in frontotemporal lobar degeneration (FTLD) identified genetic variability at the TMEM106B gene on chromosome 7p21.3 as a potential common risk modifying factor for FTLD. We replicated this association in a Flanders-Belgian patient/control cohort, providing additional evidence for the implication of TMEM106B in FTLD risk. High-density single nucleotide polymorphism (SNP) mapping suggested that the association was solely driven by the gene TMEM106B and that homozygous carriers of the TMEM106B protective alleles had a 50% reduced risk of developing FTLD. Aim: To pursue the biological variant underlying the risk-modifying effect of TMEM106B on FTLD we performed targeted resequencing of the 36 kb minimal associated region containing TMEM106B plus additionally 2.5 kb flanking region to capture the conserved regulatory regions of the promoter. Results: Targeted resequencing of the candidate region was accomplished by Sanger sequencing in 11 patients homozygous for the associated protective haplotype and 10 patients homozygous for the common haplotype. This effort identified a total of 253 single base changes or small insertion/deletions (indels). These sequence variations included 38 rare variants (observed in 1 or 2 patients) and 215 more frequent variants. Of the common variants, 100 were in perfect linkage disequilibrium (LD) with rs1990622, the strongest associated SNP of GWA studies. Further 115 variants were counted that were not in LD with rs1990622. Interpretation: Targeted resequencing captured the complete genetic variability of the associated protective haplotype at the TMEM106B locus with FTLD, identifying 215 candidate variants. Following-up on these results, we will investigate which one of the 215 SNPs shows the strongest genetic association or is the best functional candidate to explain the biology of the disease-modifying effect of TMEM106B on FTLD.

Association of IGF-1 promoter polymorphism (-383C>T) with the susceptibility to multiple sclerosis. *R. Abdolmohammadi[1], H. Ebadi[2], M. Mansoori[1], S. Bakhshandeh[3], A. Tahmasebifar[4], M. Shahbazi[5].* 1) Golestan University of Medical Sciences, Cellular and Molecular Medicine Research Center Gorgan, Iran, MSc; 2) Golestan University of Medical Sciences, Gorgan, Iran, Neurologist; 3) Cellular and Molecular Medicine Research Center Gorgan, Iran, BSc; 4) Golestan University of Medical Sciences, Cellular and Molecular Medicine Research Center Gorgan, Iran, MD-PhD; 5) Golestan University of Medical Sciences, Cellular and Molecular Medicine Research Center Gorgan, Iran, MSc-PhD.

Association of IGF-1 promoter polymorphism (-383C>T) with the susceptibility to multiple sclerosis Abdolmohammadi R, Ebadi H, Bakhshandeh S, Mansoori M , Tahmasebifar A., Shahbazi M. Medical Cellular & Molecular Research Center, Talghani Children hospital, Golestan University of Medical Sciences, Gorgan, Iran Background and aim Insulin-like growth factors (IGFs) play an important role in proper development and myelination in the CNS. Because IGF-1 exhibits neuroprotective and myelinogenetic effects, it possesses therapeutic potential in treating neurodegenerative demyelinating diseases such as multiple sclerosis (MS). This study was undertaken to investigate the association between susceptibility to MS and IGF-1 polymorphisms in MS patients and healthy indvuduals. Methods DNA samples were prepared from the whole blood of 245 patients with MS and 373 healthy controls. We amplified the fragment including the IGF-1 polymorphism at position -383 and visualized the products in a documentation system after agarose gel electrophoresis. Data were analysed using Fisher's exact tests with SPSS-v16 software. Results The T/T genotype was found in 149 individuals (60.8%) 0f MS cases and 236 individuals (63.29%) 0f controls and 78 (31.8%) of MS and 135 (36.21%) of controls carried the C/T heterozygous genotype. only 2 (0.5%) of controls carried the C/C homozygous genotype while 18 (7.4%) of MS case carried the C/C homozygous genotype (P value<0.0001).The frequency of C allele was higher in MS patients than controls (OR=1.35, P<0.0001). Also, we have found a significant difference in the frequency of the C/C genotype among MS patients and controls (OR= 14.25, P value< 0.0001). Conclusion This is first report that, IGF-1 -383 C/C genotype was associated with risk of Ms (OR=14.25, P value< 0.0001).according to main role of IGF-1 in CNS and our finding, IGF-1suggest be, play crucial role in not only MS outcome but also CNS diseases.

Expression profile of microRNAs in focal cortical dysplasia: possible clues into etiology. *S.H. Avansini[1], F.R. Torres[1], F. Rogério[3], D.B. Dogini[1], A.C. Coan[2], R. Secolin[1], C.S. Rocha[1], A.F. Costa[3], A.L.F. Costa[2], L.S. Queiroz[3], F. Cendes[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences - State University of Campinas, Campinas, SP., Brazil; 2) Department of Neurology, Faculty of Medical Sciences - State University of Campinas, Campinas, SP., Brazil; 3) Department of Anatomical Pathology, Faculty of Medical Sciences - State University of Campinas, Campinas, SP., Brazil.

MicroRNAs (miRNAs) are small noncoding RNAs which regulate post-transcriptional gene expression. Focal cortical dysplasia (FCD) is a malformation of cortical development which affects up to 36% of patients with drug-resistant epilepsy. The objective of the present work is to investigate a possible role of miRNA regulation in the etiology of FCD. We used brain tissue obtained after surgery for the treatment of medically refractory seizures from seven patients with FCD (three patients with FCD type IIa and four patients with FCD type IIb). In addition, we used brain cortical tissue from autopsy as control. Total RNA was isolated with RecoverAllTM kit (Ambion) and RNA integrity was assessed by Agilent RNA Pico Chip Kit and Bio-Analyzer 2100 (Agilent Technologies, Boeblingen, Germany). MiRNA expression profile was assessed by Affymetrix GeneChip platform miRNA array. Background correction, summarization and normalization were performed by RMA function. Differential miRNA expression was analyzed using RankProd (FDR p < 0.05). We identified 44 human differently expressed miRNAs when comparing patients and controls. Among them we observed a significant down-regulation of several elements belonging to the miR-17~92 cluster. This cluster is known to contribute to transcriptional regulation of cell cycle, aging, as well as fine-tuning of pathways involved in neuronal differentiation. However, we found no difference in miRNA expression profile between FCD types IIa and IIb.

509F

Identifying Rare Variants in Parkinson Disease via Whole Exome Sequencing. *G. Bademci[1,2], K. Nuytemans[1,2], A. Mehta[1], C. Jauregui[1], A.G Martinez[1], G. Beecham[1,2], Y. Edwards[1,2], C. Singer[3], F. Nahab[3], S. Rhodes[4], B. Ritz[4], S. Zuchner[1,2], W.K Scott[1,2], J.M Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, 33136, United States; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami FL, 33136, United States; 3) Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, 33136, United States; 4) Department of Epidemiology, UCLA School of Public Health, Los Angeles, CA, 951772, United States.

Despite multiple GWAS studies, the common disease-common variant hypothesis has provided only a few replicated variations associated with Parkinson disease (PD) on a genome-wide significant level. Rare Variants (RV) have a population frequency less than 1-2%, and have been postulated to be part of the “missing” heritability in complex diseases such as PD. Further, these RV may contribute to large differences in age-at-onset (AAO) and progression of symptom severity between PD patients. To investigate the contribution of exonic RV in non-Mendelian PD, we have currently performed whole exome sequencing (WES) on 103 PD cases and 50 controls as part of an initial discovery dataset. These include 7 extended families, 51 unrelated patients whose AAO <40 years, 8 relatives with PD who have a >27 years difference in AAO, and 20 patients who have either very fast or slow disease progression. Agilent SureSelect whole exome kits were used for capture and samples were sequenced on an Illumina HiSEQ 2000. MAQ was used for sequence alignment and variant determination; all variant calls with a minimum depth of ⁄ 8x and a Phred-like consensus quality of ⁄ 20 were considered for bioinformatics and statistical analysis. SeattleSeq was used to annotate RV into functional categories such as missense, nonsense, splice sites, coding, non-coding, UTRs and other novel variants. The average coverage at ⁄ 8X was 81%, average depth was 51X. The first step of our analysis is to screen known Mendelian genes and genes reported with genome wide significance from PD GWAS. Of the known Mendelian PD genes, RV with high Phred-like consensus quality were only seen in *GBA* (I158T, E365K, T408M, R502C) and *LRRK2* (L1795F, in one extended family), while RV were more common in the genes identified by GWAS. Further analysis will determine if exonic RV contribute to earlier AAO, disease progression and/or are risk factors for PD.

Identification of coding variants and gene interactions associated with neural tube defects using microdroplet-based targeted sequencing. *R. Blekhman[1,2], R.H. Finnell[3], G.M. Shaw[4], J.M. Musser[5], A.G. Clark[2], M.E. Ross[1].* 1) Neurogenetics and Development, Weill Medical College of Cornell University; 2) Molecular Biology and Genetics, Cornell University, Ithaca, NY; 3) Dell Pediatric Research Institute, University of Texas at Austin, Austin, TX; 4) Pediatrics, Stanford University, Stanford, CA; 5) The Methodist Hospital Research Institute, Houston, TX.

Neural tube defects (NTDs) are among the most common debilitating birth defects, with a worldwide prevalence of 0.5 to 1 per thousand. Although there are many environmental factors influencing disease risk, NTD has a strong genetic component, and many known gene mutations have been shown to produce NTD phenotypes in the mouse. However, attempts to link human mutations with NTD risk have not been as successful, mainly due to the complex nature of the disease, likely to be caused by interaction of mutations in many genes. Furthermore, the amount of DNA available in NTD patient repositories is limited and does not allow whole-genome or exome sequencing strategies. To overcome these limitations, we used microdroplet-based PCR enrichment of targeted regions followed by massively parallel sequencing, using only 50 ng of DNA extracted from newborn blood spots on Guthrie cards of 24 NTD patients. This allowed us to investigate the full coding sequences of 150 genes in which mutations are known to lead to NTD phenotypes in the mouse. By multiplexing three samples per lane of an Illumina GAII machine, we achieved a mean depth of 100X per sample in the targeted coding regions, with 95% of sites covered by at least 50 reads. We identified ~1000 SNPs and Indels on average in each sample, and ~4000 SNPs overall, of which 852 are novel. Specifically, we discovered 86 previously uncharacterized, likely damaging SNPs that could contribute to neurulation failure. Using these SNPs and data from the 1000 genomes project, we applied a gene-level weighted aggregated association test, and identified multiple genes that are significantly enriched with likely functional rare variants. In addition, we identified multi-SNP interactions that are over-represented in NTD patients compared to the general population, and so may play a role in risk of NTD. We are currently re-sequencing the full coding regions of several candidate genes in a larger NTD cohort to identify additional variants, and the functional effect of several mutations in these genes is being tested.

Two Filipino families with Pelizaeus-Merzbacher Disease (PMD). *B.V. Cavan[1,2], M.S. Modequillo[2], J.R. de la Calzada[1,2].* 1) Pediatrics, Cebu Institute of Medicine, Cebu, Cebu, Philippines; 2) Pediatrics, Perpetual Succour Hospital, Gorordo Ave., Cebu City, Cebu, Philippines.

Pelizaeus-Merzbacher disease (PMD) is an X-linked genetic condition affecting the central nervous system's white matter, specifically formation of myelin. Clinical manifestations include rotatory eye movements (nystagmus), developmental delay, hypotonia, spasticity, titubation, and cognitive problems. The condition has been attributed to mutations on the proteolipid protein 1 (PLP1) gene. This paper presents 2 Filipino families with classical PMD. Clinical presentation, MRI, and mutational studies (c.125G>A) confirmed the diagnosis in the first family. In the second family, clinical presentation, a strongly X-linked recessive pattern of inheritance and PLP1 gene analysis showing sequence variations supported the diagnosis. None of the patients tested showed gene duplication/deletion. It may be then prudent to consider gene sequence analysis, aside from duplication/deletion of the PLP1 gene, in Filipino patients suspected of having PMD due to the genetic heterogeneity noted in these families.

512F

Candidate gene analysis for rare variants in the serotonin system in autism. *E. Crawford[1], A. McGrew[1], E.H. Cook[2], J.S. Sutcliffe[2].* 1) Mol Physiology & Biophysics, Vanderbilt Univ, Nashville, TN; 2) Dept of Psychiatry, Univ Illinois-Chicago, Chicago, IL.

Rare variants in the serotonin transporter (SERT; gene symbol: SLC6A4) have been observed in multiple pedigrees with obsessive compulsive disorder (OCD). Selective serotonin reuptake inhibitors (SSRIs) that selectively target SERT are forefront in therapy for OCD. Serotonin dysregulation has long been implicated in autism (OMIM 209850), a common neurodevelopmental disorder. Patterns of repetitive behaviors and restricted interests are characteristic of the autism phenotype. MZ twin studies indicate high heritability, but evidence supports a multilocus etiology. Thorough investigation of highly complex genetic disorders such as autism should include several genes that encode proteins in the pathway of interest. Our hypotheses aims to discover genes and/or pathways related to SERT regulation and OCD behaviors that harbor autism susceptibility alleles. In this study, we tested these hypotheses following a rare variant susceptibility model. We resequenced exons for four loci, SLC6A4, HTR2A, HTR2B, and ADAMTS6 in unrelated autism probands. 5-hydroxytryptamine (serotonin) receptor 2B and 2A are 5-HT2 receptors encoded by genes HTR2B and HTR2A, respectively. ADAMTS6 encodes a disintegrin and metalloproteinase with thrombospondin motifs 6, and this locus was identified using the SCAN database (www.scandb.org) based on SNPs within this locus that significantly predict variation of SLC6A4 gene expression in lymphoblastoid cell lines. Exonic sequences for these four genes were sequenced in a pilot sample of 150 cases. Preliminary sequence analysis for HTR2A, HTR2B, and SERT has only been preformed in cases, therefore we cannot form a conclusion whether these genes show a greater mutation burden in autism vs. controls. However, multiple synonymous and nonsynonymous variants have been detected in these loci. In contrast, analysis of ADAMTS6, after an additional 130 cases and 200 controls, for rare variants revealed 10 nonsynonymous and 4 synonymous variants in cases vs 3 nonsynonymous and 1 synonymous variants in controls, suggesting a greater burden of rare, transcribed variants in ADAMTS6 in individuals with autism. The need for further resequencing of all four genes was apparent after more ADAMTS6 sequence data was collected. We conclude that further study is warranted for all four of these genes and is currently underway.

Functional assessment of a promoter polymorphism in S100B, a putative risk variant for bipolar disorder. *E. Dagdan[1,2], DW. Morris[1], M. Campbell[2], M. Hill[1], M. Rothermundt[3], F. Kästner[3], C. Hohoff[3], C. von Eiff[4], P. Krakowitzky[5], M. Gill[2,6], P. McKeon[6,7], S. Roche[2].* 1) Trinity College Dublin, Neuropsychiatric Genetics Research Group, Institute of Molecular Medicine, Ireland; 2) Smurfit Institute of Genetics, Trinity College Dublin, Ireland; 3) Department of Psychiatry, University of Münster, Germany; 4) Institute of Medical Microbiology, University of Münster, Germany; 5) Institute of Transfusion Medicine, University of Münster, Germany; 6) Department of Psychiatry, Trinity College Dublin, Ireland; 7) St. Patrick's University Hospital, Dublin, Ireland.

Background: Calcium-binding protein S100B has been implicated in the pathology of bipolar affective disorder (BPAD) and schizophrenia (SZ). S100B protein levels are elevated in serum of patients with both disorders compared to controls. We previously reported genetic association of a SNP in the promoter of S100B, rs3788266, with a psychotic form of BPAD. Methods: To test for genotypic effects of rs3788266 in vivo, S100B serum protein levels were measured in 350 Irish and German subjects of known S100B genotype. The functional effect of rs3788266 on S100B promoter activity was studied using the luciferase reporter system in U373MG glioblastoma and SH-SY5Y neuroblastoma cell lines. Allelic effects of rs3788266 on protein complex formation at the S100B promoter were investigated by an electrophoretic mobility shift assay. Results: Higher mean serum S100B levels were associated with the risk G allele of rs3788266 in BPAD cases (P=0.0001), unaffected relatives of BPAD cases (P<0.0001) and unrelated controls (P<0.0001). Consistent with the in vivo findings, luciferase gene expression was significantly increased in the presence of the G allele compared to the A allele in SH-SY5Y (P=<0.0001), and in U373MG (P=<0.0008) cell lines. The binding affinity of both SH-SY5Y and U373MG protein complexes for the S100B promoter was significantly stronger in the presence of G allele compared to the A allele promoter fragments. Conclusions: These data support rs3788266 as a functional promoter variant in the S100B gene where the presence of the G allele promotes increased gene expression and is associated with increased serum levels of the protein.

514F

A genome-wide association study identifies loci associated with aging-related decline in episodic memory. *P. De Jager[1], J. Shulman[1], L. Chibnik[1], J. Corneveaux[3], A. Myer[4], M. Huentelman[3], J. Hardy[5], R. Wilson[2], E. Reiman[3], D. Evans[2], D. Bennett[2].* 1) Neurology, Brigham & Women's Hospital, Boston, MA; 2) RUSH University, Chicago IL; 3) Neurogenomics Division, Translational Genomics Research Institute and Arizona Alzheimer's Consortium, Phoenix, AZ; 4) Department of Psychiatry and Behavioral Sciences, University of Miami, Miller School of Medicine, Miami, FL; 5) Reta Lila Weston Laboratories, Department of Molecular Neuroscience, Institute of Neurology, Queen Square, London, England.

BACKGROUND: Gene discovery in Alzheimer's disease (AD) has largely relied on the case/control study design; however, this approach is limited by heterogeneity of dementia in cases and subclinical disease in controls. We have implemented a complementary strategy using episodic memory decline, a key feature of AD, as a continuous outcome for a genome-wide association scan (GWAS). METHODS: A GWAS was performed using 6.5 million imputed single nucleotide polymorphism (SNP) genotypes and up to 15 years of prospective clinical data from the Religious Orders Study and Rush Memory and Aging Project (n=1,593). The outcome phenotype was a composite quantitative measure of episodic memory decline slope, based on longitudinal assessment of 7 cognitive tests, and adjusted for age, gender, and education as well as the top 3 principal components calculated from the genetic data. Replication of top results using a similar memory decline trait in the Chicago Health and Aging Project (CHAP) (n=588) is ongoing. RESULTS: In addition to the APOE locus, 5 loci exceed a threshold of genome-wide significance (p<5x10^-8). The SNPs tagging each locus are: rs2411399 (ADAMST12), rs2768668 (LYZL1), rs2159085 (ZNF286A), rs2377342 (intergenic), and rs2628983 (ZNF775). Replication in the CHAP cohort is ongoing and will be presented at the conference. Genomic inflation factor for this study of subjects of European ancestry: 0.998. Nominal associations of episodic memory decline with the known AD susceptibility alleles in the CR1 (p=0.048) and ABCA7 (p=0.044) were noted; in addition, SNPs other than the index SNP in the PICALM (p=2x10^-4) and BIN1 (p=3x10^-4) AD susceptibility loci demonstrated association with decline in episodic memory. CONCLUSIONS: Our strategy identifies several novel loci as being associated with susceptibility for decline in episodic memory. Such decline can be caused by multiple different processes, including AD, and therefore these loci not only offer insights into the dysfunction of a specific cognitive circuit with aging but are also excellent candidates for AD susceptibility loci.

515F

LINGO1 gene and Parkinson's disease: an association study in the Italian Population. *E.V. De Marco[1], F. Annesi[1], F.E. Rocca[1], A. Nicoletti[2], P. Pugliese[3], G. Nicoletti[1,3], G. Arabia[3], P. Tarantino[1], M. De Mari[4], P. Lamberti[4], S. Gallerini[5], R. Marconi[5], A. Epifanio[6], L. Morgante[6], A. Cozzolino[7], P. Barone[7], G. Torchia[3], M. Zappia[2], G. Annesi[1], A. Quattrone[3,8].* 1) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 2) Department of Neurosciences, University of Catania, Italy; 3) Neurologic Clinic, University Magna Graecia, Catanzaro, Italy; 4) Neurologic Clinic , University of Bari, Bari, Italy; 5) Division of Neurology, Ospedale Misericordia, Grosseto, Italy; 6) Department of Neurosciences, University of Messina, Messina, Italy; 7) Department of Neurological Sciences, University FedericoII, Naples, Italy; 8) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

A genome wide association study in European and American patients with Essential Tremor(TE) showed a significant association with the rs9652490 SNP of the leucine rich repeat and Ig domain containing 1 (LINGO1) gene. LINGO1 gene codes for a nervous system-specific transmembrane protein. Its expression is increased in the substantia nigra of some PD patients, thus suggesting that LINGO1 may be involved in PD pathophysiology. In this study, we performed a case-control analysis in the Italian population to assess the role of the LINGO1 gene in PD patients. A total of 567 patients with PD and 468 control subjects were enrolled in Central-Southern Italy. Genotyping of LINGO1 SNPs (rs9652490 and rs11856808) was performed by TaqMan pre-designed assays using an ABI 7900 HT-SDS system. Both variants were significantly associated with PD under a recessive model of inheritance before applying the Bonferroni correction. The GG genotype of rs9652490 and the TT genotype of rs11856808 were less frequent in patients than in controls, suggesting a protective effect against the disease. However, after stringent correction, only the P-values obtained from allele and genotype comparisons of the rs11856808 SNP remained significant. Our findings suggest that LINGO1 might play some role in the development of PD in the Italian population and represents an interesting candidate gene responsible for PD, due to its involvement in neurological processes.

Next-generation sequencing coupled to functional genomics implicates FOXP pathways in autism and language impairment. *P. Derizioti[1,2], B.J. O'Roak[3], L. Vives[3], J. Shendure[3], E.E. Eichler[3,4], S.E. Fisher[1,2].* 1) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, University of Oxford, Oxford, UK; 2) Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands; 3) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA, USA; 4) Howard Hughes Medical Institute, Seattle, WA, USA.

Autism spectrum disorders (ASD) comprise a range of neurodevelopmental syndromes characterized by extensive abnormalities of social interactions and communication, including language impairment and stereotyped behaviours. ASD aetiology has a strong genetic basis, but in most cases the specific molecular risk factors remain unknown. Recent sequencing of exomes in 20 parent-child trios with idiopathic autism uncovered 21 de novo mutations, 11 of which were protein-altering. One involved a single base insertion in FOXP1, introducing a frameshift and premature stop codon (A339SfsX4), in a severely affected ASD proband with regression and language delay. This is of particular interest since FOXP1 belongs to the same group of transcription factors as FOXP2, a gene implicated in rare monogenic speech and language disorders. The proteins encoded by FOXP1 and FOXP2 can directly interact with each other, with the potential to co-regulate downstream targets in neural circuits where they are co-expressed, including those involved in language function. Analyses of proband-derived lymphoblasts indicated that the majority of FOXP1-A339SfsX4 transcripts undergo nonsense-mediated RNA decay. Moreover, in functional cell-based assays we found that transcripts which escape this process yield a truncated protein that is mislocalised from the nucleus to the cytoplasm. Intriguingly, in addition to the FOXP1-A339SfsX4 mutation, this same ASD proband also carries a rare inherited missense variant of CNTNAP2, a gene that has been independently associated with ASD and common language impairments. We found that wildtype FOXP1 protein (like FOXP2) acts as a repressor of CNTNAP2 expression, while the truncated FOXP1 mutant protein leads to misregulation of this downstream target. Overall the functional data suggest that the FOXP1 mutation may amplify deleterious effects of the CNTNAP2 variant in the proband, consistent with a multi-hit model for disease risk. Building on this work, we have now performed similar functional characterisations for novel risk variants identified in targeted high-throughput sequencing of FOXP1 and FOXP2 in a large cohort of 1700 idiopathic ASD cases. Our unpublished findings demonstrate how the coupling of next generation sequencing with functional genomic assays can shed important new light on pathways underlying complex neurodevelopmental phenotypes like autism and language impairment.

Analysis of transcriptional profiles in schizophrenia. *J. Duan[1], H.H Göring[2], E.I. Drigalenko[2], J. Shi[3], W. Moy[1], J. Freda[1], J. Jacobi[1], D. He[1], . MGS[4], A.R. Sanders[1], P.V. Gejman[1].* 1) Dept Psychiatry, NorthShore University/University of Chicago, Evanston, IL; 2) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 4) Molecular Genetics of Schizophrenia (MGS) Collaboration.

Introduction. We have tested in a large clinical sample the hypothesis that there are transcriptional profiles characteristic of schizophrenia. **Methods.** Using Illumina HT-12v4 microarrays, we have assayed mRNA from EBV-transformed LCLs with pre-existing GWAS data for 446 schizophrenia cases and 457 controls of European ancestry. We have studied and controlled for known confounding effects, both epidemiological (age, sex, ancestry) and cellular (growth rate, energy status, EBV load, and LCL transformation site) characteristics. We used regression analysis to identify transcripts differentially expressed by affection status. In an effort to control for the analytical strategy, we also performed all the aforementioned analyses adding expression principle components (that also detect unknown/unmeasured confounders), with largely consistent results. **Results.** After stringent quality control, we retained 27,118 transcripts and all samples (no QC outliers). We first studied the effects of CNVs associated with schizophrenia (1q21.1, 15q13.3, 16p11.2, and 22q11.21) on local gene expression profiles. Samples with a deletion showed lowered expression for 78%, and those with duplications showed increased expression for 49% of the regional (CNV bounded) transcripts, compared to remaining samples. After regressing out known confounders, we identified 83 transcripts representing 76 genes differentially expressed by affection status at an FDR of 0.05. Histone genes from 1q21.2 and the 6p22.1 MHC region (*HIST1H4K, HIST1H2BC, HIST1H2BD, HIST1H3C, HIST1H2BG*, and *HIST1H2BH*) showed notable enrichment among these 76 genes. Eight transcripts (*CPNE5, BRWD1, ITGA1, MOXD1, THAP10, EHBP1, SV2A,* and *IFITM3*) survived Bonferroni correction for all retained transcripts, of which *CPNE5, BRWD1, ITGA1, MOXD1, THAP10*, and *EHBP1* are brain-expressed, and C*PNE5, BRWD1, SV2A,* and *MOXD1* have functions involving neurotransmitters or intercellular communication. C**onclusions.** The observed differential expression of 6p22.1 histone genes in the MHC region converges with the genetic evidence from schizophrenia GWAS, where this same region is the most significant schizophrenia susceptibility locus. Our results thus provide a plausible functional interpretation of the GWAS results. In addition, we systematically detected newly implicated individual genes with our expression profiling experiment - genes that were undetectable by pure GWAS approaches, thus providing new and functional leads.

518F

Metal content and oxidative stress in autistic Egyptian children. *H.T. El-Bassyouni[1], S.I. Ismail[2], G.S.M. El-Saeed[3], E.A. Alghroury[4].* 1) Clinical Genetics , National Research Centre, Cairo, Egypt; 2) Clinical Genetics , National Research Centre; 3) Medical Biochemistry Department, National Research Center; 4) Clinical Pathology Department, National Research Center.

Background: Many factors have been implicated in autism onset, including excess or deficiency in toxic or essential metals and impaired antioxidant systems. Exposure to metals is a putative risk factor for autism. Many metals could be implicated in autism since they typically disrupt enzyme functions and cell signalling processes and generate oxygen free radicals (ROS). Methods: Sixteen autistic patients whose age ranged from 2.6-12.7years (mean age 5.6 years) were clinically examined. Twenty healthy children matching age and gender were taken as a control group. Serum mercury, lead and nitric oxide were estimated in all patients. Results: Nine presented with seizures and epileptogenic focus in electro encephalogram (EEG). The IQ assessment showed mental retardation in all patients: 9 were moderate, 1 was severe and 6 were profound. One had microcephaly (+2.8). Assessments of the severity of autistic symptoms using childhood autism rating scale (CARS), 3 patients were mild, 6 were moderate and 7 were severe. The estimation of the level of mercury and lead in blood showed significant increase compared to control group (P value 0.0001). Furthermore, nitric oxide was significantly increased than the control group (P value 0.0001). These findings demonstrate a significant increase in both metal content and an unbalance in the oxidative status in the blood of autistic children. Conclusion: Our findings suggest the hypothesis that exposure to metals and oxidative stress may be biomarkers of toxicity in autism. We recommend that patients diagnosed with autism should be given chelators for mercury and lead to improve their condition.

From missing heritability to missing specificity: genomic convergence and pleiotropy in neurodevelopmental disorders. *B. Franke[1], G. Poelmans[2], D. Pauls[3], J. Glennon[2], J.K. Buitelaar[2].* 1) Departments of Human Genetics & Psychiatry, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 3) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston, USA.

Background: The neurodevelopmental disorders attention-deficit/hyperactivity disorder (ADHD), developmental dyslexia and autism-spectrum disorders (ASDs) often co-occur. All are highly heritable and they share heritability. Objective: In the current study, we aimed at integrating current knowledge of the molecular genetics of the three disorders to identify biological processes enriched in the findings and overlapping between disorders. Methods: Bioinformatics and systematic literature analyses were conducted based on the findings of published genome-wide studies of common and rare genetic risk factors for the three disorders. In addition, data from candidate gene association studies, cytogenetic and animal studies as well as studies of miRNAs and pharmacological gene expression were used to confirm and extend observed biological networks. Results: For ADHD, 85 genes were included in the analysis; for ASDs, a total of 200 genes were analysed. Data for developmental dyslexia were most scarce, and only 14 genes could be considered. Analysing the data for ADHD, we found the biological process of neurite outgrowth significantly enriched in the findings; this process was also found enriched in the data for developmental dyslexia, as was neuronal migration. In ASDs, we observed signalling networks regulating steroidogenesis, synaptic function and also neurite outgrowth to be overrepresented. In this disorder, for which most data were available, we also identified new drugable targets, the AKAP (A-kinase anchor protein) genes, using this approach to data integration. In all disorders, common and rare variants were found to `hit' the same networks and even the same genes. Conclusion: Genomic convergence is observed in the findings from genome-wide molecular genetic studies of all three disorders, and biological processes involved in disease etiology but also novel targets for treatment can be identified using data integration. Distinctions between multifactorial and monogenic/oligogenic causes of neurodevelopmental disorders appear artificial as both common and rare variants implicate the same signalling networks and genes. Neurite outgrowth networks are pleiotropic in that they are implicated in all three neurodevelopmental disorders and may explain the findings of overlapping heritability.

520F

Early onset Huntington disease presenting as a Neuroferritinopathy. *M.T. Gabbett[1 2], C.S. Manning[1 2], J.C. MacMillan[1 2].* 1) Genetic Health Queensland, Royal Brisbane & Women's Hospital, Brisbane, Queensland, Australia; 2) The University of Queensland, School of Medicine, Brisbane, Queensland, Australia.

Neuroferritinopathy caused by mutations in the *FTL* gene causes gradual accumulation of iron in the brain. Clinically, this results in a progressive adult-onset chorea or dystonia and subtle cognitive defects. The majority of individuals develop a characteristic orofacial action-specific dystonia that leads to dysarthrophonia. Cognitive deficits and behavioural issues become significant with time. Magnetic resonance imaging (MRI) typically demonstrates hypointensity of the basal ganglia on T2-weighted imaging. Huntington disease (HD) is a progressive disorder of motor, cognitive, and psychiatric disturbances and is caused by an expanded polyglutamine tract in the huntingtin protein. MRI typically demonstrates basal ganglia atrophy. We present the case of a 27 year old Vietnamese woman with a three year history of symptoms including dysphagia, imbalance and low vision. Her father and her brother were said to be similarly affected. MRI demonstrated decreased T2 signal within the basal ganglia, dentate cerebellar nuclei and the substantia nigra, consistent with iron disposition. The clinical presentation and MRI findings suggested an autosomal dominant neuroferrintinopathy. Testing of the *FTL* gene yielded no mutations. Testing of *HTT* demonstrated CAG trinucleotide repeats of 16 and 57, consistent with the diagnosis of HD. Hypointensity of the basal ganglia represents iron deposition on T2-weighted MRI, but has rarely been reported in HD. This case illustrates that HD should be considered as a differential diagnosis for neuroferrtinopathy.

521F

A Rare Genomic Duplication Creates Novel Transcripts from DNA Of a Patient with Schizophrenia. *M. Gasperini[1], C. Rippey[2], T. Walsh[3], A. Nord[2], C. Spurrell[2], MK. Lee[3], MC. King[3,2].* 1) University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Medical Genetics, University of Washington, Seattle, WA.

Rare, gene-disrupting genomic deletions and duplications - called copy number variants (CNVs) - have been implicated in schizophrenia; however, much remains to be understood about which genes are causative, as well as the cellular mechanisms involved. Biological characterization of individual CNVs has the potential to provide insight into the origin of schizophrenia. We used array Comparative Genomic Hybridization to screen DNA from individuals with schizophrenia for such CNVs, and focused on one found in a patient with early onset. This CNV duplicates the 5' ends of two genes that lie head-to-head on chromosome 11q22: DCUN1D5, a previously uncharacterized gene predicted to be involved in cullin neddylation of ubiquitin ligase complexes, and DYNC2H1, a dynein active in cilia. Both are expressed in brain and are plausible candidate genes for schizophrenia. In order to detect and characterize aberrant transcripts resulting from this duplication, we performed next generation sequencing (RNAseq) of total mRNA from lymphoblasts of the patient. We found multiple different transcripts unique to this patient within the duplicated region, indicating novel expression and splicing of the genomic sequence now adjacent to the 5' end of DCUN1D5. PCR and Sanger sequencing confirmed that these novel exons constitute a new 3' end of the mutant, truncated DCUN1D5. These data support the role of this mutation in schizophrenia by confirming the presence of aberrant transcripts in the patient's RNA. The data also suggest an intriguing mechanism by which a genomic rearrangement can result in a novel, stable transcript via “exonification” of otherwise non-coding sequence.

522F

Role of ANKK1 AND DRD2 gene polymorphisms in genetic susceptibility to migraine in Northern Indian population. *J. Ghosh[1], S. Pradhan[2], B. Mittal[1].* 1) Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, India; 2) Neurology, Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGIMS), Lucknow, India.

The dopaminergic system plays an important role in migraine and its clinical subtypes: migraine with aura (MA) and migraine without aura (MO). D2 receptor antagonists have been proposed in antimigraine therapy. We aimed to look for association of polymorphism in the ANKK1 [TaqI-A(rs1800497)] and DRD2 [-141Cdel (rs1799732) and NcoI(rs6275)] gene polymorphisms with migraine susceptibility. The migraine patients were recruited in two cohorts - primary (n=213) and replicative (n=128). Simultaneously, 210 healthy age-sex matched free from any neurological diseases were also enrolled. The results of primary cohort were validated in the replicative cohort. On obtaining significant associations in both the cohorts, the results were pooled by meta analysis using Fisher's method (2 and p value) and Mantel-Haenszel test for odds ratio calculation. Logistic regression analysis was applied for statistical analysis and Bonferroni correction for multiple comparisons in subgroup analysis. The study was approved by ethics committee of the Institute. For ANKK1 TaqIA polymorphism, variant genotype and allele (A1) showed highly significant ($p<0.001$) association with migraine and its subgroups in the primary cohort. The results were replicated in overall migraine and MO. Similarly, pooling data from two cohorts also confirmed the significant association in migraine susceptibility. For DRD2 NcoI polymorphism, a significant protective effect of variant (T) allele was found in both primary and replicative cohorts. Mantel - Haenszel test also revealed protective role of this allele (ORMH= 0.7678, 95%CI= 0.6249-0.9434). No significant association for migraine or its clinical subgroups were observed for DRD2 -141C del polymorphism. In conclusion, the present study suggests a significant risk of ANKK1 TaqIA polymorphism with migraine, especially in migraine without aura, and a protective role of DRD2 NcoI polymorphism. Genetic variation influencing memory ability in a population-based sample. *L. Gomez[1], J.B. Rich[2], M.L. Smith[3], C. Barr[1, 3].* 1) Toronto Western Research Institute, Toronto, ON, Canada; 2) York University, Toronto, ON, Canada; 3) Hospital for Sick Children, Toronto, ON, Canada.

Genes involved in the molecular pathways of visual-spatial learning and memory have been identified in animal models and some of these have been implicated in human memory ability. In addition a number of genes contributing to memory ability have been identified in association studies in humans. In this study, we tested three genes (BDNF, CREB1 and CAMTA1) for their contribution to visual-spatial and verbal memory ability in a sample of 100 male university students in Toronto. Quantitative methods were used to examine measures of learning and memory performance to identify genetic factors involved in visual-spatial and verbal measures of immediate, delayed and working memory, and in phonological processing. We found a single marker (rs11030108) in the BDNF gene and a single marker (rs7549382) in the CAMTA1 gene that showed significant p-value when comparing the performance on the Wechsler Memory Scale-III tests for each genotype. Lower scores for the memory tests were associated with the GG genotype for the BDNF marker and higher scores were associated with the CC genotype for the CAMTA1 marker. These preliminary results in this sample support previous findings implicating these two genes in human memory ability.

524F

Improving molecular diagnosis of Dravet syndrome by using multiple prediction algorithms. *M.C. Gonsales[1], P.M. Preto[2], M.A. Montenegro[2], M.M. Guerreiro[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas, Campinas, Brazil; 2) Department of Neurology, University of Campinas, Campinas, Brazil.

Mutations in the neuronal voltage-gated sodium channel (1-subunit gene (*SCN1A*) have been identified in several patients with phenotypes within the clinical spectrum of generalized epilepsy with febrile seizures plus (GEFS+). It is now accepted that genetic testing for mutations in *SCN1A* is clinically useful. However, the prognostic value of these mutations and a possible correlation with the different clinical subtypes remain unclear. Therefore, the aim of this study was to search for mutations in *SCN1A* in patients with Doose and Dravet syndromes, both severe forms of epilepsy included in the GEFS+ spectrum. We performed *SCN1A* mutation screening in 13 patients with Doose syndrome and 15 with Dravet syndrome. We used eight in silico prediction algorithms to analyze the possible impact of the amino-acid changes in protein function (SIFT, Polyphen 1 and 2, Pmut, MutPred, PhD-SNP, SNAP e SNP&GO). In addition, multiplex ligation-dependent probe amplification (MLPA) was used to detect copy number variations within *SCN1A*. Patients with Doose syndrome showed no mutations, whereas twelve mutations were identified in 80% of the patients with Dravet syndrome: six missense mutations, three splice-site mutations, two deletions and one insertion. All mutations that lead to amino-acid residue substitutions are predicted to affect protein function according to the prediction algorithms employed. The mutations are mostly located in the pore region and the C-terminal of the protein. No copy number variants were identified. Patients with Dravet syndrome showed a high frequency of *SCN1A* mutations (80%), confirming that molecular testing would be highly recommended in individuals with this phenotype. In addition, our strategy for predicting deleterious effect of mutations using multiple prediction algorithms was able to provide valuable information, helping clinicians with decision making. Moreover, we found that Doose syndrome does not seem to share the same genetic basis as Dravet syndrome. Furthermore, our results confirm that missense mutations can cause severe phenotypes depending on its location and the type of amino-acid substitution. Financial Support: CNPq/FAPESP.

Evidence for Association between L-Type Voltage-Gated Calcium Channel (CACNA1C) Gene Haplotypes and Bipolar Disorder in Latinos: a Family-Based Association Study. *S. Gonzalez[1], C. Xu[1], M. Ramirez[1], J. Zavala[1], R. Armas[2], S.A. Contreras[3], J. Contreras-Rojas[4], A. Dassori[3, 5], R.J. Leach[6], D. Flores[7], A. Jerez[8], H. Raventós[4], A. Ontiveros[9], H. Nicolini[10], M. Escamilla[1].* 1) Center of Excellence for Neurosciences, Texas Tech University Health Sciences Center Paul L. Foster School of Medicine, El Paso, TX; 2) Langley Porter Psychiatric Institute, University of California, San Francisco, San Francisco, CA; 3) Department of Psychiatry, University of Texas Health Science Center at San Antonio, San Antonio, TX; 4) Centro de Investigación en Biología Celular y Molecular y Escuela de Biologia, Universidad de Costa Rica, San Jose, Costa Rica; 5) South Texas Veterans Health Care System, San Antonio, TX; 6) Department of Cellular and Structural Genetics, University of Texas Health Science Center at San Antonio, San Antonio, TX; 7) Los Angeles Biomedical Research Center at Harbor, University of California Los Angeles Medical Center, Torrance, CA; 8) Centro Internacional de Trastornos Afectivos y de la Conducta Adictiva, Guatemala, Guatemala; 9) Instituto de Información e Investigación en Salud Mental AC, Monterrey, N.L., México; 10) Grupo de Estudios Médicos y Familiares Carracci, S.C., México, D.F., México.

Background: Over the past several years, genome-wide association studies (GWAS) have identified genetic variants that contribute to complex human disorders. However, GWAS have been centered on populations of European ancestry, and the degree to which the findings are applicable to other populations has not been extensively investigated. Through recent GWAS studies, several groups have reported significant association between variants in the alpha 1C subunit of the L-type voltage-gated calcium channel (CACNA1C) and bipolar disorder (BP) in Caucasian cohorts. To determine whether CACNA1C is associated with BP in the Latino population, we performed a family-based association study between CACNA1C polymorphisms and BP. Methods: This study consisted of 250 Latino families (913 individuals) recruited from the US, Mexico, Guatemala, and Costa Rica. A total of 482 participants were diagnosed with BP (263 BP Type I with Psychosis, 202 BP Type I without Psychosis, and 17 Schizoaffective BP Type). The Illumina GoldenGate Genotyping Assay was used to genotype two SNPs (rs7297582 and rs1006737) in the CACNA1C gene previously shown to be associated with BP and an additional 55 SNPs that spanned a 603 kb region encompassing the CACNA1C gene. Markers were selected using a Tag SNP method and supplemented with additional SNPs in potential linkage disequilibrium (LD) with the two SNPs previously associated with BP. Individual SNP and haplotype association analyses were performed using the family-based association test (FBAT, version 2.0.3) and Haploview software (version 4.2). Results: We found no association between the two individual SNPs and BP (rs7297582, p= 0.760; rs1006737, p= 0.469) in the Latino population studied. An 8-locus haplotype block was identified to be in high LD with these two SNPs. A positive association between this 8-locus haplotype and BP was observed (permuted P=0.005; global marker permuted P=0.002), which included the two markers previously associated with BP. Conclusions: Although we were not able to replicate findings of association between individual CACNA1C SNPs rs7297582 and rs1006737 and BP, we were able to replicate the GWA signal reported for CACNA1C with a haplotype analysis which encompassed these SNPs. These results provide additional evidence that CACNA1C is associated with BP and provides the first evidence that variations in this gene might play a role in the pathogenesis of this disorder in the Latino population.

Intracranial Tumours in a Family with CADASIL - A Case Report. *B.D. Henderson[1], E. Janse van Rensburg[2].* 1) Division Human Genetics, UFS, Bloemfontein, Free State, South Africa; 2) Department Neurology, UFS, Bloemfontein, Free State, South Africa.

BACKGROUND: Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CADASIL) is an autosomal dominant, mid-adult onset cerebrovascular disorder. It is characterized by migraine with an aura, diffuse white matter changes and infarctions progressing to dementia. It is often confused with multiple sclerosis. It has a highly variable presentation and course. Mutations in *NOTCH3* have been associated with this disorder. OBJECTIVE: A family, in which two affected persons have been proven to have CADASIL, is presented. There are two members of this family who have intracranial tumours. RESULTS: The clinical presentation and MRI findings are presented together with a discussion of the differential diagnosis and the mechanism of the disorder. To our knowledge, tumours have not previously been described in persons proven to have CADASIL. The index case has a novel mutation in exon 6 resulting in a loss of a cysteine residue. He also has a novel mutation in exon 5 of which the implication is uncertain. Studies are planned to determine if these mutations are in cis or in trans. CONCLUSION: This family adds additional information to the clinical spectrum of problems associated with CADASIL. Additional information about effects of *NOTCH3* mutations not involving a cysteine residue may be revealed by further evaluation of this family.

527F

Evidence for more than one Parkinson disease associated variant within the HLA region. *E.M. Hill-Burns[1], S.A. Factor[2], C.P. Zabetian[3], G. Thomson[4], H. Payami[1].* 1) New York State Department of Health Wadsworth Center, Albany, NY; 2) Department of Neurology, Emory University School of Medicine, Atlanta, GA; 3) VA Puget Sound Health Care System and Department of Neurology, University of Washington, Seattle, WA; 4) Department of Integrative Biology, University of California, Berkeley, CA.

In a recent GWAS conducted on the NeuroGenetics Research Consortium (NGRC) dataset, *HLA* was found to significantly associate with risk of Parkinson's disease (PD) [PMID:20711177]. The top hit was rs3129882 ($P=3x10^{-8}$), which is in intron 1 of *HLA-DRA* and is an eQTL influencing expression of *HLA-DR* and *HLA-DQ*. While the association of rs3129882 with PD has been replicated in independent datasets, some GWAS find different SNPs in the *HLA* class II region as the top hit. Most notably, a SNP near *HLA-DRB5* also reached genome-wide significance in a meta analysis [PMID:21292315]. Our aim with this investigation was to determine if different SNPs from various GWAS tag the same locus or if there could be more than one variant in *HLA* associating with PD susceptibility. We performed step-wise conditional analysis on the NGRC dataset (2000 cases, 1986 controls) and included 107 SNPs in the *HLA* region that achieved $P < 0.001$ for association with PD risk. Conditioned on the top SNP (rs3129882), 90 of 106 SNPs lost significance. We repeated the analysis, step-wise, conditioning on all SNPs identified as the most significant in the prior rounds. This yielded four SNPs which were seemingly independent in association with PD. The four SNPs were not in linkage disequilibrium (LD) with each other ($0 \le r^2 < 0.17$). Notably, SNP4, the last SNP remaining significant in NGRC, was the only one of the four SNPs that showed some LD ($r^2=0.6$) with the top hit near *HLA-DRB5* reported by the meta analysis. Haplotype analysis revealed increasing risks with the number of risk alleles at each SNP (from OR=1.3, $P=5x10^{-3}$ to OR=1.7, $P=4x10^{-8}$). To replicate, we used a peer reviewed [PMID:18985386] and publicly available GWA dataset from dbGaP (843 cases and 856 controls). We were able to replicate the seemingly independent effects of SNP1 (rs3129882, main effect P=0.006, conditioned on other significant SNPs P=0.04) and SNP4 (rs9268515, main effect P=0.004, conditioned on other significant SNPs P=0.03). We also replicated the haplotype results for SNPs 1 and 4 which yielded OR=1.3, P=0.01 for a haplotype with one risk allele and OR=1.4, $P=2x10^{-4}$ for the haplotype with both risk alleles (haplotype analysis for SNPs 1 and 4 from NGRC gave OR=1.2, P=0.003 with one risk allele and OR=1.5, $P=1x10^{-9}$ with both risk alleles). Data suggest there may be at least two associations between PD and *HLA*, one with a regulatory element in *HLA-DRA* and one with a classical *HLA-DRB*. Study was funded NIH R01 NS36960.

528F

Mapping diagnostic heterogeneity in an animal model of Fetal Alcohol Spectrum Disorders (FASD). *K. Janus[1], M. Kleiber[1], A. Chokroborty-Hoque[1], E. Wright[2], B. Laufer[1], S. Singh[1].* 1) Department of Biology, University of Western Ontario, London, Ontario, Canada; 2) Department of Neuroscience, University of Western Ontario, London, Ontario, Canada.

Fetal Alcohol Spectrum Disorders (FASD) result from prenatal alcohol exposure and are characterized by neurobehavioral abnormalities including developmental milestone defects, altered activity levels, anxiety-related behaviors, and learning and memory deficits. The phenotypic heterogeneity behind FASD is not well understood. We have modeled acute ethanol exposure in pregnant C57BL/6J (B6) mice using ethanol injections at each of the three trimesters. Our treatment protocol also includes a continuous-preference-drinking (CPD) paradigm, as B6 mice prefer (70%) to drink 10% alcohol when given a free choice between water and ethanol solutions during pregnancy. Progeny resulting from the four treatment groups are followed and assessed for a battery of FASD-related behavioral tests during periods of growth and development until early adulthood (postnatal day 70) in order to assess long-term consequences of FASD. Relevant behavioral measures include developmental milestones, locomotor activity and anxiety, and learning and memory (using Barnes Maze). Progeny from ethanol-treated groups lag behind in achieving some, but not all, developmental milestones. Activity levels are increased (p=0.005-0.001) following ethanol exposure in trimesters one and two, but reduced (p<0.001) under CPD and unchanged when treated at trimester three. Anxiety-related behaviors are increased (p=0.008-0.001) following ethanol exposure in trimester three and CPD, but decreased (p<0.001) when treated at trimester two and unchanged in trimester one. Finally, learning and memory is decreased (p=0.05-0.001) in the progeny of all treatment groups, but to varying degrees. Results demonstrate that the major determinants of phenotypic heterogeneity for FASD are explained by the neurodevelopmental timing of ethanol exposure. All treatments result in developmental milestone delays and cognitive deficits, suggesting that no time during pregnancy is safe from alcohol's teratogenic effects. We have also observed that the behavioral deficits are related to permanent alterations in the “transcriptome”, and are potentially related by epigenetic mechanisms. Some of the behavioral changes may be reflected in high resolution Magnetic Resonance Imaging (MRI) and Magnetic Resonance Spectroscopy (MRS). Additional data included in this presentation will assess any rehabilitative effects of environmental enrichment on neurodevelopment using MRI and MRS.

529F

A variant in the 3'UTR of (-endomannosidase (*MANEA*) mRNA is associated with panic disorder diagnosis and cognitive flexibility. *K.P. Jensen[1], H.R. Kranzler[2], B.Z. Yang[1], L.A. Farrer[3], J. Gelernter[1].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT and VA CT Health Care Center, West Haven, CT, USA; 2) Department of Psychiatry, University of Pennsylvania and the Philadelphia VA Medical Center, Philadelphia, PA, USA; 3) Departments of Medicine, Neurology, Ophthalmology, Genetics and Genomics, Epidemiology, and Biostatistics, Boston University School of Medicine and Public Health, Boston, MA, US.

Genes in the mannosidase family encode proteins that hydrolyze mannose residues from glycoproteins. The mannosidase gene family has been implicated in a range of human disorders from severe developmental mannosidosis to drug use behaviors. In prior family-based studies, common variants in the (-endomannosidase gene (*MANEA*) have been associated with cocaine dependence and cocaine-induced paranoia. We hypothesized that variants within this gene may be associated with other psychiatric phenotypes. Here we report that a common variant in the 3'UTR of the *MANEA* mRNA is associated with panic disorder diagnosis ($\chi^2 = 9.66$, p=0.008) in a European American case (N=199) versus control (N=1982) sample initially recruited as part of a study on the genetics of drug and alcohol dependence. Cognitive function differences often represent endophenotypes for psychiatric disorder risk; therefore we explored whether the *MANEA* 3'UTR variant was associated with cognitive test performance. We found that in non-drug dependent subjects the 3'UTR *MANEA* genotype was associated with Wisconsin Card Sorting Test scores. We investigated the potential functional effect of *MANEA* gene variants on mRNA levels and observed a significant difference in the expression of *MANEA* alleles in human blood cell RNA. These findings suggest that the 3'UTR variant may be in LD with a functional variant that affects *MANEA* gene expression. In sum, functional variants at the *MANEA* loci may underlie interindividual differences in cognitive function and psychiatric disorder risk. Future studies will refine the psychiatric phenotype associated with *MANEA* gene variants and elucidate the mechanisms by which these traits manifest.

530F

Knockdown of PBRM1, a putative risk gene for mood disorder and schizophrenia, induces widespread alterations in gene expression,cellular morphology, and proliferation. *X. Jiang, S. Detera-Wadleigh, F. McMahon.* Human Genetics Branch, NIMH, Bethesda, MD., US.

A meta-analysis of genome-wide association studies (GWAS) in mood disorders found the strongest evidence of association at a synonymous SNP in PBRM1 (McMahon et al 2010). The same SNP has been shown to be associated with schizophrenia (Williams et al. 2011). Although several genes map to the same ~350 kb linkage disequilibrium region on chromosome 3p21.1, in GWAS the causal gene will often be located near the most strongly associated SNP (Allen et al. 2010), so we have undertaken initial functional studies of PBRM1. We employed a loss-of-function paradigm by generating a stable knockdown of PBRM1in both HeLa and SHSY5Y neuroblastoma cells via lentiviral-mediated transduction of short hairpin (sh) RNA. Differential gene expression profiles examined using the Illumina Human HT 12v3 Expression Bead Array revealed 129 overexpressed and 70 underexpressed genes. Notably, PBRM1 knockdown induced a significant downregulation of PDE4B, which encodes cAMP-specific 3'5' phosphodiesterase 4B. This protein is known to interact with DISC1 (Millar et al. 2005), and altered phosphodiesterase signaling has been reported in both mood disorders and schizophrenia. We further found that the underexpression of PDE4B after PBRM1 knockdown was partially reversed by valproate, consistent with its therapeutic role in bipolar disorder. PBRM1 encodes polybromo1 (aka BAF180), which is the chromatin binding component of the Brahma-associated factor (BAF) nucleosome remodeling complex (Ho & Crabtree 2010). It is therefore interesting that 27 of the genes that were differentially expressed after PBRM1 knockdown were histone-related; 9 of these were upregulated at least 1.8-fold. HeLa and SHSY5Y cells with stable PBRM1 knockdown displayed strikingly slower proliferation and altered cellular morphology, suggesting a possible role for this gene in cell cycle control and apoptosis. If PBRM1 plays a causal role in mood disorders and schizophrenia, this role may be mediated by widespread changes in the expression of genes involved in signal transduction, chromatin remodeling, and cellular development. This study demonstrates the value of GWAS findings in directing studies to diverse biological processes potentially involved in disease etiology.

531F

Acute and long-term changes to transcriptome profiles in a mouse model of fetal alcohol spectrum disorder: evidence for the ethanol sensitivity of neurodevelopmental genetic pathways and permanent consequences of exposure. *M.L. Kleiber[1], K. Janus[1], B. Laufer[1], E. Wright[2], S.M. Singh[1,2].* 1) Molecular Genetics Unit, Dept. of Biology, University of Western Ontario, London, Canada; 2) Neuroscience, Schulich School of Medicine and Dentistry, University of Western Ontario, London, Cananda.

Maternal alcohol consumption during pregnancy results in fetal alcohol spectrum disorders (FASD), the leading preventable cause of cognitive and behavioural abnormalities in North America. Despite our increasing knowledge of the magnitude and breadth of abnormalities associated with FASD, little is known about the underlying biological mechanisms. We have established a mouse model (C57BL/6J) of FASD that uses four paradigms of ethanol exposure; binge-like doses during the first, second, and third human trimester equivalent, and voluntary maternal consumption throughout pregnancy. These paradigms result in progeny that show variable yet consistent FASD-related phenotypes. Here, we report changes in the neuro-transcriptome resulting from ethanol exposure, both acutely (4 hours post-treatment) and during young adult (postnatal day 60) for each of the four experimental paradigms. Using Affymetrix Mouse Gene 1.0 ST arrays, differentially expressed genes meeting 1.2-fold up or down-regulation (minimum) and p-value=0.05 with false discovery rate (FDR) cutoffs were subjected to gene set enrichment analysis using Gene Ontology and Kyoto Encyclopedia of Genes and Genomes (KEGG) annotations, using the web-based analysis tools PANTHER and DAVID. Consistently-affected pathways included those involved in cell survival, calcium signaling and adhesion, extra-cellular matrix remodeling, and neuroactive ligands and receptors. Acute (4h) effects were characterized by pronounced alterations in genes associated with cell survival (Jun, Bcl2-related genes, Dusp gene family) and growth factor signaling (Gdnf, Etv5). In contrast, long-term residual (day 60) analysis showed subtle changes in genes involved in a wide range of biological processes, notably cell adhesion (Ncam, cadherin gene family) and neuroactive signaling (Gabra6, Grin2d, Ht5ra). While this represents a general pattern for all four paradigms, specific differentially expressed gene sets were dependent on developmental timing of exposure. These data represent the most comprehensive examination of transcriptome disruption in current FASD literature. They may provide a foundation for the discovery of effective pharmacological targets towards the amelioration of phenotypes associated with prenatal alcohol exposure.

Molecular Epidemiological Study of *FIG4* mutations in Familial and Sporadic Amyotrophic Lateral Sclerosis in the Japanese population. *F. Kusunoki, Y. Takahashi, T. Matsukawa, J. Goto, S. Tsuji.* Neurology, Univ Tokyo, Tokyo, Tokyo, Japan.

BACKGROUND: Amyotrophic lateral sclerosis (ALS) is a severe neurological disorder, characterized by selective neurodegeneration of lower and upper motor neurons in the spinal cord, brainstem, and cortex. Approximately 5-10 % of cases are familial ALS (FALS). A number of causative genes for FALS have been identified, including *SOD1*, *FUS*, *TARDBP*, *ALS2*, *SETX*, *VCP*, *DCTN*, *ANG*, *VAPB* and *OPTN*. These genes account for approximately 30% of FALS pedigrees. The remaining 90-95% of ALS cases are sporadic ALS (SALS). A small number of SALS cases harbor causative mutations for FALS genes. Recently, mutational analysis for *FIG4*, initially reported as a causative gene for autosomal recessive Charcot-Marie-Tooth disease type 4J (CMT4J), revealed novel nonsynonymous variants in 3 out of 109 (2.8%) FALS patients and 6 out of 364 (1.6%) SALS patients of European ancestry, all of which were not present in controls. This report concluded that heterozygosity for a deleterious allele of *FIG4* appears to be a risk factor for ALS, designated as ALS11. However, frequencies of *FIG4* mutations in ALS in other ethnic populations have been unknown. The purpose of this study was to establish molecular epidemiology of *FIG4* mutations in ALS Japanese population. **METHODS:** 41 FALS patients were enrolled in this study. Previous mutational analysis for FALS causative genes identified 19 pedigrees with *SOD1* mutations, 3 with *FUS* and 1 with *TARDBP*. The remaining 18 pedigrees were subjected to mutational analysis for *FIG4*. In addition, 192 SALS patients were also enrolled. SALS patients had an average age at onset of 58.9 years. All the 23 coding exons and splice junctions of *FIG4* were amplified with genomic PCR using specific primers, and further subjected to direct nucleotide sequence analysis. **RESULTS:** 11 variants were identified, including two known nonsynonymous SNPs, rs2295837 and rs9885672 substituting methionine for leucine and valine for alanine, respectively, and a known synonymous SNP (rs9398218) in coding exons. Seven known SNPs were identified in introns, and a known SNP was identified in 3'UTR. Neither novel variants nor known mutations for ALS were identified in this cohort. **CONCLUSION:** This study suggests that mutations in *FIG4* were not the frequent cause for ALS in the Japanese population. Further investigation in large-scale cohorts or in cohorts with different ethnic backgrounds should be necessary to establish genetic epidemiology of ALS with *FIG4* mutations.

Autism spectrum disorders (ASD) are a heterogeneous group of neurodevelopmental disorders with a complex inheritance pattern. While many rare variants in synaptic proteins have been identified in patients with ASD, little is known about their effects at the synapse and their interactions with other genetic variations. Here, following the discovery of two *de novo SHANK2* deletions by the Autism Genome Project, we screened *ProSAP1/SHANK2* for copy number variants (CNVs) and coding mutations in patients with ASD (n>230) and controls (n>230). We detected a novel 421 kb *de novo SHANK2* deletion in a patient with autism and 19 non-synonymous SHANK2 variants (ASD n= 12, controls n=5, shared by both groups n=2). Unexpectedly, in an additional screen of 1590 controls, we identified a subject carrying a SHANK2 splice site mutation. In neuronal cell cultures, a majority of the variants identified in this study, even those shared by patients and controls, reduced synapse density at dendrites. Interestingly, the three patients with *de novo SHANK2 deletions* also carried inherited CNVs at 15q11-q13 previously associated with neuropsychiatric disorders. In two cases, the nicotinic receptor *CHRNA7* was duplicated and in one case the synaptic translation repressor *CYFIP1* was deleted. The control subject with the SHANK2 splice site mutation carried CNVs in different genes coding for the NLGN3/4X binding partner SNTG2 and the myelin transcription factor MYT1L. These results strengthen the role of synaptic gene dysfunction in ASD, but also highlight the presence of putative modifier genes, which is in keeping with the “multiple hit model” for ASD. A better knowledge of these genetic interactions will be necessary to understand the complex inheritance pattern of ASD.

Genetic variation in dopaminergic and cholinergic signaling moderates smoking-induced dopamine release. *T.M. Levin[1], E.L. Nurmi[1], K.S. Mallya[1], K. Ta[2], J. La Charite[2], J.T. McCracken[1], A.L. Brody[1,2].* 1) Department of Psychiatry, University of California at Los Angeles, Los Angeles, CA; 2) Dept of Psychiatry, Greater Los Angeles VA Healthcare System, Los Angeles, CA.

Objective: Genetic variation in smoking-induced dopamine release may be relevant to clinical aspects of smoking, including success with smoking cessation. We previously reported genetic variants in dopaminergic systems that predict interindividual variation in smoking-induced dopamine release measured by positron emission tomography (PET); nevertheless, variation in synaptic dopamine remains only partially explained. We hypothesized that more direct moderators of dopamine signaling in the striatum would include genetic polymorphisms in the downstream target of synaptic dopamine, the dopamine D2 receptor (DRD2), and the upstream site of nicotine action in the brain, nicotinic cholinergic receptors. **Methods:** In 102 tobacco-dependent smokers, we measured the association of smoking-induced change in 11C-raclopride binding in the ventral striatum with comprehensively tagged common genetic variation at DRD2 and six cholinergic receptor subunit genes (CHRNA3, CHRNA4, CHRNA5, CHRNA7, CHRNB2, and CHRNB4). **Results:** In addition to evidence for dopaminergic markers in smoking-induced dopamine release, our results support a role for genetic variation in the cholinergic system. Homozygotes for the common allele (GG) at an intron 2 variant in the (7 cholinergic receptor subunit (CHRNA7, rs12915695) had a greater than 3-fold reduction in radiotracer binding, indicating significantly greater smoking-induced dopamine release, compared to carriers of the minor A-allele (-10.8% vs. -3.0% respectively, p= 0.002). This result remains significant after correction for multiple comparisons. Similarly, CC homozygotes at a variant in the promoter of the (4 subunit (CHRNA4, rs755203) had almost twice the reduction in radiotracer binding (-10.7% vs. -5.7%) as carriers of the minor T-allele (p=0.047). This risk allele is in modest linkage disequilibrium with a published variant associated with nicotine dependence. We further correlated genetic variants and imaging data with behavioral measures of craving. **Conclusions:** Findings at nicotinic (4 and (7 cholinergic receptor subunits are consistent with animal and in vitro studies, implicating these subunits in dopamine-mediated reinforcement associated with smoking. Common human variants appear to exert significant effects on dopamine release. A detailed understanding of genetic moderators of nicotine reward and risk for dependence may facilitate the development and individualization of successful treatment strategies.

Calcium Channel Genes are Associated with Autism Spectrum Disorders and Their Defining Features. *A. Lu[1], R.M. Cantor[1,2].* 1) Dept Human Genetics, David Geffen School of Medicine, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Psychiatry, David Geffen School of Medicine, University of California at Los Angeles, Los Angeles.

Autism Spectrum disorders (ASD), characterized by (1) deficits in communication skills, (2) deficits in social skills and (3) the presence of restricted and repetitive behaviors, are genetically complex with few established causal genes. Evidence supporting the role of calcium channel genes (CCG) in ASD has been accumulating. CCG are suggested by 1) Timothy Syndrome (TS), a Mendelian disorder that features ASD and is caused by a missense mutation in the 8th exon of the CACNA1C gene that encodes the alpha 1C subunit protein of L-type calcium channel, and 2) independent ASD associations that implicate CACNA1G and RyR2, both CCG. We conducted association analyses on a panel of 10 of these genes to better assess the potential role of CCG in ASD. The genes selected encode the 10 (1 subunits of the CCG. First, a combined reference panel from the 1000 Genomes Project and HapMap3 was used to impute 5,658 SNPs in the 10 CCG in 543 multiplex Caucasian families (1103 trios) from the Autism Genetics Resource Exchange (AGRE), using the IMPUTE2 software and 1,389 SNPs that were genotyped as part of a prior GWAS . Because the sex ratios in ASD and TS are skewed (4:1) and the published CCG associations included sex differences in the analyses, these 7,047 SNPs were assessed using joint tests of each CCG SNP and its interaction with sex. A Bonferroni correction was applied (p<7.0e-6), and 38 SNPs in 8 CCG were associated with ASD, with 10 of these also exceeding genomewide significance (p<5.0e-08). Similar association analyses were conducted to assess whether the 3 ASD defining features , language deficits (L), social deficits (S) and repetitive behaviors (R), quantified by heritable scores derived from items on the Autism Diagnostic Instrument Revised, were also associated with CCG. Most of the ASD associated SNPs were associated (10 for L, 27 for R and 28 for S), and a ninth CCG was associated with 1 additional SNP for R and 2 additional SNPs for S. These associations provide support for the role of CCG in both ASD and the features that define it. They also provide a concrete example that SNPs in a gene for a Mendelian disorder that includes ASD, such as CACNA1C for TS, may also predispose to the genetically complex trait of ASD. A significant role for Mendelian disorder genes in complex traits is very likely.

Comprehensive resequencing of *PEX5*, *PEX13* and *PEX14* gene in patients with X-linked adrenoleukodystrophy (ALD) and association studies with the phenotypes of ALD. *T. Matsukawa[1], Y. Takahashi[1], J. Goto[1], Y. Suzuki[2], N. Shimozawa[2], H. Takano[3], O. Onodera[3], M. Nishizawa[3], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Gifu University, Gifu, Japan; 3) Niigata University, Niigata, Japan.

Background & Purpose: Adrenoleukodystrophy (ALD) is an X-linked disorder affecting primarily the white matter of the central nervous system occasionally accompanied with adrenal insufficiency. The ages at onset and clinical presentations of ALD are substantially broad. There are various kinds of phenotypes, like Childhood cerebral ALD (CCALD), Adult cerebral ALD (AdultCer), Adrenomyeloneuropathy (AMN). Despite the discovery of the causative gene, *ABCD1*, clear genotype-phenotype correlations have not been established. *ABCD1* gene encodes adrenoleukodystrophy protein (ALDP), which is localized to the peroxisomal membrane. *ABCD1* mutant mice show a milder AMN phenotype. On the other hand, mice lacking *PEX5* gene expression, which is related to peroxisomal protein import, in their oligodendrocytes develop cerebral demyelination involving the corpus callosum as occurs in CCALD. When the *PEX5* product (Pex5p) is transported to the peroxisome, it interacts with the *PEX14* product (Pex14p) and the *PEX13* product (Pex13p). Association studies based on SNPs identified by comprehensive resequencing of gene related to *ABCD1* may reveal genes modifying the phenotypes of ALD. The purpose of this study is to investigate genotype-phenotype correlations and to explore the possibility of *PEX5*, *PEX13*, and *PEX14* as the disease modifying gene. **Methods:** We analyzed 55 Japanese patients with ALD (CCALD 16, Adlescent Cerebral ALD 3, AdultCer ALD 6, AMN with cerebral (AMN-Cer) ALD 5, Cerebello-brainstem ALD 2, AMN 20, Addison disease 1, and asymptomatic 2). Sequences of all of the exons, introns around the exon-intron boundary, 5'UTR and 3'UTR of *PEX5*, *PEX13*, and *PEX14* were analyzed by direct nucleotide sequence analysis. **Result:** 2 novel non-synonymous SNPs in exon, 1 novel SNP in intron, 2 novel SNPs in 3'UTR and 2 known SNPs in 3'UTR were detected in *PEX5*. 2 known SNPs in 3'UTR were detected in *PEX13*. 1 novel and 1 known non-synonymous SNP and 1 novel and 3 known synonymous SNP in exon, 2 novel SNP in 3'UTR, and 1 known SNPs in intron were detected in *PEX14*. SNPs identified by comprehensive resequencing of *PEX5*, *PEX13*, and *PEX14* were used for association studies. There were no significant associations between these SNPs of *PEX5*, *PEX13* and *PEX14*, and ALD phenotypes in the Japanese population. **Conclusion:** The present study indicates that *PEX5*, *PEX13*, and *PEX14* are less likely the disease modifying genes, necessitating further studies to identify genes modifying the phenotypes of ALD.

537F

The application of whole-exome resequencing to identify the genetic basis of a novel autosomal recessive syndrome characterized by epilepsy, microcephaly and cognitive impairment. *L.M. McDonell[1,3,4], D. Foster[2], F.C.C. FORGE Canada Consortium[3], D.E. Bulman[1,4], K.M. Boycott[3,4].* 1) Regenerative Medicine Program, Ottawa Hospital Research Institute, Ottawa, Ontario, Canada; 2) Algoma Public Health Unit, Sault Ste Marie, Ontario; 3) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario; 4) Department of Biochemistry Microbiology and Immunology, University of Ottawa, Ottawa, Ontario.

Homozygosity mapping in consanguineous families coupled with whole-exome resequencing has been successful in identifying the causal variant for more than nine Mendelian disorders including Ochoa syndrome and van Den Ende-Gupta syndrome. Exome resequencing facilitates the rapid and efficient discovery of novel mutations by revealing variants in regions which are identical-by-descent (IBD) amongst affected individuals. This approach enables the study of rare disorders in small families where the region(s) of interest is potentially large and/or gene-rich. Here we report a consanguineous Franco-Ontarian family with four affected siblings; two males and two females. The parents are first cousins. The disorder in this family is characterized by early-onset severe epilepsy that is difficult to control requiring the use of multiple anticonvulsants, microcephaly with occipital-parietal circumference of -3SD and severe cognitive impairment. The siblings are now adults and all live in a supported care setting. Language is limited to short phrases in the two female siblings and is essentially absent in the male siblings. Dysmorphic features, minor anomalies or other neurological features are absent. Fragile X testing, MECP2 and metabolic investigations were unrevealing. The four affected family members were genotyped using SNP 6.0 arrays (Affymetrix). Homozygosity mapping using Homozygosity Mapper lead to the identification of two regions IBD on chromosomes 13 and 19 involving 2 and 265 genes, respectively. Neither of these regions contains a known phenotype associated with microcephaly or epilepsy, suggesting that this is a novel autosomal recessive disorder. Exome resequencing of one affected family member using the Agilent Sureselect 50Mb target enrichment method coupled with the Illumina Hi-Seq platform is underway and analysis of the data will be presented.

538F

Spastic paraplegia due to CYP7B1 mutations (SPG5) : what can we learn about 27-hydroxycholesterol metabolism? *F. Mochel[1,2,3], F. Lamari[3,4], D. Rinaldi[3], C. Goizet[5,6], D. Rainteau[7], V. Ratziu[8], A. Durr[1,2].* 1) INSERM UMR S975, Institut du Cerveau et de la Moelle, Hôpital de La Salpêtrière, Paris, France; 2) AP-HP, Département de Génétique, Hôpital de La Salpêtrière, Paris, France; 3) AP-HP, Unité Fonctionnelle de Biochimie Métabolique, Hôpital de La Salpêtrière, Paris, France; 4) Unité Fonctionnelle Neurométabolique, Hôpital de La Salpêtrière, Paris, France; 5) Département de Génétique Médicale, CHU de Bordeaux, Hôpital Pellegrin, Bordeaux, France; 6) Université Victor Segalen Bordeaux 2, CHU de Bordeaux, Hôpital Pellegrin, Bordeaux, France; 7) AP-HP, Laboratoire de Biochimie Métabolique, Hôpital Saint-Antoine, Paris, France; 8) AP-HP, Service d'Hépato-Gastroentérologie, Hôpital de La Salpêtrière, Paris, France.

Background: CYP7B1 encodes the cytochrome P450 7alpha-hydroxylase and plays a role in the alternate/acidic pathway for primary bile acid production. Mutations in CYP7B1 were identified in children with severe liver disease and, recently, in adult SPG5 patients presenting with hereditary spastic paraplegias (HSP) (Tsaousidou, 2008). Increased levels of 27-hydroxycholesterol (27-OHC) were reported in the plasma of 4 SPG5 patients (Schule, 2010). Besides its role in hepatobiliary metabolism, in vitro studies suggest that 27-OHC may decrease bone mineral density, inhibit the cardiovascular protective effects of estrogens and increase oxidative stress in retinal pigment epithelial cells. Methods: We investigated 9 SPG5 patients from 6 families in order (i) to determine whether plasma 27-OHC can be used as a biomarker to screen HSP patients, and (ii) to explore the non-neurological manifestations that may result from the altered oxysterols metabolism in SPG5 patients - i.e. hepatobiliary and cardiovascular functions, bone homeostasis and retina. Results: The marked elevation of plasma 27-OHC was associated with altered liver functions, reduced bone density and optic atrophy in SPG5 patients. Conclusion: Following these investigations, we are now designing a clinical trial to determine the best candidate drugs - and doses - to lower 27-OHC in SPG5 patients.

539F

Challenges in Interpreting Copy Number Alterations in Regions Associated with Autism: Deletions and Duplications within the AUTS2 Gene. *R.E. Pyatt[1,2], A. Bailes[1], A. McKinney[1], A. Brock[1], C. Deeg[1], L. Erdman[1], C. Weber[1], J. Weslow-Schmidt[1], L.M. Lehwald[3], L. Konczal[4], P. Nash[5], E. de Los Reyes[6], M. Miller[7], R.B. Pfau[7], J. Atkin[8,9], G. Herman[8,9], D.L. Thrush[1,9], S. Hashimoto[1], S. Reshmi[1,2], C. Astbury[1,2], J.M. Gastier-Foster[1,2,9].* 1) Pathology and Laboratory Medicine, Nationwide Childrens Hosp, Columbus, OH; 2) Department of Pathology, The Ohio State University, Columbus, OH; 3) Pediatric Neurology, Nationwide Children's Hospital, Columbus, OH; 4) University Hospitals, Case Western Reserve University; 5) Department of Behavioral Pediatrics, Nationwide Children's Hospital, Columbus, OH; 6) Department of Neurology, Nationwide Children's Hospital, Columbus, OH; 7) Dayton Children's Medical Center, Dayton, OH; 8) Molecular and Human Genetics, Nationwide Children's Hospital, Columbus, OH; 9) Department of Pediatrics, The Ohio State University, Columbus, OH.

Disruptions in the *AUTS2* gene have been associated with severe mental retardation and autism through a series of individuals with balanced translocations and breakpoints within the gene. The *AUTS2* gene located at 7q11.22 encodes for multiple transcripts including a full length isoform containing 19 exons, a slightly smaller isoform containing 18 exons, and a truncated isoform containing the first 4 exons and an alternatively spliced fifth exon. Benign copy number alterations are rare within the *AUTS2* gene region. We present here a series of alterations in the *AUTS2* gene identified through clinical array-comparative genomic hybridization (array-CGH) using custom designed BAC and oligonucleotide platforms. This series includes 6 deletions and 1 duplication with a likely benign loss at 9p24.3 as the only co-identified copy number alteration in one case. Deletions within the gene ranged in size from 31 to 220 kb and included single exon deletions involving the long transcript isoforms (exon 6), single exon deletions involving only the short isoform (alternate exon 5), and multiple exonic deletions (exons 3, 4, and alternate exon 5 from all isoforms, exons 6 through 19 of the long isoforms). These alterations were identified in individuals presenting with developmental delay, autism, microcephaly, and ataxia, and also as an incidental finding during parental analysis to determine inheritance of a separate array-CGH finding in a reportedly phenotypically normal mother. Parental samples were only available for one deletion proband which was determined to be de novo. Deletions restricted to intronic, non-coding regions were also found (regions within introns 1 and 6) in individuals presenting with attention deficit hyperactivity disorder, oppositional defiant disorder, ataxia, migraine episodes, and tonic paroxysmal upgaze. The 538 kb duplication identified in this series contained exons 7 through 19 of the *AUTS2* gene and a portion of the *WBSCR17* gene. To our knowledge, this is the first series of alterations identified in the *AUTS2* gene suggesting a pathogenic role or ascertainment bias due to the cohort screened. Interpretation of alterations involving regions predisposing to neurocognitive phenotypes can be challenging due to variable expressivity and incomplete penetrance, and is often not aided by parental analysis. These cases additionally underscore the need to extend the understanding of clinical array-CGH findings to the transcript level.

540F

Temporal gene expression of *bdnf* and *ntrk2b* in adult zebrafish after Pentilenotetrazole-evoked seizure. *F.C. Reis-Pinto, R.F.P. Mangolin, P.G. Barbalho, C.V. Maurer-Morelli.* Medical Genetics, Faculty of Medical Sciences-UNICAMP, Campinas, Brazil.

Animal models have been contributing to a better understanding of human diseases. In this context, *Danio rerio*, popular named as zebrafish, has been recognized for epilepsy studies. Epilepsy is a severe neurological disorder affecting a large number of individuals in the world. Besides to trophic properties, brain-derived neurotrophic factor (BDNF) appears to be associated with epileptogenesis by modifying synaptic transmission. However, there are still controversies about the main role of BDNF in epilepsy. The aim of this study was to determine temporal gene expression of *bdnf* and its receptor, *ntrk2b* after Pentilenotetrazole (PTZ) evoked seizure in zebrafish. Adults zebrafish were separated in control (n=3) and epileptic (n=3) groups (a pool of 2 brains was used to compose one sample). Animals from epileptic group were individually exposed to PTZ 15mM for 2-3 minutes and observed the three phases of epileptic behavior as previous described. Control animals were submitted to the same condition and time as epileptic group but in PTZ free water. After that, animals from both groups were placed into aquariums with PTZ free water in accordance to their groups. Twenty-four and 48h after seizure animals were anesthetized and their brains removed for RNA extraction. Quantitative Real Time PCR with TaqMan™ assays was performed to evaluate the gene expression of *bdnf* and *ntrk2b*. Runs were carried out in triplicate using 18S as endogenous control. This study was approved by animal ethical committee. Comparisons between control and epileptic groups for *bdnf* and *ntrk2b* genes showed evident up-regulation after 48h, ΔRQ= 2.18 and ΔRQ= 2.49, respectively. However, only a slightly difference was found in 24h (ΔRQ= 0.28 and ΔRQ= 0.36). Gene expression profile in the epileptic group, from 24h to 48h after seizure, found both genes highly increased (*bdnf*: ΔRQ= 2.55 and *ntrk2b*: ΔRQ= 2.74). It has been reported that both BDNF transcript and protein levels are increased after seizures in epileptic patients and in experimental models. However, in rats the transcript levels were reported to return to control levels 12h after seizure. Our results have yielded insights into a different pattern of gene expression of *bdnf* and *ntrk2b* genes after seizure insult and can contribute to the knowledge of the role of BDNF in human epilepsies. Additional studies are underway in order to point out the role of neurotrophins in epileptogenesis using zebrafish as an animal model.Support:CNPq.

Evaluation of the predisposition to autism using a combination of risk-associated common variants. *T. Rio Frio, F. Rousseau, K. Fontaine, C. Vazart, C. Amiet, F. Liebaert, J. Carayol.* IntegraGen, Evry, France.

BACKGROUND: Autism spectrum disorders (ASDs) are highly heritable complex neurodevelopmental disorders with a 4:1 male: female ratio. Early identification of children at-risk of an ASD is a key challenge given that multiple studies have shown that early intervention leads to significant improved outcome in children with an ASD. Currently, there is no clinically validated tool to identify at-risk siblings before 18 months of age. In some complex diseases, the utility of genetic scores which combine associated common variants has been demonstrated to improve risk prediction. AIM: To propose a method to identify common variants associated with autism and to explore the predictive ability of derived gender-specific genetic scores to evaluate the risk of autism. MEHODS: Gender-based genome-wide association studies (GWAS) were performed on 544 families from the Autism Genetic Resource Exchange including 967 children with autistic disorder and 304 unaffected siblings. To improve the power of detection of common variants associated with an increased risk of autism we prioritized SNPs based on GWAS results, relevant biological data, and internal validation. We then assessed the ability of gender-specific genetic scores (GS), the sum of individual risk-associated alleles of highly ranked and reproducible SNPs, to discriminate between individuals with or without autism. RESULTS: A total of 88 SNPs associated with an increased risk of autism were selected. Of these, 52 SNPs were associated with autism in both males and females, 17 SNPs were associated with autism in males only and 19 SNPs in females only. Gender-specific GSs were constructed for fully genotyped 1,034 children with ASDs and 300 unaffected siblings. For males, the area under the receiver operating characteristic curve (AUC) was 0.83 (95%CI: 0.78-0.87); a GS of 68 was associated to an 86% specificity (95%CI: 79-92) and a 56% sensitivity (95%CI: 52-59). In females, the AUC was 0.84 (95%CI: 0.80-0.88); a GS of 66 was associated to an 86% specificity (95%CI: 80-92) and a 60% sensitivity (95%CI: 52-66). Furthermore, in both male and female samples, lowest and highest genetic scores were observed only in unaffected individuals and in children with ASDs, respectively. CONCLUSIONS: Our findings demonstrate that a gender-specific genetic score based on the presence of multiple risk-associated common variants allows for the identification of children who have a significantly higher risk to develop autism.

Rare de novo and transmitted mutations in autistic spectrum disorders. *M. Ronemus[1], D. Levy[1], I. Iossifov[1], Y.-H. Lee[1], S. Gilman[2], R. Demeter[3], V. Magrini[3], A. Leotta[1], S. Marks[1], J. Kendall[1], K. Ye[4], A. Buja[5], A. Krieger[5], B. Lakshmi[1,6], S. Yoon[1,7], J. Troge[1], L. Rodgers[1], P. Andrews[1], I. Hakker[1], J. Rosenbaum[1], B. Yamrom[1], E. Mardis[3], R. Wilson[3], M. Schatz[1], D. Vitkup[2], R. McCombie[1], M. Wigler[1].* 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) Center for Computational Biology and Bioinformatics and Department of Biomedical Informatics, Columbia University, New York, NY; 3) The Genome Institute at Washington University, St. Louis, MO; 4) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 5) Department of Statistics, the Wharton School, University of Pennsylvania, Philadelphia, PA; 6) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 7) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY.

To explore the genetic contribution to autistic spectrum disorders (ASDs), we have studied rare de novo and inherited mutation in the Simons Simplex Collection (SSC). The SSC represents a large cohort of families with a single affected child and at least one unaffected sibling. The first stage of the analysis was performed by comparative genomic hybridization (CGH) of 1000 SSC families. Based on these data, we confirm a major contribution from de novo deletions and duplications, and also find evidence of a role for inherited `ultra-rare' duplications. De novo CNVs were found in 7.9% of probands and 2.0% of unaffected siblings. Relative to males, females appear to have greater resistance to autism from genetic causes, which raises the question of the fate of female carriers. By analysis of the proportion and number of recurrent loci, we set a lower bound for distinct target loci at several hundred. Because CGH-detectable de novo CNVs account for a relatively small portion of the pool of genetic variation underlying ASDs, we have initiated a finer-scale analysis by whole-exome sequencing of the SSC. From the combined CGH and sequencing analyses, we find many new candidate regions, adding substantially to the list of potential gene targets, and confirm a number of loci previously observed. The overall results point to a great diversity of genetic causes, but also suggest functional convergence upon synaptogenesis as a primary cause of ASDs.

543F

Genetic predictors of knee pain in persons with mild to moderate osteoarthritis. *D. Schutte[1], N. Mukhopadhyay[2], C. Vance[4], R. Walder[4], K. Sluka[4], B. Rakel[3], M. Govil[2].* 1) College of Nursing, Michigan State University, East Lansing, MI; 2) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 3) College of Nursing, The University of Iowa, Iowa City, IA; 4) Physical Therapy and Rehabilitation Graduate Program, College of Medicine, The University of Iowa, Iowa City, IA.

Osteoarthritis (OA) affects 10 million adults in the US and is associated with significant negative sequela, such as functional losses, disability, and risks associated with polypharmacy. Little is known about factors, including genetic variation, that influence the pain experience in this population. The purpose of this study was to examine the extent to which genetic variability influences knee pain in persons with mild to moderate OA. Seventy-five subjects diagnosed with medial compartment knee OA were recruited from the Orthopedic and Sports Medicine Department of a large Midwestern tertiary care center. Subjects exhibited a mean age of 56.3 years; females comprised 61% of the sample. Measures of pain included subjective pain intensity (VAS) at rest and with movement, cutaneous mechanical pain testing using von Frey filaments, heat pain threshold, and pressure pain threshold using a digital pressure algometer. Pain measures were obtained at the knee and anterior tibialis regions on both the ipsilateral and contralateral side. Each measurement type consists of pain response along multiple dimensions, e.g subjective pain at rest is characterized by intensity and distress values. The mean self-reported pain intensity at rest and mean distress were 22.82 and 23.03 respectively on a 0-100 scale with higher scores meaning more severe pain. Subjective measures were positively correlated; correlation between intensity and distress at rest was 0.85, whereas measures provided by instruments showed varying degrees of correlation ranging from -0.41 to 0.84. Seventy-four of the seventy-five subjects were successfully genotyped for DNA variants in 11 candidate genes with a known or hypothesized role in central or peripheral pain pathways: *NGFB*, *NTRK1*, *EDNRA*, *EDNRB*, *EDN1*, *OPRM1*, *TAC1*, *BDNF*, *BDKRB1*, *5HTT*, and *COMT*. Linear regression modeling was conducted, using PLINK, to examine genotype effect on each pain outcome on the ipsilateral side. Marker rs5333 in the *EDNRA* gene had an association p-value of 0.0019 for heat pain threshold, below the bonferroni-corrected value of 0.002. The results from this study will help guide the development and evaluation of tailored strategies to decrease pain, improve function, and prevent the development of new chronic pain syndromes in adults experiencing OA. An investigation of neurogenetic correlates of early-age physiological stress response: A prospective study. *H. Sheikh, E. Hayden, K. Kryski, H. Smith, S. Singh.* Department of Biology, Molecular Genetics Unit, University of Western Ontario, London, ON, Canada.

Psychiatric disorders such as anxiety and depression place an enormous burden on individuals and society. The etiology of these disorders is unclear but risk of developing these disorders is polygenic in nature and show a strong heritable component. Specific genes that may be involved include genes that regulate neuronal neurotransmission and their plasticity but also genes that may shape physiological correlates of psychopathology development, such as the human physiological stress response termed the hypothalamic-pituitary-adrenal (HPA) axis. Activation of the HPA axis culminates in the release of cortisol, a glucocorticoid hormone with long-lasting biological implications. Excessive and sustained cortisol reactivity (glucocorticoid exposure) could be maladaptive and reported in many individuals with depression and anxiety and posited as an important marker of early vulnerability to mood disorders. Etiological data from twin-studies show that cortisol reactivity is also highly heritable but only a handful of studies have looked at genetic variants associated with excessive childhood HPA axis reactivity. We investigated whether functional polymorphisms of genes involved in neuronal plasticity such as BDNF, GLP-1R, and neurotransmission such as SLC6A3, SLC6A4, DRD2, DRD4, COMT and MAOA are associated with child cortisol reactivity in a community sample of 410 preschoolers. Preliminary data shows that functional polymorphism of the BDNF, GLP-1R genes, are not associated with child cortisol reactivity ($p>0.05$), a finding previously unreported in this population. Additionally, we investigated genes of the HPA axis pathway, the NR3C1, CRH, CRHR1and MC2R genes, using a haplotype based association analyses. Haplotypes were generated using tag-SNPs spanning ± 10kb upstream and downstream of the key HPA axis pathway gene coding regions. Chromosomal phase was determined using expectation-maximization algorithm and the tag-SNP tests covered 100% of the genetic variance reported by HapMap for the CEPH (Caucasian) population. To our knowledge, this study is the first of its kind to investigate the early age genetic underpinnings of the human HPA axis.

545F

Exome sequencing approach to identify the responsible variant for a novel type of hereditary motor and sensory neuropathy with proximal dominancy in the lower extremities found in a Japanese descent. *H. Shibata[1], S. Miura[2], H. Kida[2], K. Noda[2], Y. Kaku[2], A. Iwaki[1], M. Ayabe[2], T. Taniwaki[2], Y. Fukumaki[1].* 1) Div Human Molecular Genetics, Dept Molecular Genetics, Medical Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 2) Div Respirology, Neurology, and Rheumatology, Dept Medicine, Kurume Univ Sc Med, Kurume, Fukuoka, Japan.

We previously reported a clinically new type of autosomal dominant disorders of motor and sensory neuropathy with proximal dominancy in the lower extremities, urinary disturbance, and paroxysmal dry cough (Miura et al. J Neurol Sci 2008). On the multipoint linkage analysis using 15 family member including six patients, we obtained the logarithm of odds (LOD) scores of > 0.7 on 1p31.1-q23.3 (LOD = 1.704) and 4pter-p15.2 (LOD = 1.421). The linkage regions included the *MPZ* gene at 1q22 of which mutations have been reported in a autosomal dominant hereditary motor and sensory neuropathy. However, we observed no mutations in the entire coding sequences of *MPZ* as well as no aberrant copy number in the *MPZ* exons. Since further genetic dissection by linkage analysis is not possible to pursue due to the limitation of the size of the family, we performed exome sequencing in seven individuals including six patients and one healthy relative. We identified 16 novel heterozygous NS mutations specifically shared by patients in 12 genes on 1p31.1-q23.3 and in 4 genes on 4pter-p15.2. None of the 16 genes have been reported to be responsible for any type of neuropathy. Although the validation by Sanger sequencing is under way, the current results suggest this disorder is not only clinically but also genetically a novel type of hereditary motor and sensory neuropathy.

546F

Absolute quantification of Survival Motor Neuron (SMN) transcripts in whole blood samples from controls, carriers, Spinal Muscular Atrophy (SMA) patients and post-treatment Carnival Type 1 patients. *L.R. SMA, a lower motor neuron disease, is caused by mutations in the *SMN1* gene. The highly homologous *SMN2* copy gene appears to produce an excess of an alternatively spliced transcript (SMN-del7) that is translated into a very unstable protein. In therapeutic strategies targeting the *SMN2* gene, measures of SMN mRNA can be used to test the effectiveness of a drug. To determine the relationship between disease status or valproic acid (VPA) treatment and SMN expression, absolute values of full-length (fl) and del7 SMN transcripts in whole blood samples was determined for 22 controls, 26 carriers, 19 type 1, 10 type 2, 18 type 3 and 13 Project Cure Carnival type 1 SMA patients. SMN1-fl transcripts were not detected in SMA patients and SMN2-fl/del7 transcripts were lacking in individuals with homozygous absence of *SMN2* exon 7. As expected, controls produced over twice the amount of SMN1-fl transcripts compared to carriers (284 vs. 107 molecules/ng RNA) whereas the levels of SMN2-fl transcripts were similar. *SMN1* and *SMN2* genes produced the same amount of total SMN transcripts in unaffected individuals. Surprisingly, type 1 patients had the highest SMN2-fl levels. Type 1 and type 3 patients had the highest level of SMN2-del7 transcripts. SMN2fl:SMNdel7 mRNA ratios ranged from 0.8 to 1.3 in SMA patients compared to 2.2 in controls suggesting that gene expression varied between *SMN2* genes and may have been affected by gene conversion events. There was no correlation between SMN expression and *SMN2* copy number. Project Cure Carnival type 1 patients fell into 3 groups regarding VPA response: 5 Type 1 patients displayed increased levels of SMN2-fl transcripts post-treatment (~38%) and 4 of these also had increased SMN2-del7 transcripts. SMN2-fl and del7 transcripts were stable or lower in group 2. Large fluctuations were detected in Group 3 patients. **Conclusions:** The highest *SMN2* expression was observed in the youngest patients consistent with down-regulation of *SMN* genes during development. Differences in SMN2fl:SMNdel7 transcripts in unaffected and affected individuals suggested that *SMN2* gene expression may be affected by gene conversion events. While VPA was likely acting to enhance *SMN2* gene expression in a subset of SMA type 1 patients, it will be important to correlate any changes in SMN expression levels with a clinically meaningful outcome measures before assessing whether SMN mRNA is a valid biomarker.

547F

Genetic influence on anti-JC-virus antibody seropositivity in MS patients and controls. *E. Sundqvist[1], C. Warnke[1], M. Khademi[1], L. Alfredsson[2], J. Hillert[1], S. Goelz[3], I. Kockum[1], T. Olsson[1].* 1) Dept. Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Biogen Idec Inc., Weston, MA, USA.

Lytic infection of oligodentrocytes by JC-virus (JCV) is considered as the cause of progressive multifocal leukoencephalopathy (PML) a condition occurring as a severe and potentially fatal complication in patients with multiple sclerosis (MS) treated with natalizumab. As there is no treatment directed towards the cause of PML, it is important to devise methods by which patients at risk can be identified, decreasing PML incidence and increasing patient safety. Ascertainment of the presence or absence of anti-JCV antibodies using the recently refined assay has been suggested as one such method in which 40-50 % of adults remain anti-JCV negative, indicating a potential genetic background to JCV susceptibility. The aim was to analyse the influence of HLA-A and DRB1 genotype on anti-JCV antibody status in incident MS cases, the majority of which were not treated with natalizumab, and matched (age, sex, and area of residence) population based controls, recruited throughout Sweden. Anti-JCV antibodies were measured in plasma, and status was determined to be either seropositive or -negative by applying a method published by Gorelik et al, 2010. HLA-A and DRB1 genotyping was performed using low resolution SSP-kits. The influence of HLA-alleles was analysed using logistic regression on 999 controls and 961 MS cases, separately and combined. Alleles with an allele frequency of over 10% in JCV-negative individuals were grouped into HLA-A*X and DRB1*X, respectively. A stepwise selection was applied, adjusting for age at sampling, sex and area of residence, and for cases, also for natalizumab treatment. For controls, DRB1*13 and 15 were associated to JCV seropositivity, OR 1.7 (1.2-2.3 95%CI) p=0.003, and 0.7 (0.6-1.0 95%CI) p=0.03, respectively. For MS cases DRB1*13 (OR 1.5, 1.1-2.2 95%CI, p=0.02), DRB1*15 (0.7, 0.6-0.9 95%CI, p=0.004) and DRB1*X (1.3, 1.0-1.6 95%CI, p=0.03) were associated to JCV-positivity. Both DRB1*15 and 13 were associated in the combined analysis (p=4x10^-6 and 0.002, respectively) with similar ORs as in the subgroups analyses. We have shown that there is a genetic influence on JCV-seropositivity and that the major MS risk allele, DRB1*15, has protective effect. Further study is needed to fully elucidate the genetic regulation of JCV seropositivity, and host genetic factors relevant to the risk for developing PML. Thus, as a first step, we are currently assessing the influence of several non-HLA genes on JCV seropositivity in the same cohort.

548F

Resequencing-based case control study of *SQSTM1* for sporadic amyotrophic lateral sclerosis based on common disease-multiple rare variant hypothesis. *Y. Takahashi, J. Goto, S. Tsuji.* Dept Neurology, Univ Tokyo, Tokyo, Japan.

[Background]Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder characterized by progressive loss of upper and lower motor neurons. Approximately 5~10% of patients were with familial ALS (FALS), about 30% of which are accounted for by known causative genes, and the remaining 90~95% of patients were with sporadic ALS (SALS). Molecular backgrounds of SALS have been largely unknown, except for small number of patients harboring causative mutations of FALS genes. Resequencing studies based on common disease-multiple rare variants hypothesis have been increasingly conducted to identify genetic factors for *SALS*. Very recently, rare nonsynonymous variants in *SQSTM1* have been reported to be associated with FALS and SALS (Fecto, F. et al. Neurology 76, 2011 (Suppl 4)). *SQSTM1* is one of promising candidates because it is suggested to be involved in the regulation of TDP-43 aggregation, one of the pathological hallmarks of SALS. [Objectives] To test the hypothesis that rare nonsynonymous variants in *SQSTM1* are associated with SALS in the Japanese population. [Subjects and Methods] Two hundred and fourteen SALS patients and 276 controls were enrolled in this study. Specific primers for genomic PCR were designed for whole exons of *SQSTM1* using ExonPrimer website. Mutational analysis for whole exons was conducted in SALS patients as well as 96 controls employing direct nucleotide sequencing method. Novel nonsynonymous variants identified in SALS patients were further analyzed in the additional 180 controls. The effects of amino acid substitutions were predicted using PolyPhen-2 website. [Results]Two novel nonsynonymous variants, R50Q and P273R, were identified in two patients (1%) with SALS. R50Q was predicted as probably damaging with a score of 0,957 and P273R as benign with a score of 0.383. These variants were not identified in the 276 controls. Resequencing of 96 controls revealed a novel nonsynonymous variant V144I in one subject, predicted as benign with a score of 0.038. [Discussion and Conclusion] The interpretation of the novel nonsynonymous variants in SALS was elusive, because such a variant was also observed in controls. This study emphasizes the importance of the resequencing of controls as well as patients to investigate the significance of rare variants. Further mutational analysis in different cohorts as well as functional studies should be essential to establish *SQSTM1* as a gene associated with SALS.

549F

PLA2G6 in patients with Parkinson's disease / frontotemporal type of dementia. *H. Tomiyama[1,2], H. Yoshino[3], K. Ogaki[1], L. Li[1], C. Yamashita[1], Y. Li[3], M. Funayama[1,3], R. Sasaki[4], Y. Kokubo[4], S. Kuzuhara[5], N. Hattori[1,2,3].* 1) Dept Neurology, Juntendo Univ Sch Medicine, Tokyo, Japan; 2) Dept Neuroscience for Neurodegenerative Disorders, Juntendo Univ Sch Medicine, Tokyo, Japan; 3) Research Inst for Diseases of Old Age, Graduate Sch Medicine, Juntendo Univ, Tokyo, Japan; 4) Dept Neurology, Mie Univ Sch Medicine, Tsu, Japan; 5) Dept Medical Welfare, the Faculty of Health Science, Suzuka Univ of Medical Science, Suzuka, Japan.

PLA2G6 is the causative gene for heterogeneous disorders such as infantile neuroaxonal dystrophy (INAD), neurodegeneration associated with brain iron accumulation (NBIA), Karak syndrome, and recently reported PARK14-linked autosomal recessive early-onset dystonia-parkinsonism. Very recently, heterozygous PLA2G6 p.P806R (c.2417C>G) mutation in exon 17 was reported to be a possible Parkinson's disease (PD)-related mutation in Singapore. To determine the significance of the PLA2G6 mutation, we conducted an association study by performing direct sequencing of PLA2G6 exon 17 in 379 Japanese sporadic PD patients and 310 controls in the Japanese general population. In this group, we found 12 patients (12/379= 3.16%) and 10 controls (10/310=3.23%) with a heterozygous p.P806R mutation (P=0.96, $\chi 2$=0.0019), suggesting that PLA2G6 p.P806R was not a disease-associated polymorphism in PD. Moreover, we performed direct sequencing of all exons and exon-intron boundaries of PLA2G6 in 116 Japanese patients with sporadic PD. Two novel single heterozygous rare variants (p.R301C or p.D331N) were found (both frequencies: 1/379 patients vs 0/310 controls), arising the possible roles for the pathogenicity or risk factors. Subsequently, we reported three Japanese patients (two families) with PARK14-linked parkinsonism. Intriguingly, our two probands with compound heterozygous mutations (age/age at onset = 35/20 and 33/25 years old) and the previously reported patients with PARK14-linked parkinsonism had dementia with frontal lobar dysfunction such as frontal executive dysfunction, frontal lobar atrophy, or frontal lobar hypoperfusion on neuroimaging. Thereafter, to determine the significance of the PLA2G6 mutation, we conducted extended mutation analysis in 23 Japanese patients (male 12, female 11) with frontotemporal type of dementia. Among them, 11 patients had family histories of frontotemporal type of dementia. As a result, direct sequencing of all the PLA2G6 exons revealed no pathogenic mutations or significant SNPs. Thus, combined with the previous report, our findings suggest that PLA2G6 mutations are unlikely to be the major causes or risk factors of PD and frontotemporal type of dementia at least in Asian populations. To clarify the possible roles of PLA2G6 for the pathogenicity or risk factors, further large studies in various populations are needed because patients with PLA2G6 mutations can show heterogeneous clinical features.

550F

The pervasive neurologic phenotype of mild Chediak-Higashi Syndrome. *C. Toro[1], A. Cullinane[2], W. Westbroek[2], M. Huizing[2], C. Groden[1], W. Gahl[1,2,3], W. Introne[3].* 1) Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD; 2) Metabolic Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD; 3) Office of the Clinical Director (OCD), NHGRI, National Institutes of Health, Bethesda, MD.

Chediak-Higashi syndrome (CHS) is a very rare autosomal recessive condition due to mutations in lysosomal trafficking regulator gene (*LYST/CHS1* gene, OMIM #606897). The CHS1 protein is thought to function in the formation and trafficking of lysosome-related organelles. Clinically, CHS is characterized by partial albinism, a bleeding diathesis, recurrent infections that are often ultimately fatal, and hemophagocytic lymphohistiocytosis, or the accelerated phase. Giant inclusions within white blood cells are diagnostic. Mortality is high in the first decade of life, and the only available treatment is bone marrow transplantation (BMT). Some CHS patients present with mild findings, i.e., inconspicuous hair and eye hypopigmentation and subtle cognitive difficulties. By their early 20s, these patients manifest slowly progressive neurological deterioration, resembling adults with typical CHS who underwent successful BMT as children. 8 young adults with confirmed CHS, but without BMT, were evaluated at the National Institutes of Health Clinical Center. Testing included neurologic examination, neuropsychiatric testing, EMG, and MRI of the brain. The CHS neurological phenotype involves a mixture progressive length-dependent peripheral neuropathy with foot drop, distal atrophy, weakness, sensory loss and Parkinsonism. Cognitive function, only mildly impaired in childhood, declines progressively with worsening executive dysfunction. Cerebellar signs, basal ganglia dysfunction, upper motor neuron and posterior column dysfunction develop progressively. By their 3rd decade, most patients have diminished capacity for activities of daily living. The pervasive, late neurologic features of CHS, which occur despite BMT, are under-recognized and can appear without the classical features of the disease. The length dependent nature of several neurological features in CHS suggests a possible disruption of axonal transport within neurons. CHS should be considered in the differential diagnosis of patients with unexplained peripheral neuropathy, cognitive decline, cerebellar symptoms, Parkinsonism or long tract findings.

551F

Combined linkage and genome-wide association analysis of multiple schizophrenia (SZ) and bipolar data (BP) sets from public repositories reveals striking new evidence of distinct and overlapping genes. *V.J. Vieland[1], K.A. Walters[1], K. Tobin[2], M. Azaro[2], T. Lehner[3], L.M. Brzustowicz[2].* 1) Battelle Ctr Math Med, Res Inst Nationwide Child Hosp, Columbus, OH; 2) Dept of Genetics, Rutgers Univ, Piscataway, NJ; 3) NIMH, Bethesda, MD.

We have revisited all of the available SZ and BP multiplex family data with available genome scans from the NIMH Human Genetics Initiative (HGI) (N = 1,341 families), together with SZ and BP GWAS data from the GAIN (N = 1,984 cases, 2,393 controls), using the PPL statistical framework for the accumulation of linkage and/or association (LD) evidence across multiple potentially heterogeneous data sets. Extensive cleaning of the family data and phenotypes led to substantial changes in linkage results relative to previous publications on these data (see Walters et al., this meeting) and PPL results differed both from original publications and results of meta-analysis. Additionally the statistical framework allows us to combine linkage information from pedigrees (PPL) with association evidence from case-control data (PPLD) in a mathematically rigorous way. We have therefore undertaken combined linkage and LD mapping separately for SZ, for BP, and also across SZ and BP data looking for common genes for both disorders. We find 5 regions in which the “omnibus” linkage signal is substantially higher for SZ-BP combined than for SZ or BP alone: 5p13.3; 6q21-q22.2; 7q36.3; 10q26.2-q26.3; 14q21.3. Within each region multiple SNPs showed evidence of LD; peak PPLDs (posterior probability of LD, or trait-marker association) per region were respectively 44% (rs376538), 99% (rs9480825, rs7770621), 99% (rs10949808), 97% (rs12245508), 46% (rs12432423). Because the PPLD can show evidence against LD as well as in favor, by comparing these results with associations occurring for SZ alone and BP alone, we are able to construct a set of loci and genes influencing one disorder but not the other as well as genes increasing the risk of both disorders.

552F

***IGF2* variants are related to human episodic memory performance.** *C. Vogler[1,2,3], A. Papassotiropoulos[1,2,3], D.J.F. de Quervain[4,5].* 1) Psychiatric University Clinic, Division of Molecular Neuroscience, University of Basel, Basel, Switzerland; 2) Department of Psychology, Division of Molecular Neuroscience, University of Basel, Basel, Switzerland; 3) Department Biozentrum, Life Sciences Training Facility, University of Basel, Basel, Switzerland; 4) Department of Psychology, Division of Cognitive Neuroscience, University of Basel, Basel, Switzerland; 5) Psychiatric University Clinic, Division of Cognitive Neuroscience, University of Basel, Basel, Switzerland.

Interindividual differences in memory performance can be partially explained by genetic variation. Therefore, behavioral genetic studies are an important tool for understanding the molecular pathways that underlie human memory. Recent findings in rodent experiments indicate that hippocampal administration of insulin-like growth factor II enhances memory retention and prevents memory loss. To investigate the association of naturally occurring genetic variation in *IGF2* with memory performance in a healthy human population, we studied a cohort of N=701 young individuals that underwent a verbal episodic memory task. The discovery cohort was instructed to learn 30 words that differ in their emotional valence for immediate recall. Five minutes and 24h after presentation of these words, subjects underwent an unexpected delayed free-recall test. Genetic variation was assessed by analyzing 21 single nucleotide polymorphisms (SNPs) that cover *IGF2* as well as 50 kbp up- and downstream of *IGF2*. SNP rs11564708 was significantly associated with memory performance for neutral words in the 24 hours delayed recall task (Bonferroni corrected p-value < 0.049, unadjusted p-value = 0.0023). The association of this SNP with memory performance for neutral stimulus material could be replicated in an independent replication cohort of N=900 individuals that underwent a similar memory performance task with emotional and neutral pictures and 10 minutes and 24 delayed free recall (p-value: 0.044). Interestingly the association was only found for neutral stimuli, which is in accordance with the experimental findings in rodents. eQTL analysis in fibroblasts showed significant association with mRNA levels of *IGF2* and SNP rs3922756, which resides in close proximity to rs11564708 (intermarker distance: 13,6 kbp, linkage disequilibrium in HapMap CEU population: r2=0.94). We conclude that *IGF2* variants are associated with human memory performance, possibly through regulation of gene expression levels.

553F

Mosaic Deletion of Both Filamin A and Emerin in a Female with Periventricular Nodular Heterotopia. *J.P. Warman[1], S. Aradhya[2], K. Boycott[3].* 1) Division of Neurology, The Ottawa Hospital, Ottawa, Ontario, Canada; 2) GeneDx, Gaithersburg, MD, USA; 3) Neurogenetics Program Children's Hospital of Eastern Ontario Ottawa, Ontario, Canada.

ABSTRACT Periventricular nodular heterotopia is a rare neuronal migrational disorder with a wide clinical spectrum, ranging from clinically asymptomatic to severe cognitive impairment with seizures. The vast majority of x-linked dominant periventicular nodular heterotopia is caused by Filamin A mutations at Xq28 locus. Centromeric to Filamin A at Xq28 is the Emerin gene. Emerin gene mutations cause Emery-Dreyfuss Muscular Dystrophy and present with humoperoneal weakness, cardiac involvement and early contractures. We describe the clinical manifestations and report the results of a patient presenting with a mosaic pattern of a complete deletion of Filamn A and Emerin genes. DNA analysis revealed a deletion with a minimum size of 34.5 kb, extending from chrX:153576890-153611431, and the maximum deleted region was 67.6 kb extending from chrX:153560505-153628073. The log2 ratios for probes in Filamin A demonstrated a mosaic deletion, and the deleted interval included both the complete Filamin A and Emerin genes. This is the first report describing mosaic deletions of both Filamin A and Emerin genes in a patient with periventricular nodular heterotopia.

The Expanding Role of the Methyl-CpG-binding Domain Family in Autism Etiology. *P. Whitehead[1], H. Cukier[1], B. Butler[1], V. Mayo[1], H. Wright[2], R. Abramson[2], J. Haines[3], M. Cuccaro[1], J. Gilbert[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL. USA; 2) University of South Carolina School of Medicine, Columbia, SC, USA; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

The methyl-CpG-binding domain (MBD) genes have been linked to autism for over a decade ever since Rett syndrome, which falls under the umbrella of autism spectrum disorders (ASDs), was revealed to be caused by mutations in the MECP2 gene. Since that time, a few classic autistic patients have carried alterations in MECP2. Recent reports also demonstrate that MBD5 deletion patients present with intellectual difficulties, impaired speech, repetitive behaviors and seizures, all features commonly found in ASD patients. We now describe the first study evaluating ASD individuals in four of the remaining MBD family members, MBD5, MBD6, SETDB1 and SETDB2. All coding exons of these genes were Sanger sequenced in 576 samples (288 ASD individuals and 288 controls). We identified a total of 180 alterations, the vast majority of which were novel (129 variants, 71.7%). These novel changes were comprised of 122 SNPs and 7 insertions/deletions. The overall mutational load between cases and controls was the same; however, we identified some potentially pathogenic alterations. Fifty-two of the alterations change an amino acid sequence, including fifty-one missense variations and a three base pair deletion predicted to remove a single amino acid. Most alterations occurred in only a single individual. To determine which alterations were most likely to contribute to ASD susceptibility, we prioritized changes that were either unique to affected individuals or that had an increased frequency in cases when compared to controls. For example, we identified a MBD6 c.-2C>A change predicted to affect the Kozak consensus sequence in sixteen cases, but only five control individuals. We also identified sixteen ASD specific novel, nonsynonymous alterations. These included a MBD5 Tyr1269Cys change transmitted from a father to all three affected children. A second alteration, SETDB1 del1067Pro, was passed maternally to both affected sons. A third ASD specific change in SETDB1 Pro529Leu was identified in five singleton families, four of which were inherited maternally and one which was de novo. In two of the families with maternal transmission, the mother presented with anxiety/panic disorder. From our studies, we provide the first examples of autistic patients carrying potentially detrimental alterations in MBD6 and SETDB1, thereby demonstrating that the MBD gene family potentially plays a larger role in rare and private genetic causes of autism than was initially believed.

GRIN2B Genetic Variants Associated with Comorbid Anxiety Disorders in Women with Bulimia Nervosa. *Z. Yilmaz[1, 2], A.S. Kaplan[1, 2, 3], C.C. Zai[1, 2], R.D. Levitan[1, 2], J.L. Kennedy[1, 2].* 1) University of Toronto, Toronto, ON, Canada; 2) Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Toronto General Hospital, Toronto, ON, Canada.

Rationale: GRIN2B gene regulates the activity of NMDA receptor NR2 subunit, which acts as the agonist binding site for glutamate and has been associated with anxiety and impulse control-related disorders. Majority of patients with bulimia nervosa (BN) also report a history of anxiety disorders and a significant proportion have impulse control problems, suggesting that BN may also be associated with glutamatergic abnormalities. The purpose of this study is to (1) examine the frequency of GRIN2B genetic variants in BN and healthy controls and (2) explore the role of the GRIN2B gene in comorbid psychiatric disorders among bulimic women. **Methodology:** For the first part of the study, we genotyped 243 women with BN and equal number of ethnicity-matched female controls for GRIN2B rs2284411, rs1806201, rs1019385 and rs890, markers previously associated with psychiatric disorders. We then performed genetic analyses on the BN probands to investigate if the GRIN2B variants and haplotypes were associated with comorbid psychiatric diagnoses and severity of eating disorder symptoms. **Results:** The data analysis for the first part of the study is currently underway. Within the BN group, we found a significant association of GRIN2B markers and haplotypes with a lifetime history of anxiety disorders ($p = .015$). GRIN2B genotypes or haplotypes were not associated with childhood ADHD or history of substance use in BN probands. **Conclusions:** To our knowledge, this is the first study to look at the role of GRIN2B gene in BN. The pathophysiology of BN with comorbid anxiety disorders may be a distinct subphenotype related to underlying glutamatergic abnormalities, and these finding may have implications for treatment for BN patients with comorbid anxiety disorders.

556F

Autosomal recessive hereditary spastic paraplegia (ARHSP) - clinical and genetic characteristics. *G. Yoon[1,6], B. Baskin[2], M. Tarnopolsky[3], K.M. Boycott[4], S. Goobie[5], B. Banwell[6], P.N. Ray[2].* 1) Div Clinical & Met Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Division of Molecular Genetics, The Hospital for Sick Children, Toronto, Canada; 3) Neuromuscular and Neurometabolic Clinic, McMaster University, Hamilton, Canada; 4) Children's Hospital of Eastern Ontario, Department of Genetics, Ottawa, ON, Canada; 5) Division of Genetics, University of Western Ontario, London, Canada; 6) Division of Neurology, The Hospital for Sick Children, Toronto, Canada.

Hereditary spastic paraplegias are a heterogeneous group of disorders and may be inherited as an autosomal dominant, autosomal recessive or X-linked trait. We describe the features of 16 patients who were screened by whole gene sequencing and multiplex ligation probe amplification (MLPA) for mutations in nine genes known to cause autosomal recessive hereditary spastic paraplegia (ARHSP). Mutations were most frequent in KIAA1840 (SPG11, 8 patients) followed by SPG7 (5 patients), PNPLA6 (SPG39, 2 patients) and ZFYVE26 (SPG15, 1 patient). The types of mutations detected included missense, nonsense, splicing, frameshift and exonic deletions. Four of the patients met the clinical criteria for ARHSP but had only one confirmed mutation. Mutations predicted to cause splice site alterations were further investigated with mRNA analyses. Onset of symptoms occurred in childhood or adolescence in the majority (12/16) patients, with the predominant symptom being gait disturbance. Motor delay was not a common feature (2/16 patients), but the majority (14/16) reported significant difficulties with ambulation and falling by adulthood. Learning disability was a feature in 6/16 patients, all of whom required a modified educational program. As expected, all patients demonstrated abnormalities in corticospinal tract function (spasticity, hyperreflexia, extensor plantar response) and 14/16 also had lower extremity weakness. Speech abnormalities were present in 9/16 patients, and 4/16 had evidence of muscle atrophy. Cerebellar involvement and neuropathy were each present in 4/16 patients. Frank dementia/cognitive decline was present in 3 patients. Whole gene sequencing of nine ARHSP genes enabled the identification of mutations in both alleles for 12/16 patients and in one allele for 4/16 patients in whom the diagnosis of ARHSP was clinically confirmed. The majority of mutations were “private”, which also supports whole gene sequencing as the preferred diagnostic option for these disorders. Although there are published data suggesting an association between some clinical manifestations of ARHSP and specific genes, most patients are tested at an early stage of the disease when phenotype/genotype correlations are not obvious. Further studies of well-characterized cohorts of patients will be essential to establishing phenotype/genotype correlations that can be used to guide genetic testing.

557F

Modeling functional significance of *NRXN1* in neurodevelopment using human embryonic stem cells (hESCs) and induced pluripotent stem cells (hiPSCs). *L. Zeng[1], P. Zhang[2], W. Lu[2], K. Wang[1].* 1) Zilkha Neurogenetic Institute, University of Southern California, 1501 San Pablo Street, Los Angeles, CA, USA 90089; 2) Eli and Edythe Broad Center for Regenerative Medicine and Stem Cell Research, University of Southern California, 1425 San Pablo Street, Los Angeles, CA, USA 90089.

NRXN1 functions as a presynaptic neuronal adhesion molecule and its genetic abnormality has been linked to complex neurodevelopmental and neuropsychiatric disorders, such as Autism Spectrum Disorders (ASDs) and Schizophrenia. There are two predominant *NRXN1* isoforms, including (-*NRXN1* and the shorter) -*NRXN1*, and we are trying to understand how (-*NRXN1* deletion influences neuron development using human embryonic stem cells (hESCs) and induced pluripotent stem cells (hiPSCs) as model. We selected the Open Biosystems TRIPZ lentivirus inducible shRNAmir knockdown system to knockdown *NRXN1* expression in hESCs and hiPSCs derived neural stem cells (NSCs). The knockdown efficiency was first tested in HEK 293T cells as they have native *NRXN1* expression. qPCR data showed that, all the three shRNAmir clones led to 85%-95% knockdown of (-*NRXN1*, and the knockdown effect was subsequently confirmed by Western blot. We then differentiated hESCs cell line H9 and hiPSCs generated from human dermal fibroblasts to NSCs *in vitro*, and infected them with lentivirus shRNAmir to knockdown the expression of endogenous (-*NRXN1*. The identity of hESCs and hiPSCs was verified by pluripotency markers *Oct4*, *Nanog*, *SSEA-4*, and *Tra-1-60/81*, using immunocytochemistry and qPCR. qPCR and Western blot indicated that more than 80% of (-*NRXN1* has been knocked down in hESCs derived NSCs, and we are currently testing whether (-*NRXN1* shRNAmir produces a similar knockdown effect in hiPSCs derived NSCs. Neurons were differentiated from NSCs by removing the growth factor from conditional media, and the identity of NSCs and neurons was verified by tissue-specific markers *PAX6*, *NESTIN* and *TUJ-1* using immunocytochemistry and qPCR. We are planning to monitor the morphological (dendrite length and synaptic connection *etc.*) and electrophysiological changes in (-*NRXN1* knockdown samples during differentiation. In addition, we will collect RNA samples at 3-4 time points during neuron differentiation stage from cells with *NRXN1* knockdown and control cells. High-throughput RNA-Seq will be performed, and sequence data will be analyzed using well-established bioinformatics analysis pipelines at the Wang Lab. Our results present strong evidence that hESCs and hiPSCs are similar in terms of differentiation potential, and we will investigate how *NRXN1* plays a crucial role in neuron development.

558F

Sleep deprivation affect adult hippocampal NG2 cells and induces depression-like and anxiogenic-like behaviors in Balb-C male mice. *R. Gonzalez Castaneda[1,2], C. Martinez-Quezada[1], A. Galvez Contreras[1], O. Gonzalez-Perez[3], F. Jauregui-Huerta[1], S. Luquin de Anda[1], J. Garcia-Estrada[1], R. Ramos-Zuñiga[1].* 1) Dept Neurosciencias, Univ de Guad, CUCS, Guadalajara, Mexico; 2) Instituto Tecnológico de Estudios Superiores de Monterrey. División de Ciencias de la Salud; Escuela de Medicina. Campus Guadalajara. Guadalajara, Jalisco. México; 3) Facultad de Psicología, Universidad de Colima. Colima,Col. México.

Background: Insomnia is one of the most common sleep disorders in humans. Due to ethical and methodological difficulties involved in human research have created mouse models to evaluate what has been called Sleep Deprivation (DS). Currently there are several investigations about possible effects, but has not been able to clarify fully the implications of owning the etiology of depressive-like (DB) and anxiogenic-like (BA) behaviors. Objective: To analyze the effect of DS model on the development of anxiogenic and / or depressed behaviors in Balb-C male. Material and Methods: We used 30 Balb/C male mice divided in three groups: controls, 48-h DS group and 96-h DS group. After DS, three behavioral analyses were conducted: Forced Swimming (SF), Open Field activity (OF) and sucrose consumption (SC). Results: DS modified the behavior of exposed animals. SC quantification showed statistically significant difference among controls (17.70 ± 1.22) as compared to the 48-h SD group (13.90 ± 4.15) and the 96-h group (12.00 ± 1.88 96; P <0.05). SF assays indicates an anhedonic immobility behavior of experimental groups: 11.38 ± 5.58 (in the 48-h SD group) and 17.75 ± 3.99 (in the 96-h SD group) as compared to controls (0.00 ± .00; P< .01) and disorganized swimming behavior: 50.25 ± 12.74 (in the 48-h SD group) and 85.50 ± 14.94 (in the 96-h SD group) as compared to controls (34.0 ± 12.54; P <0.01). The OF showed a decrease in the exploratory activity in the periphery and an increase in the core areas. Conclusions: The DS promotes and maintains depressive behavior and generates anxiety.

559F

Deficits in eye movement control in children diagnosed with 22q11.2 deletion syndrome. *S.M. Nikkel[1,2], S.A. Kalwarowsky[3], S.C. Kimmett[3], J.N. Reynolds[3].* 1) Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 2) Department of Pediatrics, University of Ottawa, Ottawa, ON, Canada; 3) Department of Pharmacology and Toxicology, Centre for Neuroscience Studies, Queen's University, Kingston, ON, Canada.

The 22q11.2 deletion syndrome is associated with both cardiac and craniofacial anomalies, but it is the central nervous system dysfunction that is most likely to affect child development and day-to-day life. The measurement of eye movement control is a powerful tool for assessing brain function in different clinical populations. Saccadic eye movement behaviours reflect the integrity of multiple brain structures and oculomotor tasks have been designed to probe different aspects of behavioural and cognitive function. This study tested the hypothesis that children with the 22q11.2 deletion syndrome would have deficits in eye movement control in comparison to typically developing children. 16 children with the deletion and 32 age and sex matched controls completed prosaccade, antisaccade, delayed memory-guided sequence and predictive eye movement tasks. The circuitry controlling visually-guided saccades was found to be largely intact. However, in the tasks requiring higher cognitive control of eye movements, regulated by the prefrontal cortex and the basal ganglia, children with the syndrome exhibited deficits. These impairments are consistent with behavioural studies that demonstrate deficits in response inhibition/suppression and working memory. Deficits in saccade metrics (e.g., accuracy, amplitude, velocity) in children with the syndrome also suggested cerebellar dysfunction, which is supported by previous studies that showed reduced volume of the cerebellum, especially the vermis and other midline structures. These volumetric reductions overlap with the structures involved in cerebellar oculomotor control. This battery of eye movement tasks may allow for the assessment of frontostriatal and cerebellar function, the areas most often atypical in this population. Further work needs to be done to determine how these deficits correlate to the development of psychiatric diagnoses in individuals with the 22q11.2 deletion.

560F

GWAS Analysis across five psychiatric illnesses - Results of a combined dataset power of 56,867 individuals. *S. Ripke[1,2], Psychiatric GWAS Consortium - Cross Disorder Group.* 1) Ctr Human Gen Researc, Mass Gen Hosp, Boston, MA; 2) Broadinstitute, 7 Cambridge Center, Cambridge, MA.

A major aim of the Psychiatric GWAS Consortium was to quantify the extent of common genetic variation across several distinct psychiatric phenotypes. This was done by analyzing a combined GWAS of unprecedented size, consisting of 46 case-control-studies, for a combined study size of 56,867 independent individuals of European ancestry (N = 31,035 cases / 25,832 controls), derived from five distinct diseases: MDD (9,229 / 7,347), BIP (6,988 / 4,859), SCZ (9,372 / 7,815), AUT (3,499 / 3,864), ADD (1,947 / 1,947), where the latter two comprise mostly family-based datasets. Access to raw genotypes was crucial for several analysis steps, e.g. creating a non-overlapping collection of samples, common imputation quality/format, polygenic analysis. Initially, we show highly significant genetic overlap across studies with polygene-analysis, as described by Purcell 2009 (Nature). To determine specific SNPs contributing to this overlap, our primary analysis performed a SE (standard error) - weighted meta-analysis of the estimates of genetic effect from the five disease-specific analyses. We obtained genome-wide significant p-values for markers in ITIH3/4 (Chr. 3), MIR-137 (Chr. 1), MHC (Chr. 6), CACNA1C (Chr. 12), CACNB2 (Chr. 10), CNNM2 (Chr. 10) and TCF4 (Chr. 18), confirming multiple genes previously implicated in either single-disease studies or previously performed cross-disorder studies. Many genes within regions with suggestive p-values are undergoing further investigation. Following this primary analysis, several follow-up analyses were performed in order to statistically assess the relative contributions of the single disease samples to the top signals from the meta-analysis. Efforts to replicate the main findings will also be discussed, along with the difficulties inherent in assembling a similar sized replication set and creating a similar weighting scheme across phenotypes. In conclusion, while these large cross-disorder meta-analyses have provided some intriguing preliminary results, they also present many challenges. We will discuss steps that the Cross-Disorder-Subgroup of the PGC has taken to address some of these issues and an outlook into future analysis plans.

MDD - major depressive disorder **BIP** - bipolar disorder **SCZ** - schizophrenia **AUT** - autism spectrum disorder **ADD** - attention deficit and hyperactivity disorder.

561F

Three mutations in two causal genes (EGR2 p.Glu412Gly and MPZ p.Asp246Asn + p.Ala15Ala) in a family with dominant type of hereditary motor and sensory neuropathy type I (HMSN I). *P. Seeman[1], D. Brožková[1], R. Mazanec[2], S. Nevšímalová[3], B. Rautenstrauss[4,5].* 1) Child Neurology, DNA Lab, Charles University, 2nd School of Medicine and University Hospital Motol Prague, Praha 5, V uvalu 84, Czech Republic; 2) Neurology, Charles University, 2nd School of Medicine and University Hospital Motol Prague, Praha 5, V uvalu 84, Czech Republic; 3) Neurology Clinic, 1st Medical School, Charles University Prague and General University Hospital, Czech Republic; 4) Medical Genetics Center Munich, Bayer Str. 3-5, Munich, Germany; 5) Ludwig Maximilian University, Friedrich Baur Institute, Munich, Germany.

Hereditary motor and sensory neuropathies (HMSN) or Charcot-Marie-Tooth disorders (CMT) are clinically and genetically heterogeneous peripheral neuropathies. The demyelinating type HMSN I may be caused by mutations in more than 11 genes. CMT1D is a rare, usually severe, autosomal dominant form caused by mutations in the EGR2 gene. Mutations in the MPZ gene cause various CMT forms ranging from early onset, demyelinating to late onset, axonal. EGR2 encodes a transcription factor regulating expression of myelin genes and Schwann cell development. We report a Czech family with four members in three generations affected by HMSN I where mutations in two genes, causal for CMT are present. The proband - is now 37 years old, he was first examined at the age of 7 years due to his gait problems and distal weakness. Subsequent neurological and electrophysiological examination in his mother and older sister revealed a demyelinating neuropathy in all of them. The proband is the most severely affected in the family with CMT Neuropathy Score (CMTNS) of 21, whereas in his mother the CMTNS is only 11 and in the sister 7. Nerve conduction study showed more pronounced abnormality in the proband (MNCV 27 m/s) compared to his mother, sister and nephew (MNCV 35-39 m/s). Most common causes of dominant HMSN I were initially excluded (no CMT1A/HNPP rearrangement and no causal mutation in GJB1, PMP22 and MPZ genes). However two variants were detected in MPZ gene: the p.Asp246Asn not segregating with the disease and present in the probands healthy father and the p.Ala15Ala - probably a rare polymorfism not likely to influence splicing. Subsequent linkage analysis using SNP chips revealed 35 regions with positive linkage including 7 regions previously associated with autosomal dominant CMT. Five of these regions comprised genes associated with CMT (NEFL, YARS, EGR2, HSPB1 and already examined MPZ gene). No causal mutations were detected by sequencing of NEFL, YARS and HSPB1 genes. In EGR2 gene we detected a novel heterozygous mutation p.Glu412Gly (c.1235 A>G) segregating with HMSN I in the family. The codon p.Glu412 is highly conserved among species and another mutation was already reported at this codon. The most severely affected proband carries two missense mutations in two CMT causal genes and we propose, his earlier and severe CMT symptoms may be caused by the negative influence of the EGR2 mutation on the otherwise asymptomatic heterozygous MPZ missense mutation. IGANS10552.

562F

Functional NPY gene polymorphisms - association with antipsychotic-induced weight gain. *E.J. Brandl[1], A.K. Tiwari[1], O. Likhodi[1], H.Y. Meltzer[2], J.L. Kennedy[1], D.J. Müller[1].* 1) Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, ON , Canada; 2) Department of Psychiatry, Vanderbilt University, Nashville, TN, USA.

Objective: Significant body weight gain (BWG) is a serious side-effect of a number of antipsychotic drugs. Previous studies have demonstrated an influence of clozapine, but not haloperidol on Neuropeptide Y (NPY) expression in the brain. Since NPY is a potent orexigenic peptide stimulating food intake and genetic variation of the gene has been shown to influence development of obesity, we investigated the impact of NPY polymorphisms on antipsychotic-induced BWG. Methods: We analyzed four polymorphisms in the NPY gene (rs16147, rs16475, rs5573 and rs5574) in schizophrenia subjects (n=80), undergoing first exposure to clozapine for 6 weeks. Association was tested using analysis of covariance with change (%) from baseline weight as the dependent variable and baseline body weight as covariate. Results: A significant association of rs16147 genotype with weight change was observed (p=.002) in patients of European ancestry. Carriers of the C-allele gained significantly more weight compared to individuals with TT-genotype (TC+CC vs. TT; 5.61±5.4 vs. 0.32±4.8). Similarly, two other polymorphisms (rs5573 and rs5574) were also significantly associated with weight change (p=.009 and p=.022). The three associated polymorphisms are in high linkage disequilibrium with each other. There was no association of rs16475 (p=.654). Conclusions: Our observation of association of NPY polymorphisms gives further evidence for a genetic influence on antipsychotic-induced BWG. The polymorphism rs16147, present in the promoter region, has been previously described to affect NPY expression both in vivo and in vitro. However, these results warrant replication in independent and larger samples.

563F

Glial cell line-derived neurotrophic factor (GDNF) variations in Parkinson's disease. *D. Tegay[1], J. Gemmill[1], E. Hatchwell[2, 3].* 1) Medicine Dept, New York College of Osteopathic Medicine of NYIT, Old Westbury, NY; 2) Pathology Dept, Stony Brook University Medical Center, Stony Brook, NY; 3) Population Diagnostics, Melville, NY.

Glial cell line-derived neurotrophic factor (GDNF) is a potent survival factor for nigrostriatal dopaminergic (DA) neurons, which are known to degenerate in Parkinson's disease (PD), and altered striatal GDNF expression levels are believed to be involved in the pathophysiology of PD. Additionally, GDNF mutations have been reported to modify risk for Hirschsprung disease and severe constipation, a significant early feature of PD. Consequently, the neuroprotective properties of GDNF have been widely studied as a potential therapeutic tool to treat PD, however, GDNF variations as a contributing factor in PD pathogenesis have been inadequately explored. We employed a retrospective case-control methodology to explore the hypothesis that deleterious GDNF variations may be associated with increased PD risk by comparing mutation frequencies in subjects with PD (cases) against population frequencies (controls).

DNA from 95 anonymous PD subjects was obtained from the Coriell Cell Repositories (Plate NDPT-089). GDNF copy number variations (CNV) were detected by analysis of data obtained on a custom designed genome-wide and PD candidate gene targeted oligonucleotide multiplex aCGH platform with Agilent Feature Extraction (v10.1) and DNA Analytics (v4.0) software. PCR primers for all GDNF isoform coding regions were designed using Primer 3 (http://frodo.wi.mit.edu/primer3) with amplification followed by standard Sanger sequencing. Sequencing data was analyzed using CodonCode sequence assembly and alignment software. Novel variations and polymorphism frequencies were compared with population frequencies ascertained through online databases (TCAG DGV [http://tcag.ca] and dbSNP [http://www.ncbi.nlm.nih.gov/projects/SNP]).

Preliminary data analysis revealed that CNV's involving GDNF were present in 2 PD subjects, while studies in TCAG indicated a frequency of GDNF CNV's of 1 in 450 HapMap control samples. Additionally, differences in GDNF polymorphism frequencies in PD can be detected in comparison to reported normal control frequencies in dbSNP. This pilot data indicates the need for further studies of GDNF variation in larger cohorts to provide increased power to further elucidate statistically significant associations with PD.

564F

Co-Occurrence of Behavioral, Psychiatric, and Medical Issues in Families Ascertained for Autism and Language Learning Impairment. *Z. Fermano[1], J. Flax[1], A. Hare[1], B. Zimmerman-Bier[4], L. Hou[3], S. Yeon[3], C. Bartlett[3], S. Buyske[1, 2], L. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway , NJ; 2) Department of Statistics, Rutgers University, Piscataway, NJ; 3) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 4) Saint Peter's University Hospital, New Brunswick, NJ.

Converging evidence suggests that when compared to control families, relatives of individuals with autism exhibit behavioral, medical, and/or psychiatric characteristics that are milder but qualitatively similar to the defining features of autism. Shared etiology is of particular interest to scientists who study the genetic basis of autism. Thus, studying family members who exhibit elevated scores on ratings of (1) language deficits, (2) rigid personality traits/social aloofness, and (3) medical and psychiatric inventories, yet, do not meet the criteria for autism, allows for more specific phenotypic characterization. Over the past seven years, The New Jersey Language and Autism Genetics Study (NJLAGS) has studied families with at least one proband with autism and a second proband with a significant language learning impairment (LLI), while each family member has also been directly assessed for measures from the three domains addressed above with the goal of identifying phenotypes and behavioral biomarkers related to language and other conditions associated with autism. Since families were preselected for having at least one family member with a history of language learning problems, the rates of language, reading, and spelling are significantly higher than what would be expected in the general population. However, one-third of the families in our sample have at least one other family member, independent of the autism proband and language learning impaired proband, with a language-based learning disability. The rates of several other behavioral and psychiatric disorders (i.e., obsessive compulsive disorder, social impairment) were greater in family members (including and excluding the autism probands) than rates of these disorders in the general population. Certain medical conditions such as gastrointestinal problems and allergies were reported at higher rates based on family history questionnaire data. Moreover, there were a number of non-spectrum family members who exhibited multiple behavioral, psychiatric, or medical conditions. This study suggests that in families who were collected for a history of autism and language disorders, there is a greater risk for other behavioral, psychiatric, and medical disorders in comparison to the general population. These findings support the theory of a broader view of autism-related behaviors in families and are an essential component of phenotypic characterization for genetic linkage and association analyses.

565F

Profiles of Language and Reading Impairment in a Family Study of Autism Spectrum Disorders and Specific Language Impairment. *A. Hare[1], J. Flax[1], Z. Fermano[1], S. Buyske[2], L. Hou[3], SY. Cheong[3], B. Zimmerman[4], C. Bartlett[3], L. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Statistics, Rutgers University, Piscataway, NJ; 3) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 4) Saint Peter's University Hospital, New Brunswick, NJ.

Over the past decade, comparing the language profiles of individuals with Autism Spectrum Disorders (ASD) to individuals with Specific Language Impairment (SLI) has been one approach to investigating shared genetic etiology in the language domain for autism. While ASD may include individuals who have significant dysfunction in communication, social interactions, and repetitive and restrictive behaviors, SLI refers to individuals who have no other obvious behavioral, cognitive, or neurological issues other than deficient language. Conflicting results from previous studies either supporting or negating the genetic link, suggest that perhaps previous language phenotypes were not refined enough to address the more subtle constructs that the two disorders may share. The New Jersey Language and Autism Genetics Study (NJLAGS) has been studying families who have at least one individual with a diagnosis of Autistic Disorder and at least one other individual with SLI, with the goal of identifying language phenotypes to serve as behavioral biomarkers for linkage and association studies. This study is unique in that in addition to segmental aspects of oral language, reading and higher order language constructs are also examined. All individuals received a comprehensive neuropsychological battery including standardized measures of oral and written language. Each family has contributed a blood or saliva sample for genetic analyses. Individual family members were categorized in terms of language impairment (LI) and reading impairment (RI) based upon their scores on each respective assessment. ASD probands were compared to other sample individuals (LI, RI, and LI+RI). ASD probands who were verbal did not significantly differ from the LI group on any language and reading tasks. ASD probands scored significantly lower than the RI group on assessments that address overall spoken language ability and metalinguistic language abilities. Also, ASD probands scored significantly higher than the LI+RI group on measures of phonological awareness and word identification. The results of this study suggest that in addition to segmental language constructs such as structure and phonology, shared language behaviors might occur on the suprasegmental level and written language level and should be considered when addressing phenotypic characterizations for genetic analyses.

The use of mixed effects modelling to identify heritable autism endophenotypes for linkage and association studies. *M. Woodbury-Smith, P. Szatmari.* Department of Psychiatry & Behavioural Neurosciences, McMaster University, ON, Canada.

Autism is a neurodevelopmental disorder of early childhood onset, characterized by specific social, communicative and behavioural abnormalities. It is one of the more common childhood onset disorders, and evidence for its genetic basis has accumulated over the years. However, despite several decades of research, familial susceptibility genes have not yet been identified. This is believed to be partly due to the genetic and phenotypic heterogeneity that underlie the disorder. Supporting this, studies that have examined genetic linkage in more homogeneous phenotypic subgroups have shown improved signals. In the study described in this presentation, a more specific empirically driven method of subgrouping is proposed, in which groups are formed according to intermediate phenotypes with a priori evidence of significant heritability. Such phenotypes represent neurobiological characteristics associated with the disorder, but which, being located upstream of its clinical expression, and thereby more proximal its genetic causality, are associated with a more simple genetic architecture. In this way samples that are not only more homogeneous but also genetically enriched can be identified, and can then form the basis of subsequent genetic linkage and association studies. This presentation describes a study investigating phonological processing as a possible endophenotype of autism. Data on a measure of phonological processing, the CTOPP, have been collected on nuclear autism families recruited across Canada as part of ongoing autism genetic studies. After demonstrating the familiality of performance on the CTOPP, a mixed effects model is used to calculate the heritability of its subdomains. The mixed effects method allows for the decomposition of phenotypic variance into genetic and environmental components according to biometrical models of familial covariance. We calculated heritabilities of between 24% and 35% for the CTOPP subdomains, lending support to phonological processing as an autism endophenotype, and its potential usefulness as a measure by which families can be stratified for further linkage analysis.

Influence of the normal allele CAG expansion at age of onset in Peruvian population with Huntington's disease. *M. Cornejo[1,2,3], R. Badillo[5], N. Mori[2,3], R. Chacon[1,3], S. Lindo[1,3], V. Marca[1,3], O. Ortega[1], C. Cosentino[3,4], L. Torres[3,4], P. Mazzetti[1,3].* 1) Neurogenetics Division, Instituto Nacional de Ciencias Neurológicas , Lima, Lima 1, Perú; 2) Fogarty International Clinical Research Scholar, University of Washington; 3) Universidad Nacional Mayor de San Marcos, Lima, Perú; 4) Movement Disorders Unit, Instituto Nacional de Ciencias Neurologicas, Lima, Peru; 5) Biomedical Research Comitee, Insituto Nacional de Ciencias Neurológicas, Lima, Perú.

Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder characterized by movement disorders, cognitive impairment and abnormal behavior with progressive and fatal course. It is caused by an unstable trinucleotide CAG expansion in exon 1 of the Huntingtin gene (HTT) in chromosome 4p16.3. The CAG expansion of the abnormal allele explains around 60% of variation in clinical presentation, particularly age of onset. Other associated factors include modulating effects of other genes and environmental conditions. Many studies mostly developed in Europe and the USA have been suggested that normal Huntingtin could modulate the effects of mutant Huntingtin and influence age of onset and also severity and progression of the disease. In Peru, we have one of the biggest focuses of HD of South America, after Venezuela. We assessed the influence of the normal over the mutant one and its effect on age of onset in Peruvian Huntington's disease population. DESIGN/METHODS We used data from the National Registry for HD at the Neurogenetics Division at the “Instituto Nacional de Ciencias Neurológicas” (INCN). All DNA samples were extracted from peripheral blood leukocytes using the standardized proteinase K method, amplification of the HTT gene were made by PCR. All patients gave written informed consent. We included all participants with clinical diagnosis of HD whose ages at onset and CAG repeat numbers in both alleles (mutant allele／ 36 repeats) were available (n= 195). Using bivariate analysis we assessed the influence of the normal allele on age of onset and severity of the disease (n= with 41 UHDRS score) stratified by two different categories of the abnormal allele expansion. RESULTS In subjects with mutant CAG expansions in low range, increasing size of the normal repeat did not correlate significantly with earlier age of onset of the disease(p=0.78), while for subjects with abnormal expansions in the high range, increasing size of the normal allele repeat correlated with later age of onset and less severe symptoms (p=0.04). CONCLUSIONS In Huntington's disease, increasing number of CAG repeats in the normal allele of HTT gene seems to influence the mutant allele to delay age of onset in affected individuals in a high expansion range. This feature could be helpful for genetic counseling of pre-symptomatic individuals for HD.

Saraiva-Pereira[1 3 5].* 1) Medical Genetics Service, Hospital de Clinicas de Porto Alegre RS, Brazil; 2) Neurology Service, Hospital de Clinicas de Porto Alegre RS, Brazil; 3) Genetic Identification Laboratory, Hospital de Clínicas de Porto Alegre RS, Brazil; 4) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Brazil; 5) Department of Biochemistry, Universidade Federal do Rio Grande do Sul, Brazil; 6) Biotechnology Centre, Universidade Federal do Rio Grande do Sul, Brazil; 7) Department of Neurology, Faculty of Medical Sciences, University of Campinas (UNICAMP), Campinas, SP, Brazil; 8) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas (UNICAMP), Campinas, SP, Brazil; 9) Center of Research in Natural Resources (CIRN) and Department of Biology, University of the Azores, Ponta Delgada, Portugal; 10) Molecular and Cellular Biology Institute (IBMC), University of Porto, Porto, Portugal.

Machado-Joseph disease/spinocerebellar ataxia type 3 (MJD/SCA3) may rarely presents a parkinsonian phenotype. Since mutations in the glucocerebrosidase (GBA) gene have been associated with Parkinson disease, we investigated whether these would be more prevalent in MJD/SCA3 patients with parkinsonian manifestations than in those without them. **Methods**: MJD/SCA3 patients with parkinsonian features were identified and compared with relatives and with a MJD/SCA3 control group without Parkinson. The GBA gene was sequenced and, in a subset of patients and in normal volunteers, the enzymatic activity of GBA was measured. **Results**: we identified nine index MJD/SCA3 patients with parkinsonian manifestations. Overall, GBA sequence variations were found in 3/9 MJD/SCA3 index-cases with parkinsonian manifestations (33%) and in 0/40 MJD/SCA3 controls without parkinsonism ($p = 0.03$, Fisher exact test). The GBA sequence variations found were p.K(-27)R, p.E326K, and p.T369M. The last two sequence variations were also found in two symptomatic relatives without parkinsonian manifestations. A MJD/SCA3 relative belonging to the first positive pedigree, and carrier of the p.K(-27)R mutation, started with ataxic symptoms two years ago and presented, in the last follow-up visit, with parkinsonian manifestations. Enzymatic activities of GBA in MJD/SCA3 patients were similar to those found in the normal control group. **Conclusion**: sequence variations at GBA gene may play a role as a minor, modifying gene of the MJD/SCA3 phenotype. This hypothetical role was not related to changes in GBA activity in peripheral leukocytes.

A polyglutamine expansion in (1A calcium channel C-terminal exerts toxicity in the cytoplasm with CREB transcriptional activation. *M. Takahashi[1], M. Obayashi[1], T. Ishigurop[1], N. Sato[1], Y. Niimi[1], K. Mogushi[2], Y. Mahmut[2], H. Tanaka[2], K. Ishikawa[1], H. Mizusawa[1].* 1) Department of Neurology and Neurolgical science, Tokyo Medical and Dental University, Tokyo, Japan; 2) Information Center for Medical Sciences, Tokyo Medical and Dental University, Tokyo, Japan.

Spinocerebellar ataxia type 6 (SCA6), caused by a small polyQ expansion in the cytoplasmic carboxy(C)-tail of (1A voltage-dependent calcium channel (Cav2.1), is characterized by Purkinje cell degeneration with microscopic Cav2.1 aggregations. Recent advances in understanding SCA6 pathophysiology have shown that a 75-kDa C-terminal fragment (CTF) containing polyQ, which remains soluble in normal brains, becomes insoluble in the cytoplasm with additional localization to the nuclei in SCA6 Purkinje cells. However, the mechanism by which CTF aggregation leads to neurodegeneration is completely elusive. We here show that the CTF with a small polyQ expansion (28Qs) of a length corresponding to the normal-repeat size for other polyQ diseases causes cell death when localized in the cytoplasm rather than in the nucleus of cultured cells. By using rat pheochromocytoma (PC12) cell lines, in which expression of CTF could be induced by doxycyclin removal, we show that cytoplasmic CTF aggregation precedes cell death and induces cAMP response element-binding protein (CREB)-dependent transcription. In addition, microarray analysis revealed that expression of hypoxia-related genes Egln3 and S100a11 were consistently altered as cell death approached. In human SCA6 Purkinje cells, microscopic polyQ aggregates co-localized with CREB as in cultured cells, and staining with other antibody was coincided with the results of microarray analysis. Taken together, the present study suggests that neurodegeneration caused by CTF with a small polyQ expansion resides in the cytoplasm of Purkinje cells, and that unique changes in gene transcription associated with CREB activation may underlie SCA6 pathogenesis.

Modifier genes of age of onset in SCA diseases. *S. Tezenas du Montcel[1,2], A. Durr[3,4,5,6], G. Stevanin[4,5,6], S. Forlani[4,5,6], P. Bauer[7], O. Riess[7], C. Cazeneuve[3], A. Camuzat[4,5], A. Brice[3,4,5,6,8] for the EUROSCA group.* 1) AP-HP, Department of Biostatistics and Medical Informatics and Pitié-Salpêtrière Charles-Foix Clinical Research Unit, Paris, France; 2) University Pierre et Marie Curie, ER4, Modelling in Clinical Research, Paris, France; 3) AP-HP, Pitié-Salpêtrière Hospital, Department of Genetics and Cytogenetics, Paris, France; 4) Université Pierre et Marie Curie-Paris6, Centre de Recherche de l'Institut du Cerveau et de la Moelle épinière, UMR-S975, Paris, France; 5) Inserm, U975, Paris, France; 6) Cnrs, UMR 7225, Paris, France; 7) University of Tubingen, Tubingen, Germany; 8) AP-HP, Pitié-Salpêtrière Hospital, Federation of Neurology, F-75013 Paris, France.

Major advances have been made in the understanding of autosomal dominant cerebellar ataxias since the 1980s. A polyQ-coding (CAG)n repeat expansion has been identified as responsible for the disease in six genes: SCA1-3, SCA6-7 and SCA17. The clinical symptoms of these SCA subtypes appear above a threshold number of CAG repeats with a negative correlation between the number of CAG repeats and the age at onset. However, the correlation factor ranges from 0.5 to 0.7 in most studies suggesting that other genetic factors contribute to the variability.

Regression analysis was used to test the influence of the size of the expanded and the normal alleles of 8 polyQ genes (SCA1-3, SCA6-7, SCA17, DRPLA, HD, SBMA) on the age at onset in 1267 patients with known SCA types (SCA1: 319, SCA2: 316, SCA3: 405, SCA6: 167, SCA7: 60), recruited through the EUROSCA consortium.

We evidenced an interaction between the expanded and the normal alleles in trans in the SCA1 and SCA7 subtypes.

In addition, we found an influence of an additional polyQ gene for several SCA subtypes. For SCA2 patients, the effect of the SCA2 expanded allele was significant only for the patients with intermediate SCA7 ($p = 0.0005$). In addition, for the patients with moderately expanded SCA2 alleles, DRPLA gene protected against effect of the SCA2 gene ($p = 0.03$) ($R^2 = 53$ %). SCA3 patients had younger age at onset with smaller SCA1 alleles ($p = 0.0008$) and SCA2 intermediate alleles ($p = 0.007$) ($R^2 = 53$ %). SCA6 patients had younger age at onset with smaller SCA3 gene ($p = 0.03$), longer SCA7 gene ($p = 0.02$) and smaller DRPLA gene ($p = 0.04$) ($R^2 = 61$%). SCA7 patients had younger age at onset with an allele of SCA2 gene longer than 22 ($p = 0.02$), and smallest number of repeats for the SCA3 gene ($p = 0.03$). For SCA1 patients, none of the PolyQ genes tested influenced the age at onset.

We have shown that the polyQ genes interacts between each other in SCA diseases modifying the age at onset even with a number of repeat considered as normal. However the variances remaining after taking into account both the major gene and, when appropriate, the additional gene are still small suggesting the role of other genetic factors in these diseases.

Complete genome sequence based genetic analysis of monozygotic twins discordant (MZD) for schizophrenia. *C. Castellani[1], S. Maiti[1], R. O'Reilly[2], S. Singh[1,2].* 1) Molecular Genetics Unit, Department of Biology, The University of Western Ontario, London, Ontario, Canada; 2) Department of Psychiatry and London Health Sciences Centre, London, Ontario, Canada.

The reality of individual genome sequencing now offers a new hope in search of the cause(s) of complex diseases. When combined with genetic relationships, individual sequences add an unrivaled proficiency. Given the near identical genetic structure of monozygotic twins, any difference between monozygotic twins discordant (MZD) for a disease will have a high likelihood of being causal. With this in mind we have sequenced the DNA of six individuals, which includes two pairs of MZ twins discordant for schizophrenia and one set of parents. Sequencing was carried out using the Complete Genomics Analysis system (Drmanac *et al*, 2010). The Complete Genomics platform has a 99.999% sequencing accuracy, 47.27-fold coverage and >99% reference genome coverage. The sequences were further assessed for accuracy in relation to SNP Array 6.0 results.

Genome wide variations including SNPs, indels, CNVs and miRNAs were assessed. It has allowed us to evaluate the similarities and differences across unrelated individuals, parents and children, as well as between MZ twins. The results show that an individual carries approximately 3.7 million SNPs, 150 CNVs, 400,000 indels and 220 miRNA variants. Also, two unrelated individuals differed for 1.5-1.8 million SNPs (~45%), a parent and child differed for 0.9-1.0 million SNPs (30%) and a pair of MZ twins differed for 100,000 (~3%) SNPs. Differences in the identity of CNVs for the three comparisons were 45%, 30% and 4%, respectively. Interestingly, CNV and SNP differences between MZD twins affect a set of genes enriched in neurodevelopment, as well as genes that have been already implicated in Schizophrenia. Potentially deleterious mutations (a nonsense mutation in PDE4DIP and a nonstop mutation in LOC339742) were found in both affected patients but not in their unaffected co-twins or parental samples.

The results support our strategy and identify patient specific genetic changes that may lead to schizophrenia. The novel results re-enforce that individual genomes harbor extensive variability, some inherited and others acquired during parental meiosis and/or mitosis. There is no single human genome sequence. Even monozygotic twins are not identical and each individual may be a mosaic, potentially carrying different sequence variations in different cells.

Association between the *CLOCK* gene and autism symptoms in a community-based twin cohort. *L. Jonsson[1], H. Larsson[2], L. Westberg[1], H. Anckarsäter[3], P. Lichtenstein[2], J. Melke[1].* 1) Department of pharmacology, Neuroscience and physiology, Univ. of Gothenburg, Gothenburg, Sweden; 2) Department of medical epidemiology and biostatistics, Karolinska institute, Stockholm, Sweden; 3) Department of forensic psychiatry, Neuroscience and physiology, Univ. of Gothenburg, Gothenburg, Sweden.

Autism spectrum disorders (ASDs) are pervasive developmental disorders that include Autistic disorder, Asperger syndrome, and pervasive developmental disorder-not otherwise specified (PDD-NOS). Many patients with ASD have sleep impairments and timing problems, suggesting disturbances in the regulation of circadian rhythm as causative factors for these disorders. Indeed, low levels of melatonin are recurrent biological findings and we have previously found association between genes in the melatonin pathway and ASDs. Melatonin is closely related to the circadian rhythms, which is mainly regulated in the suprachiasmatic nucleus (SCN) by a set of clock genes. Genetic variation in the clock genes have previously been investigated in autism patients showing an association with the clock genes *PER1* and *NPAS2*. In this study, we have investigated the possible association of five core circadian clock genes on autism symptoms in a community based twin cohort. The subjects (N=1771, 9-12 years old) in this study are a subset of the "The Child and Adolescent Twin Study in Sweden" (CATSS), identified through the Swedish Twin Registry. Autism symptoms flexibility, language and social interaction were measured by the Autism-Tics, AD/HD, and other Comorbidities inventory (A-TAC), a telephone interview designed for large-scale epidemiological research in neuropsychiatry. To cover most of the genetic variability in the investigated genes, a total of 26 SNPs were genotyped in the clock genes *CLOCK*, *CRY1*, *CRY2*, *NPAS2*, and *PER1*. Our results show a significant association in girls between rs1801260, in the 3'-UTR, of the *CLOCK* gene, and the symptom flexibility ($p = 10^{-5}$), but not with the symptoms language and social interaction. Carriers of the CC-genotype had significantly higher means on the symptom flexibility. Thus, our results support the hypothesis that clock genes may be involved in autism related disorders. Moreover, since not all symptoms of autism showed similar association with the investigated genes in this study, our findings also emphasizes that genetic research may benefit from taking a symptom-specific approach to finding genes associated with autism.

573F

Genetic exploration of genome-wide variation in monozygotic twins discordant (MZD) for schizophrenia. *S. Maiti[1], K. Kumar HB[1], C. Castellani[1], R. O'Reilly[2], S. Singh[1,2].* 1) Molecular Genetics Unit, Department of Biology, The University of Western Ontario, London, Ontario, Canada; 2) Department of Psychiatry and London Health Sciences Centre, London, Ontario, Canada.

We have assessed genome-wide copy number variations (CNVs) and single nucleotide polymorphism (SNPs) in eight individuals representing two nuclear families, each with a pair of monozygotic twins discordant (MZD) for schizophrenia, using Affymetrix Human SNP array 6.0. This presentation will deal with the distribution of CNVs and SNPs across each individual. The results have allowed us to conclude the following:

Each individual carried 35 to 65 CNVs, majority (~80%) represented gains. Also, ~10 % of the CNVs were *de novo* (not present in parents). Of these, 30% arose during parental meiosis (and are present in both twins) and 70% arose during developmental mitosis (not present in parents and different between twins). We also observed novel SNPs (not present in parents) in the twins, which constituted 0.12% of all SNPs seen in the twins. In 65% of cases these SNPs arose during parental meiosis compared to 35% during development (mitosis). The best explanation for the observed differences in CNVs and SNPs between MZ twins - that started life as a single zygote - is *de novo* mutations, probably occurring during early embryogenesis. The results show that (unlike the assumption of 100% genetic identity), monozygotic twins are genetically different.

These results have major implications in the understanding of development including disease discordance. CNV and SNP differences between two MZD pairs used have led to the identification of potential genes that may explain their discordance for schizophrenia. They include three genes (PSMC1, C14orf102, KIAA0146) for family 1 and two different genes (DPRX1 and ZNF331) for family 2. Interestingly, a number of these genes have already been implicated in schizophrenia. They provide a foundation for observed genetic heterogeneity and individual specific genomic changes implicated in this complex disease. We conclude that enduring genome-wide changes, often ignored in genetic analyses involving large number of patients, if incorporated with selected patients will reinforce the search for disease related genetic changes, begin to interrogate the mechanisms involved and offer novel strategies for diagnosis and treatment.

574F

Adenosine deaminase G22A polymorphism and sleep electroencephalogram spectral power in a large population sample from Sao Paulo, Brazil. *D.R. Mazzotti, A.A.L. Souza, C. Guindalini, R. Santos-Silva, L.R.A. Bittencourt, S. Tufik.* Universidade Federal de São Paulo, São Paulo, SP, Brazil.

Background: Sleep is a complex phenomenon and certain aspects of sleep electroencephalogram (EEG) indicate that it is a heritable trait. Slow wave oscillations in EEG during sleep may reflect both sleep need and intensity, which implies in a homeostatic regulation. Adenosine is strongly implicated in sleep homeostasis and a single nucleotide polymorphism in adenosine deaminase gene (*ADA* G22A) has been associated with deeper and more efficient sleep. Objectives: The present study aimed to verify the association between sleep EEG spectral power and *ADA* G22A polymorphism in a large population sample from Sao Paulo, Brazil. Methods: Nine-hundred and fifty eight individuals of both genders participating in the Epidemiologic Sleep Study of Sao Paulo city, Brazil with age range from 20 to 80 years were subjected to an extensive sleep survey followed by full-night polysomnography. *ADA* G22A genotyping was conducted by allele-specific polymerase chain reaction. Spectral analysis of the EEG was carried out in all individuals using the Fast Fourier Transformation of the oscillatory signals for each sleep stage and for each EEG electrode. Results are represented by mean spectral power ($\mu V^2/Hz$) ± standard error of the mean, and analyses were controlled by age, body mass index and apnea/hypopnea index. Results: When compared to GG genotype carriers, A allele carriers (GA and AA genotypes) showed higher spectral power of theta bandwidth in rapid eye movement (REM) sleep (3.01±0.03 vs. 1.98±0.07; p=0.01) and in Stage 2 of non-REM sleep (2.85±0.03 vs. 1.77±0.06; p<0.01). In addition, A allele carriers also showed higher spectral power of delta bandwidth in Stage 1 (16.92±0.08 vs. 15.01±0.21; p=0.04), Stage 2 (18.20±0.09 vs. 17.21±0.22; p=0.03) and Stages 3 and 4 of non-REM sleep (18.10±0.08 vs. 16.99±0.24; p=0.03). Conclusions: The present findings suggest that the sleep of individuals carrying the A allele might be more intense, as evidenced by higher spectral power of waves related to deeper sleep. Therefore, *ADA* G22A polymorphism may exert a more refined effect on sleep by modifying specific spectral power of the sleep EEG, thus being an important source of variation in response to sleep homeostasis in humans. Acknowledgements: This work was supported by grants from AFIP, FAPESP and CNPq.

***De novo* CNVs affecting multiple genes/pathways may explain discordance of monozygotic twins for schizophrenia.** *R. O'Reilly[1], C. Castellani[2], S. Maiti[2], S. Singh[1,2].* 1) Department of Psychiatry and London Health Sciences Centre, London, Ontario, Canada; 2) Molecular Genetics Unit, Department of Biology, The University of Western Ontario, London, Ontario, Canada.

Schizophrenia is a common (1%) psychiatric disorder of high heritability (80%) and low concordance (48%) between monozygotic twins. Such epidemiological features are best explained by involvement of genetic, epigenetic and environmental interactions. Given an extensive genetic heterogeneity implicated in this disease we feel that an explanation for the discordance of MZ twins (MZD) using genome-wide analysis of rare twins may offer an insight into the causation of this disease. Specifically, we report on genome-wide copy number changes (CNCs) between six MZD twin pairs that allow identification of pair specific *de novo* CNCs that may explain their discordance.

We (O'Reilly, Psychiatrist) identified six pairs of monozygotic twins discordant for schizophrenia and collected their leukocyte DNA. The DNA was hybridized to Affymetrix Human SNP Array 6.0 that includes 1.8 million markers. CNVs were called by Affymetrix Genotyping Console 4.0 as well as Partek Genotyping Suite software. Twin pairs differed for one to thirteen CNVs. The best explanation for the observed differences in CNVs between MZ twins is *de novo* mutation (DNM) occurring during early embryogenesis. This explanation was confirmed in two of the six pairs using parental genotypes. Our analysis shows that each MZD pair differs for a number of SNPs and CNVs. More important, the SNP and CNV differences between ill and well twin invariably affect a set of genes that are implicated in neurodevelopment as identified by Ingenuity Pathways Analysis and GENEMANIA. In addition, they include already reported potential contributors to schizophrenia by family and population studies. Further, each of the six MZD pairs is different with respect to the schizophrenia related gene(s) affected. The only common pathway affected in more than one pair involves olfactory receptors that have been implicated in the development of schizophrenia.

The results show that genome wide *de novo* changes are common during ontogeny. Depending on the nature of changes and the genes involved they may contribute to discordance of MZD twins for any feature including disease. The fact that different MZD pairs have identified different genes offers support for the extensive genetic heterogeneity in schizophrenia and may argue for the need for “patient specific” etiology and treatment strategies for schizophrenia.

Gene environment interactions with a novel polymorphic Monoamine Oxidase A transcriptional enhancer element. *J.M. Plume[1], P. Wernett[1], H. Packer[1], S. Beach[2], C. Cutrona[3], G. Brody[4], R. Philibert[1].* 1) Department of Psychiatry, University of Iowa, Iowa City, IA., USA; 2) Department of Psychology, University of Georgia, Athens, GA., USA; 3) Department of Psychology, Iowa State University, Ames, IA., USA; 4) Department of Child and Family Development and Center for Family Research, The University of Georgia, Athens, GA., USA.

Monoamine Oxidase A (MAOA) is a key regulator of monoaminergic neurotransmission. Traditionally, activity of this gene has thought to be regulated by a 22 bp variable nucleotide repeat (VNTR) that is approximately 600 bp upstream of the translational start site. Unfortunately, clinical studies utilizing genetic data from this VNTR system have been not been routinely reproducible. One of the reasons for this lack of reproducibility may be the VNTR itself may be in tight linkage equilibrium with a second more functional motif. Recently, using data from the Iowa Adoption Studies, we demonstrated the existence of a 10 bp VNTR system, termed MAOA P2, that is approximately 600 bp from the first VNTR and which has both markedly greater enhancer effects and better predicts clinical outcomes. In this communication, we extend these studies to other ethnic groups and show that African Americans have considerably greater genetic diversity at this locus with at least two additional alleles. We compare and contrast the relative enhancer capacities of each of these alleles and provide an improved nosology for the classification of genetic variation in the MAOA promoter region. We conclude that the genetic regulation of the MAOA locus is more complex than previously thought and suggest that improved power for genotype/phenotype studies of this locus can obtained through the genotyping of the MAOA P2 locus.

577F

Serotonin Transporter Gene in Bulimia Nervosa: A Multiple Model Meta-Analysis. *G.N. Polsinelli, V. De Luca.* Psychiatry, Center for Addition and Mental Health (CAMH), Toronto, Ont, Canada.

Objective: Several lines of research have found that genes in the serotonergic system may cause susceptibility to eating disorders (EDs). In particular, functional polymorphisms of the serotonin transporter gene 5-HTT have been suspected to play a role in the pathogenesis of EDs. Several previous studies have investigated the association between the 5-HTTLPR polymorphism and bulimia nervosa (BN), though the results of these investigations have been unclear. The aims of this meta-analysis were (1) to investigate the association between 5-HTTLPR and BN under different models (i.e. dominant, recessive and additive); (2) extend upon previous meta-analyses by including recently published studies. Method: PsychINFO, ISI and PubMed databases were searched for studies published up until May 2011. Ultimately, eight articles were included. Data was pooled using both random and fixed effects models. Results: Using a fixed effects model, a trend was observed for the short allele conferring risk for BN (p = 0.066). However, this trend was lost once data was analyzed using a random effects model (p = 0.183). Hence, there was no association found between the 5- HTTLPR polymorphism and BN. Discussion: Considering a dominant effect, the short allele showed a slight trend in conferring risk for BN although no statistical significance was observed. However, this does not detract from recent research suggesting that the 5-HTTLPR polymorphism is one contributor within the serotonergic system that may be responsible for the phenotypic variability of psychopathological symptoms observed in patients diagnosed with BN. This should continue to be an area of further research.

An association study of the serotonin 1B receptor gene with suicidal behavior in an population isolate from Colombia. *M. Cuartas[1,2], C. Palacio[2], J. Garcia[2], M. Duque[2], G. Montoya[2], G. Bedoya[2], C. Lopez[2], CODI Grant. University of Antioquia.* 1) Psychology , University of SanBuenaventura , Medellin, Colombia, san Benito 56C Nro. 51 - 90; 2) University of Antioquia, Medellin, Colombia. calle 67 No. 53 - 108.

Background: 5-HT1B Receptor Gene interacts with inhibitory G-proteins to decrease adenylyl cyclase (AC) activity. Polymorphisms in the gene for 5-HT1B, including a common G861C marker (rs6296)has been associated with several psychiatric phenotypes;and postmortem brain studies suggest that abnormalities in serotonin 1B may be associated with suicide. Methods: in a case- control study, we tested for genetic association between the 5-HT1B G861C polymorphism and suicide associate with major depression, using a logistic regression and analyzed multiple inheritance models (co-dominant, dominant, recessive, over-dominant and log-additive), and analysis of interactions (gene-gene or gene-environment). Results: The “G” allele of a polymorphic gene at the HTR1B locus was associated with suicide behavior in patients with major depression personality disorders[(OR: 1.63 P-value: 0.03) n = 372]. Conclusions: This finding suggests that allelic variability at the HTR1B locus may be associated with suicide assocaited to major depression. This analysis was applied to historically related local population which currently are considered to be genetically isolated.

Gene Regulation by Drugs Used to Treat Mood Disorders. *X.Y. Deng[1], K. Doudney[1], P.C. McHugh[1], P.R. Joyce[2], M.A. Kennedy[1].* 1) Department of Pathology, University of Otago, Christchurch, New Zealand; 2) Department of Psychology and Psychological Medicine, University of Otago, Christchurch, New Zealand.

Antidepressant and mood stabilizer drugs are the main treatments for mood disorders including major depressive disorder and bipolar disorder.Although widely used, the mechanisms of action of these drugs are not well understood. This project seeks to establish a model system in which we can explore specific effects of such drugs on gene regulation. Findings in this area using animal models of mood are often conflicting and confusing, and we sought to develop a simple, easily manipulated model system with a relevant cellular context. Initial work focused upon promoter regions of candidate genes chosen from the literature and previous results from our laboratory. Nineteen constructs were investigated in the rat serotonergic cell line RN46A, using a luciferase reporter assay and a commonly prescribed SSRI antidepressant paroxetine. Although significant differences in expression were noted between drug-exposed and control cell cultures, the system proved inconsistent,despite considerable care in experimental design and execution. For a broader, more reliable approach, real-time quantitative PCR was utilised to detect drug-induced gene expression differences in RN46A cells. Five drugs were used: the antidepressants paroxetine, citalopram and nortriptyline; the antipsychotic haloperidol; and the mood stabilizer sodium valproate(VPA). Of five potential reference genes, Actb, G6pd and Rnf4 were stably expressed over differing treatments. We screened 39 candidate genes for expression changes attributable to drug exposure. The most striking results included a reproducible up-regulation of two genes in the biopterin pathway by the drug VPA. Members of this pathway are involved in the biosynthesis of neurotransmitters,and have previously been implicated in the biology of depression. Another gene, the serotonin receptor 2A (Htr2a) was significantly down-regulated by the SSRIs paroxetine and citalopram. Subsequently, western blotting confirmed increased protein expression of one of the upregulated biopterin pathway genes in treated cells, and detected at least three isoforms recognised by a commercially sourced antibody. Collectively, these data established the biopterin biosynthesis protein and a number of other proteins in the aetiology of mood disorders and their treatment, and provide a basis for further study of the effects of valproate and antidepressants in a mammalian setting.

Evolution of Cognition in Humans is Linked with Down regulation of the Calreticulin Gene. *E. ESMAEILZADEH GHAREHDAGHI[1], M. Ohadi[1], E. ESMAEILZADEH GHAREHDAGHI[2], A. HEIDARI[1].* 1) Genetics Research Center, University of Social Welfare , Tehran, Tehran, Iran; 2) Tehran University of Medical Sciences.

Tissue-specific expression of the CALR gene in the brain gray matter in late-adolescence and early adulthood coincides with the expression of the psychoses phenotypes. Indeed, increased expression of the chaperone genes in the prefrontal cortex has recently been reported in patients affected by schizophrenia. We have recently reported cases of psychosis-associated mutations in the CALR gene promoter. One of those mutations at -48 was found to increase the expression of the gene in comparison with the wild type sequence. A recently identified mutation at -220 reverts the conserved block harboring nucleotide -220 to the ancestral type, and has an approximate prevalence of 0.7% in psychoses. In this study, we analyzed the functional implication of this mutation in the human neuroblastoma cell line BE(2)-C, and non-neural Human Embryonic Kidney 293 (HEK-293), and show that the -220A mutation results in a constitutive increase in the expression of the CALR gene($p<0.0003$). We checked homology of the first 1000-bp CALR promoter sequence across species, and found that nucleotide -220C is the only human-unique nucleotide in that stretch. The -220A mutation ,on the other hand, co-occurs with severe cognition deficit in humans, and is the rule across the species except humans. To our knowledge, the -220A mutation is the first reported instance of a cognition deficit-associated mutation which reverses the human promoter to the primitive type. It may be speculated that, at least the basal transcription of the CALR gene, relating to the proximal promoterregion, has been decreased during the process of evolution to humans.

Examination of Serotonin Transporter Sequence Variation and Gene Expression in African-Americans. *M. Vijayendran[1], C. Cutrona[4], S.R.H. Beach[3], G.H. Brody[3], D. Russell[4], R.A. Philibert[1,2].* 1) Psychiatry, University of Iowa, Iowa City, IA; 2) Neuroscience and Genetics Programs, University of Iowa, Iowa City, IA; 3) Institute for Behavioral Research, The University of Georgia, Athens, GA; 4) Iowa State University, Ames, IA.

Although sequence variation in the coding sections of genes typically garners the most attention, other forms of genetic variation, in the form of both genetic and epigenetic variation may have greater impact on gene expression and cellular behavior. The serotonin transporter (SLC6A4) is a critical regulator of serotonergic neurotransmission and its protein product is the main target for the vast majority of anti-depressants on the market. Unfortunately, despite repeated examinations, the mechanisms underlying the regulatory control of the serotonin transporter and their relationship to major depression remain inadequately characterized, in particular with respect to depression in populations containing the Very Long (VL) gene variant. In order to better determine the relationship between the serotonin transporter linked polymorphic region (5HTTLPR) variation and gene transcription, we conducted genotyping and splice variant expression analyses using biomaterial from 180 lymphoblast cell lines contributed by African-American subjects who participated in the Family and Community Health Studies. For females, the expression levels of both exons one and eight were more statistically significant ($p<0.007$ and $p<0.051$ respectively) as compared to the expression levels of males ($p<0.17$). Also, for females, there is a significant relationship between genotype and SLC6A4 expression as measured by the exon one probe ($p<0.001$, ANOVA), but not the exon eight probe ($p<0.051$, ANOVA). Consistent with prior analyses, there was only a modestly strong correlation between exon one and exon eight transcript levels which taken together with the prior results just that the exon one assay more accurately captures the effects of the 5HTTLPR variation and that several splice variants may be expressed inside the lymphoblast cell lines. Finally, despite suggestions that the VL allele may result in greater transcriptional activation than the more common long (L) allele, we found no difference in gene expression between those cell lines possessing the VL or just the L allele. We conclude that variation in the serotonin transporter is an important regulator of transcription and that a fuller understanding of that regulation necessitates measuring more than one splice variant.

Brain transcriptome analysis by RNA-Seq reveals novel genes differentially expressed in bipolar disorder. *N. Akula[1], J.R. Wendland[1], G. Laje[1], K. Choi[2], S.K. Sen[3], H.C. Bravo[4], S.D.D. Wadleigh[1], F.J. McMahon[1].* 1) Mood and Anxiety Disorders Section, Human Genetics Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, MD, USA; 2) Department of Psychiatry and Program in Neuroscience, Uniformed Services University of the Health Sciences, Center for the Study of Traumatic Stress, Bethesda, MD, USA; 3) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 4) Center for Bioinformatics and Computational Biology, University of Maryland, College Park, MD, USA.

RNA-Seq is a relatively new technique that leverages high-throughput sequencing technologies to provide estimates of transcript abundance at a precision level not accomplished by previous hybridization-based microarray assays. RNA-Seq also enables the detection of novel, low abundant transcripts, allele-specific expression, alternative splicing, and post-transcriptional modifications, such as RNA editing. In this preliminary study, we used RNA-Seq to characterize the brain transcriptome in individuals with bipolar disorder. We performed deep-sequencing (~130M paired-end reads) of high quality total RNA (RNA-Integrity Number ⁄ 7) extracted from the prefrontal cortex (PFC) of post-mortem brains from 4 bipolar I disorder cases and 5 age- and sex-matched, psychiatrically-healthy controls, obtained from the Stanley Medical Research Institute. Fragmentation, cDNA library preparation, and PCR enrichment of the target RNA was followed by paired-end sequencing on the Illumina GA-IIx system. The resulting reads were mapped and aligned to the reference genome (hg18) using TopHat (Trapnell et al. 2009). Preliminary analysis of differential expression of known (NCBI-RefSeq and Ensemble) and alternate transcripts was performed using Cuffflinks (Trapnell et al. 2010), in parallel with HTSeq (http://www-huber.embl.de/users/anders/HTSeq/) and DESeq (Anders and Huber 2010) analyses. The transcripts with raw counts ≤ 50 were excluded from downstream analysis. Differentially expressed transcripts were identified based on a p-value ≤ 0.05, adjusted for multiple testing. These transcripts were further analyzed using DAVID (Dennis et al. 2003; Huang da et al. 2009) in order to detect enriched functional groups of genes. A total of 172 transcripts were differentially expressed by as much as tenfold; of these 154 transcripts were down-regulated in the PFC of individuals with bipolar disorder. Differentially-expressed transcripts showed significant enrichment of the Gene Ontology terms such as “neuronal development,” “apoptosis,” “G-protein coupled receptors,” and “calcium ion homeostasis.” Further analyses to identify novel alternate transcripts that are differentially expressed in the PFC of individuals with bipolar disorder are underway. These preliminary results demonstrate that RNA-Seq may reveal gene expression changes in biologically-relevant pathways that were not detected consistently in previous microarray-based expression profiling studies.

Gene RNA expression study and eQTL analysis for genes located at 13q13-q14 that showed reproductible linkage with schizophrenia and bipolar disorder in multigenerational families from Eastern Quebec. *Y.C. Chagnon, A. Bureau, J. Croteau, C. Mérette, M-A. Roy, M. Maziade.* Dept Molec Psychiatry, Laval University Robert-Giffard Res Ctr, Quebec, PQ, Canada.

BACKGROUND. We observed in our multigenerational pedigrees from the Eastern Quebec region different significant linkages with schizophrenia (SZ) and bipolar disorder (BP) in 11 chromosomal regions. Among these, a linkage at 13q13-q14 (NPLpair=2.62) proved to be replicated in a second sample of the same origin (NPLpair =3.36; combined NPLpair=5.21). OBJECTIVE. To identify possible candidate genes for this linkage at 13q13-q14 by analysing gene RNA expression for subjects from the family showing the strongest linkage at 13q13-q14. SAMPLES. 21 subjects including 4 BP, 2 SZ and 15 unaffected relatives were selected from one large pedigree showing the strongest linkage at 13q13-q14. METHODS. We evaluated RNA expression in the immortalized lymphocytes using Nimblegen whole-genome expression microarray (12 x 135K) with a MAUI hybridisation and washing system, and a Tecan 2 uM scanner. Microarray scan results were interpreted using the NimbleScan software (Roche). RESULTS. Suggestive differences between cases and non-affected relative subjects were observed for several genes on chromosome 13 including the already known candidate gene DAOA/G72 at 13q34. A variance component linkage analysis was performed on the log normalized RNA expression values of the genes showing suggestive differences between cases and non-affected relative subjects using 44 microsatellite markers covering the entire chromosome 13. The strongest linkage signals we observed ($0.0006<p<0.004$) were between the expression level of predicted gene AK095260, located at 110 Mb (5 Mb telomeric to DAOA) and D13S1493, D13S1248 and D13S1312 located respectively at 32.9, 39.7, and 44.8 Mb, the later 2 within our 13q13 linkage region, suggesting a possible interaction between the two linked regions 13q13 and 13q34 that we observed in our families. In summary, this preliminary analysis confirmed linkage results at 13q13 and provide promising leads for candidate genes selection and analysis at 13q13-q14 in our population.

Comparative co-expression network analysis of RNA-sequencing data from post-mortem brain tissue of patients of schizophrenia, bipolar disorder and healthy controls. *S. Hong[1], J. Chen[2], J. Xu[3], F. Xu[3], Y. Zhang[3], Z. Peng[3], M. Xiong[1], X. Chen[2].* 1) Department of Biostatistics, University of Texas Health Science Center, Houston, TX.,; 2) Department of Psychiatry and Virginia Institute for Psychiatric and Behavioral Genetic, Virginia Commonwealth University, Richmond, VA 23219; 3) BGI-Shenzhen, Shenzhen, China.

We have recently finished mRNA sequencing for 82 post-mortem brain samples from the collection from Stanley Medical Research Institute, of them 31 were from schizophrenia patients, 25 were from bipolar disorder patients and 26 were from healthy controls. In this study, we take advantage of the rich RNA-seq data to explore the co-expression networks amongst the 3 groups. After base-calling assessment, qualified reads are aligned to human genome reference, and mapped to known genes and transcripts. The levels of gene expression are calculated with the RPKM algorithm and normalized by sequencing batch, total number of reads per sample, brain pH, sex and age. Differential expressions amongst the groups are evaluated by t test. We find that there are 405 differential expressed genes between cases (schizophrenia and bipolar) and controls. We then use sparse graphical model to construct co-expression networks of these 405 differentially expressed genes for schizophrenia, bipolar disorder and normal tissues samples, respectively. The co-expression networks for schizophrenia, bipolar disorder and control samples share 405 common nodes, but they have considerably different numbers of edges (378, 214 and 228 respectively). We then construct differentially expressed networks (DENs) amongst the groups by subtracting the common nodes and edges between the comparing groups. The DEN between schizophrenia and control consists of 271 nodes and 340 genes and the DEN between bipolar disorder and control has 166 nodes and 180 edges. From the DENs, we have identified multiple modules that are involved in neuron development and differentiation, synaptic transmission, cell projection organization and neuronal cell morphogenesis. A total of 11 genes playing key roles in the DENs are reported to be associated with schizophrenia and bipolar disorder in the literatures.

The analysis of two SNPs of the reelin gene in a South African Autistic and Control population. *Z. Arieff[1], J. Rajan Sharma[1], F. October[1], M. Davids[1], M. Kaur[2], L. van der Merwe[1,3].* 1) Biotechnology, University of the Western Cape, Bellville, Western Cape, South Africa; 2) Computational Bioscience Research CenterTechnology, King Abdullah University of Science and Technology, Thuwal 23355-6900, Kingdom of Saudia Arabia; 3) Biostatics Unit, Medical Research Council, PO Box 17090, Tygerberg, 7505, South Africa.

Autism is a disorder characterized by a triad of impairments; namely impairment in social interaction, impaired communication skills and restrictive and repetitive behavior. Magnetic resonance imaging studies show that autism is a neurological disorder affecting the development of the brain. The reelin gene (RELN) has been identified as necessary for proper formation of brain, which indicates that RELN abnormalities could contribute to the etiology of several neurogenetic diseases such as autism. The gene is located on chromosome 7, a chromosome that has demonstrated suggestive association to autism spectrum disorders (ASD). Two SNPs on RELN, intronic rs736707 and exonic rs3622691, were investigated for evidence of association in ASD in South African autistic and healthy population. We have followed DSM-IV criteria and the screening for autism was carried out using CARS. Genomic DNA was isolated from cheek cell swabs from three distinctive South African ethnic groups (Black, Caucasian and Mixed ancestry). The Taqman ®Real-Time PCR and Genotyping assay was utilized to ascertain the distribution of alleles and genotypes. Our study group consisted of 141 unrelated autistic children and 217 unrelated control children. More than 90% were successfully typed for each SNP. The genetic association with autism was tested with logistic regression models, adjusting for gender and ethnicity. We tested association of autism with genotypes, alleles and haplotypes, inferred from the genotypes. We observed a significant additive (G) allelic association with autism (OR=0.67; 95% CI=0.45-0.98; p=0.0413, after adjusting for race and gender) for intronic SNP rs736707 of RELN in the total SA group. The G allele of SNP rs736707 is under-represented in the autistic group, indicating a possible protective effect. In addition, haplotype analysis showed that the A-G haplotype (rs736707-rs3622691) is significantly (p =0.0388; 64% versus 54%, respectively in autistic and control group after adjusting for ethnicity and gender) more prevalent in the autistic population than in control population. In conclusion, these results are interesting but require further investigation.

Brain-derived neurotrophic factor gene in Thai major depressive patients. *D. Buntup[1], S. Nuengkeaw[2], N. Sitdhiraksa[3], V. Praphanphoj[4], P. Govitrapong[2,5].* 1) Addiction Studies Program, ASEAN Institute for Health Development, Mahidol University, Nakhon Pathom, Phuthamonthon, Thailand; 2) Research Center for Neuroscience, Institute of Molecular Biosciences, Mahidol University; 3) Department of Psychiatry, Faculty of Medicine Siriraj Hospital, Mahidol University; 4) Center for Medical genetics research, Rajanukul Institute, Bangkok, Thailand; 5) Center for Neuroscience and Department of Pharmacology Faculty of Science, Mahidol University, Bangkok, Thailand.

The results from Thai national survey of epidemiology in 2003 found that major depressive disorder (MDD) is the major population among psychiatric disorders. However, the factors that influence of this disease remains unclear. Many researchers have focused on the study of the genetic risk factors. Brain-derived neurotrophic factor (BDNF) is a member of the nerve growth factor family and found in the brain of mammalian. Previous studies indicated that functional polymorphism of the BDNF gene plays an important role in development of MDD. We examined whether genetic variations in the BDNF (rs6265, Val66Met) could be associated with increased susceptibility for MDD by using a PCR-RFLP and gel electrophoresis. Blood samples were collected from 189 of patients and 184 of controls. The data showed that no significant differences were found in the frequencies of the alleles and genotypes of tested BDNF gene between patients and normal control group. This study suggests that polymorphisms in the BDNF gene may not play a major role in the genetic vulnerability for MDD in our studied population. **Acknowledgements:** This study was supported by a Mahidol University Research Grant to PG and NS and a TRF-senior Research Scholar Fellowship from the Thailand Research Fund to PG.

Neurexin 3 is associated with nicotine dependence. *E. Docampo[1], M. Ribases[2], M. Gratacos[1], R. Rabionet[1], C. Sanchez-Mora[2], C. Arribas[3], S. Moran[3], M. Montfort[3], G. Nieva[4], E. Bruguera[4], M. Casas[4], X. Estivill[1].* 1) Genes and Disease Program, Center for Genomic Regulation (CRG-UPF), CIBER en Epidemiología y Salud Publica (CIBERESP), Barcelona 08003, Catalonia, Spain; 2) Psychiatric Genetics Unit, Vall d'Hebron Research Institute (VHIR), Barcelona, Spain; 3) Barcelona Genotyping Node, CeGen-ISCIII, Barcelona, Catalonia, Spain; 4) Department of Psychiatry, Hospital Universitari Vall d'Hebron, Barcelona, Spain.

Nicotine dependence has been previously associated with Neurexin 1 gene, and prior studies on Neurexin 3 point towards its pivotal role in alcohol dependence, illegal substance abuse as well as in obesity. In order to evaluate the possible role of neurexin 3 in nicotine dependence susceptibility, we evaluated tagSNPs and candidate SNPs located along the genomic region that contains the neurexin 3 gene (NRXN3). The study included 157 samples from smoker individuals and 1,439 controls. Nicotine dependence was assessed by Fagerström index and the number of cigarettes smoked per day. All participants were of Caucasian origin. Based on the CEU HapMap genotyped SNPs, we selected Tag SNPs covering the genomic region of NRXN3 (1,170 Kb), and we forced Haploview software to include potential functional variants located near splice sites as well as SNPs that had been previously associated with disease. Case-control association analyses were performed using PLINK software. Haplotype analysis was performed with SNPassoc package of R software. After quality control, 35 SNPs and 153 cases and 1,425 controls were included for the analyses. Allelic and genotypic (log-additive model) association test showed that four SNPs were nominally associated with a lower risk of being a smoker. Based on the linkage equilibrium (LD) of the region, we defined 10 blocks. The haplotype analysis showed that one block of 35 Kb, and consisting of three of the significant SNPs in the single-SNP analysis, was also associated with lower risk of being a smoker (OR = 0.50 [0.31-0.80]; permuted P = 0.037). These preliminary results show the potential involvement of genetic variants in NRXN3 with nicotine dependence. All the significant tagSNPs and are located in introns, and although their potential biological effect is unknown, we cannot discard that they in are in LD with a true causing functional unknown variant. Finally, the replication of these results in a larger cohort of nicotine dependence is warranted.

588F

Characterization of three intronic functional polymorphisms conferring risk of schizophrenia. *A.M. Dulencin[1,2,3], N.S. Wratten[4], P.G. Matteson[1], E. DiCicco-Bloom[5], L.M. Brzustowicz[4], J.H. Millonig[1,4,5].* 1) Center for Advanced Biotechnology and Medicine, University of Medicine and Dentistry of New Jersey, Piscataway, New Jersey 08854, USA; 2) Graduate School of Biomedical Sciences, University of Medicine and Dentistry of New Jersey, Piscataway, New Jersey 08854, USA; 3) Biotechnology Training Program, Rutgers The State University of New Jersey, Piscataway, New Jersey 08854, USA; 4) Rutgers University Department of Genetics, 145 Bevier Road, Piscataway, New Jersey 08854, USA; 5) Department of Neuroscience and Cell Biology, University of Medicine and Dentistry of New Jersey-Robert Wood Johnson Medical School, Piscataway, New Jersey 08854, USA.

Schizophrenia is a common and a serious neuropsychiatric disorder with a strong genetic basis. Previous reports demonstrated significant linkage for schizophrenia to chromosome 1q22 in a sample of 22 Canadian medium-sized and multi-generational pedigrees. Further mapping and association studies identified Nitric Oxide Synthase 1 Adaptor Protein 1 (NOS1AP) as a likely susceptibility gene. NOS1AP is involved in NOS, PSD95 and NMDAR signaling which have been implicated to play role in schizophrenia pathology.

Recent experiments have identified three SNPs in intron 2 associated with schizophrenia: rs12742393 (A and C), rs1415263 (C and T), and rs4145621 (C and T). Alleles A, T, and C, respectively, are overtransmitted to affected individuals, and are also likely to be inherited together as they are in strong LD with each other (r2>0.73). Luciferase assays determined that all three intronic SNPs are functional, and that they are functional in the same way. Transfection constructs used in the assays contained 850bp of a conserved intronic sequence encompassing each allele followed by a NOS1AP promoter with a luciferase reporter gene. The schizophrenia-associated alleles increased levels of a luciferase reporter expression in rat primary cortical neurons ($p<0.01$) and in human neuronal cells (rs12742393 only, $p<0.05$). Increased expression of the schizophrenia-associated alleles for each SNP was especially noteworthy since the pairs of plasmids for each SNP differed by only a single nucleotide. Furthermore, electrophoretic mobility shift assays demonstrated that over-transmitted alleles of all three SNPs bind nuclear factors more avidly than the non-associated ones, providing a molecular explanation for the increase in expression. Moreover, bioinformatic analysis and mass spectrometry identified candidate proteins that bind better to the schizophrenia-associated alleles. Considering the unbiased approach of identification, it is compelling that many of these proteins are transcription factors and mRNA regulators known to directly participate in pathways involved in schizophrenia risk.

Identification and validation of these factors will not only link NOS1AP with pathology and phenotypic manifestations of schizophrenia, but will also suggest potential drug targets for personalized therapies.

Genetic analysis of GABRB3 in autism, schizophrenia, and heroin addiction. *C-C. Huang[1,2], SS-F. Gau[3,4], D-L. Liao[5], Y-Y. Wu[6], H-M. Tsai[7], C-H. Chen[1,7].* 1) Institute of Medical Sciences, Tzu-Chi University, Hualien, Taiwan; 2) Department of Anesthesiology, Buddhist Tzu-Chi General Hospital, Hualien, Taiwan; 3) Department of Psychiatry, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Psychiatry, National Taiwan University Hospital, Taipei, Taiwan; 5) Bali Psychiatric Center, Department of Health, Executive Yuan, Taipei, Taiwan; 6) Department of Psychiatry, Chang Gung Memorial Hospital- Linkou Medical Center, Chang Gung University College of Medicine, Tao-Yuan, Taiwan; 7) Division of Mental Health and Addiction Medicine, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan.

Objectives: Genetic variants of the GABRB3 gene have been shown to be associated with psychiatric diseases such as autism, schizophrenia, and drug addiction. The aim of this study was to search for functional genetic variants at the promoter of the GABRB3 gene and investigate their association with autism, schizophrenia, and heroin addiction in Taiwanese patients. Methods: We resequenced the 5' region of the GABRB3 gene in our subjects and carried out reporter gene activity assay of the haplotypes derived from genetic variants identified in this study. In addition, we conducted genetic association of a tag SNP (rs4906902) at the promoter region among autism, schizophrenia, and heroin addiction, and control subjects. Results: We identified three SNPs (rs4906902, rs8179184, and rs20317) at the 5' region of the GABRB3 gene which formed strong linkage disequilibrium in our population. Reporter gene activity assay revealed that two major haplotypes derived from these three SNPs had significant differential reporter activities. We observed significant differences in genotype and allele frequency distributions of the tag SNP rs4906902 between heroin addicts and control subjects, but no association with autism and schizophrenia. However, further analysis showed a significant heterozygous advantage in male control subjects compared to male autism ($p=0.01$). Conclusions: Our data indicated that SNPs at the 5' region of the GABRB3 gene may confer differential expression of GABRB3 gene, and associate with subgroups of heroin addicts and autism, given the clinical and genetic heterogeneity in autism patients. Further investigation will be of great value to explore the nature of the gene.

590F

Genetic Examination in a Subset of Autism Spectrum Disorders with Aggression. *J. Lee Robinson[1], D. Ma[1], A. Griswold[1], P. Whitehead[1], L. Nations[1], J. Haines[2], M. Cuccaro[1], M. Pericak-Vance[1].* 1) University of Miami, Miami, FL; 2) Vanderbilt University, Nashville, TN.

Genetic and phenotypic heterogeneity has been a widely recognized obstacle to understand the genetics of autism spectrum disorders (ASDs). It is estimated that up to 30 percent of individuals with ASDs display some form of aggression, potentially representing a unique subset of ASDs. Twin and adoption studies have demonstrated that genetic and environmental factors play a role in aggression. In this study, we targeted a subset of ASD families where the affected individuals display moderate to severe aggression. A genetic examination was conducted at both SNP-based association level on aggression-related genes and copy number variation (CNVs) level to see if aggression could serve as an endophenotype to dissect the heterogeneity of ASDs. A literature review of previously identified genes linked to aggression either through twin, association, or animal model studies revealed 21 potential candidate genes for analysis. Using ratings on the Autism Diagnostic Inventory-Revised (ADI-R) self-injury, aggression to caregivers and aggression to non-caregivers questions, we identified a total of 468 unrelated affected individuals with idiopathic ASD who displayed either moderate to severe aggression from 468 families. Families were ascertained through University of Miami, Vanderbilt University and the Autism Genetic Resource Exchange. Using data from high density SNP arrays, family-based association analysis was carried out using Combined Association in the Presence of Linkage test (CAPL). CNV detection was carried out on samples genotyped by Illumina 1M chip. High confidence CNVs were detected by two distinct algorithms. 199 SNPs fell into the 21 candidate gene regions. Only six SNPs presented a p-value of less than 0.05 [0.014, 0.043]. None of these survived the multiple testing corrections. A total of 327 case-unique CNVs were identified among the 129 patients who were genotyped using illumina 1M chip. However, none of the 21 candidate genes appear to be disrupted by these CNVs. In addition, a search of disrupted genes within a subset of 66 patients who had the most severe form of self-injurious behavior provided no evidence for common genetic changes. Based on these results, the subset of ASDs with aggressive behavior does not present its genetic independence indicating it may not serve as a good endophenotype to assist in dissecting the genetic heterogeneity in ASDs and suggests the potential genetic complexity of aggression itself in ASDs.

***CNR1* and *DGCR2* genes interaction may have an effect upon pathogenesis and treatment response in schizophrenia.** *V.C. Mrad[1,2], A.F.S. Filho[2,3,4], A. Gadelha[2,3,4], V.K. Ota[1,2], M.L. Santoro[1,2], F.T.S. Bellucco[1], L.M.N. Spíndola[1,2], D.M.L.V. Rocha[2,3,4], D.M. Christofolini[1], J.J. Marí[4], M.I. Melaragno[1], M.A.C. Smith[1], R.A. Bressan[2,3,4], S.I.N. Belangero[1,2].* 1) Genetics Division, Department of Morphology and Genetics, Federal University of Sao Paulo (UNIFESP), Sao Paulo, Brazil; 2) Interdisciplinary Laboratory of Clinical Neurosciences (LiNC), Sao Paulo, Brazil; 3) Schizophrenia Program (PROESQ), Department of Psychiatry, Federal University of Sao Paulo (UNIFESP), Sao Paulo, Brazil; 4) Department of Psychiatry, Federal University of Sao Paulo (UNIFESP), Sao Paulo, Brazil.

The pathogenesis of schizophrenia involves a complex interaction between genetic vulnerabilities and environmental risk factors, like cannabis use. The endocannabinoid system is involved in this process and has implications not only in its psychopathology, but also in the pharmacological response to antipsychotic drugs. The *CNR1* gene, that encodes the cannabinoid receptor 1, is on chromosome 6q14, a susceptibility locus for schizophrenia, as well 22q11.2 region, that includes several genes as the *DGCR2* (DiGeorge syndrome critical region gene 2), an adherence receptor protein coding. We aimed to investigate the interaction between *CNR1* and *DGCR2* and its influence on treatment response and on schizophrenia etiology. We recruited 143 schizophrenia patients (71 refractory and 72 non refractory). They were assessed and diagnosed according to DSM-IV and genotyped for the polymorphisms *CNR1* rs806380 and *DGCR2* rs807759 and rs2073776 by real time PCR. It was correlated to schizophrenia diagnosis, treatment refractoriness and cannabis use. Genetic stratification analysis was made in order to correct statistical confounding ethnic factors. We found a significant association between the interaction of the *CNR1* and *DGCR2* polymorphisms and the treatment refractoriness. Carriers of AA(rs807759) and AG(rs806380) genotypic combination were more frequent than the GG (rs807759)/GG (rs806380) carriers in non-refractory patients (p=0.018; OR= 0.249). Moreover, there was a notable association between the interactions of these two genes with schizophrenia etiology, showing that the AG (rs806380)/TT (rs2073776) carriers were more frequent than the CNR1 GG (rs806380)/CC (rs2073776) carriers in schizophrenia patients (p=0.011; OR=3.365). We found no kind of association with the cannabis use or the polymorphisms individually. These results showed an interaction between *CNR1* and *DGCR2* genes, where AG-genotype associated with AA-genotype, respectively, seem as a protection factor for antipsychotics refractoriness. Our data suggest these genes seem to play a role on treatment response and they could be prediction factors in the pharmacogenomics. The association with the etiology of schizophrenia reinforces the literature, suggesting a role of *CNR1* and *DGCR2* in the pathophysiology of schizophrenia. Thus, it would be interest to investigate these two genes even more in order to unravel the action mechanism of antipsychotics in the brain and validate this data in different populations.

Results from dense SNP genotyping and CNV analysis of the 9q22-q31 CRI in ASP from the NIMH and NCRAD cohorts. *R.T. Perry, H. Wiener, R.C.P. Go.* Dept Epidemiology, Assistant Professor, Univ Alabama at Birmingham, Birmingham, AL.

Background: Our original linkage scan of Alzheimer's Disease (AD) families followed by additional microsatellite genotyping confirmed and narrowed a 9q22 signal to 11.5 cM. Four candidate genes located between 2-6 Mb proximal to this peak have been reported from candidate gene and genome wide association studies to be significantly associated with AD and we have confirmed the association of one of these genes, *NTRK2*, in a separate set of families from NCRAD. Methods: We performed dense genotyping of this 18 Mb region using haplotag SNPs and unblocked SNPs from HapMap. Additional SNPs located in reported CNVs from this region were also identified and chosen. Finally, SNPs from *TOMM40*, *PICALM*, *CR1*, and *CLU* were similarly identified and genotyped. A total of ~ 5700 SNPs in 4500 individuals were genotyped using the iSelect platform from Illumina. Our preliminary genotyping results from family based association testing suggested several signals and CNVs from the 9q22 region to follow-up. Results: Using Family Based Association Testing, several signals from the 9q22 region were just below the level of significance (10-4) under an additive model after multiple testing. The only signal that reached significance was from *TOMM40* (10-13). CNV analysis was performed using PennCNV and ~15 % of the individuals were identified with at least one CNV or indel in the 9q22 region. Approximately a dozen “hot spots” appeared to be present in most of these individuals. Initial association testing of one of these “hot spots” was marginally significant (p=0.06). Conclusion: Dense SNP genotyping of the 9q22 candidate region and six Mb of genome proximal to the candidate region identified several signals that are just below the threshold of significance to AD in ASP from NIMH and NCRAD cohorts. There are also several CNVs present and preliminary testing indicates there is suggestive association with AD. Using the CNV information and the presence of functionally relevant genes and/or regulatory elements, we have begun selecting the most promising signals from the 9q22 region to follow-up by sequencing in selected families.

Paraxial mesoderm developmental genes in Chiari type I malformation: A genetic case-control association study in the Spanish population. *A. Urbizu Serrano[1], MA. Poca[2], C. Toma[3], A. Berlanga[1], J. Sahuquillo[2], B. Cormand[3], A. Macaya[1].* 1) Pediatric Neurology, Institut de Recerca Hospital Vall d'Hebron, Barcelona, Barcelona, Spain; 2) Neurosurgery, Hospital Vall d'Hebron, Barcelona, Barcelona, Spain; 3) Department of Genetics, Faculty of Biology, University of Barcelona, Barcelona, Barcelona, Spain.

Chiari type I malformation (CMI) is a disorder characterized by hindbrain overcrowding into an underdeveloped posterior cranial fossa, often causing progressive neurological symptoms. The estimated prevalence is 1/1200, with a male to female sex ratio of approximately 1:2. Diagnosis relies upon radiological evidence of downward herniation of the cerebellar tonsils, least 3-5 mm through the foramen magnum. The etiology of CMI remains unclear and is most likely multifactorial. A genetic contribution to CMI is suggested by familial aggregation and twin studies; however, the genes involved are presently unknown. Experimental models and human morphometric studies have provided evidence of occipital bone underdevelopment in CMI, suggesting an underlying paraxial mesoderm insufficiency. We performed a case-control association study of 49 candidate genes involved in early paraxial mesoderm development in a sample of 415 patients and 524 sex-matched controls. According to genetic coverage parameters we selected 384 tagSNPs from genes that participate in the signaling gradients that occur during segmental patterning of the vertebrae and included genes from the FGF8/Wnt/retinoic acid pathways and from BMP, Notch, Cdx and Hox pathways. In addition, genes from the VEFG family, critical for placental development in the 4th week embryo and genes responsible for two conditions frequently associated with CMI, NF1 and STAT3, were also included. Single-marker analysis identified nominal associations of the phenotype with eighteen SNPs in fourteen genes (CDX1, FLT1, RARG, NKD2, MSGN1, RBPJ1, FGFR1, RDH10, NOG, RARA, LFNG, KDR, ALDH1A2, BMPR1A). None of these overcame corrections for multiple comparisons, although we obtained p-values <0.002 in three genes. In contrast with previous reports in Chiari malformation type II, we did not find evidence that common variants in some of the genes involved in paraxial mesoderm or placental development in the human embryo may confer genetic susceptibility to develop the complex disorder CMI.

594F

Association analysis of Casein kinase2 with Schizophrenia in the Japanese Population. *A. Yoshikawa[1,2], F. Nishimura[1,3], M. Tochigi[1], Y. Kawamura[4], T. Umekage[5], T. Sasaki[6], K. Kasai[1], C. Kakiuchi[1].* 1) Department Neuropsychiatry, Medicine, University of Tokyo, Japan; 2) Department of Psychiatry, Fukui Memorial Hospital; 3) Department of Psychiatry, Saitama Kounan Hospital; 4) Department of Psychiatry, Yokohama Clinic; 5) Division for Environment. Health and Safety, University of Tokyo; 6) Department of Halth Education, Graduate School of Education, University of Tokyo.

Background: Schizophrenia is a devastating mental illness with worldwide lifetime risk of approximately 1%. The onset of the disease starts in young adolescence. The pathophysiological mechanisms underlying schizophrenia have not been fully elucidated. However, according to the previous family and twin studies, there is a strong evidence for a genetic contribution to the etiology. The NMDA receptor (NMDAR) is involved in the glutamatergic synatptic transmission and plays a critical role in synaptic plasticity, learnign and memory. A hypofunction of NMDA receptor has been implicated in the pathophysiology of schizophrenia. By the postmortem studies, reduced NR2B mRNA expression in hippocampus has been reported. NMDARs are composed of two NR1 subunits and two NR2A or NR2B subunits in the brain of mammals. During the critical period, the composition of the NMDAR subunit changes dramatically from NR2B to NR2A, and it may contribute to neuronal maturation process. Recently Casein kinase 2 (CK2) is reported to regulate the `switching' of NMDAR subunit via endocytosis of NR2B, and the activity of CK2 reaches their highest level during the critical period. The reduced CK2 levels in the postmortem brain of the patients and the increased levels of CK2 by antipsychotic drugs were reported. Thus, we conducted the genetic association study between CK2 and schizophrenia. **Aim of the study:**To investigate the genetic association of Casein kinase2 with schizophrenia. **Methods:**We performed a case-control association study between CK2 and schizophrenia in 384 healthy controls and 384 age and sex matched patients with schizophrenia diagnosed by DSM-IV criteria. All the subjects were ethnically Japanese. Written informed consent was obtained from all the subjects. The Ethics Committees of the Faculty of Medicine, University of Tokyo approved the study. We selected the 19 tag SNPs from the JSNP database. Genotyping was performed using the fluorogenic 5' nuclease method (Taqman, ABI7900HT). We analyzed the association by using the Haploview programs. **Results:**We detected no evidence of significant association with any tested SNPs and haplotypes of CK2. **Discussion:**No significant association was found between CK2 and schizophrenia in the Japanese population. Assessing the association with well-phenotyped schizophrenic samples such as the onset age will be needed. It will be also interesting to examine the association of other genes regulating the NMDAR switching with schizophrenia.

595F

Rare and common CLU variants and susceptibility to Alzheimer disease. *K. Bettens[1,2], N. Brouwers[1,2], S. Engelborghs[2,3], J-C. Lambert[4], R. Vandenberghe[5], F. Pasquier[6], E. Rogaeva[7], P. St. George-Hyslop[7], P.P. De Deyn[2,3], P. Amouyel[4,6], C. Van Broeckhoven[1,2], K. Sleegers[1,2].* 1) Neurodegenerative Brain Diseases Group, Department of Molecular Genetics, VIB, Antwerpen, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerpen, Belgium; 3) Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerpen, Belgium; 4) INSERM U744, Institut Pasteur de Lille, Université Lille Nord de France, Lille, France; 5) Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium; 6) Université Lille Nord de France, CHR&U de Lille, Lille, France; 7) Centre for Research in Neurodegenerative Diseases, Departments of Medicine (Neurology) and Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada.

Background: Recent GWA studies provided compelling evidence for association of the clusterin gene (CLU) and Alzheimer disease (AD) susceptibility. In this study an in-depth genetic CLU analysis was performed on a Flanders-Belgian cohort. Secondly, findings were replicated in French and Canadian samples and meta-analyses were performed on rare and common CLU variants. Methods: Additional common variants at the CLU locus were genotyped. CLU was sequenced in Flanders-Belgian individuals (849 AD patients, 659 control individuals). Significant findings were followed up sequencing exons encoding the CLU beta-chain in French (1465 AD,716 controls) and Canadian samples (525 AD,520 controls). Allele frequencies of rare variants were collapsed across the beta-chain. All possible pathogenic variants in the beta-chain were meta-analyzed combining information on 6,740 AD patients and controls. Results: Five common CLU SNPs were nominally associated with AD in the Belgian cohort ($p<0.05$). Meta-analyses combining the Belgian, French and Canadian sample confirmed association for these variants (fixed-effect p-values from 0.001 to 0.045). Additionally, patient specific rare variants (MAF<1%) were found clustering in the CLU beta-chain in the Flanders-Belgian cohort. Interestingly, five were predicted to have possible and probable damaging effects on CLU protein function. Furthermore, we observed an almost four times increase of rare protein-affecting mutations in the CLU beta-chain in AD patients compared to variants found in controls only ($p=0.02$). Sequencing the CLU beta-chain coding exons in the French and Canadian samples identified 4 patient-specific predicted pathogenic missense mutations and one deletion previously identified in Flanders-Belgian patients, and one novel mutation in a French patient. Meta-analyzing our novel sequence information with previously published information on rare predicted pathogenic variants in the CLU beta-chain, strengthened the increased presence of rare pathogenic variants in the beta-chain in AD patients compared to healthy control persons (ORMH= 1.50 [95%CI 1.12-2.01], pMH=0.005). Conclusions: Fine-mapping previous CLU association signals, our findings suggest that both common and rare CLU variants are independently contributing to AD susceptibility in populations of different ethnicity. Our results call attention to the CLU beta-subunit and warrant further functional elucidation of rare CLU variants in disease.

Genetic Association of Antidepressant Response and Meta-analysis of the Brain-Derived Neurotrophic Factor (BDNF) Val-66-Met Polymorphism in Obsessive-Compulsive Disorder (OCD). *G. Zai[1,2], C. Zai[1], E. Burroughs[3], J.L. Kennedy[1,2], M.A. Richter[1,2,3].* 1) Neurogenetics Section, CAMH, Toronto, ON, Canada; 2) Department of Psychiatry, Toronto, ON, Canada; 3) Department of Psychiatry, Sunnybrook Health Science Centre, Toronto, ON, Canada.

Background: Brain-derived neurotrophic factor (BDNF) has extensive effects on the nervous system including cell survival, differentiation, growth, and maintenance. It promotes synaptic plasticity and interacts with serotonergic neurons. The BDNF Val66Met polymorphism has been studied in obsessive-compulsive disorder (OCD) with mixed results. Other BDNF gene variants could play an important role in the etiology of OCD and could lead to changes in brain circuitry that would in turn cause variable response to antidepressants. Hypothesis: We hypothesized that genetic variation in BDNF may be associated with OCD and may predict serotonin reuptake inhibitor (SRI) response in OCD patients. Method: Meta-analysis of nine different association studies including our own between Val66Met and OCD was performed using CATMAP (R version 2.11.0). We have performed Family-Based Association Test to analyze association between BDNF and OCD, Yale-Brown Obsessive-Compulsive Scale score, and age at onset, in 150 families with an OCD proband, in addition to case-control analyses using Pearson χ^2 in 83 case-control pairs. Retrospective response data on SRI trials was collected in 107 OCD patients. Individuals were grouped into those who improved following an adequate trial of ⁄ 1 SRI(s) as compared with those who reported “minimal”, “no change”, or “worsening”. We examined four BDNF polymorphisms in addition to Val66Met. Results: Meta-analysis was negative (OR-Val=1.061, 95% CI 0.844-1.336, P=0.610). We did not detect family association between BDNF and OCD. We found nominally significant results in case-control analyses with OCD for single polymorphisms (P=0.015-0.033) including the Val allele of Val66Met (P=0.051; males: P=0.035), and a four-marker haplotype (P=0.039). C270T was associated with response to fluvoxamine treatment (genotype: P=0.025; allele: P=0.035), any SRI response (genotype: P=0.028; allele: P=0.034), and any SSRI response (genotype: P=0.028; allele: P=0.034). Conclusion: The BDNF gene may play an important role in OCD. Replication in larger and independent samples is required.

597F

A Metallothionein Gene Family Co-expression Module Is Differentially Expressed in Multiple Studies of Schizophrenia Postmortem Brains. *C. Chen[1], L. Cheng[1], F. Pibiri[1], C. Zhang[1], J. Badner[2], E. Gershon[2], C. Liu[1].* 1) Department of Psychiatry, University of Illinois at Chicago, CHICAGO, IL; 2) Department of Psychiatry and Behavioral Neuroscience, The University of Chicago, CHICAGO, IL.

Studies of differential gene expression in the brains of schizophrenia(SZ) patients have each yielded a long list of interesting candidate genes, but very few findings are consistent and replicated among studies. This may be largely due to strong heterogeneity of samples and relatively small changes in patients. We hypothesized that coordinated gene expression changes in patient brains are more robust than individual gene expression change is. We used weighted co-expression network analysis(WGCNA) to detect such changes. Five different data sets were studied, including three different brain regions (cerebellum[CB], parietal cortex [PC] and prefrontal cortex [PFC]) of the same 45 SZ and 46 normal samples from the Stanley Medical Research Institute (SMRI) collection, and two independent replicates of PFC data from the Charing Cross Hospital prospective collection (CCHPC)(28 SZ and 23 controls) and the Victorian Brain Bank Network(VBBN)(30 SZ and 29 controls). After strict quality control measures, we performed two different disease correlation tests for detected modules. First, we ran multiple linear regression models for each gene individually, with all covariates controlled, including age, pH, sex and postmortem interval (PMI). The Wilcoxon rank-sum test was applied to the correlation coefficients of cases and controls from each module, to test whether that module was enriched in disease-associated genes. Second,we calculated singular value decomposition (SVD) for each module. The top module eigengene, which is equivalent to the first principal component in principal component (PCA), was referred to as the module eigengene (ME). We tested correlation between ME and disease after adjusting all covariates by linear regression model.We found that one module, containing MT1X, MT1E, MT1F, MT1G and MT2A from the metallothionein(MT) gene family, was significantly correlated with schizophrenia in SMRI PC samples (FDR q<0.05, by both Wilcoxon rank-sum test and ME-based correlation test). This disease correlation was replicated in all the other four CB and PFC data (nominal p value<0.05) with various sample sources and microarray platforms.The MT gene family proteins can be regulated by metals and stress,are related with neuroprotection against central nervous system inflammation, neurodegeneration and cell death.It suggestedthat MT gene family is involved in schizophrenia pathogenesis.

598F

Translational profiling of serotonergic neurons identifies BRUNOL6 as a candidate gene for autism. *J.D. Dougherty[1], L. Sonnenblick[2], G. Coppola[2], A.G. Ercan-Sencicek[3], B.S. Abrahams[4], D.H. Geschwind[2], N. Heintz[5].* 1) Genetics and Psychiatry, Washington University School of Medicine, St. Louis, MO; 2) UCLA Center for Autism Research and Treatment, Semel Institute of Neuroscience, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 3) Yale University School of Medicine, New Haven, CT, USA; 4) Depts. of Genetics & Neuroscience, Albert Einstein College of Medicine, New York, NY, USA; 5) Laboratory of Molecular Biology, The Rockefeller University, New York, NY, USA.

The immense molecular diversity of neurons challenges our ability to deconvolute the relationship between the genetic and the cellular underpinnings of neuropsychiatric disorders. We suspected that comprehensive approaches to parsing this complexity may inform human genetics studies. The serotonergic system has long been suspected in a variety of disorders, including autism. We generated a bacTRAP mouse line to permit the in vivo profiling of all ongoing translation in these cells. From this, we identified 174 serotonergic-cell enriched and specific genes, including all known markers of these cells. Analysis of common variants in these genes in human families with autism implicated two genes, C1QTNF2 and the RNA-binding protein BRUNOL6. Screening for rare variants in BRUNOL6 identified a premature stop codon found only in a family with autism. This work provides a reproducible and accurate method to assess the translational profiles of serotonergic neurons under a variety of conditions in vivo, and suggests cell-specific information may provide some insight into the genetic etiology of complex psychiatric disorders.

599F

Investigation into the cause of Myoclonus Dystonia. *A. Smith[1,2], DA. Grimes[1,2,3], DE. Bulman[1,2].* 1) Ottawa Hospital Research Institute, Ottawa, Ontario, Canada; 2) University of Ottawa, Ottawa, Ontario, Canada; 3) The Ottawa Hospital, Ottawa, Ontario, Canada.

Myoclonus Dystonia (MD) (DYT11) is classified as a dystonia plus-syndrome. MD is a neurological disorder characterized by rapid muscle contractions (myoclonus) and sustained twisting movements resulting in abnormal and painful postures (dystonia). Mutations in epsilon-sarcoglycan (SGCE) have been found in approximately 40% of patients with MD. In muscle, members of the sarcoglycan (SG) family are known to form a complex. This muscle SG complex is part of the dystrophin-glycoprotein complex (DGC), which acts as a scaffolding complex. The importance of the SG complex in muscle is evident as mutations in (,) , . and +-SGs cause different forms of autosomal recessive limb girdle muscular dystrophy (LGMD). Conversely little is currently known about the DGC and the function of SGCE in the central nervous system (CNS). To determine the role of SGCE in the CNS, we have set out to characterize both the known and unknown members of SG complex members present within neurons using a mouse neuroblastoma cell line, N1E-115. First to identify the known complex members we used both RT-PCR and immunoprecipitations and found that) , + and , SG's are not only expressed in neurons but also form a complex, whereas (and . were not detected. Expanding on this we have been investigating the presence of other known members of the muscle DGC complex within our neuronal cell line using RT-PCR. We detected sarcospan, caveolin, (and) -dystroglycan, whereas dysferlin was not detected. Next, to identify the yet uncharacterized binding partners of SGCE within neurons, we are using tandem affinity purification-mass spectrometry (TAP-MS), which is an effective approach for identifying novel protein complexes, as no prior knowledge of complex members is necessary. The TAP-MS is a two-step purification process which is meant to minimize non-specific interactions. With a N1E cell line stably expressing our SGCE-CTAP fusion protein we have isolated the SG-complex present in neurons using the TAP-tag method. After purification the collected complexes have been sent for mass spectrometry. The SGCE interacting proteins will then validated and functional assessment of the interacting proteins will be performed. Elucidation of the SG complex in the brain will provide us with an understanding of how mutations in SGCE cause MD. Furthermore, the interacting proteins will be candidates for other forms of dystonia, just as the binding partners in muscle cause other forms of muscular dystrophy.

600F

Correlation between ATRA-induced and basal *CD38* expression: Clinical implications of basal expression as a response indicator to treatment of autism spectrum disorder (ASD) with retinoids. *P.S. Lai[1], O.S. Yim[2], S. Chhabra[1], H. Muralidharan[1], M. Monakhov[3], R.P. Ebstein[2].* 1) Department of Pediatrics, Yong Loo Lin School of Medicine, National University of Singapore, Singapore 119228; 2) Department of Psychology, Faculty of Arts and Social Sciences, National University of Singapore, Singapore 117570; 3) Department of Economics, Faculty of Arts and Social Sciences, National University of Singapore, Singapore 117570.

CD38 is a transmembrane glycoprotein with ADP-ribosyl cyclase activity expressed in lymphocytes, neurons and glial cells. Recently, CD38 has been shown to be essential for secretion in the brain of oxytocin (OT), a nonapeptide hormone that mediates social relationships in mice and men. Two independent studies have shown genetic association between CD38 SNPs and autism spectrum disorder (ASD). We have also shown reduced transcription of this gene in lymphoblastoid cells derived from autism subjects. Since CD38 can be upregulated in lymphocytes cultured in the presence of all-trans-retinoic acid (ATRA), an isomer of Vitamin A, we suggest the notion that retinoids may be novel therapeutic agents in ASD. Notably, basal CD38 and ATRA-modulated expression of this gene show marked individual differences prompting us to investigate whether this variability is in part due to genetic factors. To clarify the molecular basis for this variability in expression, two CD38 SNPs, rs6842880 and rs13137313, were investigated for their relationship with ATRA-induced expression. METHODS: Fresh lymphocytes from 21 subjects were cultured with and without 0.1 μM ATRA. Quantitative assay of CD38 expression was carried out using SYBR Green and normalized to) -actin mRNA. Genotyping was carried out using Taqman assays. Psychological questionnaires measuring autism, empathizing and systemizing quotients were administered to all subjects. Statistical tests were carried out using MINITAB for Windows (v.15). RESULTS: There was no significant association between the two SNPs and induced fold increase of CD38 expression. However, there was a trend of association between SNP rs6841880 and CD38 basal level (p=0.0062) with the homozygote common allele having a lower basal level. Interestingly, this genotype was associated with a higher systemizing ability (p=0.0040), a common personality trait in ASD subjects. Significant negative correlation was observed between CD38 fold increase and basal level of CD38 expression (p=0.001), suggesting that subjects with lower basal level might be more sensitive to ATRA exposure. CONCLUSION: This is the first report showing a link between basal CD38 basal levels and CD38 fold increase following ATRA treatment, suggesting that the former can be used an indicator of responsiveness to ATRA. The possible clinical implications of this study will be discussed.

Increased incidence of Attention Deficit Hyperactivity Disorder (ADHD) in children with Nail Patella Syndrome (NPS). *I. McIntosh[1,2], C. López-Arvizu[3,4], A. Diaz-Stansky[3,4], E.P. Sparrow[3,7], M.J. Strube[5], C. Slavin[2,3], J.E. Hoover-Fong[2,6], E. Tierney[3,4].* 1) Dept Molecular & Cell Biology, American University of the Caribbean, Cupecoy, St. Maarten; 2) Mckusick-Nathans Inst Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Kennedy Krieger Institute, Baltimore, MD; 4) Dept Psychiatry & Behavioral Sciences, Johns Hopkins University, Baltimore, MD; 5) Dept Psychology, Washington University, St. Louis, MO; 6) Greenberg Center for Skeletal Dysplasias & Dept Pediatrics Johns Hopkins University, Baltimore, MD; 7) Sparrow Neuropsychology, P.A., Raleigh, NC.

Nail Patella Syndrome (NPS, OMIM 161200), is an autosomal dominant disorder that is the result of loss-of-function mutations in LMX1B, a LIM-HD transcription factor. Ablation of Lmx1b has been shown to result in abnormalities in the development of the dopaminergic and serotinergic pathways. We hypothesized that subjects with NPS would present with ADHD symptoms and have shown previously that adults with NPS exhibit increased incidence of both ADHD and Major Depression. The Conners' Parent Rating Scales, Revised: Long version (CPRS-R:L) were completed for 18 children with NPS. All subjects were determined to have NPS by clinical exam. LMX1B mutation detection was carried out in subjects' genomic DNA. Elevation was reported for the following scales: Cognitive Problems/Inattention, Psychosomatic, ADHD Index, DSM-IV ADHD Inattentive, and DSM-IV ADHD Total. Overall, ADHD symptoms were present in 40% of children (vs. 2-7% in general North American population). LMX1B mutations were found in 14 of 18 subjects. There was no association between type of LMX1B mutation and elevation in any of the scales, consistent with the concept that LMX1B haploinsufficiency underlies NPS. In conclusion, inattention may comprise part of the neurobehavioral phenotype of NPS.

Summary of Elevations (T⁄ 60) on CPRS-R:L Scales of interest for 18 Boys & Girls

	DSM-IV ADHD Inattent	Cognitive Prob/ Inatt	Psycho-somatic	ADHD Index	DSM-IV ADHD Total
F	4 of 10 (40%)	5 of 10 (50%)	3 of 10 (30%)	4 of 10	3 of 10 (30%)
M	4 of 8 (50%)	4 of 8 (50%)	3 of 8 (38%)	4 of 8 (50%)	4 of 8 (50%)
Total	8 of 18 (44%)	9 of 18 (50%)	6 of 18 (33%)	8 of 18 (44%)	7 of 18 (39%)

Generation and characterization of a WNK1/HSN2-/- mouse model of hereditary sensory autonomous neuropathy type II (HSAN2). *V. Lavastre[1,2], S. Ramalingan[1,2], G. Houle[1,2], J. Laganiere[1,2], S. Laurent[1,2], R. Gaudet[1,2], P. Hince[1,2], D. Rochefort[1,2], G. Castonguay[1,2], K. Huot[1,2], P.A. Dion[1,2,3], G.A. Rouleau[1,2,4].* 1) Medicine, CHUM Research Center, Montreal, Canada; 2) Centre of Excellence in Neurosciences, Montreal, Canada; 3) Department of Pathology and Cellular Biology, Universite de Montreal, Montréal, Canada; 4) Research Center, CHU Ste-Justine, and Department of Pediatrics and Biochemistry, Universite de Montreal, Montréal, Canada.

Hereditary sensory and autonomic neuropathy type II (HSAN2) is a rare recessive and progressive disease typically diagnosed in the first decade of life. This autosomal disorder is characterized by variable sensory and autonomic dysfunction such as distal loss of sensitivity to thermal and painful stimuli leading to infections, fractures, and lacerations. Although recessive mutations in the nervous system-specific HSN2 exon of WNK1 (refers as WNK1/HSN2 isoform) and in the FAMB134B gene have been discovered, the cause of HSAN2 remains unknown. Moreover, WNK1/HSN2 is principally expressed in sensory components of the peripheral nervous system and the CNS, associated with sensory and nociceptive signals. The aim of this study is to elaborate and characterized a knock-out mouse model that reproduce part or all of the features of HSAN2 with the purpose to evaluate if the WNK1/HSN2 is required in the animal for normal behavioral responsiveness. Consequently, we generated a WNK1/HSN2 conditional ko model which targets the HSN2 exon by using the Cre/Lox conditional ko system to inactivated this gene in a temporal and spatial manner (by crossing the mouse with different Cre recombinase line). We designed a targeting vector corresponding to the WNK1/HSN2 flanked by loxP site (Flox). This construct was electroporated into embryonic stem cells. Once identified, the positive clone was injected into blastocysts and implanted in the uterus of a foster mother. The transgenic offsprings were identified by standard method and termed HSNloxP. These animals were absolutely normal, as expected, and there expression of the HSAN protein was normal. To remove the WNK1/HSN2 exon, we then crossed those mice with PCX-NLS general deletor Cre recombinase mice. Following proper recombination, this mating removed the DNA between the two loxP sites resulting in the loss of the WNK1/HSANII expression and was revealed by RT-PCR, Northern and Western blot. We are monitoring the animals on a monthly basis to test for the apparition of any disease-relevant behavioral and/or histological phenotype.

603F

A novel transgenic mouse model of Machado-Joseph Disease: genetic, phenotypic and pathologic similarities with the human disease. *S.D. Silva, A.S. Fernandes, A.N. Carvalho, A.T. Castro, C.S. Cunha, P. Maciel.* Health Sciences School, Life and Health Sciences Research Institute/3B's, Braga, Portugal.

Machado-Joseph disease (MJD), also known as Spinocerebellar Ataxia type 3 (SCA3), is an autosomal dominant neurodegenerative disorder caused by the expansion of a polyglutamine tract (polyQ) in the C-terminus of the ATXN3 gene product, ataxin-3. Although ataxin-3 is ubiquitously expressed, only restricted neuronal populations of the central nervous system are affected in the disease. We have generated three lineages of transgenic mice expressing human ataxin-3 with an expanded CAG tract under the control of the CMV promoter: CMVMJD83, CMVMJD94 and CMVMJD135, carrying Q83, Q94 and Q135 polyQ stretches, respectively. Behavioral analysis revealed that transgenic CMVMJD83 mice did not manifest motor deficits during their lifetime (84 weeks), whereas CMVMJD94 animals developed a mild motor uncoordination phenotype starting at 16 weeks of age. Interestingly, CMVMJD135 transgenic animals developed a more aggressive motor uncoordination phenotype along with other neurological features such us gait impairment, body balance deficit, loss of limb clasping, grasping and muscular tonus. Immunohistochemistry revealed that ataxin-3 is located mainly in the perinuclear regions of neurons forming small-punctate aggregates in CMVMJD94 and CMVMJD135 mice brains. In contrast, in the CMVMJD135 model we observed large intranuclear inclusions, although not exclusively in the affected areas. In summary, we have created two mouse models for MJD with different pathological and phenotypical features that may model different stages of the disease, which may contribute substantially for the understanding of MJD pathogenesis. In addition, these models are currently being used for therapeutical trials targeting different molecular pathways that might be involved in the disease such as autophagy, transcription deregulation, oxidative stress and protein aggregation/misfolding.

604F

Somatic mutations mediated by Alu in schizophrenia. *M. Ueno, A. Akahane, T. Hata, S. Nanko.* Department of Psychiatry, Teikyo University School of Medicine, Tokyo, Japan.

Recently, the dynamics of mobile elements L1 have been reported to contribute to the neuroplasticity in adult brain. The dynamics of mobile elements is not fully fixed, and might be progressively in human genome. In previous reports, we have identified the de novo mutations mediated by mobile elements in the patients with schizophrenia. Herein, we have attempted the screening of somatic mutations mediated by mobile elements Alu to clarify the dynamics of genome in schizophrenia.

DNA samples were obtained from a monozygotic twin discordant for schizophrenia and the sequential samples collected for every 5 years from a patient and a control. We performed to screen the mutations by the microarray assay using Alu-PCR products from each samples. Thereafter, Fluorescent in situ hybridization (FISH) analysis was performed on combed DNA using Alu probe and BAC probes which were containing the mutated genes regions.

Consequently, we have identified the somatic mutations mediated by Alu. The microarray assay reveals that the somatic mutations in the sequential samples and unaffected twin showed a tendency for Alu to delete. Moreover, FISH analysis on combed DNA allows us to detect the progressive deletions of Alu in the latest sample from the patient. Our results provided the evidence in support of one possible role of dynamics of Alu in schizophrenia for recovery and protection. Further research using the screenings of progressive somatic mutations is needed to clarify the etiology in schizophrenia.

This study was done under the approval of the Ethical Committee for Genetic Research, Teikyo University School of Medicine.

605F

The effect of TOMM40 poly-T length and APOE genotype on age of onset of neurodegenerative diseases: a pilot study of frontotemporal lobe dementia. *I. Grossman[1], A.M. Saunders[2], M.W. Lutz[2], O. Chiba-Falek[3, 4], K.M. Hayden[5, 6], D.G. Crenshaw[2], C.M. Hulette[7], B.L. Plassman[6], K.A. Welsh-Bohmer[5, 6], J.R. Burke[4, 5], A.D. Roses[1-4].* 1) Cabernet Pharmaceuticals, Chapel Hill, NC, USA; 2) Deane Drug Discovery Institute, Duke University, Durham, NC, USA; 3) Institute for Genome Sciences & Policy, Duke University, Durham, NC, USA; 4) Division of Neurology, Department of Medicine, Duke University, Durham, NC, USA; 5) Joseph and Kathleen Bryan ADRC, Duke University, Durham, NC, NC, USA; 6) Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, USA; 7) Department of Pathology, Duke University, Durham, NC, USA.

Background: Frontotemporal lobe dementia (FTLD) is the 4th most common form of dementia. Clinically, late onset FTLD can resemble Alzheimer's disease (AD) and often cases are misdiagnosed as AD until postmortem examination confirms FTLD pathology. Subtypes of FTLD can be characterized based on histopathological brain protein deposits, as well as presence of mutations in several genes, e.g. microtubule-associated protein tau (*MAPT*) and progranulin (*PGRN*). However, only a minority of FTLD cases carries these mutations and the high heritability attributed to FTLD (~42%) remains largely unexplained. A meta-analysis (2002) reported a trend association between the *APOE*, 2 allele and earlier onset of FTLD, an unexpected finding as *APOE*, 2 alleles are infrequent in late-onset AD and are associated with later disease onset. Additionally, we recently discovered a variable length poly-T tract in the *TOMM40* gene (rs10524523), which, together with *APOE* genotype, plays a fundamental role in age of onset (AOO) of late-onset AD. Hypothesis: *TOMM40* rs10524523 interacts with *APOE* genotype, and both influence onset age of FTLD. Methods: *TOMM40* rs10524523, *APOE* rs429358 and *APOE* rs7412 were genotyped in autopsy-confirmed, unrelated FTLD cases from the Duke ADRC and the Duke Twins Study cohorts. Genetic data were analyzed in association with AOO of first symptoms and diagnosis. Results: An initial cohort of 32 cases had an age of disease onset ranging from 42-84 (median=62). *APOE*, 2 carriers (, 2/2, , 2/3) developed FTLD significantly earlier (average AOO=51.1, N=9) than non-carriers (, 3/3, , 3/4, average AOO=65.6, p=0.0006). Stratifying each *APOE* genotype group by rs10524523 length identified a trend for the shorter poly-T to be associated with earlier FTLD AOO, particularly for *APOE*, 3 carriers. Additional samples (total N=52) are currently being analyzed. Conclusions: *APOE-TOMM40* haplotypes influence susceptibility and possibly onset age of FTLD. Our data suggest that FTLD and AD share a complex locus that affects the rate of progression to disease onset. This suggests two hypotheses: 1. there may be a common mitochondrial mechanism for dementia, despite pathologically distinct diagnoses, and 2- AD and FTLD are distinguished by a difference in amyloid pathology, but share an important genetic mechanism of differential intraneuronal cleavage of apoE2 compared to apoE3 and apoE4 proteins. Follow-up in independent, larger cohorts of FTLD and related disorders is warranted.

SCA7: clinical and genetic analysis of an Italian family. *D. Italiano[1], P. Tarantino[2], C. Lombardo[1], E.V. De Marco[2], C. Pastura[1], P. Bramanti[1], A. Quattrone[3,4], G. Annesi[2]*. 1) IRCCS Centro Neurolesi "Bonino-Pulejo", Messina, Italy; 2) Institute of Neurological Sciences, National Research Council, Cosenza, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy; 4) Neuroimaging Research Unit, National Research Council, Catanzaro, Italy.

Spinocerebellar ataxia type 7 (SCA7) is a rare form of autosomal dominant cerebellar ataxia (ADCA)clinically characterized by progressive ataxic syndrome and retinal degeneration. In several studies it represents about 2% of all ADCA. The disease is caused by the expansion of a CAG trinucleotide repeat within the SCA7 gene, encoding for a protein termed ataxin-7, of unknown function. Normal SCA7 alleles harbor from 4 to 35 CAG repeats. De novo expansions occur on intermediate alleles carrying from 28 to 35 CAG repeats. SCA7 appears to be very rare in Italy (~1%), with only four families diagnosed so far. Here we describe a family from Sicily whose proband was clinically and genetically diagnosed as SCA7. Complete neurological and ophthalmic examinations were performed to evaluate the clinical features of the disease. Molecular tests for SCA expansions were performed by polymerase chain reaction (PCR). PCR products were separated onto a capillary sequencer (3130Xl genetic analyzer Applied Biosystems) and the length of specific SCA fragments was calculated referring to a size standard and to related SCA controls. The proband was a 49-year-old man presenting progressive gait disturbances, clumsiness and visual impairment for three years. Neurological examination revealed bilateral and symmetrical gait and limb ataxia, dysarthria, slight solid dysphagia and dysmetria. Brain MRI showed vermian and hemispheric cerebellar atrophy. Ophthalmologic work-up revealed markedly decreased visual acuity, hypermetric saccadic eye movements and pigmentary changes in macular and peripheral retinal regions. Molecular analysis identified an expanded allele with 38 CAG repeats within the SCA7 gene. The 25-year-old proband's son was normal at neurological examination, but he had complained of visual impairment for two years. Ophthalmologic examination revealed reduced visual acuity and early macular pigmentary disturbances. He refused to undergo genetic analysis. In this family the proband presented a low number of pathologic GAC repeats (38) and his parents were reported as not exhibiting any neurological disturbance, so we can argue that the disease is probably caused by a de novo expansion of a premutated intermediate allele carried by one parent. The proband's son can be considered as probably affected since his retinal changes were strongly suggestive of cone-rod dystrophy. This would confirm the extreme anticipation (20 years /generation) previously observed in SCA7.

Two new Rett syndrome families: expanding the knowledge of *MECP2* frameshift mutations. *K. Ravn[1,2], G. Roende[1], M. Duno[3], K. Fuglsang[1], KL. Eiklid[4], Z. Tümer[2], JB. Nielsen[1], OH. Skjeldal[5]*. 1) Center for Rett syndrome, Kennedy Center, Glostrup, Denmark; 2) Center for Applied Human Molecular Genetics, Kennedy Center, Glostrup, Denmark; 3) Department of Clinical Genetics, University of Copenhagen, Rigshospitalet, Denmark; 4) Department of Medical Genetics, Oslo University Hospital HF, Ullevål Hospital, Oslo, Norway; 5) Women and Children's Clinic, Vestre Viken Hospital Thrust, Norway.

Background: Rett syndrome (RTT) is an X-linked dominant neurodevelopmental disorder, which is usually caused by *de novo* mutations in the *MECP2* gene. More than 70 % of the disease causing *MECP2* mutations are eight recurrent C to T transitions, which almost exclusively arise on the paternally derived X chromosome. About 10 % of the RTT cases have a C-terminal frameshift deletion in *MECP2*. Only few RTT families with a segregating *MECP2* mutation, which affects female carriers with a phenotype of mental retardation or RTT, have been reported in the literature. In this study we describe two new unrelated families with three and four individuals, respectively. Furthermore, we compare the type of mutations observed in RTT families to those of the sporadic cases and we present our study on the parental origin of *de novo MECP2* frameshift mutations in our RTT cohort. **Results**: In both families a C-terminal frameshift mutation segregates. Clinical features of the mutation carriers vary from classical RTT to mild mental retardation. XCI profiles of the female carriers correlate to their respective geno-/phenotypes. The majority of the de novo frameshift mutations occur on the paternally derived X chromosome (7/9 cases), without a paternal age effect. **Conclusions**: The present study suggests a correlation between the intrafamilial phenotypic differences observed in RTT families and their respective XCI pattern in blood, in contrast to sporadic RTT cases where a similar correlation has not been demonstrated. Furthermore, we found *de novo MECP2* frameshift mutations frequently to be of paternal origin, although not with the same high paternal occurrence as in sporadic cases with C to T transitions. This suggests further investigations of more families. This study emphasizes the need for thorough genetic counselling of families with a newly diagnosed RTT patient.

Analysis of modulation of FXTAS rCGG-mediated neurodegeneration by CUGBP1 in Mus musculus. *Z.A. Zalewski[1], P. Jin[2], L.T. Timchenko[3], D.L. Nelson[1]*. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) Department of Molecular Physiology and Biophysics, Baylor College of Medicine, Houston, TX.

Fragile X-associated Tremor/Ataxia Syndrome, or FXTAS, has been identified as a late-onset neurodegenerative disorder in Fmr1 premutation carriers, principally in older males. The neuropathological hallmarks of FXTAS include ubiquitin-positive intrauclear inclusion bodies throughout the brain and marked dropout of cerebellar Purkinje neurons. We hypothesize that FXTAS arises though an RNA-mediated gain-of-function toxicity model. In this model, the ribo-CGG (rCGG) repeat acts to functionally limit rCGG repeat-binding proteins. Previous work in Drosophila demonstrated the singular sufficiency of rCGG to exert a toxic gain-of-function. The Drosophila ortholog of hnRNP A2/B1 was found to be capable of suppressing phenotype and binding rCGG. A subsequent genetic screen identified CUGBP1 as a specific interacting partner of hnRNP A2/B1, and also as a modifier of rCGG-mediated toxicity. We report our recent work in furthering these earlier results using mouse models. We previously reported two Purkinje neuron -specific transgenic models in which a CGG premutation is fused to a reporter (FMR1 or EGFP), and are also making use of the "knock-in" model developed by the Oostra group, which replaces the endogenous 5 CGG repeats with a >100 CGG-repeat fragment within the Fmr1 locus. We predict that reduced levels of CUGBP1 will exacerbate rCGG phenotypes and that CUGBP1 overexpression will rescue the FXTAS phenotype. To this end, we have developed two mouse models to examine the role of Cugbp1 in FXTAS pathogenesis: a gene trap loss-of-function, in which vector pGT1Lxf has been inserted into the second intron within the coding sequence of Cugbp1, and mice with tetracycline-controlled overexpression of Cugbp1 in Purkinje neurons. We have crossed these mice to our FXTAS mouse models and are in the process of determining the resulting phenotypes. These results should significantly advance our understanding of FXTAS pathogenesis, and provide potential targets for therapeutic intervention.

Bayesian SNP-set Analysis for Case-control Genome-wide Association Studies. *X. Wang[1], D. Qian[2].* 1) Department of Population Science, City of Hope, Duarte, CA 91010; 2) Department of Biostatistics, City of Hope, Duarte, CA 91010.

Despite the success in genome-wide association studies (GAWS), the single marker association tests suffer from the limited power to identify disease genes. Some genes may be genuinely associated with disease trait, but each marker within a gene may contain little variation and not satisfy a stringent genome-wide significance threshold in any GWAS. Therefore, association analysis requires statistical methods that can effectively combine the information across markers within a gene or several genes and estimate their overall effect. In this study, we extend a Bayesian SNP set analysis method using Bayesian generalized linear model to test the joint effect of each SNP set while adjusting for additional covariate effects including demographic and environmental variables. Our method jointly models the overall effect of a SNP set and the weights of multiple markers within the SNP set. Rather than predetermining the weights of markers in the existing methods, our method estimates them based on their contributions to disease trait. Using simulated data, we have shown our method can control type I error rates very well. We will conduct more extensive simulation studies to evaluate the performance of our method by comparing with the existing methods.

Multivariate quality control improves genotyping accuracy and call rate. *B.T. Webb[1], J.E. Dellava[1], L.M. Hack[1], M.C. Neale[1], A. Corvin[2], M. Gill[2], F.A. O'Neill[3], D. Walsh[4], K.S. Kendler[1], B.P. Riley[1].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 2) Department of Psychiatry, Trinity College Dublin, Dublin, Ireland; 3) Department of Psychiatry, Queens University, Belfast, Northern Ireland, United Kingdom; 4) Health Research Board, Dublin, Ireland.

Genotype calling using SNP arrays can be biased by inclusion of poor quality samples in a data set. Identifying and removing problematic samples can be time consuming and subjective but keeping poor quality samples can lead to spurious results. Ideally, an iterative process of identification and exclusion followed by recalling should be used. Although many quality control (QC) measures are routinely generated as part of genotyping pipelines, few variables are commonly used to filter samples (e.g., call rate and contrast QC for Affymetrix arrays). This study aimed to develop and evaluate a multivariate approach to identifying poor quality samples in order to maximize genotyping calling and accuracy. Using 4548 Affymetrix 6.0 SNP arrays genotyped as part of the Welcome Trust Irish Schizophrenia Case Control Sample (ISCCS), factor analyses were performed on QC variables generated pre and post genotyping. Using 19 measures, a four factor solution fit best and accounted for 0.758 of the cumulative variance. Since loadings differed by sex, a three factor model fit best for sex specific analysis. Factor scores were then used to calculate a median Mahalanobis distance score. Replicate arrays were used to evaluate the utility of the multivariate Mahalanobis Score (MVMS) based sample filtering in improving genotype call quality. The MVMS, call rate, and contrast QC were correlated with discordance. Removing the worst 5% of arrays by MVMS resulted in a substantial reduction of discordant genotypes than using a single QC measure. To further test the MVMS, a subset of 162 replicate arrays representing 73 samples were recalled (Birdseed v2) under three conditions. The 162 replicates were paired with an additional 162 arrays representing the best, random, and worst arrays by MVMS. Discordance and fail rate was examined in high and low quality SNPs. The fail rate was highest and lowest in the replicates called in the presence of the worst and best MVMS arrays, respectively. Little difference was observed between the best and random array sets. The effect of external array quality on replicate array fail rate and discordance was increased for poor SNPs. In conclusion, the MVMS has the advantage of identifying samples that are lower quality across different domains but would fail to be excluded using only univariate thresholds. Therefore, using the MVMS potentially reduces the number of samples needed to be excluded to improve genotype calling.

Characterisation of genome-wide association epistasis signals for serum uric acid in human population isolates. *W. Wei[1], G. Hemani[2], A. Hicks[3], V. Vitart[1], C. Cabrera-Cardenas[1], P. Navarro[1], J. Huffman[1], C. Hayward[1], S. Knott[4], I. Rudan[5,6], P. Pramstaller[3,7,8], S. Wild[5], J. Wilson[5], H. Campbell[5], N. Hastie[1], A. Wright[1], C. Haley[1,2].* 1) Biomedical System Analysis, MRC Human Genetics Unit, Edinburgh, Scotland, United Kingdom; 2) The Roslin Institute and R(D)SVS, University of Edinburgh, Roslin, Midlothian, UK; 3) Institute of Genetic Medicine, European Academy Bozen/Bolzano (EURAC), Bolzano, Italy. Affiliated Institute of the University of Lübeck, Germany; 4) Institute of Evolutionary Biology, University of Edinburgh, Edinburgh, UK; 5) Centre for Population Health Sciences, University of Edinburgh, Edinburgh, UK; 6) Croatian Centre for Global Health, University of Split, Split, Croatia; 7) Department of Neurology, General Central Hospital, Bolzano, Italy; 8) Department of Neurology, University of Lübeck, Lübeck, Germany.

Genome-wide association (GWA) studies so far have identified nine loci underlying human serum uric acid (SUA) levels including the *SLC2A9* gene. Gene-gene interactions (epistasis) are largely unexplored in these GWA studies. We performed a full pair-wise genome scan in the Italian MICROS population (n = 1201) to characterise epistasis signals in SUA levels. In the resultant epistasis profile, no SNP pairs reached the Bonferroni adjusted threshold for the pair-wise genome-wide significance. However, *SLC2A9* was found interacting with multiple loci across the genome, with *NFIA - SLC2A9* and *SLC2A9 - ESRRAP2* being significant based on a threshold derived for candidate gene interactions and jointly explaining 8.0% of the phenotypic variance in SUA levels (3.4% by interaction components). Epistasis signal replication in a CROATIAN population (n = 1772) was limited at the SNP level but improved dramatically at the gene ontology level. In addition, gene ontology terms enriched by the epistasis signals in each population support links between SUA levels and neurological disorders such as cognitive aging. We conclude that GWA epistasis analysis is valuable in small isolated populations.

Analyze X: A Comparison of X Chromosome and Autosomal Results in GWAS. *A. Wise, L. Gyi, T. Manolio.* National Human Genome Research Institute (NHGRI), Bethesda, MD.

Genome-wide association studies (GWAS) have identified over 1,200 associations with p<5x10-8 for over 200 traits, yet only 7 such associations have been reported on the X chromosome (chr). This raises the question: why is the X chr so poorly represented in GWAS results? A review of over 300 GWAS suggests that this is largely due to exclusion of X chr variants from analyses as one of the first steps of quality control, despite these regions being assayed on many current microarray platforms. Reviewing the NHGRI Catalog of Published GWAS (www.genome.gov/gwastudies) showed that only 121 of 374 (32%) of GWAS published from Jan 2010 through Mar 2011 reported analyzing the X chr in their Methods sections. Accounting for the number of genes on the X chr also does not eliminate the gap in GWAS associations; as the X chr (1,669 genes) has only 7 reported associations at 5 distinct loci, while chr 7 (1,880 genes) has 48 reported associations at more than 20 distinct loci. Interrogating all of the variants found in papers that identified X chr hits at p<1x10-5 in the NHGRI Catalog, to account for sample size and genotyping platform variations, X chr variants have similar minor allele frequencies (MAFs) as autosomal variants (X chr avg MAF=0.34 and autosomal avg MAF=0.39, p=0.27). Median p-values for the hits found on the X chr were higher, however, by approximately 1 order of magnitude than those seen for autosomal variants in these same studies (p=0.04), indicating that power may indeed be an issue perhaps due to smaller effective chr numbers. Comparing the functional classes assigned to these variants by NCBI, none (0/51) of the variants on the X chr were missense or synonymous variants, as compared to 5% (27/582) of the autosomal variants. Intronic variants were found in similar proportions in the X chr and autosomal hits, 31% and 37% respectively; while intergenic variants, on the other hand, were more common amongst the X chr hits, 67% versus 49%, p=0.02. Given the similarity found between the X chr and other autosomes in variant MAFs, and overall number of genes, these factors cannot explain why the X chr is so poorly represented in GWAS results. However, the higher p-values found on the X chr and lack of missense or synonymous variants point towards potential issues with power. Improvements in genotype calling accuracy and methods developed specifically for the X chr may thus improve power to detect important associations on the X chr in future GWAS.

613F

Detecting Pleiotropy via Bayesian Latent Variable Modeling. *L. Xu[1], R. Craiu[1], A.D. Paterson[2,3], L. Sun[2,1].* 1) statistics, University of Toronto, Toronto, Ontario, Canada; 2) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto,Toronto, Ontario, Canada; 3) Genetics and Genomic Biology, Hospital for Sick Children, Toronto, Ontario, Canada.

Pleiotropy occurs when a single gene influences multiple quantitative or qualitative phenotypes and is present in many loci for complex diseases or traits. For example, in genetic studies of complications or secondary manifestations of a disease, it is often believed that there are common genetic risk factors for the different phenotypes. In other cases, the primary and often conceptual phenotype (e.g. disease severity) may not be directly measured and a set of surrogate response variables must instead be used. Robust and powerful methods for the study of pleiotropy are underdeveloped in the literature due to data complexities, which include a) the phenotypes of interest can be continuous or discrete or combinations, b) the joint effect of the covariates on the multiple phenotypes is difficult to specify, and c) the familial, temporal/longitudinal and other correlations are often present in the data. To overcome these challenges, we propose to use the latent variable (LV) methodology. LV has been widely used in many scientific fields including economics, psychology and social sciences but yet to be exploited in the context of genetic studies. The LV approach links the multiple observed phenotypes by introducing an unobserved latent random variable. The effect of pleiotropic locus on the multiple phenotypes is indirect and induced via the LV, i.e. the locus (and relevant covariates) has a direct effect on LV, and in turn LV (and relevant covariates) influences the phenotypes. We base our LV inference on a Bayesian model that provides useful statistics such as mean, variance and percentiles of the posterior distribution of the unknown population parameters. Samplings from the posterior distribution are obtained using Markov Chain Monte Carlo (MCMC) algorithms. The parameter expansion technique is used to improve the mixing of chains and the Bayesian deviance information criteria and the posterior predictive discrepancy measures are used for model selection. Extensive simulations show that our method performs well in capturing the correlations among the multiple traits due to pleiotropy and other common covariates and in selecting the correct model. Application to a genome-wide association study of type 1 diabetes complications also demonstrates the utilities of the proposal method.

614F

Quantitative trait prediction based on SNP-array data, a simulation study. *W. Yip, C. lange.* Dept Biostatistics, HSPH, Boston, MA.

Using simulation studies for quantitative trait loci, we evaluate the prediction quality of regression models that include covariates SNPs which did not achieve genome wide significance. We compare the results of such regression models to the standard approach which is to include only SNPs that are significant. Using MSPE as the model metric, our simulation results suggest that by using the coefficient of determination value as a guideline to increase or reduce the number of SNPs included in the regression model, we can achieve better prediction quality. However, important parameters such as trait heritability, the approx. no. of QTLs have to be determined from other studies.

615F

Common Variants near *FRK/COL10A1* and *VEGFA* are Associated with Advanced Age-Related Macular Degeneration. *Y. Yu[1], T.R. Bhangale[2], J. Fagerness[3,4], S. Ripke[3,4], G. Thorleifsson[5], P.L. Advanced age-related macular degeneration (AMD) is a leading cause of visual loss in people older than 60 years. In the last 6 years, common risk variants for AMD have been identified in several genes by genome-wide association studies (GWAS) or candidate gene studies. Despite significant progress in the identification of genetic loci for AMD, not all of the heritability has been explained. To identify additional variants that might account for the remaining genetic susceptibility, we performed a large meta-analysis of GWAS for advanced AMD. We imputed >6 million SNPs in 2594 cases and 4134 controls using the 1000-Genomes reference genotypes, followed by replication genotyping to confirm association of top signals in 5640 cases and 52,174 controls (total combined effective sample size of 8639 cases and 8639 controls). We identified two new common susceptibility alleles, rs1999930 (T) on 6q21-q22.3 near *FRK/COL10A1* (odds ratio 0.87; P= 1.1×10^{-8}) and rs4711751 (T) on 6p12 downstream of *VEGFA* (odds ratio 1.15, P=8.7×10^{-9}). In additional to the two novel loci, ten previously reported loci in *ARMS2/HTRA1* (rs10490924, P=3.6×10^{-322}) , *CFH* (rs1061170, P = 1.3×10^{-261} and rs1410996, P=7.4×10^{-235}), *CFB* (rs641153, P=5.5×10^{-31}), *C3* (rs2230199, P=4.6×10^{-29}), *C2* (rs9332739, P=2.4×10^{-23}), *CFI* (rs10033900, P=4.1×10^{-10}), *LIPC* (rs10468017, P=2.7×10^{-12}), *TIMP3*(rs9621532, P= 2.2×10^{-15}) and *CETP* (rs3764261, P=6.9×10^{-9}) were confirmed with genome-wide significant signals in this large study. Loci in the recently reported genes *ABCA1* (rs1883025, P=1.2×10^{-7}) and *COL8A1* (rs13095226, P=9.7×10^{-7}) were also detected with suggestive evidence of association with advanced AMD. Using a standard liability threshold model, we estimated that all of the above loci combined explain approximately 39% of the total variance (or 55% of the heritability) of advanced AMD. Based on these associated variants, we generated a genetic risk score that can be used to predict advanced AMD risk for individuals with different genetic profiles. This study identified two novel variants and suggested that angiogenesis (*VEGFA*) and extracellular collagen matrix (*FRK/COL10A1*) pathways, in addition to the complement and HDL cholesterol pathways, contribute to the development of advanced AMD. This study increases our understanding of common variants that influence individual risks of AMD and provides new clues for developing effective therapies.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Design of genotyping arrays using imputation and a hybrid SNP selection algorithm. *Y. Zhan[1], T. Hoffmann[2], J. Gollub[1], M. Kvale[2], Y. Lu[1], G. Mei[1], M. Shen[1], T. Webster[1], P. Kwok[2], C. Schaefer[3], N. Risch[2,3].* 1) Affymetrix Inc, Santa Clara, CA; 2) UCSF Institute for Human Genetics, San Francisco, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

Four custom Axiom™ genotyping arrays were designed for genome-wide genotyping of 100,000 participants from the Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging. The detailed design strategy of the first array (Axiom™ Genome-Wide EUR Array), specifically for European ancestry populations, has been reported. A similar strategy was used to design the second array (Axiom™ Genome-Wide EAS Array), which focuses on populations of East Asian ancestry. For both designs, most SNPs were picked by a greedy SNP selection algorithm, which selects SNPs to efficiently tag, through pairwise r^2, a large set of target SNPs in one or more populations while also considering factors such as genotyping performance. When imputation is a planned step of the GWAS data analysis, imputation-based coverage, as well as coverage based on pairwise tagging, could be considered in the SNP selection process. To this end, we developed a hybrid SNP selection method, which is based on the greedy SNP selection method, but also considers imputation-based coverage. SNPs are selected in consecutive rounds of greedy tag SNP selection; after each round, SNPs are considered covered and removed from the target set if they can be imputed with an $r^2>0.8$. The hybrid SNP selection method produces enhanced imputation-based coverage compared to results from simple greedy SNP selection in tests where SNPs were selected based on YRI genotype data and coverage tested in HapMap ASW samples.

For the design of the last two custom arrays (Axiom™ Genome-Wide AFR and LAT Arrays, focusing on subjects with African and Latino ancestries, respectively), we first pre-selected about 198K SNPs considered to have high value, including SNPs with known associations with diseases/traits from earlier studies, SNPs from gene regions with different levels of special interest, and SNPs used to tag these important SNPs in YRI, similar to the process for designing the Axiom EUR and EAS Arrays. We then applied the hybrid SNP selection algorithm to achieve genome-wide coverage in populations of interest. Coverage was also enhanced by tiling of high performing SNPs with a single representation on the arrays, which yielded a total of 894K SNPs for the AFR array and 817K SNPs for the LAT array. The resulting arrays achieve high coverage for the targeted populations with SNPs that each can fit into a single Axiom Array.

Imputation reference panel selection using maximal phylogenetic diversity. *P. Zhang[1,2], N.A. Rosenberg[1], S. Z&oumlllner[1,2,3].* 1) Center for Computational and Medicine and Bioinformatics, Univ Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, Univ Michigan, Ann Arbor, MI; 3) Psychiatry, Univ Michigan, Ann Arbor, MI.

Genotype imputation has become an important component of genome-wide association studies (GWAS). Imputation methods typically rely on a reference panel of densely genotyped individuals to predict missing genotypes at untyped markers in a GWAS sample. Until recently, reference panels in most GWAS have been constructed from existing resources such as the HapMap project. The selection of reference data affects the quality of genotype imputation. For study populations that differ substantially from the HapMap populations in ancestral background, the HapMap data may poorly represent the study populations in their patterns of genetic variation, resulting in reduced imputation accuracy in the study populations. With sequencing costs continuing to drop, it is becoming feasible to sequence a subset of a study sample, and to then treat the sequences as reference data for imputation in the remaining sample. A natural challenge that arises is the selection of the optimal subset for sequencing. Here, we propose a novel algorithm that selects for sequencing the subset of a sample with maximal phylogenetic diversity. Intuitively, the most diverse reference panel can benefit the imputation of less common variants, because it is designed to capture higher diversity in a sample than randomly selected subsets of study individuals. Such a reference panel is therefore more likely to include individuals that carry rarer variants. Our algorithm first constructs a neighbor-joining tree of individuals using pairwise genotype differences between study individuals in pilot genotyping data. It then applies a greedy algorithm to select a reference panel with maximal phylogenetic diversity. To evaluate the proposed algorithm, we simulate sequences of 100kb in length under different scenarios. We then perform imputations on the simulated datasets, separately using reference panels constructed by our phylogenetic diversity algorithm and reference panels consisting of randomly selected individuals. We summarize the performance of our algorithm using several metrics, including the discordance rates between imputed and simulated genotypes and imputation accuracy as measured by estimated r^2. We identify scenarios where the proposed algorithm for selecting sequenced individuals improves imputation quality. Thus we provide a novel tool of leveraging existing genotype data when planning sequencing studies.

A High-Performance Computing Package for Relatedness and Principal Component Analysis in GWAS. *X. Zheng, D. Levine, J. Shen, C. Laurie, B. Weir.* Department of Biostatistics, University of Washington, Seattle, WA.

Genome-wide association studies (GWAS) are widely used to understand the genetic basis of diseases and traits, but pose many computational challenges. We developed SNPRelate, a high-performance parallel computing R package to accelerate two key computations in GWAS: principal component analysis (PCA) and relatedness analysis using identity-by-descent (IBD) measures. R is the most popular statistical environment, but by default it is not optimized, nor does it perform calculations in parallel. The kernels of our algorithms are written in C/C++ and have been highly optimized by blocking the computations to exploit the high-speed cache memory available on modern computer architectures. Benchmarks show the uniprocessor implementations of PCA and IBD in SNPRelate are ~10 to 45 times faster than the implementations provided in the popular EIGENSTRAT and PLINK programs, respectively, and can be sped up further by utilizing multiple cores. SNPRelate can analyze tens of thousands of samples with millions of SNPs. As an example, our package was used to perform PCA on 55,000 subjects from the “Gene-Environment Association Studies” (GENEVA) consortium studies. Our study is supported by National Institutes of Health (HG 004446).

The Effect of Genome-Wide Autozygosity on Cognitive Ability. *D.P. Howrigan[1], G. Davies[2], B.M. Neale[3], A.F. McRae[4], S.E. Harris[2], N.G. Martin[4], M.J. Wright[4], N. Pendleton[5], A. Payton[5], M. Horan[5], W.E. Ollier[5], A. Tenesa[6], J.M. Starr[7], I.J. Deary[2], P.M. Visscher[4], M.C. Keller[1].* 1) Dept. of Psychology and Neuroscience, University of Colorado at Boulder, Boulder, CO; 2) Department of Psychology, University of Edinburgh, Edinburgh, UK; 3) Broad Institute, Harvard University and MIT, Boston, MA; 4) Genetic Epidemiology, Molecular Epidemiology and Queensland Statistical Genetics Laboratories, Queensland Institute of Medical Research, Brisbane, Australia; 5) School of Translational Medicine, University of Manchester, Manchester, UK; 6) Colon Cancer Genetics Group, Institute of Genetics and Molecular Medicine, University of Edinburgh and MRC Human Genetics Unit, Edinburgh, UK; 7) Geriatric Medicine, University of Edinburgh, Royal Victoria Hospital, Edinburgh EH4 2DN, UK.

Hundreds of scientific investigations on plants and animals have found that offspring of genetically related individuals tend to have weaker constitutions and lower fertility, a phenomenon called “inbreeding depression.” Previous studies based on known pedigrees have found small but reliable inbreeding depression effects for the intelligence quotient (IQ) in humans. An alternative to the pedigree approach of studying inbreeding depression of IQ is to use genome-wide SNP data to detect interpersonal differences in the levels of autozygosity (stretches of the two homologous chromosomes within the same individual that are identical by descent). Autozygosity is a genetic signature of inbreeding, even at low levels, and can reveal the full effects of rare, partially recessive, deleterious alleles that negatively impact cognitive ability. We hypothesize that individuals with a larger burden of autozygous segments in their genome will express more cognitive-impairing, recessive, deleterious alleles, which will manifest as a negative relationship between autozygosity burden and IQ. To test this hypothesis, we examined genome-wide SNP data and measures of general cognitive ability from 4,489 Caucasian individuals from five geographic regions: British Isles (n=3,229), Australia (n=537), Northern Europe (n=365), North America (n=290), and Spain (n=68). We scanned genomes for runs of homozygosity (ROH), and used thresholds tuned specifically to capture autozygosity, both within and across the five geographic regions. After controlling for possible confounds such as sex, age when cognitive test was taken, year born, income, and education, we test the association of genome-wide ROH burden on general cognitive ability. Preliminary analysis on ~1,000 subjects in a combined sample found higher ROH burden to be significantly and negatively associated with general cognitive ability (beta=-3.27, p=0.002). Results from the entire sample set, to be completed in summer of 2011, will determine the whether these initial findings are reliable.

Loss of accuracy when imputing genotypes in previously phased individuals. *P.H. Keung[1], B.L. Browning[2].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA.

It is now possible to impute genotypes for >10 million markers using data from the 1000 Genomes project as a reference panel. Imputation of such large numbers of genotypes is computationally expensive, and one strategy for reducing computation time is to phase the to-be-imputed samples prior to imputation. However, pre-phasing the to-be-imputed individuals may cause significant losses in imputation accuracy since imputation algorithms can no longer take into account haplotype phase uncertainty in the to-be-imputed data. We investigate the differences in imputed genotype accuracy between phased and unphased to-be-imputed panels from the 1958 UK birth cohort and the GAIN African-American Schizophrenia datasets using 3 popular imputation software packages: Beagle, Impute and Mach/Minimac.

We masked every 10th marker in the to-be-imputed data and evaluated imputation accuracy using two metrics: genotype discordance between imputed and masked genotypes and squared correlation between imputed and masked minor allele dosage. We used two reference panels for each data set: a perfectly-matched reference panel from the same data set and a 1000 Genomes Project reference panel.

Our results demonstrate that pre-phasing the to-be-imputed data can result in a noticeable loss in imputation accuracy. Thus, one has to consider whether the loss in accuracy is worth the savings in computation effort obtained by pre-phasing.

"Next Generation" Imputation: Assessing the 1000 Genomes Project reference panel and imputation into multi-ethnic cohorts. *S.C. Nelson[1], C.C. Laurie[1], B.L. Browning[2], S.M. Gogarten[1], J. Li[3], M. Sale[4], B.B. Worrall[5], K. Doheny[6], E. Bookman[7], GARNET Collaborative Research Group.* 1) Dept of Biostatistics, University of Washington, Seattle, WA; 2) Dept of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 3) Dept of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Center for Public Health Genomics, University of Virginia, Charlottesville; 5) Dept of Neurology, University of Virginia, Charlottesville, VA; 6) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 7) National Human Genome Research Institute, Bethesda, MD.

The 1000 Genomes (1000G) Project has increased the potential for genotype imputation to enhance genome-wide association studies. In particular, 1000G panels will enable the imputation of many more and rarer variants. We also expect imputation accuracy to improve as the number and genetic diversity of samples sequenced increases. Using BEAGLE software, we assessed the robustness of imputation in two domains: (1) accuracy of 1000G imputation for variants that are not on standard SNP microarrays and (2) effect of imputing multiple ethnic groups together using a cosmopolitan reference panel. For aim (1), we compared imputed genotypes for two unrelated CEU samples to those observed in the 1000G pilot 2 deep sequencing project. HapMap3 SNPs served as the imputation input, and all CEU and TSI HapMap 3 samples not in the 1000G EUR reference panel were included in the to-be-imputed sample. Our results show that imputation accuracy using the EUR reference is consistently high (mean per-SNP concordance rates of 96%) at SNPs with minor allele frequency (MAF) ⁄ 0.1 in the reference, but decreases rapidly as MAF falls below 0.05. While indicating that 1000G imputation accuracy at very rare variants is currently limited, these results also suggest that remaining variants are imputed as well as if not better than when using a HapMap3 reference. Taking imputation quality into account during downstream analysis is advisable to compensate for this range in accuracy. As the Project matures, yielding larger and higher quality datasets, we expect imputation at these rarer variants to improve. To address aim (2), we compared two separate imputations of 2,069 participants from the Vitamin Intervention for Stroke Prevention (VISP) trial, using HapMap 3 references. While the majority of VISP participants have European genetic ancestry (EA), 18% show significant Asian and African components. We compared the correlation between results for the EA participants from imputing (a) EA alone using a CEU and TSI HapMap 3 reference versus (b) all VISP together using a combination of 10 HapMap 3 populations. We show that expected allele dosages for EA participants in the two scenarios are highly correlated (mean=0.994), indicating that imputation need not be restricted to a genetically homogenous set of study samples. Our findings from both aims (1) and (2) support a broader goal for genetic studies to include more genetically diverse samples and interrogate rarer variants.

Challenges and future directions for causal inference from multiple omics datasets using Structural Equation Modeling. *S-Y. Shin[1], A-K. Petersen[2], K. Small[3], E. Grundberg[1,3], P. Deloukas[1], T.D. Spector[3], K. Suhre[4,5], C. Giegar[2], N. Soranzo[1,3].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) Institute of Epidemiology, Helmholtz Zentrum München, Neuherberg, Germany; 3) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 4) Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum München, Neuherberg, Germany; 5) Faculty of Biology, Ludwig-Maximilians-Universität, München, Germany.

Recent developments in technology allow us to collect multiple highly-dimensional `omics' datasets from thousands of individuals in a highly standardized and unbiased manner. For instance, the characterization of such datasets, including genome-wide SNP data, transcriptomics, proteomics, metabolomics and others, collected in deeply-phenotyped population-based cohorts, can be applied to search for new biomarkers and to characterize pathways underlying disease risk. Open questions remain how best to integrate or bridge the multiple omics datasets to understand underlying biological mechanisms and infer causal pathways. We have begun exploring causal relationships between genetic variants, clinically-relevant quantitative phenotypes and metabolomics datasets using Structural Equation Modeling (SEM), applied to a subset of the common disease loci identified from genome-wide association studies. We provide proof-of-principle evidence that SEM analysis is able to identify reproducible path models supporting association of SNPs to intermediate phenotypes through metabolomics intermediates. In this study, we aim to address further challenges arising from the analysis of multiple omics datasets and suggest future directions for causal inference using SEM and other statistical inference methods. Firstly, complex biological systems tend to be nonlinear in nature. We seek here to detect and incorporate nonlinearity into our model. Another further concern is how to deal with the correlated structure of the data when seeking to extend these analyses to more complex data structures including multiple genetic variants and traits. While Principal Component Analysis (PCA) can be applied to extract useful information out of a high dimensional highly correlated dataset, it is hard to interpret and not applicable to multiple omics datasets. Performing dimensionality reduction on the complete dataset simultaneously, preserving the important links between the data types would be more desirable. We explore other projection based and machine-learning techniques to overcome these limitations and extend our original analysis.

A comparison of seven statistical methods for detecting rare variant association. *R. Weyant, C. Fuchsberger, T.M. Teslovich, W. Chen, Y. Hu, M. Boehnke.* Biostatistics, University of Michigan, Ann Arbor, MI.

Large-scale sequencing projects such as the 1000 Genomes Project have identified millions of low frequency and rare genetic variants in human populations. Multiple methods have been proposed to analyze genes harboring rare variants to test for disease association and so to better understand how these rare variants contribute to human disease risk. In planning a genetic association study, an investigator might ask: which analysis method is best for my data? Is one method best to address certain genetic hypotheses, but less powerful for others? Is there a single test that is uniformly most powerful under a reasonable set of constraints? We are carrying out a computer simulation study to compare seven prominent methods for rare-variants genetic association tests: C-ALPHA (Neale et al.), the variable threshold method (Price et al.), the weighted sum test (Madsen and Browning), the CMC test (Li and Leal), and SKAT (Wu et al.), in addition to other methods, which use intuitive sum statistics, alternative weightings or find variants unique to cases. We compare the performance of these methods under a variety of disease models. Specifically, we simulate several loci with different fractions of causal variants of various allele frequencies and effect sizes. Additionally, we vary the locus length and recombination patterns to simulate different scenarios, and examine the effect on power when associated loci contain both protective and risk rare variants. Initial simulation results suggest that under the null model, most methods maintain an approximate type I error rate, while the frequency-based weighted sum method appears anti-conservative as locus size increases. We are now carrying out simulations to allow us to compare power of the various methods under biologically plausible scenarios.

Characterisation of the glaucoma phenotype in patients carrying risk alleles at novel open angle glaucoma genes, *TMCO1* and *CDKN2B-AS1*. *K.P. Burdon[1], R. Casson[2], A. Crawford[1], A.W. Hewitt[3], S. Macgregor[4], D.A. Mackey[5], J.E. Craig[1].* 1) Dept Ophthalmology, Flinders University, Adelaide, SA, Australia; 2) South Australian Institute of Ophthalmology, Hanson Institute and Adelaide University, Adelaide, SA, Australia; 3) Centre for Eye Research Australia, University of Melbourne, Royal Victorian Eye and Ear Hospital, Melbourne, VIC, Australia; 4) Genetics and Population Health, Queensland Institute of Medical Research, Brisbane, QLD, Australia; 5) Lions Eye Institute, University of Western Australia, Centre for Ophthalmology and Visual Science, Perth, WA, Australia.

Open Angle Glaucoma (OAG) is a progressive neuropathy of the optic nerve affecting 3% of the population over age 50 years, and may lead to severe visual loss. We recently identified SNPs in *TMCO1* and *CDKN2B-AS1* that are associated with OAG at genome-wide significance with subsequent replication (Burdon et al. *Nat Genet.* 2011 43(6):574-8). Here we describe the clinical characteristics of OAG patients with glaucoma risk alleles at these loci compared to patients without these risk alleles in order to better characterise the phenotype associated with these loci. We obtained data from 1432 glaucoma patients with genotype data available at the most significantly associated SNPs at both loci from the published GWAS (rs4656461 and rs7518099 at *TMCO1* as well as rs1012688 and rs4977756 at *CDKN2B-AS1*). Data was available for a range of OAG risk factors including intraocular pressure (IOP), cup:disc ratio and central corneal thickness as well as age at diagnosis and sex. Linear regression was used to detect associations between the SNPs of interest and these traits. The risk alleles at the *TMCO1* locus result in younger age at diagnosis (p=0.003) which remains significant after adjustment for all other variables (p=0.020). The risk alleles at *CDKN2B-AS1* are associated with lower peak intraocular pressure in this cohort, independently of other covariates (p=0.004). To investigate the combined effect of the two loci, the number of risk alleles at SNPs rs4656461 and rs4977756 were added to generate a total number of risk alleles (ranging from 0 to 4). An increasing number of glaucoma risk alleles is associated with a younger age of onset (p=0.005) and larger cup:disc ratio (p=0.001), however only age of onset remained significant under multivariate analysis (p=0.022). The CDKN2B-AS1 locus is associated with cup:disc ratio in the normal population, consistent with that observed here. In conclusion, glaucoma risk alleles at the *TMCO1* gene are associated with a younger age of glaucoma diagnosis while a relationship was observed between the *CDKN2B-AS1* locus and IOP. Carriers of 4 risk alleles are diagnosed around 6 years younger than carriers of 0 or 1 allele. These results suggest that carriers of these risk alleles are more likely to develop glaucoma at a younger age and without displaying elevated IOP. These genetic variants may be useful for identification of patients at high risk of progression in the absence of the traditional risk factors, elevated IOP and age.

625F

A phenome-wide analysis of SNPs in the National Human Genome Research Institute genome-wide association catalog. *J. Denny[1,2], L. Bastarache[1], M. Ritchie[1,3,4], M. Basford[6], J. Pulley[6], R. Crawford[3,4].* 1) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Vanderbilt University, Nashville, TN; 3) Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 5) Division of Epidemiology, Mayo Clinic, Rochester, MN; 6) Office of Research, Vanderbilt University, Nashville, TN; 7) Department of Biomedical Statistics & Informatics, Mayo Clinic, Rochester, MN; 8) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 9) Group Health Research Institute, Seattle WA; 10) Department of Medicine, Northwestern University, Chicago, IL; 11) Office of Population Genomics, National Human Genome Research Institute, Bethesda, MD; 12) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 13) Department of Cell & Molecular Biology, Northwestern University, Chicago, IL; 14) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 15) Department of Pharmacology, Vanderbilt University, Nashville, TN; 16) Center for Genetic Medicine, Northwestern University, Chicago, IL.

Candidate gene and genome-wide association studies (GWAS) have provided greater understanding of the genetic underpinnings of many traits. Genetic data coupled to electronic medical records (EMR) offer the possibility of the inverse experiment, a “hypothesis-free” analysis of many phenotypes, or phenome-wide association scan (PheWAS). In this study, we used a cohort of 13,859 European-ancestry individuals genotyped in the Electronic Medical Records and Genomics (eMERGE) network. We performed PheWAS on 945 SNPs significantly associated ($p<5x10^{-8}$) with traits in the NHGRI GWAS catalog. We examined each SNP for association with 947 phenotypes algorithmically defined using billing codes derived from normal clinical processes. We used logistic regression models for each phenotype adjusted for age, gender, and principal components. PheWAS replicated 42%; (226/545) of GWAS catalog SNP-trait associations in 57 phenotypes, and 63% (82/130) of associations sufficiently powered for replication given our case size. A total of 46 SNP-phenotype associations in 24 phenotypes achieved genome-wide significance in PheWAS; 34 of these were previously known. Replications included Alzheimer's disease (*APOE*/*TOMM40*, $p=1x10^{-25}$), hemochromatosis (*HFE*, $p=2x10^{-25}$), type 2 diabetes (*TCF7L2*, $p=3\ x10^{-16}$), ischemic heart disease (9p21.3, $p=1.10^{-12}$), and prostate cancer (8q24.21, $p=9x10^{-8}$). New associations included acquired hypothyroidism ($p=4x10^{-12}$) with *FOXE1* variants previously associated with thyroid cancer; skin neoplasms ($p=4x10^{-17}$) and actinic keratosis ($p=8x10^{-11}$) with *IRF4* variants previously associated with skin color; and aplastic anemia ($p=3x10^{-6}$) with *WDR66* variants previously associated with mean platelet volume. Known pleiotropy at the 9p21.3 region (myocardial infarction, abdominal aortic aneurysm, and cerebrovascular disease) was replicated, and new associations were suggested (carotid stenosis, asthma, atherosclerosis, and other aneurysms, all $p<10^{-5}$). *IRF4* variants were the most pleiotropic, with 14 phenotypes associated at $p<10^{-5}$. EMR-based PheWAS replicated many SNP-disease associations in a real-world cohort, and thus can serve as a tool to improve confidence in GWAS associations. This analysis also suggested new, biologically plausible associations (“hypothesis-generating”) for further study. Future use of PheWAS in tandem with traditional genetic analysis may help define pleiotropy and improve understanding of the genetic architecture of complex diseases.

626F

Sub-clinical Phenotypes used to Dissect Genetic Heterogeneity in Cleft Lip with/without Cleft Palate. *M.L. Marazita[1], M.E. Cooper[1], M. Govil[1], R.S. DeSensi[1], T. McHenry[1], S. Weinberg[1], J.C. Murray[2], K. Neiswanger[1], C. Brandon[1], A.E. Czeizel[3], A.R. Vieira[1], E.E. Castilla[4], F. Poletta[5], J.M. Resick[1], S. Daack-Hirsch[2].* 1) Center for Craniofacial and Dental Genetics, Univ Pittsburgh SDM, Pittsburgh, PA; 2) Pediatrics, University of Iowa, Iowa CIty, IA; 3) Foundation for the Community Control of Hereditary Diseases, Budapest, Hungary; 4) Department of Genetics, FIOCRUZ, Rio de Janeiro, RJ, Brazil; 5) CEMIC, Buenos Aires, Argentina.

Orofacial clefts (OFCs), particularly cleft lip with/without cleft palate (CL/P), are the most common craniofacial birth defects in every population worldwide. Our group and others have made major strides in recent years in identifying genes and genomic locations that increase the risk of OFCs, notably IRF6, 8q24 (a gene desert region), FOXE1, MAFB, ABCA4-ARGHAP29 and others. Sequencing studies are underway in the genes/regions identified in order to identify etiologic variants. Thus, a current challenge for studies of OFCs is to understand the genetic heterogeneity implicit in our results to date. We hypothesize that evaluation of sub-clinical phenotypes (physical features with no major health consequences) is a valuable tool to dissect the observed genetic heterogeneity. In the current study we performed genetic studies incorporating three phenotypes (lip muscle discontinuities--OOM, lip print whorls---LIP, and velopharyngeal insufficiency--VPI). The study sample is 364 families (1,814 individuals—529 cleft affected, 1285 unaffected) ascertained and phenotyped as part of a large international collaboration, with genotypes including a genome-wide panel of 5,755 SNPs plus SNPs in the genes/regions above. Association analyses using FBAT were done: (1) with OFC as affected (baseline), (2) adding OOM, LIP or VPI as affected, (3) in groupings of families based on phenotypes; e.g., OOM-Yes families had at least one family member with OOM, and OOM-No did not. RESULTS: (1) adding sub-clinical phenotypes increased statistical significance compared to baseline association analyses for multiple SNPs; e.g. from p=0.002 to 0.00008 for rs1002122 in CNTN5. (2) notably, there were also significant differences between the pattern of results in OOM-Y vs. OOM-N, LIP-Y vs. LIP-N, and VPI-Y vs. VPI-N. For example, at baseline and in OOM-Y there was no significant association with rs12697439 (near ZNF131), but in OOM-N there was (p=0.0002). Further, the difference between the results for OOM-Y vs. OOM-N was significant (p=0.00004). In summary, these results indicate that sub-clinical phenotypes have the potential to be a powerful tool for understanding genetic heterogeneity in CL/P. Understanding the genetic architecture of CL/P via phenotyping could also lead to important clinical implications since such phenotypes can be viewed as “rescue” of the birth defect in some family members carrying CL/P risk factors. Support: DE016148, DE008559, DE018085.

Rare variant association methods and their performance when confounded by population substructure. *T.D. O'Connor[1], G. Wang[2], E. Kenny[3], C.D. Bustamante[3], S.M. Leal[2], M.J. Bamshad[1,4], J.M. Akey[1] on behalf of the NHLBI Exome Sequencing Project.* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Genetics, Stanford University, Palo Alto, CA; 4) Department of Pediatrics, University of Washington, Seattle, WA.

With advances in next-generation sequencing technology it is now possible to systematically test the contribution of rare variation to the burden of Mendelian and complex disease. It is well known that association tests of common alleles can lead to false positives in the presence of population stratification. However, the influence of population structure on association methods for rare variants remains poorly defined. To address this critical gap in knowledge, we performed exhaustive coalescent simulations, whose parameter values were carefully calibrated with over 300 European-American exomes, to evaluate the performance of ten rare variant association tests. We find that all methods have an inflated type I error rate for parameter values consistent with levels of differentiation and differences in disease prevalence among European populations, and in some cases dramatically so. For example, at a nominal significance level of 5%, some test statistics have a false positive rate as high as 40%. We investigated two approaches for mitigating spurious associations in the presence of population structure; the incorporation of covariates, such as eigenvectors from principle component analysis (for methods that allow covariates) and a matching strategy where cases and controls are matched based on population origin. In both cases, the type I error rate is reduced to nominal, or near nominal, levels. In conclusion, population stratification is a confounding factor that can lead to spurious associations in rare variation association methods, but relatively simple approaches can ameliorate such issues, though at a slight cost to power. Thus, our results have important implications for the design, analysis, and interpretation of genome-wide association studies of rare variants.

Genome-wide scan in Italian isolated populations identify loci for food preferences. *N. Pirastu[1], C. Lanzara[1], A. Robino[1], G. Pistis[2], M. Traglia[2], C. Sala[2], D. Toniolo[2], B. Tepper[3], Y. Koelliker[3], P. Gasparini[1].* 1) Medical Genetics, IRCCS Burlo Garofolo/Università degli Studi di Trieste, Trieste, TS, Italy; 2) Division of Genetics and Cell Biology, San Raffaele Scientific Institute, Milano, Italy; 3) Department of Food Science, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ.

Taste is the most important factor guiding food choices, and the knowledge of the genetic basis of taste perception is increasing year by year. However these efforts focused mainly on taste receptor genes and not on food preferences themselves. In this study we present the first genome wide scan looking for genes that underlie food preferences in 3 isolated Italian populations coming from the Italian Network of Genetic Isolates (INGI): Carlantino (CARL, Southern Italy), Friuli Venezia Giulia (FVG, North-Eastern Italy) and Val Borbera (VB, North-Eastern Italy). In particular we administered, during a wider screening, a questionnaire on 55 food preferences (such as ham, eggplant, ice cream, etc.) in a total of 2769 people. Each person had to score liking for each food from 1 to 9 where 1 was “I don't like it at all” and 9 was “I like it a lot”. For all people information on health parameters genealogy and life styles were available. Moreover all of the samples were genotyped with the 370k Illumina Chip and subsequently imputed to the 2.5M HapMapII SNP set using MACH. In order to understand the genetic bases of food preferences we defined 2 measures: the first was “absolute preference” based on the liking scores; the second was corrected for each person's median liking score across all the foods, which we called “relative preference”. Relative preference measures liking of individual foods relative to all foods. For each trait we ran a genome-wide scan corrected for kinship using the GenABEL/ProbABEL suite using sex and age as covariates. Each population was run separately and pooled together through inverse variance meta-analysis for a total of 110 total genome wide scans. We identified 4 genome wide significant loci ($p \leq 5x10\text{-}8$) for Whole Milk, Hot Tea, Ice Cream and Chilli Pepper liking, plus 29 genome wide suggestive loci ($p \leq 5x10\text{-}7$). Three out of four significant identified genes which have not been previously described for taste, but that have interesting chemosensory and cell signalling functions while the third one falls close to a gene of unknown function. We believe that this study represents a good starting point for understanding the genetics of food preferences. This knowledge will impact deeply in our views on taste and food choice and will help understand the basis of obesity and other diseases in which food intake is a strong component.

Matullo[1,2].* 1) Human Genetics Foundation, Turin, Italy; 2) Department of Genetics, Biology and Biochemistry, University of Turin, Italy; 3) Department of Environment and Primary Prevention, ISS, Rome, Italy; 4) Department of Clinical and Biological Sciences, University of San Luigi Gonzaga, Turin, Italy.

Individual DNA repair capacity (DRC) is modulated by the genetic background to which hundreds of SNPs or haplotype combinations in DNA repair genes are likely to contribute. In order to identify functional SNPs modulating DNA repair phenotypes and to investigate their potential impact on cancer risk, we have performed a genotype-phenotype correlation study evaluating levels of DNA damage and DRC in blood cells treated at low doses of different DNA damaging agents. We investigated the association between genotypes and the DRC measured with the following DNA repair phenotypic assays on cryopreserved lymphocytes from 225 healthy individuals: Comet assay after treatment with BPDE, phosphorylation of histone H2AX after treatment with gamma-rays, OGG1 glycosylase activity, OGG1 and ERCC1 expression levels. 65 DNA repair genes and a total of 768 SNPs have been analysed on the 225 DNA samples by using a custom GoldenGate SNP chip (Illumina). Genotype-phenotype correlation analysis identified some new functional variants and haplotypes. A confirmation of some already described interplays between different DNA repair pathways have been obtained from SNP analysis and a suggestion of new possible cross-talks have been identified that need further experimental validation. Our results can contribute to identify subjects carrying combinations of less efficient DNA repair variants/haplotypes possibly at increased cancer risk or who can better benefit from anti-cancer therapies.

Rare and Common SNPs in DRD5 Have Unique and Independent Effects on Risk for Childhood ADHD. *I. Waldman[1], M. Nikolas[2], K. Jernigan[3], J. Nigg[4], K. Friderici[3].* 1) Dept Psychology, Emory Univ, Atlanta, GA; 2) Dept Psychology, Michigan State University, East Lansing, MI; 3) Dept Micro. and Mol. Gen., Michigan State University, East Lansing MI; 4) Dept Psychiatry, Oregon Health and Science University, Portland OR.

Considerable controversy exists in the recent genetics literature regarding the contributions of common versus rare variants in conferring risk for common disorders and traits. In this study, we resequenced the dopamine receptor D5 gene (DRD5) to search for rare variants that may confer risk for childhood ADHD. DRD5 is an important candidate gene for ADHD, but examination of it as a risk factor has been hampered by its location in a segmentally duplicated chromosomal region. Restriction enzyme digestion of genomic DNA was used to eliminate the pseudogenes prior to PCR amplification of the functional gene. Resequencing of DRD5 was conducted on 319 children with ADHD and 296 control children. The sample was 56% male, aged 6-17 years (M=10.8, SD=2.3), and ethnically diverse, with 20% having some African-American ancestry. Sequencing revealed 13 rare SNPs (6 non-synonymous, 6 synonymous, and 1 frameshift mutation) and 2 common SNPs. Rare variants were found disproportionately on haplotypes containing the minor alleles of the 2 common SNPs. Generalized Linear Models with GEE were used to test for the association of the SNPs with ADHD and its diagnostic subtypes and symptom dimensions. Analyses revealed that neither the genotypes of the 2 common SNPS nor the presence of a rare variant were associated with ADHD, nor with the Combined or Inattentive subtypes. In contrast, levels of hyperactive-impulsive (but not inattentive) symptoms were uniquely and independently associated with both of the 2 common SNPs and the presence of rare variants (p-values ranging from .005 to <.001). The 2 common SNPs explained 2% and 3.7% of the variance in hyperactive-impulsive symptom levels, with the presence of a rare variant contributing an additional 1.3% of the variance. Children with a rare DRD5 variant showed an increase of 2.1 hyperactive-impulsive symptoms as compared with children with no rare variants. Similarly, children with the risk-inducing allele at the 2 common SNPs showed increases of 1.6 and 2.0 hyperactive-impulsive symptoms as compared with children with the low-risk allele at those markers. These results suggest that both common and rare SNPs in or near the coding region of DRD5 make unique and independent contributions to the risk for the hyperactive-impulsive symptoms of ADHD in children. Our results also highlight the signal importance of using genotyping procedures that avoid segmentally duplicated chromosomal regions common to DRD5 and other genes.

HIV-associated nephropathy and focal segmental glomerulosclerosis: APOL1 trypanolytic mutations underpin a major health disparity. *C. Winkler[1], G. Nelson[2], G. Genovese[3], M. Pollak[3], J. Kopp[4].* 1) Basic Research Laboratory, Center for Cancer Research, SAIC-Frederick, NCI, NIH, Frederick, MD; 2) Basic Science Program-Center for Cancer Research Genetics Core, SAIC-Frederick, NCI, NIH, Frederick MD; 3) Beth Israel Deaconess Medical Center, Harvard Medical School, Boston MA; 4) NIDDK, NIH, Bethesda, MD.

HIV-associated nephropathy (HIVAN) occurs in 10% of HIV-infected African Americans (AA) in the absence of antiretroviral treatment, but was rarely observed in non-Africans. We recently showed that two APOL1 alleles, (S342G-I384M (G1) and N388del:Y389del (G2), occurring on mutually exclusive haplotypes, are recessively associated with kidney disease in AA. These mutations also restore APOL1 lysis activity against Trypansoma b. rhodensiense in plasma from carriers of one or two copies of either G1 or G2; thus there appears to be a heterozygous advantage/homozygous disadvantage. The role of these variants in HIVAN has not been investigated. We studied patients with HIVAN and focal segmental glomerulosclerosis (FSGS) to test for interaction between HIV and APOL1 risk alleles, to determine effect sizes, and to determine if APOL1 risk alleles are associated with particular clinical phenotypes. Genotypes were obtained for 439 cases with HIVAN or FSGS and 939 normal controls or HIV-infected subjects with no evidence of kidney disease. In a recessive model, APOL1 variants were strongly associated with HIVAN (OR= 29; 95% CI 13, 68) and FSGS (OR= 17; 95% CI 11, 26) for FSGS. For FSGS associated with two APOL1 risk alleles, compared to other FSGS patients, onset age was earlier (p=0.03), steroid sensitivity was similar (p>0.5), and progression to ESKD was faster (log-rank p<0.01). Two APOL1 risk alleles confer an attributable risk of 67% for FSGS and HIVAN and explain 35% of HIVAN and 18% of FSGS. HIV-infected, untreated individuals with two risk alleles have an estimated 50% lifetime risk for developing HIVAN compared to a 4% risk of FSGS for uninfected individuals with two risk alleles. APOL1 kidney risk alleles are present only on African chromosomes and the risk alleles are most frequent in West Africans (342G-384M~36%; deletion~8%). The finding that individuals carrying two copies of G1 or G2 have a greatly increased risk of HIVAN and FSGS provides a genetic basis for a major global health disparity. These findings have particular relevance for sub-Saharan Africans where the HIV prevalence is high and the frequencies for the risk alleles exceed 40% among some West African populations.

Association Tests for Rare Variants Based on Regularized Regression Methods. *C. Xu[1,2], M. Ladouceur[1,3], J.B. Richards[2,3,4,5], A. Ciampi[2], C. Greenwood[1,2,6].* 1) Lady Davis Institute for Medical Research, Montreal, QC; 2) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, QC; 3) Department of Human Genetics, McGill University, Montréal, QC; 4) Department of Medicine, Jewish General Hospital, McGill University, Montreal, QC; 5) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 6) Department of Oncology, McGill University, Montreal, QC.

Collapsing or pooling methods are often used to detect association with rare variants while ignoring common variants, even though they may have direct or indirect association with the outcome. We compare a variable selection method (LASSO) and a dimension reduction method (partial least squares regression, PLS) with two commonly used pooling methods (weighted minor allele counts, and variable threshold technique). For LASSO and PLS, the models are fit with and without pooling rare variants. Power of these methods was compared in simulations, where continuous phenotypes were generated but genotypes were generated from Sanger sequencing of one gene in 1998 individuals (provided by GlaxoSmithKline). Permutations ensured valid type 1 error. Simulation results for three scenarios are shown in the following table. In Scenario 1, 30% of the SNPs with 0.001<MAF≤0.01 are causal. In Scenario 2, 10% of SNPs with MAF≤0.01 are causal. Finally, in Scenario 3, there are 4 causal rare SNPs with MAF≤0.01 and 4 causal common SNPs. All rare variant effects acted in the same direction. The rare SNPs effects follow a normal N(-1.64, 0.02) distribution, non carriers follow N(0,1), and the common SNPs effect are simulated from N(-0.07, 0.01). LASSO and PLS outperform simple pooling approaches in some situations. These novel association tests will be evaluated in additional sequenced genes.

Scenario	Count weighted by 1/MAF	Variable threshold	LASSO w/o rare pooling	LASSO with rare pooling	PLS w/o rare pooling	PLS with rare pooling
1	0.78	0.97	1.00	1.00	1.00	1.00
2	0.39	0.58	0.72	0.73	0.68	0.71
3	0.88	0.72	0.87	0.69	0.71	0.65

633F

Identifying rare variants with heterogeneous effects from pooled sequencing data. *Q. Zhang[1], K. Wang[2], M.A. Province[1], I. Borecki[1].* 1) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO, USA; 2) Department of Biostatistics and Epidemiology, College of Public Health, East Tennessee State University, Johnson City, TN, USA.

Separately sequencing pooled DNA from two groups of subjects with discrepancy in a target trait and comparing allele frequencies between the groups provide an economical strategy for identifying rare variants (RVs) associated with human complex traits; however, statistical methods for association analysis of pooled sequencing data, are very limited, especially the methods for collectively testing a group of RVs with heterogeneous (i.e. some positive and some negative) effects on a trait. All existing data-driven methods for collective test of heterogeneous effects of multiple RVs were developed for individuals' sequence data, and are inapplicable to the data from pooled experiments because they require permutation test which cannot be performed with no individuals' information. In this study, we propose three methods, a Fisher's combined probability test (FCPT), a likelihood ratio test (LRT) and an exact probability test (EPT), for collectively detecting heterogeneous effects of a group of RVs from pooled sequencing data. Unlike the commonly-used cohort allelic sums test (CAST) method (Morgenthaler and Thilly,2007) that tests the difference in the total RV numbers between two groups of samples, our methods test whether a group of RVs are randomly distributed in samples. Our simulation shows that the three proposed methods substantially increase power in comparison with CAST; the EPT method produces the most unbiased false positive rate (FPR) under the null hypothesis, and overall, demonstrates the best receiver operating characteristic (ROC). The appeal of the proposed approach is illustrated in an application to real sequence data. Finally, we discuss how to use simulation-based approach to appropriately approximate p-values when dataset is too large and the EPT method is too time-consuming to be used.

Next-generation haplotype phasing: combining identity-by-descent with haplotype frequency models. *B.L. Browning[1], S.R. Browning[2].* 1) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Biostatistics, University of Washington, Seattle, WA.

Standard methods for inferring haplotype phase for a population sample incorporate sophisticated population haplotype frequency models, but do not explicitly detect or make use of recent shared ancestry between individuals. We present a new haplotype phasing method that uses both sources of information to phase pedigree and population data. Combining phasing constraints imposed by identity-by-descent (IBD) with population haplotype frequencies can provide a substantial improvement in phasing accuracy over the best existing methods. The new method achieves high phase accuracy for an individual in regions where the individual has a detectable IBD tract with another genotyped individual. Our previous work has shown that IBD tracts due to a common ancestor within approximately the last 25 generations are ubiquitous in large samples and can be detected with high power and low false discovery rate [1]. We demonstrate improved genotype phase accuracy using Wellcome Trust Case Control Consortium and HapMap data. This new haplotype phasing method will be incorporated in version 4 of the BEAGLE software package.

Validation of a method for classical HLA allele imputation. *C.S. Franklin[1], M. Hernandez-Fuentes[2], I. Rebollo-Mesa[2], J. Mollon[2,3], F. Delaney[2], E. Perucha[2], P. Conlon[4], M.E. Weale[2,3], N. Soranzo[1], G. Lord[2], United Kingdom and Ireland Renal Transplant Consortium, WTCCC3.* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) MRC Centre for Transplantation, King's College London, London, UK; 3) Department of Medical and Molecular Genetics, King's College London, London, UK; 4) Royal College of Surgeons in Ireland, Dublin, Ireland.

The classical HLA loci play important roles in susceptibility to autoimmune, infectious and a wide range of other diseases. Furthermore, they are known to affect the outcome of organ transplantation, therefore HLA alleles are typically determined prior to transplant. It has been shown that classical HLA alleles can be determined from dense SNP data through imputation (Dilthey et al 2011). However, the accuracy of the HLA imputation software has not been extensively tested. As part of the WTCCC3 renal transplant dysfunction project, we have genotyped 2,500 kidney donor and recipient pairs using Illumina Human660-Quad SNP arrays. Classical HLA alleles were determined prior to transplant. We have used the HLA*IMP program (Dilthey et al 2011) to obtain imputed HLA alleles and tested the concordance of these imputations with the directly typed alleles for a subset of the samples. We show that imputation provides highly accurate results at the 2-digit allele resolution, with concordance exceeding 97% for all alleles tested (HLA-A, HLA-B, HLA-C and HLA-DRB). This independent validation demonstrates that the HLA*IMP program can provide accurate HLA information in datasets with genome-wide SNP data. This suggests that imputation is a viable strategy for studying the contribution of HLA alleles to genetic risk in a range of diseases where genome-wide SNP data are available.

Association of PPARG gene polymorphisms with obesity and insulin resistance syndrome in north India. *J. prakash[1], N. Srivastava[1], S. Awasthi[2], C. G. Agarwal[3], B. Mittal[4].* 1) Physiology, Chatrapati Shahuji Maharaj Medical University, Lucknow, Uttar Pradesh, India; 2) Pediatrics, Chatrapati Shahuji Maharaj Medical University, Lucknow, Uttar Pradesh, India; 3) Medicine, Chatrapati Shahuji Maharaj Medical University, Lucknow, Uttar Pradesh, India; 4) Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, U.P., India.

The worldwide increasing prevalence of obesity is considered as a major health problem, since excess body fat deposition is a strong risk factor for insulin resistance, type 2 diabetes (T2D) and dyslipidemia, leading to premature morbidity and death. Peroxisome proliferator-activated receptor gamma (PPAR-.), a nuclear hormone receptor, controls adipocyte differentiation and regulates a number of genes associated with energy homeostasis. In the present study, we investigated the association of PPAR-. gene Pro12-Ala (rs1801282) and C1431T (rs3856806) polymorphisms with morbid obesity and related phenotypes, in north Indian population. A case control study was conducted with 642 (309 obese, BMI⁄ 30) and 333 non-obese, BMI<30) subjects. Insulin and adiponectin levels were determined by enzyme-linked immunosorbent assay RIA (Linco Research, Inc.). The degree of insulin resistance was calculated according to the homeostasis model assessment (HOMA). The fasting glucose concentration was measured by Glucose oxidase-Peroxidase (GOD-POD) method. Commercial enzymatic test kits were used for determining HDL, total serum cholesterol and triglyceride concentrations, while LDL cholesterol was calculated by the formula of Friedewald. All subjects were genotyped by PCR restriction fragment length polymorphism (PCR-RFLP). All statistical analyses were conducted using SPSS for Windows version 15.0. Informed consent was obtained from each participant and the study was carried out in accordance with the local ethics committee. The ProAla+AlaAla genotypes of PPAR-. Pro12Ala were significantly associated with higher risk of obesity while C1431T polymorphism did not show any significant association. None of the haplotypes defined by both SNPs showed association with morbid obesity. However, a strong association of variant haplotypes was observed with lower levels of insulin, HOMA-IR index, and higher serum adiponectin concentrations. The combined variant haplotypes (Pro-T, Ala-C and Ala-T) also showed association with percentage body fat and fat mass, while these haplotypes did not show any association with the hypertension and lipid profile. PPAR-. polymorphisms influence obesity phenotype in a complex manner, probably involving insulin sensitivity in north Indian population. Acknowledgment: Indian Council of Medical Research, Department of Biotechnology, Department of science and Technology, New Delhi, India.

Fine-mapping of autoimmune susceptibility loci using Immunochip identifies novel susceptibility loci for psoriatic arthritis. *J. Bowes[1], P. Ho[1,2], E. Korendowych[3], N. McHugh[3], H. Marzo-Ortega[4], J. Packham[5], I.N. Bruce[1,2], A. Barton[1,2].* 1) Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, UK; 2) The Kellgren Centre for Rheumatology, Central Manchester Foundation Trust, NIHR Manchester Biomedical Research Centre, Manchester, UK; 3) Royal National Hospital for Rheumatic Diseases and Dept Pharmacy and Pharmacology, University of Bath, UK; 4) NIHR-Leeds Musculoskeletal Biomedical Research Unit, Leeds Institute of Molecular Medicine, University of Leeds, UK; 5) Haywood Hospital, Stoke on Trent and Arthritis Research UK Primary Care Centre, Keele University, UK.

Psoriatic arthritis (PsA) is a chronic inflammatory joint disease that typically accompanies psoriasis vulgaris (PsV). Both conditions are considered to be complex diseases with both genetic and environmental susceptibility factors. Comparing the results from genome-wide association studies performed across many common autoimmune diseases, including PsA and PsV, has revealed an extensive overlap in the genetic liability between autoimmune diseases in general.

Based on the observed sharing of susceptibility loci across autoimmune diseases, the aim of this project is to identify novel susceptibility loci for PsA by fine-mapping all the currently confirmed susceptibility loci for 12 autoimmune diseases.

Data was available for 929 PsA cases and 4537 healthy controls genotyped using the Immunochip Illumina iSelect array at the Sanger Centre (www.sanger.ac.uk). Control data was sourced from the WTCCC (www.wtccc.org.uk). This custom array was designed to comprehensively fine-map confirmed autoimmune susceptibility loci and contains 196,524 SNPs covering approximately 200 candidate regions. A strict SNP-focused quality control process was applied to the dataset followed by single point analysis using the Armitage test for trend.

Association analysis of 182,883 high quality SNPs in 862 cases and 4306 controls detected robust association to previously confirmed PsA risk loci; *HLA-C* (p_{trend}=8.2x10-35), *IL23R* (p_{trend}=8.4x10-8) and *TRAF3IP2* (p_{trend}= 2.8x10-7), *IL12B* (p_{trend}=6.5x10-6). In addition we find convincing evidence to support association to a number of novel loci not previously reported for PsA, including; 17q21 (p_{trend}=3.3x10-05, *SMARCE1*), 18p11 (p_{trend}=2.0x10-05, *PTPN2*), 11q23 (p_{trend}=1.4x10-05, *TREH*), and 19p13 (p_{trend}=9.8x10-05, *TYK2*). Interestingly, we also find convincing evidence for association to the *CARD15* gene, supported by multiple SNPs.

Validation of these results is currently underway in an independent sample collection. This preliminary single-point analysis will be followed by analyses to identify independent effects at known and newly discovered loci.

638F

Evidence for a role of the familial cylindromatosis tumor suppressor *CYLD* in inflammatory bowel disease. *I. Cleynen[1], E. Vazeille[2], M. Artieda[3], M. Szczypiorska[3], M. Bringer[2], H.W. Verspaget[4], P.L. Lakatos[5], F. Seibold[6], A. Tariq[7], R.K. Weersma[8], I. Arijs[1], S. Müller[6], A. Tordai[9], D.W. Hommes[4], K. Parnell[7], C. Wijmenga[8], P. Rutgeerts[1], D. Lottaz[10], K. Van Steen[11], A. Darfeuille-Michaud[2], S. Vermeire[1], IBDase FP7 European Consortium.* 1) Targid, Gastroenterology, KU Leuven, Belgium; 2) Université d'Auvergne, Clermont-Ferrand, France; 3) Progenika Biopharma, S.A., Derio, Spain; 4) Gastroenterology and Hepatology, LUMC, the Netherlands; 5) Medicine, Semmelweiss University, Hungary; 6) Gastroenterology, Spitalnetz, Switzerland; 7) Peninsula Medical School, UK; 8) Gastroenterology and Hepatology, UMC Groningen, the Netherlands; 9) Molecular Diagnostics, Hungarian National Blood Transfusion Service, Hungary; 10) Rheumatology, Inselspital, Switzerland; 11) Electrical engineering and computer science, Montefiore Institute, ULG, Belgium.

Proteases and protease inhibitors (P/PI) affect several components that contribute to mucosal barrier integrity. We aimed to elucidate whether and if any P/PIs are involved in pathogenesis of Inflammatory Bowel Disease(IBD)trough a genetic association study. Selection of genes was based on a previous performed systematic review of relevant published genetic studies in IBD, in which the comprehensive list of P/PIs was ranked according to available genetic evidence for association with IBD. A total of 185 tagging SNPs in 23 genes were genotyped in an exploratory cohort of 650 Crohn's disease (CD) patients (CD1), and 542 healthy controls (HC1). Replication of SNPs with $p_{uncorrected}$<0.1 was performed in 4 independent cohorts: CD2 (n=634), HC2 (n=900); CD3 (n=377), HC3 (n=354); CD4 (n=432); and CD5 (n=227). Cases and controls were compared based on an additive genetic model (SVS v7.4.0). P-values were corrected for multiple testing using FDR correction. 12 SNPs showed significant association (p_{FDR}<0.05) in the combined cohort [CD1-5 (n=2320) vs HC1-3 (n=1796)]: 5 SNPs in *USP40*, 2 in *APEH*, 1 in *USP3*, and 4 in *CYLD*. Strongest signals were seen in *CYLD*, a cytoplasmic deubiquitinating enzyme located 9kb downstream of *CARD15*. Logistic regression including the *CARD15* and *CYLD* SNPs pointed to independent signals (p*CYLD*rs12324931<0.001, OR=1.8[1.3-2.5]; p*CARD15*rs2066845<0.001, OR=3.1[1.7-5.4]; p*CARD15*rs2066847<0.001, OR=3.4[2.2-5.4]). *CARD15*-negative patients showed significant association with rs12324931 (p=0.008). Interaction analysis showed significant interaction between rs2066844 and rs12324931, also after correction for main effects (p=0.001). CYLD has previously been shown to be highly downregulated in the intestine of IBD patients. Upon transfection of T84 intestinal epithelial cells with siRNA directed against CYLD, the CD-associated adherent-invasive *Escherichia coli* strain LF82 showed significantly increased adhesion (2.3-fold, p<0.01), invasion (2.6-fold, p<0.03) and survival ability (2.1-fold, p<0.05), compared to control siRNA transfected cells. We provide strong evidence for association of *CYLD* on 16q12.1 with CD, which is independent from *CARD15*. CYLD is a known key negative regulator of NF-2B, and as shown in this study, could play a role in CD trough regulation of antibacterial defense. Moreover, we identified several genetic variants in other protease/protease inhibitor genes which are implicated in CD, and which warrant further follow-up.

Novel genes for Crohn's Disease using a genetic-localisation approach: the way forward in Genome-Wide Association mapping. *H. Elding, W. Lau, D.M. Swallow, N. Maniatis.* Research Department of Genetics, Evolution & Environment, University College London, London, United Kingdom.

Despite extensive Genome Wide Association (GWA) studies on Crohn's Disease (CD) only 20-25 percent of the reported genetic risk has been accounted for. With the aim of shedding light on the remaining genetic contribution, we have re-analysed the publicly available Wellcome Trust (WTCCC) data using a powerful multi-marker mapping approach. This model takes directly into account the underlying Linkage Disequilibrium (LD) structure by modelling on genetic distances in Linkage Disequilibrium Units (LDU) rather than physical locations. This method also provides an estimated location of the causal variant. Here we report novel susceptibility genes, which were replicated using an independent GWA dataset. New genes include *LPP*, *IL1R2*, *SOX4*, *MARCKS*, *IFNGR1*, *MTUS1*, *FAS*, *CDH1/CDH3*, *IRF8* as well as several other genes. The function of the genes mentioned here can be classified into 4 different categories: cell-cell adhesion and motility, phagocytosis, apoptosis and immunity and inflammation, all four being of great relevance to the phenotypic characteristics which define CD. Interestingly, some of the above mentioned genes have been reported for other immune-related diseases, which share similar characteristics with CD. *LPP* was previously reported for Celiac Disease and Vitiligo whereas *FAS* was reported for Immunoglobulin A deficiency. *IL1R2* was identified for Ankylosing Spondilitis and for Ulcerative Colitis (UC), which is the other form of Inflammatory Bowel Disease (IBD) together with CD. Remarkably, *SOX4* was identified in a study on Bone Mineral Density, an indirect indicator of Osteoporosis, where the latter also happens to be one of the extra-intestinal manifestations of CD. The method used for this study not only gives novel insights into the genetics underlying CD and evokes the fact that the well-reported missing genetic contribution could be the result of the methods currently in use, but also provides a promising way forward in understanding the genetics of CD and other complex disorders.

640F

Combining family- and population-based genetic association from multiple rare variants. *D. Fardo[1], A. Druen[1], I. Ionita-Laza[2].* 1) Dept. of Biostatistics, University of Kentucky College of Public Health, Lexington, KY; 2) Dept. of Biostatistics, Columbia University Mailman School of Public Health, New York, NY.

Genetic association studies can be broken into two broad categories: population studies (most often of the case-control variety) that collect unrelated individuals, and family studies that recruit related pedigrees. It is not uncommon for studies of both categories to be available for a particular disease. In this situation, it is more powerful to combine the evidence for association rather than to conduct the analyses separately. Various aggregation approaches have been developed, but they have all been designed in the context of common variants.

Recently developed next generation sequencing technologies have made it feasible to assess association between multiple rare variants and disease. This, in combination with motivation to target the so-called `missing heritability' from genome-wide association studies, has made the study of rare variation particularly attractive. Methods to handle the problems due to the sparsity of rare variants generally focus on rules to collapse variation across some genetic unit, e.g., a gene. We present here a unified method to aggregate population and family data using resequencing data and assess its performance using simulation.

Use of 1000 Genomes Project Data to Search for Functional Variants in the GWAS Catalog. *J. Farrell.* Biomedical Genetics L320, Boston Univ Med, Boston, MA.

Genomes-wide association studies have successfully found highly significant associations between SNPs and many diseases. Detecting the functional variants that are driving these signals is more challenging. Often the most significantly associated SNPs in a GWAS are not biologically relevant but are instead in strong linkage disequilibrium (LD) with one or more nearby functional variants. To prioritize the search for functional variants, a bioinformatics tool has been developed to find all non-synonymous SNPs in strong LD with the top results of a GWAS analysis. With the recent availability of the 1000 genomes project data, a comprehensive list of all potential variants in LD with top GWAS results is now feasible. To demonstrate the tool, an LD scan for all non-synonymous SNPs were completed on all SNP-trait associations listed in the May, 2011 version of the NHGRI GWAS Catalog available for download from the UCSC genome browser. At the time of the analysis, the GWAS catalog had 5631 SNPs associated with 419 phenotypic traits. Among these cataloged associations, there were a total of 205 traits with associations with non-synonymous SNPs (3.6%). The European 1000 Genomes Data (August, 2010 release) were scanned for all non-synonymous SNPs in strong LD with the GWAS Catalog SNPs. An LD scan of the 5631 SNPs detected an additional 1306 non-synonymous SNPs in strong LD (r2 > 0.4). Of these, 791 SNPs were in very strong LD (r2> 0.8). A total of 242 of these non-synonymous SNPs were predicted to be possibly or probably damaging based on the Polyphen-2 prediction regarding the impact of the amino acid change. The usefulness of this approach can be seen with a phenotype such as Alzheimer's disease which has a previously well established association (pre-GWAS) with APOE4. In the GWAS Catalog, the most significant p-values reported are for SNP rs2075650 (p-value= 1x10-295) which is found in the intron of the nearby TOMM40 gene and not APOE. The LD scan of non-synonymous SNPs in strong LD with rs2075650 did find SNP rs429358 (r2=0.45). SNP rs429358 is one of the 2 non-synonymous SNPs that define the amino acid changes found in the APOE4 protein. The use LD scans of the 1000 genomes data for non-synonymous SNPS appears to be a computationally efficient method to rapidly detect a comprehensive list of potential functional variants for replication, pathway analysis and follow-up experiments for genome wide association studies.

Dense mapping across a European population shows association with Ikaros family member *Aiolos* in SLE. *S.G. Guerra[1], J. Bentham[1], D.L. Morris[1], V. Anand[1], C.L. Pinder[1], A.M Delago-Vega[2], P.R Fortin[3], J. Wither[3], J. Martin[4], M.E. Alarcón-Riquelme[5], J.D Rioux[6], T.J Vyse[1], D.S. Cunningham-e Graham[1], BIOLUPUS, CaNIOS-GenES.* 1) Department of Medical & Molecular Genetics, King's College london, London, United Kingdom; 2) Department of Genetics and Pathology, University of Uppsala, Dag Hammarsjölds väg 20, 75185 Uppsala, Sweden; 3) Toronto Western Hospital, Main Pavilion, 399 Bathurst St, Toronto, Ontario, M5T 2S8, Canada; 4) Instituto de Parasitología y Biomedicina Lopez-Neyra, CSIC, Calle del Conocimiento, 18100 Armilla, Spain; 5) GENYO, Centro de Genómica e Investigación Oncológica Pfizer, Universidad de Granada, Junta de Andalucía, Avenida de la Ilustración 114, 18007 Granada, Spain; 6) Montreal Heart Institute, Université de Montréal, 5000 rue Belanger, Montreal, Quebec, H1T 1C8, Canada.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterised by hyperactive T and B cells, autoantibody production and immune complex deposition. The exact aetiology of the disease is not fully understood; however, a strong genetic component has been established. We conducted a genome-wide association study (GWAS), comprising (post QC) 4,254 European SLE cases and 8,578 controls on 750,000 SNPs (Omni1-Quad chip. Analysis of these data suggests *Aiolos* is a novel risk locus for SLE. *Aiolos* (*IKZF3*), a transcription factor of the Ikaros zinc-finger protein family, plays an important role in B cell differentiation and proliferation. Located at 17q21, *Aiolos* can form heterodimers with *Ikaros* (*IKZF1*), located at 7p12, important in B cell differentiation and proliferation. *Aiolos* and *Ikaros* have previously been associated with other autoimmune diseases such as RA and *Ikaros* has been associated with SLE p=2.79x10^{-23}. Previous reports in *Aiolos*$^{-/-}$ mice have shown increased levels of pre-B and immature B cells with a hyperactive BCR signalling leading to spontaneous auto-antibody production. These mice also present an increased rate of apoptosis suggesting a wider role of *Aiolos* in cell survival. The aforementioned are all characteristics seen in SLE.

Our data shows multiple associated SNPs in *Aiolos* after SNPTEST analysis of our European cohort. Our top associated SNPs were rs34758895 and rs9899345 (both intronic), p values of 1.71x10^{-8} and 2.79x10^{-8}, respectively, OR=[1.33-1.82, 1.30-1.75]. Preliminary analysis using SNPTEST, suggests 3 independent associated signals, with 1 signal in the 3'UTR and 2 intronic signals. We will perform a meta analysis combining our data with published GWAS data (1716 cases, 3500 controls) to improve the power of our study. Using qPCR we are currently quantifying levels of *Aiolos* transcript isoforms in B cells of cases and controls. Expression levels will be correlated with genotype and sub-phenotype groups such as nephritis. Our data suggest variants in *Aiolos* increase the susceptibility of SLE. Further work is needed to analyse the function of *Aiolos* in B cell development and the effect that variants have on B cell differentiation and proliferation. Further investigation is also needed into interactions between *Aiolos/Ikaros* and the effect variants have on these heterodimers and their pathway.

Integrated pipeline for copy number variation, linkage and homozygosity, aids interpretation of variants identified through Next-Gen sequencing. *K. Schmitz[1,2], K. Markianos[1,2].* 1) Genetics, Harvard Med, Boston, MA; 2) Genetics, Children's Hospital Boston, MA.

With the wide, low cost availability of Next Generation sequencing, there is a need to combine information from family linkage, copy number variation (CNV) as well as population level homozygosity to aid interpretation of sequencing results. We integrate existing methods into an automated pipeline that will facilitate the search for disease genes. For CNV analysis we use multiple calling algorithms to improve specificity and our own common variation database to improve interpretation of the results. For Affymetrix 6.0 SNP data, we use Birdsuite, Penncnv, Nexus and Affymetrtics Genotyping Console to obtain copy number events. To increase specificity, we use the intersection of two or more algorithms. To eliminate common variation in our results, we have compiled a CNV catalog of 1257 samples from the International HapMap project using the same pipeline. We automatically filter new findings against known variants using locus, matching CNV status (copy number 0, 1 or gain) and an optional minor allele frequency (MFA). Data management has been implemented and extended with links to Genome browsers as UCSC and DVG (Database of Genomic Variants) to visualize all the results in one composite view. Linkage and traditional homozygosity mapping can also be incorporated in the analysis and visualized along CNV results to highlight putative susceptibility loci. We present successful application of the pipeline in real world projects. Currently, we are working with brain malformations as Autism, Walker-Warburg, Microcephaly and mental retardation. For Congenital Sideroblastic Anemia (CSA), we were able to interpret a rare case with a two locus hit. A rare CNV (duplication) in the alpha globin (HBA) locus and a pathogenic mutation in the beta (HBB) locus. In addition to CSA the patient has been already diagnosed with Beta Thalassemia. For Centronuclear myopathy, we are performing functional analysis for a gene identified using linkage, CNV and overlapping mutations from exome sequencing. In our experience automation of the process minimizes the error inherent in manual curation of discrete genetic information and greatly speeds up interpretation of large data sets.

Genetic variation that predicts white blood cell count differential leukocyte types in the eMERGE Network. *D. Crosslin[1,4], A. McDavid[3], N. Weston[2], S. Nelson[4], X. Zheng[4], E. Hart[2], M. de Andrade[5], I. Kullo[6], C. McCarty[7], K. Doheny[8], E. Pugh[8], A. Kho[9], M. Hayes[9], S. Pretel[10], A. Saip[12], M. Ritchie[11], D. Crawford[11,12], P. Crane[13], K. Newton[2], D. Mirel[14], A. Crenshaw[14], E. Larson[2], C. Carlson[3], G. Jarvik[1], The electronic Medical Records and Genomics (eMERGE) Network.* 1) Division of Medical Genetics, University of Washington, Seattle, WA; 2) Group Health Research Institute, Center for Health Studies, Seattle, WA; 3) Fred Hutchinson Cancer Research Center, Public Health Sciences Division, Seattle WA; 4) Department of Bi statistics, University of Washington, Seattle, WA; 5) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 6) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 7) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 8) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 9) Division of Endocrinology, Metabolism, and Molecular Medicine, Northwestern University, Chicago, IL; 10) National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD; 11) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 12) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 13) Division of General Internal Medicine, University of Washington, Seattle, WA; 14) Program in Medical & Population Genetics, Broad Institute of Harvard & MIT; Cambridge, MA.

We performed a joint and ancestry-stratified genome-wide association analyses to identify variants associated with white blood cell count (WBC) differential leukocyte types in 13,923 subjects in the electronic Medical Records and Genomics (eMERGE) Network. The Network is a consortium of five U.S. cohorts linked to electronic medical record (EMR) data for conducting large-scale, high-throughput genetic research. A majority of the subjects had multiple visits over many years for the duration of the EMR, which presented challenges and opportunities to assess different association methods utilizing repeated measures. The cell types are measured as a proportion of the total WBC. These types, in order of predominance, include neutrophils, which respond to acute infection; lymphocytes, both B and T cells with antigen receptors; monocytes, large, phagocytic cells; eosinophils, antiparasitic markers of allergic disease; and basophils, that release histamine.

Results for neutrophil count and lymphocyte count strongly resembled two WBC-associated regions ($p \leq 5.0e\text{-}8$) that we previously reported. These include the region surrounding the Duffy antigen/chemokine receptor gene (*DARC*) on chromosome 1 in the African ancestry subjects and chromosome 17 in the European ancestry subjects. SNPs in the latter region tag three genes (*GSDMA*, *MED24* and *PSMD3*) that have been reported to be associated with inflammatory diseases including asthma and Crohn's disease.

Variants in two genes were associated with monocyte count; in *ITGA4*, which encodes a receptor for fibronectin in WBC and participates in T-cell interactions with target cells (p for rs2124440 = 5.7e-17); and in *IRF8*, which encodes a transcription factor that specifically binds to the upstream regulatory region of type I IFN and IFN-inducible MHC class I genes (p for rs424971 = 2.8e-16).

The joint sample reveals multiple regions with genome-wide significant associations for eosinophil and a single region for basophil counts. This single region includes *GATA2* on chromosome 3 that has been reported to be associated with coronary heart disease. Assessment of the contribution of top hits to candidate pathways is underway.

645F

A Genome-Wide Meta-Analysis of Serum Total IgE among Racially and Ethnically Diverse Populations. *A.M. Levin[1], R.A. Mathias[2], L. Huang[2], L.K. Williams[3], K.C. Barnes[2], The EVE Consortium.* 1) Public Health Sciences, Henry Ford Hlth System, Detroit, MI; 2) Department of Internal Medicine, The Johns Hopkins University, Baltimore, MD; 3) Center for Health System Research, Henry Ford Hlth System, Detroit, MI.

Immunoglobulin E (IgE) is an important mediator in allergic inflammation and is often elevated in atopic conditions, such as asthma. Recently published genome-wide association studies for asthma and serum total IgE levels suggest that there are some, but not many, overlapping common single nucleotide polymorphisms (SNPs) in genes associated with these phenotypes. Additionally, serum total IgE levels are also known to differ by population group in the U.S. However, African Americans and Latinos have not been well represented in genome-wide association studies of total IgE to date. The EVE consortium comprises nine U.S groups with genome-wide association data on individuals with and without asthma, and includes associated phenotypes, such as total IgE levels. We carried out a genome-wide meta-analysis of serum total IgE levels across this broadly representative patient population. In total, 5,064 individuals (2,456 African Americans, 1,563 European Americans, and 259 Latinos) were available for analysis. Race-ethnic specific association analyses were carried out within each of the EVE study groups stratified by asthma case and control status. The resulting p-values and directions of effect were combined via an inverse normal meta-analysis weighted by the number of individuals contributing to each association model. Eleven unique regions were identified in the combined analysis which met a threshold p-value of $5x10^{-6}$ and were informative in at least two of the three race-ethnic groups. Ten of these regions were novel, and three of these appeared to be unique to populations with a component of African admixture (i.e., African American and Latino participants). One region, HLA-DQB1, which had been previously identified as associated with total IgE among Europeans and European Americans, was associated with IgE in our overall analysis ($p=1.9x10^{-6}$) and within the individual race-ethnic groups (African American p=0.002, European American p= 0.035, and Latino $p=6.4x10^{-6}$). We also validated a number of previously identified genes associated with total serum IgE levels across multiple race-ethnic groups; these genes included FCER1A, RAD50, STAT6, IL13, HLA-DRB1, RORA, IL4R/ IL21R, IL4, FCERB1, and SLC22A5. This study provided new insight into the genetics of total IgE by confirming previously identified loci across multiple race-ethnic groups and by identifying potentially novel race-ethnic specific effects in African American and Latino individuals.

Immunochip-based GWAS follow-up study identifies novel primary biliary cirrhosis risk loci and better defines allelic architecture at known loci. *J.Z. Liu[1], M.A. Almarri[1], G.F. Mells[2,3], H.J. Cordell[4], M.A. Heneghan[5], J.M. Neuberger[6], P.T. Donaldson[7], D.E. Jones[7], G.J. Alexander[3], R.N. Sandford[2], C.A. Anderson[1], The UK PBC Consortium and The Wellcome Trust Case Control Consortium 3.* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 2) Academic Department of Medical Genetics, Cambridge University, Cambridge, UK; 3) Department of Hepatology, Cambridge University Hospitals National Health Service (NHS) Foundation Trust, Cambridge, UK; 4) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, UK; 5) Institute of Liver Studies, King's College Hospital NHS Foundation Trust, Denmark Hill, London, UK; 6) The Liver Unit, Queen Elizabeth Hospital, Birmingham, UK; 7) Institute of Cellular Medicine, Medical School, Newcastle University, Newcastle upon Tyne, UK.

Primary biliary cirrhosis (PBC) is an autoimmune disorder characterized by immune-mediated destruction of the hepatic bile ducts resulting in cholangitis and, ultimately, cirrhosis of the liver. PBC is a leading cause of liver transplantation and the prevalence in the UK is around 35 per 100,000 adults. Although the etiology is poorly understood, a complex interplay of genes and environment is known to drive disease susceptibility and progression. Genome wide association studies (GWAS) have confirmed 19 loci associated with PBC risk, and highlighted the role of NF-KB signaling, T-cell differentiation and toll-like receptor (TLR) and tumor necrosis factor (TNF) signaling in disease pathogenesis. In an effort to identify further disease associated loci and better define causal variants we performed an association and fine-mapping study of approximately 3000 PBC cases and 7000 population controls genotyped using Immunochip. The Immunochip is an Illumina iSelect HD custom genotyping array that contains SNPs derived from population based sequencing efforts (such as 1000genomes) across confirmed autoimmune disease risk loci. Seventeen previously associated loci achieve genome-wide significance (P<5x10-8) with the remaining two loci showing convincing evidence of replication (P<5x10-3). Through conditional analysis we found evidence for secondary independent genome-wide significant associations at three distinct loci (2q32, 7q32 and 16p13), while an additional locus on chromosome 3q26 contained three such associations. At the previously associated 17q12 locus, we identified a 1000genomes derived SNP within *IKZF3* that was more than four orders of magnitude more significant than the most associated SNP from our recent GWAS. This preliminary finding suggests that *IKZF3*, rather than *ORMDL3*, could harbor the causal variant(s) at this locus. We also discovered five novel PBC regions, thus implicating several functional candidates involved in immune regulation and inflammation such as *CCL20*, *IL12B*, *TYK2*, *ICOSLG* and *IL22RA2*. These loci have previously been reported to be associated with other distinct autoimmune disorders including type 1 diabetes, systemic lupus erythematosus, Crohn's disease and ulcerative colitis. This study further highlights the shared genes and pathways in autoimmunity and illustrates the use of cost-effective custom-made chips in exploring disorders of similar genetic etiology.

647F

Genome-wide genetic investigation into variation of food allergen antibodies in participants of the San Antonio Family Heart Study. *R. Rubicz[1], R. Yolken[2], E. Drigalenko[1], T.D. Dyer[1], J. Kent, Jr.[1], M. Carless[1], J. Curran[1], M. Johnson[1], S.A. Cole[1], L. Almasy[1], E.K. Moses[1], J. Blangero[1], H.H.H. Göring[1].* 1) Dept of Genetics, Texas Biomed, San Antonio, TX; 2) Dept of Pediatrics, Johns Hopkins School of Medicine, Baltimore, MD.

Aberrant responses to dietary antigens affect millions each year in the U.S., with symptoms generally consisting of gastrointestinal dysfunction and autoimmunity. Previous research indicates that such hyperactive immune response to certain food proteins tends to run in families, and although genetic factors have been implicated in some instances (i.e., 27 different loci associated with celiac disease) the underlying disease processes remain largely unknown. Here we quantify the genetic contribution to antibody levels against food antigens, and attempt to localize genetic factors influencing these traits. Participants included >1300 Mexican Americans in the San Antonio Family Heart Study. Antibody titers were determined by ELISA for the following food antigens: bovine casein; two forms of wheat gliadin; two forms of bovine serum albumin (BSA), as well as human serum albumin (HSA). In addition to food allergies, these antibodies have been associated with autoimmune and psychiatric disorders. Additive genetic heritability (h2) was calculated using variance component (VC) pedigree analysis with the computer program SOLAR, and the influence of shared environmental factors was assessed by including a random effects household component in the VC model. Genome-wide variance components linkage and measured genotype association analyses were performed using 931,219 SNPs. Heritability estimates are significant for all traits, ranging from h2=0.15 (BSA-a) to 0.53 (gliadin-b), and shared household is also significant for all traits (0.06-0.33, for BSA-b and gliadin-b, respectively). Although no significant genome-wide linkage or joint linkage and association results were obtained, there are suggestive association results for gliadin-b (p=9.75x10-8) for SNP rs7192 located in the HLA region on chromosome 6, and casein (p=3.33x10-7) for SNP rs11635085 on chromosome 15. We also performed genome-wide expression profile analysis using expression data from peripheral blood lymphocytes (for >16,000 transcripts), as an independent means of prioritizing likely candidate genes and to help interpret the linkage/association results. Significantly correlated transcripts were identified for 3 of 5 food allergens (BSA-a, gliadin-a, and gliadin-b) and for HSA. These results demonstrate that individual genetic differences contribute to food allergen antibody measures in this population, and further investigation may help elucidate the underlying immunological processes involved.

648F

Heritability and genetic mapping of hundreds of immune-related quantitative traits measured in a large Sardinian cohort. *S. Sanna[1], G. Sole[1], M. Steri[1], M. Dei[1], S. Lai[1], F. Virdis[1], D. Schlessinger[2], M. Congia[3,4], S. Naitza[1], V. Orrú[1], E. Fiorillo[1], F. Cucca[1,5].* 1) IRGB-CNR, Monserrato, Italy; 2) Laboratory of Genetics, NIA, Baltimore, MD, USA; 3) Dipartimento di Scienze Biomediche e Biotecnologie, Università degli studi di Cagliari, CA, Italy; 4) Azienda Sanitaria Locale n.8, Cagliari, Italy; 5) Dipartimento di Scienze Biomediche, Università di Sassari, SS, Italy.

Genome-wide association scans (GWAS) have identified over hundreds of regions associated with immune diseases, but identification of the specific causal variants and clarification of the underlying functional mechanisms remain a great challenge. In particular, GWAS discovery of pathogenetic changes in the immune system have been largely limited to major classes of white cells. Here we systematically evaluated quantitative variation of the majority of lymphocyte cell populations (T cells, B cells, Natural Killer (NK) cells, regulatory T cells, dendritic cells, and their subsets) as well as T cell maturation in minimally manipulated fresh blood samples by polychromatic flow cytometry, resulting in 56 immune-related traits. This approach can be informative not only for the understanding of associated loci but also for identification of novel genetic factors in health and disease through the dissection of the endo-phenotypes. Some of the cellular populations were assessed both as absolute count (cell/ul) and as percentage referred to parents and grandparents, leading to a total of 184 quantitative traits for analysis. To avoid confounding effects due to the pathology itself, these phenotypes are being measured in a large cohort of >6,000 healthy individuals enrolled in the SardiNIA project. A preliminary assessment on 946 individuals in 317 families showed that 117 traits are highly heritable (>40%), and for all traits sex and age play an important role in explaining part of the non-genetic variation (up to 50%). Using existing data, we also performed a GWAS for all traits to evaluate the additive effect of ~2.5 Million markers, either genotyped or imputed. Despite the small sample size, we observed 21 loci showing genome-wide significant pvalues for 20 non-redundant traits ($1x10^{-12} < P < 5x10^{-8}$). Notably, in addition to completely novel loci, our results include the previously reported association within the cluster of genes from the Schlafen family and NK cell level variation (rs9916629, $P=3x10^{-8}$). Two other loci have been previously associated with ulcerative colitis, proving the relevance of our approach for the understanding of the biological mechanisms underlying complex immune-related diseases. In conclusion, we have initiated a systematic evaluation of immune-phenotypes on a large, intensively genotyped cohort and established the bases for a biologically informative extensive battery of GWAS for the identification of the associated genetic factors.

649F

Parent-of-Origin Effect of a T2D-associated *GRB10* Polymorphism on Glucose Homeostasis. *J. Liu, C.M. Damcott, J.R. O'Connell, B.D. Mitchell, A.R. Shuldiner, Y. Cheng.* Dept Human Gen, Univ Maryland, Baltimore, MD.

Genome-wide association studies (GWAS) have identified common variants in growth factor receptor-bound protein 10 (*GRB10*), which encodes an adaptor protein regulating insulin receptor signaling, as a strong candidate for glucose homeostasis and type 2 diabetes (T2D). Nevertheless, genetic associations between *GRB10* and T2D have not been consistently replicated. *GRB10* is an imprinted gene that is expressed in an isoform- and tissue-specific manner. Therefore, we hypothesize that the effect of genetic variants of *GRB10* is dependent on the parent-of-origin (POO). In our previous T2D GWAS study, rs2237457 (T/C polymorphism) in *GRB10* showed the strongest association with T2D (OR=1.64, p=1.1x10-5, T allele) and was also associated with glucose area under the curve (GAUC) in response to an oral glucose tolerance test (OGTT) in non-diabetic individuals (p=0.001). To test our hypothesis, we studied an extended Amish cohort (n=745) characterized for 2 hour glucose (2hGlu, mmol/l) and GAUC (mg/dl-hr) in response to OGTT and genotyped for rs2237457. The paternal and maternal alleles of rs2237457 were inferred by breaking the large Amish pedigree into smaller nuclear families and estimating the most likely pattern of gene flow in the families as implemented in MERLIN software. We first confirmed the initial associations of rs2237457 and OGTT traits in this extended cohort: GAUC () =15.04, p=5.24X10-5) and 2hGlu () =0.35, p=1.46X10-4), adjusting for age, sex, BMI, and familial relatedness. To examine the effect of rs2237457 according to their POO, we divided heterozygous individuals (n= 268) into two groups: paternal T/maternal C (TpCm) genotype and maternal T/paternal C (TmCp) genotypes. Compared with CC genotypes (n=307), the paternal T allele (TpCm) was significantly associated with GAUC ($)_{GAUC}$= 16.31, p=0.007) and 2hGlu ($)_{2hGlu}$=0.47, p=0.002), but the maternal T allele (TmCp) was not ($)_{GAUC}$=0.99, p=0.89 and $)_{2hGlu}$=0.12, p=0.49). We further compared glucose levels directly between heterozygous subjects with the paternal T allele transmitted vs. those with the maternal T allele transmitted. These comparisons revealed POO effects to be significant for GAUC (p= 0.01) and marginally significant for 2hGlu (p=0.05). In conclusion, we found that the paternal, but not maternal, allele of rs2237457 was associated with OGTT glucose traits in the Amish, suggesting POO could be one possible mechanism underlying the contribution of GRB10 to the risk of glucose homeostasis and T2D.

650F

A new statistical model for family-based case-control studies of genetic imprinting. *Z. Wang[1], R. Wu[2].* 1) Division of Biostatistics, Yale University, New Haven, CT; 2) Center for Statistical Genetics, The Pennsylvania State University, Hershey, PA.

Genetic imprinting has been recognized to play an important role in the formation and pathogenesis of human diseases. In this study, we present a statistical model for testing the effect of genetic imprinting (or parent-of-origin) on a human disease in case-control studies with family structure. For each subject sampled from a case and control population, we not only genotype its own single nucleotide polymorphisms (SNPs), but also collect its parents' genotypes. By tracing the transmission pattern of alleles from parental to offspring generation, the model allows the characterization of genetic imprinting effects based on χ^2 tests of a contingency table. The model is expanded to test the interactions between imprinting effects and additive, dominant, and epistatic effects in a complex web of genetic interactions. Statistical properties of the model are investigated and its practical usefulness is validated by a real data analysis.

Genetic variations and interactions in anti-inflammatory cytokine pathway genes in the outcome of Leprosy. *S. AGGARWAL[1], S. Ali[1], R. Chopra[1], A. Srivastava[1], K. Arasan[1], D. Malhotra[1], S. Gochhait[1], V.K. Garg[2], S.N. Bhattacharya[3], R.N.K. Bamezai[1].* 1) National Centre of Applied Human Genetics, School of life Sciences, Jawaharlal Nehru University, New Delhi, 110067, India; 2) Department of Dermatology and Sexually Transmitted Diseases, Maulana Azad Medical College, Lok Nayak Jai Prakash Hospital, New Delhi, 110002, India; 3) Department of Dermatology and Venereology, University College of Medical Sciences and GTB Hospital, India, G.T.B. Hospital, Delhi, 110095, India.

Mycobacterium leprae is the etiologic agent of leprosy, an ancient scourge that still causes illness in several regions of the world. The role of host genetic factors in conferring susceptibility to this disease has long been a focus of research, with the discovery of many loci by segregation, twin, case-control and genome-wide studies. To identify, how genes in a pathway control and in unity contribute to disease susceptibility, we genotyped 51 SNPs in anti-inflammatory cytokines (IL10, TGFB1, IL6, IL4 and IL13) and receptors (IL10RA, IL10RB, TGFBR1, TGFBR2, IL6R, IL4R, IL5RA, IL5RB and IL13RA1) using Sequenom Mass Array. We included a total of 2082 individuals, including patients and controls from the North Indian population and replicated our results in an East Indian population, from the geographically distinct state of Orissa. Significant associations (P<0.05) were observed for 8 polymorphisms (rs1800871, rs1800872, rs1554286 of IL10; rs3171425, rs7281762 of IL10RB; rs2228048, rs744751 of TGFBR2 and rs1800797 of IL6) with leprosy. This association was replicated for 4 SNPs (rs1554286 of IL10, rs7281762 of IL10RB, rs2228048 of TGFBR2, rs1800797 of IL6). Beside this, we also evaluated the effect of SNP-SNP interaction in providing risk or protection to leprosy depending upon the combination of genotypes. The interaction study revealed significantly greater effect of leprosy risk than that obtained for any SNP individually. Furthermore, we also established the functional status of the SNPs through in-vitro reporter assays. Our results unravel the role of as yet unknown functional polymorphisms in immunologically important genes, to understand the severity of the disease. In conclusion, this study provides an interesting cue to cumulative polygenic host component which regulates leprosy pathogenesis.

Estimating Heritability of Human Papilloma Virus (HPV) Vaginal Infection in Korean Women. *M. Han[1], D. Lee[1], H. Lee[4], J. Lee[4], K. Go[4], Y. Song[2], K. Lee[3], J. Sung[1].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health Seoul National University; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, SungKyunKwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea; 4) Department of Environmental Health, Institute of Health and Environment, School of Public Health, Seoul National University, Seoul, Korea.

Cervical cancer is the second most common cancer in women worldwide. Infection with the human papilloma virus (HPV) is regarded as a sexually transmitted disease (STD). Also HPV infection is well-established and the most important causes uterine cervix cancer. Several studies indicate that genetic background of host is important for cervical cancer susceptibility. However, only limited evidence has been reported regarding whether the host genetic susceptibility contributes to the HPV infection. This study aims to assess overall genetic contribution to HPV infection quantitatively in terms of heritability. Vaginal smears during the Papanicolau test were taken from 951 women, (including 327 monozygotic (MZ)) between 2006 and 2009, (mean age 48 ± 11.4, 25~79 year old) counting 663 families, in the Healthy Twin study: a twin-family cohort in Korea. To detect HPV, Polymerase chain reaction (PCR) was executed using two primer sets of GP5+/GP6+ and PGMY09/PGMY11. The identification of HPV was confirmed by nucleic acid sequence analysis. Phylogenetic analysis was performed using the neighbor-joining method to confirm the genotype of HPV. Among HPV genotyping result of the participants 7.3% were positive for HPV, among which HPV 16 type observed in 13.9%, HPV 18 in 11.1%, and high risk genotype including HPV 16, 18 infection in 66.7%. Behavioral, reproductive characteristics, socioeconomic position (SEP), and male factors were assessed by questionnaire. The odds ratio (OR) for taking oral contraceptives and not taking oral contraceptives is 1.87 (95% C.I. 1.08~3.24). Tetrachoric correlations about HPV-positive were 0.39, 0.16, 0.13 and 0.10 for MZ pairs, sisters, any first degree (sisters together with mother-daughter pairs) , and mother-daughter pairs, respectively. Heritability was calculated by Variance component method using Sequential Oligogenic Linkage Analysis Routines (SOLAR). Heritability estimation for HPV infection was 0.24 to 0.33 in AE model, 0.21 to 0.30 in ACE model. In AE model, Additive genetic factors (A) is 0.31, unique environmental factor (E) is 0.69 adjusting for age, oral contraceptives intake, smoke and alcohol. In ACE model, A is 0.27, common environment factor (C) is 0.02 and E is 0.71. The study results indicate that there is a hereditary component of HPV infection. After adjusting to environmental, genetic factors were shown. These findings provide evidence that there is genetic susceptibility of HPV infection.

Detection of Genotyping Errors in Dense Markers on Large Pedigrees. *C.Y.K. Cheung[1], E.A. Thompson[3], E.M. Wijsman[1,2].* 1) Dept. Biostatistics, University of Washington, Box 357232, Seattle, WA. 98195-7232, USA; 2) Dept. of Medicine, University of Washington, Box 359460, Seattle, WA. 98195-9460, USA; 3) Dept. of Statistics, University of Washington, Box 354322, Seattle, WA 98195-4322, USA.

Accurate results in linkage analysis depend on clean genotypes. To detect genotyping errors in pedigrees, Mendelian inconsistent (MI) error checks and multi-point methods, which flag Mendelian consistent (MC) errors with improbable joint genotypes, have been developed. However, detection of MC errors with exact computation for dense markers is restricted to small pedigrees due to computational reasons. In addition, the existence of linkage disequilibrium adds complication to error detection for dense markers. Here we introduce a new computationally-efficient method that allows detection of errors on very dense markers (e.g. SNPs and sequencing data) typed even on large pedigrees. Our method first samples inheritance vectors (IVs) using a moderately sparse but informative set of markers (framework panel) with gl_auto, a program in the MORGAN package that samples IVs either with exact Lander-Green calculations or a Markov Chain Monte Carlo approach. This scheme avoids violation of the necessary assumption of linkage equilibrium between dense markers and allows otherwise intractable computation. Conditional on IVs realized at framework positions, we then efficiently sample IVs at positions of dense markers. For error detection, we calculate either the percentage of IVs inconsistent with jointly observed genotypes (S1) or the posterior probability of error configurations (S2) and flag markers when the chosen statistic exceeds a threshold.

We tested our method on a simulated 5 generation 52-member pedigree, in which 34 subjects in the lower generations were observed. We simulated a clean framework panel of SNPs at 0.5cM density on a 100cM chromosome to infer IVs. We independently simulated 25000 markers with genotyping errors at a fixed rate of ~0.1%. Of 825 markers with at least 1 error, only 12.7% were MI. Applying our method to MC markers, with specificity of 99.9%, S1 and S2 flagged 85.3% and 85.8% of the remaining erroneous markers, respectively, with corresponding positive predictive value of 95.9% and 96.1%. S2 attributed error to the appropriate individual with 84.1% accuracy. The above results suggest that our method is effective in detecting MC genotyping errors. Moreover, the much quicker S1 statistic closely matches the performance of S2 while not requiring knowledge of marker allele frequencies or the use of an error model. Meanwhile, S2 allows us to attribute a detected error to an individual.

Polygenic Modeling of Disease Risk. *J. He, G. Chen, B. Henderson, C. Haiman, D. Stram.* Preventive Medicine, University of Southern California, Los Angeles, CA.

Purpose: Purcell et al (Nature 2009) described a substantial polygenic component to the risk of schizophrenia by constructing a risk score with thousands of SNPs. Here we evaluated the validity of this method in the African American Prostate Cancer Genome-Wide Association Study (AAPC GWAS) Methods: Using the actual AAPC GWAS data, we divided 3334 prostate cancer cases and 3472 controls into a discovery set (1500 cases/ 1451 controls) and a target set (1903 cases/ 1952 controls) based on distinct US geographic regions. 1047986 SNPs were tested for association with prostate cancer in the discovery set using logistic regression adjusted for ten principal components. SNPs with P values lower than a P value threshold were to contribute to the score as $\Sigma \log(OR_i) \times X_i$ for each SNP i. The score was then tested for association with prostate cancer in the target population. In order to determine the sensitivity of this method to long-range hidden relatedness we simulated disease status based on the genotypes in AAPC GWAS in which only a fraction (or none) of the causal SNPs were actually in LD with the SNPs that were treated as measured in the simulations. We randomly sampled 1000 SNPs on even number chromosomes as causal SNPs, each with effect bi (~normal(0,1)) used to explain half the total individual liability for disease. Two scores were calculated. The first score was constructed using all SNPs as candidate SNPs, while the second score was using only SNPs on odd number chromosomes (and thus not in LD with any causal variants except due to residual hidden relatedness not captured by principal components). These scores were then tested for associations with simulated disease status in the target sample. P value thresholds ranging from 10-4 to 0.5 were used in score construction. Results: In the AAPC GWAS, both the statistical significance and pseudo R square increased as a greater number of SNPs were included in the score when tested in the target population. In the simulation study, the performances of both scores in the target population were strongly significant ($p<10^{-4}$) when using P value thresholds between 0.01 and 0.05 in score construction. We conclude that the method used by Purcell et al may quite sensitive to subtle sample relatedness at least when applied to geographically separate African American populations.

Two-Layer Clustering Model For Linkage Disequilibrium With Applications in Population Structure, Local Ancestry Inference, And Haplotype-Phenotype Association Mapping. *Y. Guan.* Pediatrics and Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

We present a two-layer clustering model that aims to emulate the coalescent process with recombination, where a marginal coalescent tree is approximated by a hierarchy of star trees, and ancestral recombination is approximated by switching clusters within each hierarchy. The lower layer clusters represent haplotypes and the top layer clusters enforce structure on those haplotypes. Depending on the cluster-switching frequencies, such a structure may reflect difference in ancestries or more subtle difference of haplotype frequencies between case and control groups in disease association studies. In the former scenario, the population structure can be inferred using dense genotype data. Moreover, one can accurately infer local ancestries for multi-way admixed individuals. In the later scenario, one can detect haplotype-phenotype association in candidate regions. The model can be fitted for genetic data of a typical modern genome wide association study. It also has potentials in rare variants calling/imputing for next-gen sequencing data and we discuss related computational challenges and possible solutions.

The effect of missing data on type I error rate and power of family-based association tests. *T. Hiekkalinna[1,2], M. Perola[1,2], J.D. Terwilliger[2,3,4,5,6].* 1) Public Health Genomics Unit, National Institute for Health and Welfare (THL), Helsinki, Finland; 2) Institute for Molecular Medicine Finland FIMM; 3) Department of Psychiatry, Columbia University, New York, NY, USA; 4) Department of Genetics and Development, Columbia University, New York, NY, USA; 5) Columbia Genome Center, Columbia University, New York, NY, USA; 6) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY, USA.

Missing data is ubiquitous in family-based association (FBA) studies, as not all individuals will be alive or consent to be studied, especially parents of individuals with late onset diseases. Most FBA methods claim to work in the presence of incomplete data, but how well they behave in those circumstances is unclear. To this end, we have compared empirical type I error rates and power of several commonly used implementations of FBA tests, as a function of how much data is missing, using datasets composed of mixtures of singletons and families. We compare the performance of these tests under three hypotheses: (a) No linkage and no association; (b) Complete linkage and no association; (c) Complete linkage and association. The first two represent potential null hypotheses in (a) joint tests of linkage AND association; and (b) conditional tests of association given linkage. In power simulations, power was estimated for all methods for both joint tests and conditional tests, over a range of effect sizes for the functional locus, and a range of LD between the functional locus and a marker. The most notable result is that conditional tests of LD given linkage can have enormous type I error rates with some of the most popular methods for conditional testing, especially when the proportion of missing data is large. This can lead to an unacceptable rate of spurious conclusions about the presence of association, leading to fruitless follow up studies. Power is also shown to be optimal for methods based on full likelihood analysis of complete pedigree data, rather than methods based on the TDT. Results from a simulation-based study will be presented.

657F

Detection of phenotype-modifier genes using two-locus linkage analysis. *A. Bureau[1,2], J. Croteau[2], C. Mérette[2,3], A. Fournier[2], Y.C. Chagnon[2,3], M.-A. Roy[2,3], M. Maziade[2,3].* 1) Médecine sociale et préventive, Faculté de Médecine, Univ Laval, Québec, Canada; 2) Centre de recherche Université Laval Robert-Giffard, Québec, Canada; 3) Psychiatrie, Faculté de Médecine, Univ Laval, Québec, Canada.

In complex disorders, specific phenotypes such as disease diagnoses are often part of a broader disorder spectrum. For instance, schizophrenia (SZ), bipolar disorder (BP) and schizo-affective disorder are three diagnoses in the spectrum of major psychotic disorders. In families where multiple patients have a specific phenotype, the observation that relatives exhibit other forms of a broader phenotype suggests that some genes may increase risk for an array of phenotypes, while other causes determine which specific phenotype arises. In this context, we propose to test whether other genes determine the specific phenotype using a two-locus linkage analysis model where a gene 1 increases the risk for a broad phenotype and a gene 2 increases the risk of the specific phenotype, but only in carriers of the gene 1 susceptible genotype (i.e. gene 2 is a modifier). We deal with heterogeneity by selecting families showing evidence for linkage to the gene 1 locus. In a simulation study, we compared the proposed model to a single-locus analysis within subjects with the broad phenotype. We observed that the joint modeling of the specific and broad phenotypes had greater power to detect the modifier gene 2 than the single-locus approach (power = 0.96 vs. 0.54 under a simulation scenario including heterogeneity). This joint modeling was also more powerful than all analytic approaches considering only the specific phenotype. The strategy was then applied to a sample of 12 SZ and BP Eastern Quebec kindreds to identify genes conferring specific susceptibility to SZ or to BP by modifying the effect of a gene 1 at a locus linked to major psychosis as a broad phenotype. Among markers located within 11 regions where we previously detected linkage signals to SZ and/or BP, D8S1110 at 8p22 shows the strongest evidence of linkage to a gene predisposing specifically to BP among subjects already at risk of major psychosis because of the action of another gene at 10p13 (marker D10S245) in a subset of 6 families linked to 10p13 (conditional maximized LOD (cMOD) = 4.34, $p = 5 \times 10^{-5}$). The cMOD increases to 6.34 when including an additional 21 BP families. Some evidence of this modifying effect (cMOD = 3.45, $p = 3 \times 10^{-4}$) was also obtained when conditioning on 3q21-q23 (marker D3S2418). These results suggest that the proposed strategy is promising for detecting modifier genes conferring susceptibility to a specific phenotype in the presence of a gene predisposing to a broad phenotype.

A Robust Method for Identifying the Genes that Influence an Entire Spectrum of Disease-Related Phenotypes. *A. RoyChoudhury, W.C.L. Stewart, S.E. Hodge, D.A. Greenberg.* Department of Biostatistics, Columbia University, New York, NY.

Purpose: For some complex disease studies, individuals tend to be recruited for disease-related phenotypes. However, it is often difficult to know which of these individuals should be counted as affected in the subsequent genetic analysis. This is the disease definition problem, and the power of many studies depends crucially on how this problem is addressed. Here, we present a powerful and robust method that circumvents this problem by considering all possible disease definitions. Methods: We consider the case where families are ascertained on the basis of three disease-related phenotypes, S1, S2, and S3. From these phenotypes, we consider three possible disease definitions: S1 alone; S1 or S2; and S1 or S2 or S3. This particular scenario is inspired by our earlier work where families were ascertained for having at least one of three different panic disorder syndromes. Our robust linkage detection method, RLOD, is the lod score maximized over all possible disease definitions. To assess the power of the RLOD, we analyzed simulated data where the disease-related phenotypes of individuals were influenced by both genetic and environmental factors. Specifically, the following penetrance probabilities were used: $0 = Pr(Si \mid G0, E0) < Pr(Si \mid G0, E1) < Pr(Si \mid G1, E0) < Pr(Si \mid G1, E1) = 0.31$ for i = 1, 2, 3, where G1 and E1 are genetic and environmental risk factors, respectively. Furthermore, the difference in risk is only 1% between those who have G1and E1 versus those who have G1 and E0. Hence, in our simulations, the genetic risk factor tends to dominate over the environmental risk factor. Also, to control the type I error we used simulations under the null to estimate the critical value. From the analysis of 100,000 datasets with 25 nuclear families per dataset, we find that RLOD had 90% power to detect the disease gene, compared to 85%, 25%, and 6% power for competing methods that considered S1 or S2 or S3 as affected, just S1 or S2 as affected, and S1 alone, respectively. We also simulated data from a genetic model, which was inspired from our earlier work in epilepsy. Specifically, an abnormal EEG is an endophenotype or subclinical marker related to, and required for the diagnosis of epilepsy. However, among patients with epilepsy, individuals may have any combination of myoclonic and absence seizures. In these simulations, we find a similar pattern, and note that RLOD has more than 90% power to detect the disease gene.

Practical Issues for Designing Efficient Sequence-based Genetic Studies of Quantitative Traits. *R.C. Banuelos[1], D.J. Liu[1,2], S.M. Leal[1,2].* 1) Statistics, Rice University, Houston, TX; 2) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

There is great interest in understanding the role of rare variants in complex quantitative trait (QT) etiology. Although the cost of performing next generation sequencing has greatly decreased, the expense of sequencing and analyzing large datasets is still prohibitive. Therefore, implementing efficient genetic studies are crucial for maximizing power and reducing sequencing cost. Two study design strategies can be applied: 1.) Sampling individuals with extreme traits and 2.) Combining and jointly analyzing publically available phenotyped cohorts, such as the NHLBI's Exome Sequencing Project (ESP). For most QT studies, there is usually one tail of the QT distribution that is of main clinical interest (risk tail) e.g. the high extreme of body mass index for obesity research, or high fasting glucose levels in diabetes studies. Samples from the other extreme are used as a comparison group (comparison tail). Practical issues related to designing efficient rare variant QT association studies were investigated using extensive simulations under rigorous population genetic and realistic complex trait models. It is shown that for a fixed size of whole-exome sequence samples 1.) Analyzing full QT is consistently more powerful than dichotomizing the QT and analyzing it as a binary disorder. 2.) For samples that are ascertained from the general population, using less stringent phenotypic cutoffs will require screening a much smaller number of individuals. However, the power is only slightly decreased if full QT is analyzed. 3.) When selective sampling is carried out from an existing cohort of samples, sequencing an equal number of samples from each extreme is not the optimal study design. Instead, sequencing a fewer number of individuals from the risk tail and more samples from the comparison tail can increase power. This is because of the increased difference in causal variant carrier frequency between the two tails. 4.) When a public phenotyped cohort such as ESP is available, the most powerful design is to only sequence samples from the risk tail and use the public cohort as the comparison group. In conclusion, the results and study designs presented will provide important guidance for implementing efficient sequence-based QT studies. The R code for carrying out the power calculations will be made publically available to aid investigators in customizing their study designs.

Statistical power of population-based linkage analysis. *S.R. Browning[1], E.A. Thompson[2].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Statistics, University of Washington, Seattle, WA.

Recently there has been significant interest in population-based linkage analysis, also known as identity by descent (IBD) mapping, as a method for mapping trait-associated regions using genome-wide SNP data. The underlying idea is that with dense SNP data, short segments of IBD can be detected between supposedly unrelated individuals in the sample, and non-parametric linkage analysis applied to these data could yield significant associations.

We investigate the power of this approach using a combination of theoretical results, simulations, and analysis of real data. We focus on the statistic of Purcell et al. (2007), which compares the rate of IBD in case-case pairs to the rate of IBD in other pairs (control-control and control-case pairs). For large outbred populations it is difficult to derive realistic scenarios in which IBD mapping will have an acceptable level of power. However, we show that the approach can have power in a founder population, particularly if the population has undergone recent expansion and if the disease of interest has higher prevalence in the founder population than in outbred populations. If the founder population has a high prevalence of disease, this suggests that the causal alleles have drifted to a higher allele frequency in the founder population, which increases power.

Identification of the PTPRD gene involved in genetic susceptibility to keratoconus by combining evidence of genome-wide association and genetic linkage. *Y. Bykhovskaya[1], X. Li[2], K. Taylor[2], D. Siscovick[3], A. Aldave[4], L. Szczotka-Flynn[5], S. Iyengar[5], J.I. Rotter[2], Y.S. Rabinowitz[1,2,6].* 1) Regenerative Medicine Institute, Department of Surgery, Division of Surgical Research, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Departments of Medicine and Epidemiology and Cardiovascular Health Research Unit, University of Washington, Seattle, WA; 4) The Jules Stein Eye Institute at UCLA, Los Angeles, CA; 5) University Hospitals Eye Institute, Department of Ophthalmology & Visual Sciences, Case Western Reserve University, Cleveland, OH; 6) Cornea Genetic Eye Institute, Cedars-Sinai Medical Center, Los Angeles, CA.

Testing for genome-wide association (GWA) is a powerful tool for discovery of common variants associated with complex disease traits. To identify genetic locations of keratoconus susceptibility genes by testing for genetic association, we performed a comprehensive GWAS using a discovery and replication design (Li et al., manuscript submitted). A discovery panel of 222 Caucasian cases/ 3324 controls was genotyped on Illumina 370K beadchips. To select SNPs for confirmation and fine mapping, we aligned GWAS results with the previously identified linkage peaks (Li et al. 2005) by translation of genetic and physical map distances using the Marshfield genetic map and MapViewer. We identified SNPs with p-values ranging from 10-6 to 10-4 in 10 out of 11 linked regions. All SNPs selected for confirmation were genotyped in an independent replication case-control panel (304 cases/ 518 controls) and a family panel of 307 subjects in 70 families. Two SNPs, rs10959090 and rs1323486, located in the intron of the PTPRD (protein tyrosine phosphatase, receptor type D) gene at the 9p23 chromosomal region showed suggestive association in the discovery panel of the GWAS study (p=2x10-4 and 0.02, respectively) and were confirmed in the replication panel with p=0.04 and 0.03; meta p=3x10-5 and 0.003, respectively). Two additional SNPs rs10816206 and rs10491919 located in the PTPRD gene were associated in a confirmation panel with significant p=2x10-5 and 6x10-5, respectively, and in a family panel with significant p=0.03 and suggestive p=0.08, respectively. PTPRD gene codes for the receptor protein tyrosine phosphatase (RPTP) delta, a member of the three-member leukocyte antigen-related (LAR) RPTP subfamily of the protein tyrosine phosphatase family which plays a role in regulating integrity of cell-cell contacts, differentiation, and proliferation. Expression of one of the members of the LAR RPTP subfamily, LAR, has been repeatedly found to be increased in keratoconus cultures and corneas (Chiplunkar et al. 1999; Zhang et al. 2005). Additionally, phosphatase inhibition affected cell-cell contacts of corneal endothelial cells (Chen et al. 2005). Convergent findings of genetic linkage and association coupled with potential biological significance of the protein tyrosine phosphatase pathway in corneal biogenesis are supportive of a genuine effect of the variation in the PTPRD gene on keratoconus susceptibility.

Genome-wide association meta-analysis of pubertal growth in males and females. *D.L. Cousminer[1], N.J. Timpson[2], D. Berry[3], J.T. Leinonen[1], W. Ang[4], N.M. Warrington[4], E. Thiering[5], J.P. Bradfield[6], E.M. Byrne[7], C. Holst[8], J. Kaprio[1,9,10], C.E. Pennell[4], O. Raitakari[11], M-R. Järvelin[12], E. Widén[1] on behalf of the EGG Consortium.* 1) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Finland; 2) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol, UK; 3) Centre for Pediatric Epidemiology and Biostatistics, Institute of Child Health, London, UK; 4) School of Women's and Infants' Health, The University of Western Australia, Perth, Australia; 5) Helmholtz Zentrum München, German Research Center for Environmental Health, Institute of Epidemiology, Neuherberg, Germany; 6) Center for Applied Genomics, Children's Hospital of Philadelphia Research Institute, Philadelphia, PA, USA; 7) Queensland Statistical Genetics, Queensland Institute of Medical Research, Brisbane, Australia; 8) Institute of Preventive Medicine, Copenhagen Capital Region, Copenhagen University Hospitals, Copenhagen, Denmark; 9) University of Helsinki, Hjelt Institute , Dept of Public Health, Helsinki, Finland; 10) National Institute for Health and Welfare, Dept of Mental Health and Substance Abuse Services, Helsinki, Finland; 11) Department of Clinical Physiology, University of Turku, Finland; 12) Department of Epidemiology and Public Health, Imperial College London, London, United Kingdom.

Puberty, a highly variable complex trait influenced by both genetic and environmental factors, is a childhood growth phase with implications on adult disease risk. In particular, epidemiological studies show that advanced puberty associates with increased risk for adult health outcomes like obesity, type 2 diabetes, and hormone-dependent cancers. Uncovering genes underlying these observations may shed light on predicting lifetime disease risk. A recent genome-wide association study (GWAS) uncovered many gene variants associated with age at menarche (AAM), while genes influencing male pubertal maturation remain unknown. To identify genes influencing the timing of central pubertal onset in both males and females, we ran GWAS meta-analyses on simple measurements of the pubertal height growth spurt similar in both sexes. To characterize the effect of the discovered genetic variants across pubertal growth, we utilized longitudinal height measurements available in many cohorts to investigate association between the leading signals and height or BMI at cross-sectional age bins from pre- to post-puberty. The study will also address the association between these variants and pubertal timing using Tanner breast and genital staging data. GWAS of (1)height at age 10 in girls and 12 in boys, (2)height increase from 7-adult, and (3)height increase from 14-adult revealed 9 genome-wide significant loci and 24 suggestive loci previously associated with adult stature, AAM, and/or BMI. We took forward suggestive novel signals (n= 23) and replicated a single variant (rs4788196, $p=6x10^{-11}$, n=18,737). Height analysis across puberty showed that this variant associated with tall pre-pubertal stature and declining relative height growth during puberty. rs4788196 is an eQTL in lymphoblasts for *ERK1*, encoding a MAP kinase involved in many developmental processes, including long bone growth in mice. Also significantly associated with pubertal growth was rs1172294 near *POMC*, previously associated with both childhood obesity and adult height. The BMI-increasing allele showed decreased pubertal height growth, with no effect on height prior to puberty. This study unveiled heavy genetic overlap between pubertal growth in both sexes and related traits as well as discovery of a novel variant near *ERK1*. With access to the unique resource of frequent longitudinal height measurements, we were able to describe the distinct height growth effects of each variant across puberty.

New developments in the genetic fine mapping of a non-Mendelian trait through the coalescent process with recombination. *M. Dupont[1], G. Boucher[2], MH. Descary[1], F. Larribe[1].* 1) Département de Mathématiques, Université du Québec à Montréal, Canada; 2) Institut de cardiologie de Montréal, Québec, Canada.

We present new developments relating to a fine mapping methodology (MapARG) by means of the ancestral recombination graph (ARG). The coalescent theory with recombination allows us to construct genealogies that are consistent with a sample of haplotypes composed of specific markers. The likelihood of rT , the unknown location of a *Trait Influencing Mutation* (TIM), is calculated from these genealogies, through a combination of Monte Carlo approximation and importance sampling. The evaluation of this likelihood being computationally intensive, these analyses are performed using composite likelihood by means of windows of markers. As linkage disequilibrium should be present in the data, the distribution of the haplotypes should be dependent on the known phenotype. An EM algorithm has been developed to estimate the distribution of haplotypes in the population conditionally on the phenotype and the genotype. Moreover, the method can handle phenocopy and incomplete penetrance. We investigate the effect that different models of penetrance can have on the performance of MapARG. These results show that the method is somewhat efficient when the relative risks f_1/f_0 and f_2/f_0 are large enough. As the RRs increase, error rates vary along the sequence, improving in closeness to the TIM. The algorithm permits MapARG to correctly localize the TIM, even in cases where f_1/f_0 and/or f_2/f_0 are/is relatively small. We present results obtained from this methodology against the usual simple statistics used in this context. We show cases where, although the χ^2 standard test fails to indicate the correct location of the TIM, MapARG makes use of the information contained in the markers' linkage disequilibrium to give an accurate estimate of the TIM's position. Starting from a simple rare and recessive model, we showed how to enrich the method to a more general complex model with few restricting hypotheses. The method uses the coalescent with recombination in combination to the Fearnhead/Donnelly's proposal distribution to locate the position of disease gene; these models and methodologies are rich and methodologically well founded. This is a work in progress, but first results are very encouraging. The method uses as much information as currently possible, and should be more powerful than other methods, especially those based on pairwise statistics.

Trans-ethnic fine-mapping of Type 2 Diabetes susceptibility loci using a "Cosmopolitan" reference panel for imputation. *M. Horikoshi[1], S. Wiltshire[1], N. Kato[2], J. Asimit[3], N. Rayner[1], N. Robertson[1], F. Takeuchi[2], A. Mahajan[1], T. Yik Ying[4], E. Zeggini[3], A. Morris[1], M. McCarthy[1], T2D-GENES.* 1) The Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 2) Research Institute, National Center for Global Health and Medicine, Tokyo Japan; 3) Wellcome Trust Sanger Institute, Cambridge UK; 4) Department of Statistics and Applied Probability and Department of Epidemiology and Public Health, National University of Singapore.

More than 40 type 2 diabetes (T2D) susceptibility loci have been identified in recent genome-wide association studies (GWAS). However, it has not been possible to identify the specific causal variant(s) at most of these loci. As one approach to refine the localisation of causal variants, we performed trans-ethnic meta-analysis of 13 study populations of European, South Asian and East Asian descent (14,329 cases and 22,833 controls) as part of the T2D GENES Consortium. We focused on fine-mapping of 5 established T2D loci with evidence of differential linkage disequilibrium patterns between non-African populations: *CDKAL1, CDKN2A/B, FTO, IGF2BP2* and *KCNQ1*. We combined directly genotyped and imputed data (using a "Cosmopolitan" reference panel which incorporates the variants shared across all populations from the 1000 Genomes Aug 2010 release), testing for association under an additive model. We combined these results using: (i) traditional fixed-effects meta-analysis; (ii) an in-depth "split and filter" regression analysis; and (iii) a Bayesian meta-analysis that incorporates a prior model for heterogeneity in effects between ethnic groups based on their shared ancestry. The resolution of fine-mapping was highly improved at *CDKAL1*. Fine mapping highlighted two out of the much larger group of SNPs showing equivalent evidence of association in Europeans as showing the most consistent evidence of association across ethnic groups. The two SNPS are rs9368222 ($p = 8.3x10^{-16}$) and rs7766070 ($p = 9.8x10^{-16}$) with fixed-effects OR = 1.15 [1.11-1.19] for both. There was evidence of two independent signals of association at the *KCNQ1* locus first reported in the Japanese population. The strongest association was at rs2237892 ($p = 5.3x10^{-16}$), with consistent effects across ethnic groups (fixed effects OR = 1.20 [1.15-1.27], 11.9% posterior probability of heterogeneity). The secondary association signal was at rs2237895 ($p = 3.4x10^{-11}$, OR = 1.16 [1.11-1.22]; CEU $r^2 = 0.00$ and CHB+JPT $r^2 = 0.26$ with rs2237892), with strongest effects observed in East Asians (100% posterior probability of heterogeneity). Our results highlight the potential of trans-ethnic GWAS for fine-mapping causal variants, and show promise for further refinement with additional samples from more diverse population groups, including those of African and/or Hispanic descent.

A genome-wide association study for loci influencing stunting in children from Bangladesh. *J.C. Mychaleckyj[1], S.S. Rich[1], P. Concannon[1], R. Haque[2], T. Ahmed[2], X. Hou[1], Z. Li[1], W.A. Petri[3].* 1) Dept Public Health Sci, Ctr Public Health Genomics, University of Virginia, Charlottesville, VA; 2) International Centre for Diarrhoeal Disease Research, Dhaka-1000, Bangladesh; 3) Dept Medicine, Division of Infectious Diseases, University of Virginia, Charlottesville, VA.

Malnutrition is implicated in 50% of deaths due to infection and 35% of all deaths among under-five children. Stunting affects ~ 1/3 of children under age 5 and occurs in the -9 to +24 month age window. The majority of stunted children live in Asia, where the average child is born moderately stunted (height adjusted Z-score (HAZ) of -0.75). These children experience rapid growth faltering to an HAZ of -2.25 by 2 years of age. Current interventions, even if extended to all children, are predicted to reduce stunting by ~ 1/3. We are performing a genome-wide association study (GWAS) to identify genetic risk factors that may increase risk for stunting. Three cohorts of children (N=1700) are being recruited from Dhaka, Bangladesh for the GWAS. A principal components analysis of the genotype data for the initial 462 subjects recruited indicated that the study population displayed considerable similarity to Caucasian populations and clustered most closely with the Gujarati Indian (GIH) HapMap population. These results support the use of standard commercial high-density genotyping platforms in this study population (Illumina 1M and 2.5M chips) and for imputation based upon HapMap data. A preliminary analysis using height adjusted for age and sex (a surrogate for HAZ) was performed using 1M SNP genotypes and imputed to 7.8 million SNPs on the first 932 study subjects. The Bangladeshi cohorts displayed little evidence of residual population stratification in unadjusted tests of association. No common (>5% minor allele frequency) SNPs were associated with stunting at genome-wide significance. However, a number of common SNPs with P<10-6 clustered on chromosomes 2 (two loci), 3, 13 and 14. These SNPs are located in/near genes associated with lipid metabolism, signaling and immune function. Validation genotyping on a separate platform confirmed these results. Analyses using an additional 336 subjects from Bangladesh have replicated four of the five loci. Additional replication genotyping/analyses are being conducted, as is analysis of rare (MAF < 5%) variants. Knowledge of genetic risk factors that contribute to malnutrition-related phenotypes could potentially direct interventions and suggests novel therapeutic approaches.

Gene-gene interaction analysis accounting for multiple level of genetic relatedness. *J. Namkung, R. Elston.* Biostatistics and epidemiology, Case Western Reserve Univ., cleveland, OH.

Population stratification is a frequent confounding factor in genetic association studies. When data comprise families of multiple ethnicities and/or an admixed population, the correlation structure becomes complex and thus accounting for it becomes more challenging. Various approaches have been reported to tackle this issue, including mixed models, transmission disequilibrium test (TDT) type statistics, and adjusting for ancestry effects using principal component analysis (PCA). However, the effect of population stratification on gene-gene interaction analysis has not been well studied. In this study, we propose an extension of the multifactor dimensionality reduction (MDR) method to analyze gene-gene interaction in the presence of various types of correlations. We use a polygenic mixed effect model to account for the familial correlation structure and PCA to obtain ancestry information for founders. We use as input to generalized multifactor dimensionality reduction (GMDR) residuals from a polygenic mixed model containing variables of ancestry information as covariates. We extensively investigate the effect of multiple levels of genetic relatedness by simulation studies. As a result, we show how greatly the performance of gene-gene interaction analysis can be improved by this procedure. We also compare the performance of our proposed approach with that of Pedigree-based GMDR (PGMDR), which is known to be immune to population structure because it conditions on parental genotypes. As an example, the proposed method is applied to data from the Framingham Heart Study, which has diverse European ethnicities.

Moving beyond inferential limits of GWAS to discover genetic mechanisms in autoimmunity: how end-organ pathways contribute to pathogenesis. *L. Petukhova[1, 2], A.M. Christiano[2, 3].* 1) Deptartment of Epidemiology, Columbia Univ, New York, NY; 2) Deptartment of Dermatology, Columbia Univ, New York, NY; 3) Deptartment of Genetics & Development, Columbia Univ, New York, NY.

Recently, genome-wide association studies (GWAS) in autoimmune diseases, including our work in alopecia areata (AA), have been tremendously successful in identifying many robust associations, although the vast majority of these reside in immune response genes and reveal very little about the end-organ. We postulate that this occurs because of an inherent feature of GWAS, that the method relies upon the assumption that the disease allele will be common in the population. Since immune response genes are subject to positive selection (which increases allele frequencies), this class of genes is particularly amenable to detection by GWAS. Likewise, we postulate that AA susceptibility genes specific to the hair follicle (HF) may fail to achieve statistical significance because of low allele frequencies, thus eluding detection by GWAS. These genes should be amenable to detection by a method well-suited for rare variants, e.g. linkage. In this study, we aimed to identify HF genes in AA using convergent evidence between our GWAS and linkage studies in AA. To probe for HF genes in our GWAS data, we chose a liberal threshold for significance ($p<0.01$) and mapped the top 5000 SNPs to a set of 3347 genes. We then extracted a set of 476 genes with evidence for expression in the HF. Of these, only 5 genes contained SNPs that exceeded statistical significance in the GWAS (p<5x10-7; PPP1R14C, CREBL1, SUOX, CDK2, STX17), while the vast majority (471) contained SNPs that achieved only nominal significance. We next integrated these results with our two previous linkage analyses in AA, and found that 121 genes fell into regions with at least suggestive evidence for linkage (1<LOD<4). We found that a number of linkage peaks contain clusters of HF genes that are nested within our nominally significant GWAS findings. This study demonstrates that integration of genetic mapping approaches with expression data can allow us to gain novel insight into the genetics of autoimmunity, in particular, identifying genes of the end organ.

Fine-mapping in Linkage Peaks for Osteoarthritis Biomarkers in a Large North American Pedigree. *X. Qin[1], S.H. Shah[1, 2], H.C. Chen[2], C. Haynes[1], T. Stabler[2], J.L. Huebner[2], S.G. Gregory[1,2], W.E. Kraus[2], J.M. Jordan[3], E.R. Hauser[1,2], V.B. Kraus[2].* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Dept of Medicine, Duke University, Durham, NC; 3) Thurston Arthritis Research Center, UNC, Chapel Hill, NC.

Previous genome-wide linkage analysis of five osteoarthritis biomarkers in a 10-generation North American pedigree of Native American and African ancestry identified significant linkage peaks on chr. 6 for type IIA collagen N-propeptide (PIIANP max. multipoint LOD=2.25 at 50cM) and hyaluronan (HA max. multipoint LOD=1.69 at 50 cM), chr. 8 for PIIANP (LOD=4.33 at 8 cM) and for cartilage oligomeric matrix protein (COMP LOD=3.18 at 62 cM) and chr. 14 for COMP (LOD=2.57at 66 cM) (Chen et al. Arthritis Rheum. 2010). The pedigree includes 3327 members of which 333 provided both biomarker and genotype data. To further explore these results we genotyped 1536 SNPs selected to cover the common variation in these regions based on HAPMAP CEU and YRI samples. Of these,1328 (86.4%) SNPs met lab-wide quality control benchmarks. We took a multistep analysis approach starting with a simple ANOVA analysis for genotype effect on biomarker levels and identification of significant SNPs. For the significant SNPs we performed measured genotype analysis with adjustment for age and sex and for the familial relationships as implemented in SOLAR. We concentrated on SNPs with consistent statistical evidence for association that gave an ANOVA p-value <.05, SOLAR fixed effect for SNP genotype p-value <.05, and a drop in the LOD score >1 LOD unit for linkage at the SNP location comparing models with and without the fixed effect for the SNP genotype. Using this procedure we identified 4 SNPs (rs204899, rs204899 and rs411337 in TNXB and rs2794719 in HFE) for PIIANP on chromosome 6. We identified 3 SNPs (rs1438214, rs6996668, rs3860862) for PIIANP and 2 SNPs (rs10958731, rs6474169) for COMP on chromosome 8. No other regions and phenotypes produced SNPs meeting these criteria. Additional validation of this approach as well as validation of these associations in an existing GWAS data set consisting of 344 nuclear families with osteoarthritis is underway. In preliminary analyses SNP rs2794719 (HFE) showed an association (p<.04) with PIIANP in this data set. Association of a coding variant in HFE has been associated with osteoarthritis in a population-based study (Alizadeh et al. Ann Rheum Dis, 2007). These results suggest a genetic basis for OA phenotypes related to PIIANP levels.

Cross-ethnic locus transferability evaluation of 26 non-HLA celiac disease risk loci in north Indians. *S. Senapati[1], G. Trynka[2], A. Sood[3], V. Midha[3], J. Romanos[2], L. Franke[2], B.K. Thelma[1], C. Wijmenga[2].* 1) Department of Genetics, University of Delhi, South Campus, New Delhi, Delhi, India; 2) Genetics Department, University Medical Center and Groningen University, 9700RB Groningen, The Netherlands; 3) Dayanand Medical College and Hospital, Ludhiana, Punjab, India.

Currently there are 26 non-HLA loci associated to celiac disease (CeD), all of which have been identified by genome-wide association studies (GWAS) in European populations. Here we investigated an ethnically different and old population from a distinct area in the north of India. The aim of the study was to gain insight into the genetic architecture of CeD in India. We performed cross-ethnic mapping using very dense genotype information from Immunochip, which enables high resolution analysis of CeD associated loci, therefore possible localization of actual disease risk variants. As we expected the linkage disequilibrium (LD) patterns between Europeans and north Indians to differ substantially, we carried out locus transferability analysis instead of direct association testing for the top GWAS SNPs. We genotyped 880 individuals from northern India (371 cases, 509 controls) and 2323 Dutch subjects (1150 cases and 1173 controls) on the Immunochip, a custom made genotyping platform comprising ~200,000 SNPs including >50,000 rare variants. The chip is densely probed for the 26 non-HLA CeD loci, by using variants from the 1000 Genomes-pilot and additional CeD re-sequencing projects. We carried out locus-wide comprehensive evaluation of association signals for all HapMap CEU variants in LD ($r^2 \geq 0.05$) with the reported European variants. Eleven loci were transferred (p-permuted= 0.004) with no significant heterogeneity in effect size estimates which signifies true locus transferability. Four of the 26 GWAS reported CeD top SNPs were also associated in north Indians: IL12A, PTPRK/THEMIS, ZMIZ1 and ICOSLG. A comparison of the LD blocks between the north Indian and the Dutch population revealed less extensive long range LD in the north Indian population. Hence, we were able to successfully narrow down the association signal for ITGA/UBE2E3 and the LPP loci to relatively smaller LD blocks. Currently we are investigating if these CeD loci are under different selection pressure in Indians and Europeans. The findings advocate the necessity of multi-ethnic approaches towards fine-mapping of disease associated loci to identify causal variants.

Incorporating genotype uncertainties into the genotypic TDT for main effects and gene-environment interactions. *M.A. Taub[1], H. Schwender[2], T.H. Beaty[3], T.A. Louis[1], I. Ruczinski[1].* 1) Department of Biostatistics, Johns Hopkins University, Baltimore, MD, USA; 2) Faculty of Statistics, TU Dortmund University, Dortmund, Germany; 3) Department of Epidemiology, Johns Hopkins University, Baltimore, MD, USA.

As increasingly dense panels of polymorphic genetic markers have become available through the HapMap and the 1000 Genomes Projects, imputation has become an option for researchers to expand their genotype datasets to improve signal precision and power in tests of genetic association with disease. While methods for incorporating imputed genotype probabilities into statistical tests for case-control data are routinely used, no methods have yet been presented for efficiently incorporating uncertain genotype calls in the analysis of case-parent triad data. Here, we present the statistical framework for genotypic transmission-disequilibrium tests (gTDTs) using observed and imputed genotypes. The implementation extends our recent work in obtaining closed-form solutions for the parameter estimates in gTDTs, thus allowing for assessment of hundreds of thousands of markers within minutes. We also present an extension to assess gene-environment interactions for binary environmental variables. We illustrate the performance of our method on a large set of trios from the International Cleft Consortium.

672F

Genome-wide association analysis of skeletal maturation in healthy children from the Fels Longitudinal Study. *B. Towne[1], J. Blangero[2], J.E. Curran[2], C. Bellis[2], T.D. Dyer[2], K.D. Williams[3], E.W. Demerath[4], A.C. Choh[1], M. Lee[1], R.M. Siervogel[1], S.A. Czerwinski[1].* 1) Wright State University School of Medicine, Dayton, OH; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) Temple University, Philadelphia, PA; 4) University of Minnesota, Minneapolis, MN.

Knowledge of skeletal development genetics comes mostly from studies of monogenic disorders. Few studies have examined genetic influences on normal variation in skeletal development, though the skeletal age (SA) of a normal child can vary up to 3 years from that child's chronologic age. We present here results from genome-wide association analyses of the SA of children at chronologic ages 1 to 18 years. SA data were obtained from hand-wrist radiographs taken annually from 1931 to the present of over 1,000 children from families in the Fels Longitudinal Study (Roche, 1991). Estimates of SA were made using the FELS method (Roche et al., 1988) that assesses various indicators of skeletal development appropriate for any given chronologic age. Most individuals have been genotyped with the Illumina Human 610-Quad BeadChip containing more than 550,000 SNPs. Association analyses were conducted using measured genotype analysis implemented in SOLAR (Almasy and Blangero, 1998) allowing for residual non-independence among relatives. Sample sizes ranged from n=365 at age 1 year to n=561 at age 8 years. SNP rs2120968, on 15q11 at 20,483,952 in an intron of CYFIP1, shows significant peak effects at age 3 ($p=1.1\times10^{-7}$). The minor allele (A) has a frequency of 0.24 and is associated with a 0.450 SDU decrease in SA at age 3, accounting for 7.1% of the variation in SA at that age and exhibiting significant pleiotropy across ages 1-7. SNP rs11873322, on 18q12 at 32,394,649 in an intron of FHOD3, shows significant peak effects at age 7 ($p=7\times10^{-8}$). The minor allele (A) has a frequency of 0.36 and is associated with a 0.373 SDU increase in SA at age 7, accounting for 5.8% of the variation in SA at that age and exhibiting significant pleiotropy across ages 2-13. SNP rs7629566, on 3q29 at 197,923,141 near the 5' end of PIGX shows significant peak effects at age 14 ($p=7\times10^{-8}$). The minor allele (G) has a frequency of 0.07 and is associated with a 0.598 SDU decrease in SA at age 14, accounting for 6.2% of the variation in SA at that age and exhibiting significant pleiotropy across ages 12-17. Skeletal maturation throughout childhood is a complex process. Results of this study indicate that there are significant specific genomic region effects on skeletal maturation centered on ages spanning: 1) early to mid-childhood, 2) mid-childhood to puberty, and 3) puberty to post-puberty. Supported by NIH grants R01HD012252, R01HD036342, F32HD053206, and R37MH59490.

A comparison of methods to detect complex trait rare variant associations implementing the RarePower tool. *G. Wang[1,2], SM. Leal[1,2].* 1) Baylor College of Medicine, Houston, TX; 2) Rice University, Houston, TX.

There is currently great interest in detecting rare variant associations using next generation sequence data. A large number of association methods which aggregate variants across a region e.g. a gene have been developed specifically to analyze rare variant data. It is not clear which existing method is the most powerful and should be applied to test for associations using exome/genome sequence data. To compare rare variant association methods both realistic phenotype models and spectrum of variants across a region must be generated. We compared the power for 12 methods to detect associations for qualitative and quantitative traits. Power was evaluated for case-control, extreme quantitative trait sampling and population based study designs. For each method, power was determined for scenarios which included 1. analysis of a. only rare variants & b. rare (<1%) and low (1-5%) frequency variants; 2. detrimental and protective variants within a gene region; 3. misclassification a. exclusion of causal variants & b. inclusion of non-causal variants; 4. different underlying population demographic model for both Africans and Europeans and 5. gene size. It was observed that there is not a single method that is most powerful in all situations. The majority of rare variants methods had only small incremental difference in power. Rare variant association methods which were powerful in a variety of situations include the Variable Threshold (VT) method, Weighted Sum Statistic (WSS) and Kernel Based Adaptive Cluster (KBAC) method. Those methods which were developed to detect associations when both protective and detrimental variants are within an associated region (e.g. C-alpha) are usually less powerful than more general rare variant association methods. The evaluated methods vary in their computation efficiency and ability to control for confounders. Additionally, in order to optimize performance and increase power to detect associations we have we have modified several rare variant methods including the KBAC, aSum, VT and combined multivariate and collapsing (CMC) method. The RarePower tool with its user friendly graphical interface can be used to determine sample sizes which are necessary to detect rare variant associations under a large variety of complex trait and population demographic models.

Developing Weighted Test Statistics for Testing Association of Rare variants Using Pairs of Affected and Unaffected Individuals. *Y. Yao[1], Y. Zhu[2], W. Guo[1], M.M. Xiong[2].* 1) Division of Intramural Research Program, National Institute of Mental Health, Bethesda, MD., USA; 2) 2.Division of Biostatics, , University of Texas School of Public Health, Houston, Texas USA.

Recently, a number of statistical methods become available for analyzing the contribution of rare variants to the development of complex traits. These methods include Combined Multivariate and Collapsing (CMC) Method, Multivariate test of collapsed sub-groups Hotelling T2 test, MANOVA, Fisher's product method, Weighted Sum Method and Kernel-based adaptive test. While the merits of these methods have been evaluated extensively for population-based association studies, none of these methods can be used to analyze the pedigree based association analysis using exome sequencing or whole genome sequencing data. It is known that many common diseases are clustered in families and one can reasonably expect that human pedigrees will be enriched with causal rare variants. However, traditional linkage analysis may not be a good tool for testing association of rare variants. There is an urgent need to develop efficient statistical methods for sequence-based pedigree analysis. We will extend collapsing principle for population-based association analysis of rare variants which collectively evaluate contribution of multiple rare variants within a genomic region to the diseases, to the pedigree analysis of rare variants. Particularly, we use pairs of affected and unaffected individuals as a study design by integrating all rare variants within a gene or a genomic region into an overall variable. We will develop family-based rare variants analysis approach by treating each affected relatives as dependent pairs and the dependency will be accounted for using correlation matrix. Specifically, similar to the weighted sum statistics for testing association of rare variants in unrelated individuals, we have developed a novel weighted statistic that compares difference in the value of the integrated overall variables between affected and unaffected individuals weighted by their IBD coefficients. Further, we use large-scale simulation to evaluate its type 1 error and power under several disease models. This method will be used to analyze a reasonable number of bipolar disorder pedigrees with exome data. Power studies and real data analysis demonstrate that the proposed statistic for sequence-based pedigree analysis may emerge as a powerful tool for genetic studies of complex diseases.

Admixture mapping analysis of BP and BMI in Family Blood Pressure Program (FBPP). *X. Zhu[1], Z. Zhang[1], B. Tayo[2], A. Morrison[3], C. Hanis[3], C. Cooper[2], S. Kardia[4], D.C. Rao[5], H. Tang[6], N. Risch[7].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Department of Preventive Medicine and Epidemiology, Loyola University Medical Center, Maywood, IL; 3) Human Genetics Center, The University of Texas School of Public Health, Houston, TX; 4) Department of Epidemiology,University of Michigan, Ann Arbor, MI; 5) Division of Biostatistics, School of Medicine, Washington University in St. Louis, St. Louis, MO; 6) Stanford School of Medicine, Stanford, CA; 7) Department of Epidemiology & Biostatistics, University of California, San Francisco, CA.

African Americans are, on average, at higher risks for hypertension and obesity, compared to European Americans. Previously we have used admixture mapping to identify candidate regions, which both contribute to disease risks and to disparity between populations. In this report, we perform admixture mapping analysis using 4012 subjects from 830 African-American families from FBPP project with GWAS data available. We first infer each individual's local ancestry using both dense SNPs and family information. We next test the association between local ancestry and BP and BMI incorporating family structure. We will report the results by admixture mapping using both the family and dense SNP data.

The Rutgers Map: A third-generation combined linkage-physical map of the human genome. *T.C. Matise[1], A.Q. Nato[1], S. Buyske[2].* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) Dept Statistics and Biostatistics; Dept Genetics, Rutgers Univ, Piscataway, NJ.

Accurate and comprehensive linkage maps remain critical for the success of positional cloning and genetic linkage analyses. We have created a third-generation high-resolution genetic map (The Rutgers Map) that combines physical map positions from the current genome assembly (Build 37) with recombination data from a comprehensive collection of publicly available genotype data from the CEPH pedigrees. Physical positions for the SNPs have been updated from the current version of dbSNP (Build 132). As a result of changes to the assembly and/or the SNP database, a small number of markers that were on our previous map have been dropped in the current map. Markers that have been merged in dbSNP are represented by their current rsID, and linkage analysis was used to evaluate physical map discrepancies, such as for several markers that have multiple physical positions on multiple chromosomes in dbSNP. This third-generation Rutgers map includes just under 28,000 markers, of which 60% are SNPs, 35% are STRs, and the remainder are mostly RFLPs. We have recalculated our “smoothed maps” using a quadratic fit local regression procedure. The smoothed maps provide a unique map position for every marker, which cannot be determined from the recombination data alone, and which can be readily used to interpolate a linkage map position for any marker or genetic element with a known physical position. The Rutgers Map website provides a tool for interpolating markers onto the map (http://compgen.rutgers.edu/). A major new feature of the revised map is that we have used it to interpolate a linkage-map position for 94.9% of the reference SNPs in dbSNP (N=22,181,252). The remaining reference SNPs lie outside of our map boundaries or do not uniquely map to the genome. Linkage map positions for these SNPs, as well as for SNP panels from most of the Affymetrix and Illumina GWAS panels, are available on our website. The updated Rutgers combined physical-linkage map provides a single source of linkage map positions for nearly all markers genotyped in the CEPH pedigrees.

Using a Second-order Hidden Markov Model to Identify Regions of Identity-By-Descent in Exome Sequencing Data. *S. Hicks[1], S.E. Plon[2,3], M. Kimmel[1].* 1) Department of Statistics, Rice University, Houston, TX; 2) Human Genome Sequencing Center, Houston, TX; 3) Texas Children's Cancer Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas.

Identifying regions of identity-by-descent (IBD) in heritable disorders is an effective approach in identifying disease-causing mutations. Rödelsperger et al. [Bioinformatics 27: 829-836,2011] applied an inhomogeneous first-order hidden Markov model (HMM) to genotype data produced from exome sequencing to identify chromosomal regions of IBD in siblings with an autosomal recessive disorder. The goal of this study is to extend the model to a second-order HMM investigating the second-order dependence structure between the observed variant calls in siblings. This second-order HMM has to be inhomogeneous to account for position, distance and sex-specific recombination rates which are incorporated into the transitions between regions of IBD or not IBD. Predictions of IBD or not IBD at each locus are reported as well as a marginal probability of being in an IBD region. We compared the results from the first and second order HMMs using simulated and real exome sequencing data from two affected siblings. Viterbi predictions from first and second-order HMMs follow each other closely, but marginal posterior probabilities are more variable using the second-order HMM. This effect might be caused by the second order HMM revealing a finer IBD structure along the chromosomes compared to the first-order HMM. Supported by CPRIT grant RP101089 to SH, SEP and MK, and NCI T32 training grant CA096520 to SH.

Developing temporal models for multiple simultaneous time series of sequenced public health genomic data. *R. Hoffmann[1], S. McLellan[2].* 1) QHS, Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) University of Wisconsin-Milwaukee, Milwaukee, WI.

Purpose: To study the temporal changes in prevalence of bacterial taxa over a 3 year period and relate these to public health problems during the same time periods. In order to examine these relationships, it is necessary to obtain temporal models to identify common patterns of bacterial prevalence that can be adjusted for other environmental conditions such as temperature, rainfall, flow, etc. Methods: Samples were taken from two different, but related, sites in lake Michigan over a three year period. We collected 19 paired sewage influent samples from the two sites in lake Michigan that were part of the Milwaukee Metropolitan Sewerage District under different conditions over a three-year period. The service area consists of more than 10,000 km of local municipal pipes that converge into a municipal interceptor system either of the two regions. One site is a a separated residential/industrial system as well as a combined sewer system in the oldest, most urbanized area of the while the other primarily processes residential sewage. Bacterial pyrotags (individual sequences) were used to identify the taxa. Since the samples were taken during different seasons and at different points in time, determining temporal effects required methods that were both flexible and did not required regular measurements. Wavelet analysis, after filtering to reduce sampling noise, was used to determine the temporal aspects of the multivariate time series because of the irregular occurrence of the sampling points over time. Results: Analysis of 1,085,939 bacterial pyrotags (eg: individual sequences) identified a total community complexity of 1,057 different taxa. We identified 18 taxa that were in high abundance in sewage and present at minimal relative abundance in surface water. These 18 taxa accounted for 66% of the pyrotags found in sewage influent. The most common were Acinetobacter (16.1%), Aeromonas (9.8%), Trichococcus (7.7%). After fitting the wavelet models, the wavelet coefficients were clustered into 6 groups. Group 1 had 8 taxa and sub-taxa including acinitobacter tag 1. Group 2 had 7 taxa and sub-taxa including acintobacter tag 2. This group had a clear difference in time of peak and nadir from group 1. Group 3 had two taxa and sub-taxa and were partially similar to group 2. The remaining 3 taxa had distinct features that did not match the above groups nor did they match each other.

Aberrant Recombination in Trisomy 21 Nondisjunction is Associated with Differential Hot-Spot Usage. *C. Middlebrooks[1], T. Oliver[1], S. Tinker[1], E.G. Allen[1], L. Bean[1], R. Chowdhury[2], F. Begum[3,4], M. Marazita[3,5], V. Cheung[6,7,8], E. Feingold[3,4], S.L. Sherman[1].* 1) Human Genetics Department, Emory University, Atlanta, GA; 2) Department of Pediatrics, University of Pennsylvania, Philadelphia, PA; 3) Department of Human Genetics, Graduate School of Public Health University of Pittsburgh, Pittsburgh, PA; 4) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 5) Center for Craniofacial and Dental Genetics, Division of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 6) Departments of Pediatrics and Genetics, University of Pennsylvania, Philadelphia, PA; 7) Howard Hughes Medical Institute, University of Pennsylvania, Philadelphia, PA,; 8) Department of Genetics, University of Pennsylvania, Philadelphia, PA.

Several genomic features have been found to be associated with recombination placement. These features include CpG islands, GC content, Poly AT content, gene coverage and hot-spot location. As altered placement of recombination is associated with nondisjunction (NDJ), we sought to determine if the quantity of the aforementioned genomic features differed at sites of exchange between normally and abnormally segregating chromosomes. Potentially this would help identify features important for chiasma stabilization and proper chromosome segregation. We characterized our normally disjoined maternal chromosomes 21 from publically available family data and nondisjoined maternal chromosomes 21 from trisomy 21 offspring and their parents using 1534 genotyped SNPs along 21q. 21q was divided into three regions with the following designations and analyzed separately: centromere (13.6 -18.6 Mb), medial (18.6 - 23.6 Mb) and telomere (23.6 -48.5 Mb). Next, each region was divided into 500kb bins and the quantity (proportion or counts) of observed recombinant events and of each genomic feature was determined. Finally, linear regression was used to determine if the quantity of each genomic feature was a significant predictor of recombination within each region of 21q. This analysis included 222 meiosis I (MI), 202 meiosis II (MII) errors and 1272 euploid chromosomes 21 of maternal origin. Overall our results suggested that recombination along nondisjoined chromosomes 21 in oocytes did not fall into hot spots that have been defined by normal disjoining chromosomes. Specifically, we found that the number of hot spots at the centromeric and medial regions of chromosome 21 was directly proportional to the number of recombination events in those regions in our normal meiotic events; however, hot spots were not significant predictors of recombination placement for maternal MI or MII NDJ errors. For the first time, we have shown that aberrant recombination patterns observed among maternal nondisjoining chromosomes 21 may be the result of differential hot-spot usage. No significant differences in genomic features listed above at recombination breakpoints for disjoining and nondisjoining chromosomes were evident. Interestingly, studies have shown that variation in the PRDM9 gene is associated with differential hot-spot usage. Potentially, variation in PRDM9 leads to altered patterns of recombination on chromosome 21 that increase the risk for NDJ.

Single Marker and Pathway Analysis of a Genome Wide Association Study in Obese and Lean Subjects of Northern European Ancestry. *S. Ghosh[1], J. Vivar[1], R. Davies[2], R. Dent[3], R. McPherson[2].* 1) Biomed Biotech Research Inst, North Carolina Central Univ, Durham, NC; 2) University of Ottawa Heart Institute, Ottawa, CANADA; 3) Weight Loss Management Clinic, Ottawa Hospital, Ottawa, CANADA.

Background: Genome wide association studies (GWAS) have been highly successful in identifying novel genetic loci associated with polygenic obesity but traditional single marker analysis ignores many moderately associated SNPs during multiple testing corrections. Pathway based analyses can be useful in uncovering pathways consisting of genes for which no individual SNP satisfies the traditional genome wide significance threshold (p<5e-8), but for which there exists an excess of variants with low to moderate effects on the disease. **Methods**: SNP genotyping was carried out on Affymetrix 6.0 arrays in a cohort of 985 obese and 869 lean subjects drawn from the tails of the population BMI distribution (mean BMI 43.1+8.7 and 20.3+1.84 kg/m2 for obese and lean subjects, respectively). SNPs were filtered as follows: MAF>3%, HWE<1e-6, call rate > 90%, info >0.8. Single marker association analysis was carried out via logistic regression after adjusting for gender and the first two principal components of ancestry. Analysis was performed under additive, dominant and recessive model assumptions. Pathway analysis was carried out via pathway enrichment tools such as DAVID and iGSEA4GWAS and by querying pathway databases including KEGG and PANTHER. SNPs were assigned to genes based on HapMap (NCBI build 36). A gene wide p-value was obtained from the most significant p-value of all SNPs belonging to the gene. **Results**: Single marker analysis identified several SNPs in the FTO genomic locus (16q12.2) as strongly associated to obesity (p<1e-13. No other single marker reached a genome-wide significance level of p<5e-8. Pathway analysis in DAVID identified pathways related to cytoskeletal organization, cardiomyopathy signaling, inositol phosphate metabolism, and calcium signaling, as being enriched in gene variants associated with obesity (p<1e-3). IGSEA4GWAS analysis further suggested the Wnt signaling and type II diabetes mellitus pathways (p<1e-3) as obesity-associated under additive or dominant model assumptions. **Conclusion**: The strong association of SNPs in the FTO locus to obesity is consistent with earlier results in several populations. Despite only modest associations observed for the other SNPs, pathway analysis further identified several candidate biological mechanisms that could lead to obesity from an enrichment of genetic variants of moderate to low effects. These findings can provide new hypotheses on the genetic architecture underlying polygenic obesity.

Genome-wide association study identifies three genetic loci associated with Thyroid function. *R. Rawal[1], A. Teumer[2], G. Homuth[2], H. Wallaschofski[3], T. Ittermann[5], B.O. Åsvold[6], K.H. Greiser[7], D. Tiller[8], A. Kluttig[8], H. Meyer zu Schwabediss[9], A. Doering[4], C. Gieger[1], C. Meisinger[4], T. Bjøro[10].* 1) Institute for Genetic Epidemiology, Helmholtz Center, Munich/ Neuherberg, Germany; 2) Interfaculty Institute for Genetics and Functional Genomics, Ernst-Moritz-Arndt-University Greifswald, Germany; 3) Institute of Clinical Chemistry and Laboratory Medicine, University Medicine Greifswald, Germany; 4) Institute of Epidemiology, Helmholtz Center, Munich/ Neuherberg, Germany; 5) Institute for Community Medicine, University Medicine Greifswald, Germany; 6) Department of Public Health, Norwegian University of Science and Technology, and Department of Endocrinology, Trondheim University Hospital, Trondheim, Norway; 7) German Cancer Research Center (DKFZ), Division of Cancer Epidemiology , Im Neuenheimer Feld, Heidelberg, Germany; 8) Institute of Medical Epidemiology, Biostatistics, and Informatics, Martin-Luther-University Halle-Wittenberg, Halle (Saale), Germany; 9) Department of General Pharmacology, University Medicine Greifswald, Germany; 10) Department of Medical Biochemistry, Oslo University Hospital, and Faculty of Medicine, University of Oslo, Oslo, Norway.

Thyroid hormones play a key role in cellular growth, development and metabolism. Changes in thyroid function cause thyroid disorders, and affect many tissues and the metabolism in general. Circulating concentrations of triiodothyronine (T3) and thyroxine (T4) are tightly regulated by thyrotropin (TSH) and have a strong heritable component. A large portion of heritability is supposed to be under polygenic control, but the genes responsible are mostly unknown. In order to identify genetic loci associated with the thyroid function, we performed meta-analysis of genome-wide association study with 4907 individuals (1287 individuals from the Cooperative Health Research in the Augsburg Region study (KORA F4, Southern Germany) and 3620 participants of the Study of Health in Pomerania (SHIP)). Three genetic loci were associated with serum TSH on a genome-wide level of significance and one locus was at borderline significance level. The first locus was at 5q13.3 in the phosphodiesterase 8B (PDE8B) gene. A second locus was found at 1p36 located upstream of and within the CAPZB gene (capping protein (actin filament) muscle Z-line,beta) encoding the beta subunit of the barbed-end F-actin binding protein that modulates actin polymerization, a process crucial in the formation of pseudopodia that engulf the colloid within the follicular lumen during thyroglobulin mobilization in the thyroid. A third locus associated with TSH was upstream of the nuclear receptor subfamily 3, group C, member 2 (NR3C2) gene at 4q31. Another locus which was just at the borderline significance level, represents a “gene desert” on chromosome 16q23, located directly downstream of the predicted coding sequence LOC440389, which meanwhile has been removed from the NCBI data base as a result of the standard genome annotation processing. Experimental proof of the formerly predicted mature mRNA, however, demonstrates that LOC440389 indeed represents a real gene. Free T3 and free T4 were not found to be associated with any loci at a genome-wide significant level. The log of the T3/T4 ratio was associated at the borderline significance level with SNPs from a locus at 1p33-32 in the deiodinase, iodothyronine, type 1 (DIO1) gene (p=2.7 X 10-7). These results may increase the knowledge about genetic factors and physiological mechanisms of thyroid function.

Using spatial-clustering of rare-variants in the association analysis of case/control studies: a powerful and robust approach with an application to sequencing data for nonsyndromic cleft lip with or without cleft palate. *H. Fier[1], D. Holler[1], T. AlChawa[2], K.U. Ludwig[2,3], R. Fimmers[4], M.M. Noethen[2,3], E. Mangold[2], C. Lange[1,5,6].* 1) Dept. of Genomic Mathematics, University of Bonn, Bonn, Germany; 2) Institute of Human Genetics, University of Bonn, Bonn, Germany; 3) Department of Genomics, Life and Brain Center, University of Bonn, Bonn, Germany; 4) Institute for Medical Biometry, Informatics and Epidemiology, University of Bonn, Bonn, Germany; 5) Department of Biostatistics, Harvard School of Public Health, Boston, USA; 6) German Center for Neurodegenerative Diseases (DZNE), Bonn, Germany.

For the analysis of rare variants in sequence data, fixed and flexible threshold approaches have been proposed that collapse the rare-variant genotypes of a region into a single degree-of-freedom test statistic. While such collapsing approaches provide powerful test statistics that can incorporate information on allele frequencies and prior biological knowledge, the spatial clustering/physical distribution of rare variants in cases and controls cannot be incorporated. Based on the assumption that deleterious variants and protective variants cluster in different regions, we propose testing strategies for rare variants based on spatial-cluster methodology whose power is not affected by varying effect size directions of the variants. In simulation studies, we assess the power of the approach and compare it to exiting methodology. Our simulation studies suggest that our approach is well powered, even in situations that are ideal for standard collapsing approaches. An application to a sequencing study in patients with nonsyndromic cleft lip with or without cleft palate in which a region is followed that was implicated by a GWAS, the proposed testing strategies show highly significant findings, while standard approaches fail to detect an association.

683F

An Ensemble Pipeline to Enable Detection of Epistasis in Genomic Data. *B.J. Grady[1], T. Cattaert[2], K. Van Steen[2], M.D. Ritchie[1].* 1) CHGR, Vanderbilt Univ, Nashville, TN; 2) Systems and Modeling Unit, Montefiore Institute, University of Liege, Grande Traverse 10, 4000 Liège, Belgium.

Although our capability to gather large quantities of information on genetic variation has increased exponentially, our ability to understand the complexity of the relationship between this variation and disease has been unable to keep pace. While GWAS has had great success in uncovering novel variation associated with disease, these variants account for vanishingly small modulations in disease risk and even in aggregate they leave unexplained large amounts of the heritability estimated from family studies. One of the primary issues with our current treatment of genetic data lies in the veracity of our assumption of simplicity, with most analyses focusing only on effects of singular loci in isolation. We hypothesize that no one method is best for the analysis of all data types and that employing a hybrid approach will be beneficial. In this study we describe an ensemble procedure to exploring epistasis in genetic studies. This procedure includes filtering the data prior to analysis to reduce both computational and multiple-testing issues. For filtering, the Evaporative Cooling software and a genotypic Chi-square test are utilized. Within the genetic data passing filtering criteria, we perform separate, exhaustive pair-wise analysis utilizing the Model-Based Multifactor Dimensionality Reduction (MB-MDR) software and a Likelihood Ratio Test (LRT) containing terms for interaction between the pair of genetic loci being examined. One thousand permutations are used to determine significance of results from each method. The performance of the data analysis pipeline is evaluated by simulating 100 case-control datasets of 1000 SNPs for 1000 cases and 1000 controls over 77 different two-locus disease models with different disease penetrance and genetic effects and in which some models possess no detectable marginal effect. Ten representative models were used to further test the pipeline procedure in 2500 SNP data. We show that use of this data analysis pipeline increases the power to detect a breadth of potential genetic interactions.

Bloat control methods substantially reduce computation time for detecting gene x gene interactions in ATHENA. *E.R. Holzinger, S.M. Dudek, E.S. Torstenson, M.D. Ritchie.* Ctr Human Gen Res, Vanderbilt Univ, Nashville, TN.

Recent advancements in human genetics research have spurred the increase in popularity of the genome-wide association study (GWAS) to identify the etiology of common disease. GWAS have been successful at identifying thousands of single nucleotide polymorphisms (SNPs) that contribute to hundreds of human traits; however, these variations only account for a tiny portion of the overall estimated heritability. One hypothesis is that this hidden heritability lies in non-linear interactions between multiple loci that would be missed by single-locus analyses. Testing for interactions is not a trivial task due to the computational burden of exhaustive analysis. To address this problem, our lab has incorporated two machine learning methods, Grammatical Evolution Neural Networks (GENN) and Grammatical Evolution Symbolic Regression (GESR) into ATHENA (Analysis Tool for Heritable and Environmental Network Associations). Both methods use genetic programming (GP)-based techniques to evolve a random population of solutions to find the correct susceptibility model without exhaustively testing all loci combinations or biasing on main effects. One issue with GP-based methods is that the solutions tend to bloat, or get larger but not better. This results in a substantial increase in computation time and over-fitting. Several methods have been developed to control bloat, but none have been specifically tested for human genetic data analysis. For this experiment, we compared two bloat-control techniques, prune and plant (P&P) and double tournament (DT), with no bloat control using simulated data sets with 100 SNPs (2 functional and 98 non-functional), 1000 cases, and 1000 controls. The data sets were generated using penetrance functions that included interaction and main effects for the two functional loci across four different heritabilities (0.005, 0.03, 0.01, and 0.1) and two different minor allele frequencies (0.2 and 0.4). Our results show that both P&P and DT result in a significant decrease in computation time (6-fold and 2-fold, respectively) with no negative impact on detection power.

Incorporating biological knowledge for model-based clustering of genomic data: a recursively partitioned mixture model for DNA methylation data. *D.C. Koestler[1,2], B.C. Christensen[5], C.J. Marsit[3,4], K.T. Kelsey[6], E.A. Houseman[7].* 1) Department of Biostatistics, Brown University , Providence, RI; 2) Section for Biostatistics and Epidemiology, Dartmouth Medical School, Lebanon, NH; 3) Department of Pharmacology and Toxicology, Dartmouth College, Hanover, NH; 4) Norris Cotton Cancer Center, Dartmouth College, Hanover, NH; 5) Department of Community and Family Medicine, Dartmouth Medical School, Lebanon, HN; 6) Department of Epidemiology, Brown University, Providence, RI; 7) Department of Public Health, College of Health and Human Sciences, Oregon State University, Corvallis, OR.

DNA methylation is a well recognized epigenetic mechanism that has been a host to growing body of literature, typically centered on the identification and study of profiles of DNA methylation and their association with human diseases and exposures. Unsupervised clustering of DNA methylation data is often used to identify classes of samples with distinct methylation patterns and has played an integral role in our understanding of the development and progression of a vast array of different human diseases. In recent years, a number of unsupervised clustering algorithms, both parametric and non-parametric, have been proposed for clustering large-scale DNA methylation data. However, most of these approaches do not incorporate known biological relationships of measured features, and in some cases, rely on unrealistic assumptions regarding the nature of DNA methylation. We propose a modified version of a recursively partitioned mixture model (RPMM), a hierarchical model-based method for clustering high-dimensional genomic data. The modified RPMM we propose integrates information related to the proximity of CpG loci within the genome to inform correlation structures from which subsequent clustering analysis is based. Integrating biologically-informed correlation structures to enhance modeling techniques is motivated by the rapid increase in resolution of DNA methylation microarrays and the increasing understanding of the biology of this epigenetic mechanism. We have demonstrated, in simulations and several real methylation data sets, that integrating biologically informative correlation structures within RPMM can result in improved goodness of fit and clustering consistency compared to the standard RPMM which assumes class conditional independence of CpG loci.

Investigating the `missing heritability' of Meconium Ileus in Cystic Fibrosis: contributions from a hypothesis-driven GWAS (GWAS-HD). *W. Li[1,2], X. Li[2], F. Lin[3], T. Chiang[2], M. Drumm[4], M. Knowles[5], G. Cutting[6], P. Durie[7], J. Rommens[3,8], L. Sun[1,9], L. Strug[2,1].* 1) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 2) Child Health Evaluative Sciences, Hospital for Sick Children, Toronto, Ontario, Canada; 3) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Departments of Pediatrics and Genetics, Case Western Reserve University, Cleveland, Ohio, USA; 5) Cystic Fibrosis Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 6) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 7) Physiology and Experimental Medicine, Hospital for Sick Children, Toronto, Ontario, Canada; 8) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 9) Department of Statistics, University of Toronto, Toronto, Ontario, Canada.

The Cystic Fibrosis (CF) gene modifier consortium conducted a GWAS for the early CF complication of Meconium Ileus (MI), identifying and replicating SLC26A9 and SLC6A14. Although the heritability of MI is estimated to be > 88% (Blackman et al. 2006), these two genes account for < 5% of the phenotypic variance. The GWAS-HD prioritization approach (Strug et al. 2010) has established that the collection of the 157 apical plasma membrane (APM) genes is associated with MI in two independent cohorts (Li et al. ASHG 2011), suggesting potential genetic heterogeneity in MI. We hypothesized that the APM genes account for a substantial amount of the missing heritability in MI. Here we determine which APM genes contribute to MI, and estimate the proportion of phenotypic variance these genes jointly explain. Jointly analyzing 4,029 SNPs within ±10kb of the 157 APM genes (including SLC26A9) and SLC6A14 using Lasso (Tibshirani, 1996), 48 SNPs from 36 different genes were retained in the model to predict MI. These SNPs explained ~17% of the phenotypic variance (area under the curve (AUC) = 0.73), a ~ 2.5-fold increase from GWAS findings. Permuting the phenotype and re-analyzing with Lasso resulted in a model including only two SNPs from two genes, providing an example of what would be expected by chance alone. Using the 1000 Genomes data (www.1000genomes.org) as reference, we next imputed SNPs across the APM genes to determine whether additional phenotypic variance could be explained by improved genomic coverage. Jointly analyzing 21,193 genotyped and imputed SNPs, Lasso selected 48 SNPs (37 imputed SNPs) spanning 27 unique genes (24 genes overlapped with the 36 genes identified using genotyped SNPs only), explaining ~16% of the phenotypic variance (AUC = 0.73). In summary, we identified SNPs that account for an appreciable amount of the phenotypic variance in MI, highlighting the advantage of GWAS-HD and joint-SNP analysis. These SNPs reflect a contribution by many APM genes. The inclusion of imputed SNPs did not lead to gains in percentage of variance explained or prediction accuracy. Although the APM genes are clearly associated with MI, their predictive ability is low indicating limited application towards personalized medicine. We are currently replicating the 48-SNP model in an independent CF cohort, determining causal variants, and identifying additional MI susceptibility loci.

A Methodologic Proposal for Genetic Population: Surnames. *F. Loeza-Becerra[1,2].* 1) Embriología, Fac. Medicina Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Michoacán, Mexico; 2) Secretaría de Salud.

In classic Genetic Popuation it's necessary to know genetic markers' inheritance, selective forces, genetic structure, geographic variations and history if we need well known the population. Surnames like `neutral alleles' are useful tool and short way to know genetic structure specially in countries where the economy is shortest. In precolumbian America, some groups had lineages and `family names' an now, surnames. We employed amerindian's surnames and its families as incruent samples and methodologic tool prior to employ HLA and others blood markers in three “tarascan” localities (60 kms between them) in Michoacan MEXICO Each one has census, pedigrees and classified surnames: Autocton ('A') if origin local or prehispanic and No-Autocton ('NA') if not; its local staying by three or more generations checking this in regional registries. HLA haplotypes were matched to families. Registered proportions A/NA, kind of surnames and frequencies intra/intercommunities, consanguinity, isonimy, difussion private ('P') if only one site or more ('C'), familial reproductive story and losses ('G' -gray- if abortus, mortinatus, etc. or `W' -white- if not). There are N=299 surnames `A' (42%) in N=1932 families, in similar composition in all three sites but many `A' had few families (viceversa in `NA'), bottlenecks and n=26 epidemics in four centuries (in two lastest, four) and disappear more 60& from `A' pioners against `NA' immigrants whom growing more by increased fertility (survivors `G'). Surnames `A' and `C' reveals ancestry, mixture and migrations. They are in Hardy-Weinberg equilibrium, simpatry and endogamy but no consanguinity; more 40% living in their original community. Maximun genetic mixture estimated by surnames was 60%; less 30% by blood genetic markers. Prehispanic component is remarkable in three localities. Surnames were incruent indicators useful to select better sites `representatives', in this case, from Tarascan (or Purépecha) ethnic group. Geography and prehispanic toponimies aren't sufficient. Surnames can to explain easy, quickly and really history and mixture and contributes to good selection for mollecular studies. Markers like HLA haplotypes was according with surnames. In this kind of peoples, surnames gives methodologic guides to integral study of populations.

688F

Combinations of phenotypes that best capture the genetic variation in CARe pilot dataset. *Y. Meng[1], L.A. Cupples[2], M. Fornage[3], B. Keating[4], E. Larkin[5], G. Papanicolaou[6], W. Post[7], A. Reiner[8], S. Rich[9], J. Rotter[10], D. Siscovick[8], J.G. Wilson[11], J.N. Hirschhorn[1].* 1) Metabolism Initiative, Broad Inst, Cambridge, MA; 2) Boston University, Boston, MA; 3) The University of Texas Health Science Center at Houston, Houston, TX; 4) University of Pennsylvania, Philadelphia, PA; 5) Vanderbilt University, Nashville, TN; 6) National Heart Lung and Blood institute, Bethesda, MD; 7) Johns Hopkins University, Baltimore, MD; 8) University of Washington, Seattle, WA; 9) University of Virginia, Charlottesville, VA; 10) University of California, Los Angeles, CA; 11) University of Mississippi, Jackson, MS.

For association studies, we typically use individual clinical endpoints or quantitative traits as the phenotypes of interest. Most studies also include a number of phenotypic measures, sometimes correlated, that can be used to characterize disease or intermediate phenotypes and that may be related to similar genetic factors. For example, body mass index (BMI), waist circumference, fat mass, percentage of fat mass (PFM) and other measures can be used to assess related aspects of obesity; LDL, HDL, lipid lowing medication, and triglycerides can be used to assess different aspects of lipid levels. Traditionally, each of these phenotypes is studied individually, but genetic variants may influence a combination of phenotypes, with perhaps different variants showing different pleiotropic profiles. In order to maximize the chance of identifying the genetic contributors to phenotype, knowing the phenotypic profile that most closely corresponds to the effects of underlying genetic factors would be beneficial. Our goal is to generate composite phenotypes that are more closely associated with validated functional SNPs than are the individual phenotypes. These new composite phenotypes could then be used in more comprehensive genotype-phenotype analyses. In effect, we are reversing the usual process of starting with a phenotype and searching through genotypes for association; rather we use methods that start with a validated genotype and search for the most closely associated composite phenotype. Using genotype data from the Candidate Gene Association Resource (CARe), we first created three sets of phenotypes from training data: the original traits, principal components (PC) of the traits, and factors of the traits. Second, for each SNP, we ran three models, where the SNP was the dependent variable, and each set of original traits, PCs, and factors were independent variables. We transformed the test datasets to PCs and factors using loading scores from the training dataset, and assigned weights using the coefficients from each training analysis to generate three composite phenotypes (multiscore, pcscore and factscore). In preliminary analyses the multiscore method showed the best power to detect associations between SNPs and multiple related traits, with a reduction in p value of 1~4 orders of magnitude compared to the results using single traits, across an array of SNP-phenotype associations, e.g. p value for rs11591147 for HDL reduced from $3.87X10^{-9}$ to $3.28X10^{-12}$.

Accurate identification of low-level DNA contamination through genotyping array data as a quality control precursor to low-depth sequencing. *L. Moutsianas, RD. Pearson, KJ. Gaulton, C. Groves, W. Rayner, N. Robertson, MI. McCarthy.* Wellcome Trust Centre for Human Genetics, Univ of Oxford, Oxford, United Kingdom.

Whole genome sequencing (WGS) studies are increasingly popular as a means to interrogate genetic variation. Low-depth sequencing (4-5x coverage) offers the opportunity to identify variants in larger numbers of samples at a given cost compared to high-depth sequencing (20-30x), with little reduction in allele detection for common variants. A drawback to low-pass sequencing studies, however, is that the evidence supporting rare alleles is often limited and thus sensitive to even minor sources of error.

In some early WGS data sets, we had seen that low level cross-sample contamination during sample processing could lead to inflated heterozygosity in low-pass sequence data that was difficult to detect a priori. Genotyping arrays are relatively inexpensive and can be used as pre-screening tools, prior to sample inclusion in costly sequencing studies. Thus, we have developed a method to detect low-level human DNA contamination that can be used as a QC precursor to low-depth sequencing.

Our methodology consists of identifying variants with homozygote genotype calls from array data, grouping them by the population allele frequency of the unseen allele, and averaging the raw intensity values of the unseen alleles across each group. A regression line is then fitted to the values, where the slope is related to the amount of DNA contaminant from the specified population. We calibrated the method by creating a double dilution series of 10 known mixtures of DNA (50% - 0.1%) from two European samples obtained from the ECACC collection. Each mixture was then genotyped in duplicate on the Illumina MetaboChip array. Using our approach we were able to distinguish contaminant DNA from pure DNA samples down to the lowest tested mixture.

We provide as a resource an R package that can be used to identify DNA contamination down to 0.1% using SNP array data and population allele frequencies. We are currently extending our method to directly estimate the amount of contamination in a given sample and to determine the contaminant sample. We also provide a reference dataset from the different mixtures of 2 pure DNAs that can be used to validate, calibrate and compare contamination detection methods.

Cumulative Meta-analysis for Genetic Association: When is a New Study Worthwhile? *M.A. Rotondi[1, 2], S.B. Bull[1, 2].* 1) Samuel Lunenfeld Research Institute, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, Toronto, Ontario, Canada.

Meta-analysis is useful to examine potential associations between complex traits and single nucleotide polymorphisms (SNPs) of interest. This approach typically detects smaller genetic associations than those that could be ascertained in any individual study. We propose a statistical technique to examine the potential impact of a newly planned association study on an existing meta-analysis. Specifically, we address the question: How large a sample size would be required to show genome-wide significance in a meta-analysis of a newly planned study together with the existing one? or alternatively: Will a planned study of size *n* be able to provide evidence of a genetic association when this study is combined with a current meta-analysis? Through the use of a simulation-based algorithm, the approach provides an empirical estimate of the power of the updated meta-analysis to detect genome-wide significance or the expected *P*-value for a specified SNP. Although such an approach is useful for both common and rare variants, as well as genome-wide association studies (GWAS) and candidate gene studies, the technique is illustrated in the context of an updated meta-analysis of case-control studies in Paget's disease. A variation of the described algorithm provides a second example; which illustrates the impact of a newly planned study on the associations of two SNPs (rs3796529 and rs2516448) with human height.

691F

Incorporating Gene Pathway Information in Genetic Association Studies. *J.L. Walker, C.J. Verzilli.* NCDE, London School of Hygiene and Tropical Medicine, London, United Kingdom.

Genome wide association studies and next generation sequencing studies have identified a number of disease susceptibility variants but, so far, these only explain a small fraction of genetic variation in disease risk. It seems likely that a substantial fraction of unexplained variation is contributed by variants which have either small effect or are very rare, for which current studies are in most cases underpowered. Existing biological knowledge could prove useful in the search for disease susceptibility variants and in disentangling genuine associations from spurious ones. This could be achieved for instance by informing the search using information on gene pathways. Several gene pathway databases now exist, which assign genes to functional categories according to their roles in shared biological processes. Here we investigate the use of prior information on gene pathway in genetic association studies. The underlying idea is to give more weight to plausible genomic regions when searching for susceptibility variants, and to boost signals that appear to be consistent with a pathway relevant to the disease studied. Gene pathways can be depicted as undirected graphs with nodes as genes, and edges connecting two nodes representing a biological functional relationship. Our approach is fully Bayesian which enables incorporation of prior information naturally. In particular, the prior of a particular gene being in model depends on whether they appear in pathway(s) relevant for the disease examined and we describe dependencies amongst genes in pathways using Markov Random Field (MRF) priors. We examine the performance of the proposed methodology using simulated data under various scenarios. We show that the probability of detecting gene-specific association is increased by having a spatially dependent MRF prior that reflect prior biological knowledge. These results were compared to single locus methods and we found that our methods increase the chances of finding associations, especially when effects are small.

692F

Robust methods for analyzing secondary phenotypes in case-control genetic association studies. *C. Xing[1], A. Allen[2].* 1) Biostatistics, Boston University, Boston, MA; 2) Biostatistics and Bioinformatics, Buke University, Durham, NC.

The case-control study is an economical approach to studying disease/exposure associations. When a disease is rare or when exposures are expensive to collect, the case-control study can represent a considerable costs savings relative to studying a cohort prospectively. For these reasons, genome-wide and whole exome association studies often utilize a case-control design. The substantial costs involved in these large-scale genetic studies also puts a premium on making the most out of these datasets. Most of these studies will measure other phenotypes, either because they are readily available, or because they are thought to be related to the underlying disease process. Studying the genetic influences of these `secondary' phenotypes may be of interest in itself or may help our understanding of the biologic pathways involved in the disease process. However, the case-control sample does not constitute a random sample from the general population. As a result, any population association between genetic variants and secondary phenotypes can be distorted in the case-control sample. Thus analysis methods that ignore the case-control design can give biased estimates of the population effect of a genetic variant on a secondary phenotype. We propose an inverse-probablility weighted estimating equation (IPWEE) approach for analyzing secondary phenotypes in case-control studies. We derive estimators that are appropriate when the disease is rare as well as estimators that utilize existing population level disease prevalence information. We evaluate our methods in an extensive simulation and compare the IPWEE approach with several existing methods. We found the IPWEE approach to perform well over a wide spectrum of scenarios. We found that IPWEE had nearly the same power as the (optimal) full-likelihood approach when the model was correctly specified. However, we found that IPWEE was substantially more robust than the full-likelihood approach, both in terms of validity and power, when the model was misspecified. The IPWEE approach is also far more computationally efficient, requiring, on average, 10 times less computing time than the full likelihood approach.

693F

An Empirical Bayes based method to identify cis-eQTLs across multiple related conditions. *C. Ye[1], B. Han[2], T. Choi[3], A. Regev[1], E. Eskin[2].* 1) Broad Institute, Cambridge, MA; 2) University of California, Los Angeles, CA; 3) Predictive Biology, Carlsbad, CA.

Large-scale eQTL studies are now being conducted where tens of thousands of phenotypes (transcript expressions) are collected across multiple related conditions (e.g. tissue, cell type, treatment or population). These studies try to identify genetic variations associated with expression levels in specific conditions. Powerful multivariate analyses (e.g. MANOVA) of the data are often prohibitive because of computational complexity, lack of statistical robustness and difficulty of interpretation. Instead, most current methods perform a series of univariate tests one transcript, one SNP and one condition at a time. This approach suffers from the “Winner's Curse” phenomenon that systematically results in limited power to detect cis-eQTLs shared between multiple conditions thus artificially inflating the proportion of condition specific cis-eQTLs. We present a novel and efficient Empirical Bayes approach that leverages the similarity between multiple transcripts and conditions to identify cis-eQTLs. We show through simulation that this method has higher power to detect cis-eQTLs shared between multiple conditions while exhibiting strong control of false discovery rate. We apply this approach to datasets collected over multiple tissue types in both mouse and human detecting more cis-eQTLs, both shared and condition specific than standard approaches at the same FDR thresholds. Computationally, we show that using a greedy algorithm to estimate a limited number of parameters, our approach is more robust and efficient than other EB based methods thus making it suitable for large-scale eQTL studies.

CpGassoc - An R Function for Analysis of DNA Methylation Microarray Data. *R.T Barfield[1], V. Kilaru[2], A.K Smith[2], K.N Conneely[3].* 1) Dept of Biostatistics and Bioinformatics, Emory University School of Public Health, Atlanta, GA; 2) Dept of Psychiatry, Emory University School of Medicine, Atlanta, GA; 3) Dept of Human Genetics, Emory University School of Medicine, Atlanta, GA.

CpGassoc - An R Function for Analysis of DNA Methylation Microarray Data The analysis of DNA methylation data has recently garnered attention among researchers from a variety of backgrounds, due to the availability of high-throughput methylation microarrays. The number of CpG sites that can be analyzed is growing rapidly - for example, the latest Illumina Infinium BeadChip interrogates ~450,000 CpG sites. With the growing interest in DNA methylation and the growing volume of data analyzed, there is a need for software to perform these types of analyses. We created CpGassoc, an R package that is designed to perform association tests between CpG sites and a user-specified phenotype that can be a continuous or categorical variable. CpGassoc will fit a linear fixed or mixed effects model to model the beta values (proportion of DNA methylated) at each CpG site as a function of the phenotype and other covariates. Users can specify an unlimited number of continuous and categorical covariates, as well as a fixed or random effect to control for batch or chip effects. The output of CpGassoc is an R object containing the test statistics and p-values for each CpG site, as well as indicators of which CpG sites are genome-wide significant according to False Discovery Rate and Bonferroni approaches. The resulting R object can easily be output in a variety of text or spreadsheet formats, or can be passed to other R functions for further analysis. The CpGassoc package includes additional functions for analyzing output, including functions to assess significance empirically via a permutation test or to create quantile-quantile and CpG-specific plots based on the observed results. CpGassoc is designed to be a modular package, with the flexibility to add modules in the future. Currently we are working on modules to address issues of data cleaning and normalization, and hope to add further modules as new approaches to analysis of methylation data are developed. Because of the open source nature of R, users will have the ability to modify the functions in CpGassoc to create custom analyses or to create their own packages to complement CpGassoc. In conclusion, we have developed a useful and versatile tool for analyzing methylation microarray data that allows for a variety of different analyses, and can grow flexibly to meet the needs of a growing field.

Method to Detect Differentially Methylated Loci with Case-Control Designs. *S. Wang.* Dept Biostatistics, Columbia Univ, New York, NY.

It is now understood that virtually all human cancer types are the result of the accumulation of both genetic and epigenetic changes. DNA methylation is a molecular modification of DNA that is crucial for normal development. Genes that are rich in CpG dinucleotides are usually not methylated in normal tissues, but are frequently hypermethylated in cancer. With the advent of high-throughput platforms, large-scale structure of genomic methylation patterns is available through genome-wide scans and tremendous amount of DNA methylation data have been recently generated. However, sophisticated statistical methods to handle complex DNA methylation data are very limited. Here we developed a likelihood based Uniform-Normal-mixture model to select differentially methylated loci between case and control groups using Illumina arrays. The idea is to model the data as three types of methylation loci, one unmethylated, one completely methylated, and one partially methylated. A three-component mixture model with two Uniform distributions and one truncated normal distribution was used to model the three types. The mixture probabilities and the mean of the normal distribution were used to make inference about differentially methylated loci. Through extensive simulation studies, we demonstrated the feasibility and power of the proposed method. An application to a recently published study on ovarian cancer identified several methylation loci that are missed by the existing method.

New pipeline for microarray expression data analysis. *C.S. Rocha, C.V. Maurer-Morelli, I. Lopes-Cendes.* Molecular Genetics - FCM, Unicamp, Campinas, São Paulo, Brazil.

Objective: Expression profile using microarrays has become a widely used method for studying gene expression patterns. These studies produce a large amount of data which makes the analysis complex and time consuming. As the arrays' quality becomes more reliable the critical point remains the bioinformatics tools used to process and analyze the data generated in these large experiments. Therefore, we aimed to developed a pipeline that runs all the steps of data processing such as background correction, quality control, normalization, detection of differentially expressed genes and clustering analysis. In addition, our tool allows the choice of several parametric and non-parametric tests to be used for group comparisons. Furthermore, it can be used for data mining, searching for relevant information of genes as well as creating links to various public available databases. **Methods:** The pipeline is web based in a GNU/Linux operational system. A SQL database was created with the annotation data from public databases using MySQL. The tool is written in Perl using the CGI module for web application and the DBI module for data manipulation. In addition, we use several Bioconductor packages in R environment designed for statistical analysis of microarray experiments. **Discussion:** Using the tolls in the pipeline the user can perform non-parametric tests, such as RankProduct and Mann Whitney U test, as well as parametric statistical analysis such as Student's t-test. In addition, it is possible to perform corrections of p-values with the Benjamini and Hochberg or Bonferroni methods. Cluster analysis can be performed using PCA (Principal Component Analysis), Hierarchical Clustering and SOM (Self-Organizing Maps). Correlation analysis was also implemented. Starting with a list of identifiers (Probe Set IDs) the annotation tool can search a specific database for the annotation corresponding to these identifiers. To facilitate data mining we have included links to other databases such as: NetAffx, UniGene, Ensembl, SwissProt and OMIM. In addition we implemented a filter by chromosome, allowing the user to direct the search to a specific chromosome of interest. **Conclusion:** The main goal of this pipeline is to provide researchers working with microarray data a user friendly tool which includes customized statistical analysis. In addition we provide a filter by chromosome in the annotation tool which may be useful in gene identification projects.

Genome-wide association study of three dimensional facial morphology identifies a variant in the PAX3 gene responsible for normal variation in face shape. *D.M. Evans[1,2], L. Paternoster[1,2], A.M. Toma[3], A.I. Zhurov[3], J.P. Kemp[1,2], B. St Pourcain[2], N.J. Timpson[1,2], G. McMahon[1,2], S.M. Ring[2], G.D. Smith[1,2], S. Richmond[3].* 1) MRC CAiTE, University of Bristol, Bristol, UK; 2) School of Social and Community Medicine, University of Bristol, Bristol, UK; 3) Department of Applied Clinical Research & Public Health, Cardiff University, Cardiff, UK.

Craniofacial morphology is highly heritable, as demonstrated by twin and family studies, however, the individual genetic variants which affect normal variation in human facial features have yet to be identified. We conducted to our knowledge the first genome-wide association study of three dimensional (3D) facial morphology in a population-based cohort in order to identify SNPs associated with normal variation in facial characteristics. 3D high resolution facial images were obtained using two Konica/Minolta laser scanners in 4747 15 year old children from the Avon Longitudinal Study of Parents and Children. 3D images were initially aligned in three reference planes and the generalised Procrustes analysis was then applied. We identified 22 landmarks on the facial shells and used their location to generate 54 3D distances. These measures were then tested for association in a discovery cohort comprising 2185 individuals who had been genotyped genome-wide on the Illumina 317K and Illumina 610K SNP chips and subsequently imputed to HapMap. Genome-wide significant association was observed between the SNP rs7559271 in the PAX3 gene and 3D distance between the nasion and the mid-endocanthion (p=2.2x10-10). This association was subsequently replicated in a further 1645 individuals from the same cohort who had been genotyped on the Illumina 550K SNP chip (p=4.4x10-7). In order to investigate the association further, we deconstructed the 3D distance into one and two dimensional distances. Association was observed in both the z (nasion prominence) and y (height of nasion relative to the mid-endocanthion) dimensions, but not the x dimension (p > 0.05). Additionally, the associations in the y and z dimensions were independent of each other, suggesting that the locus influences growth and development in the yz plane, but not the yz angle between the nasion and mid-endocanthion. There was also no association between the SNP and distance between the eyes. The PAX3 gene has previously been associated with Waardenburg syndrome, a condition which involves characteristic facial morphologies including a flattened nasal bridge and widely spaced eyes. Our study suggests that less pathogenic mutations within the PAX3 gene may produce non-pathological variation in face shape within the normal range.

Novel insights into the genetics of Parkinson's disease on chromosome 17. *W. Lau, H. Elding, D. Swallow, N. Maniatis.* RESEARCH DEPARTMENT OF GENETICS, EVOLUTION AND ENVIRONMENT, UNIVERSITY COLLEGE LONDON, LONDON, United Kingdom.

Parkinson's disease (PD) is the second most common neurodegenerative disease. Several Genome Wide Association (GWA) studies have been preformed to date focusing primarily on sporadic PD. These studies have reported a relatively small number of susceptibility loci even though recent studies have indicated a large genetic contribution. Here we show significant progress by using high-resolution metric linkage disequilibrium maps to identify new genes on chromosome 17 that harbours the *MART* gene (strongest replicated GWA signal on 17q). Our analysis of the NINDS GWA data (Illumina 550, 677 cases and 538 controls) has identified the *MAPT* gene-region but with an estimated location of the casual variant downstream of *MAPT*. This localization was replicated with precision using an independent GWA on sporadic PD (Illumina 1M, 2,000 cases and 1,986 controls). Here we report several additional novel genes, including *ALOX15, RABEP1, PER1, CENTA2, THEM100, AXIN2, CD300LE, LGALS3BP*. All these signals have been replicated with great precision and most of our location-estimates point to causal variants within regulatory regions. The use of metric linkage disequilibrium maps can bring a much greater resolution and hence they can accelerate progress in identifying the genetic factors to PD and other complex disorders.

699F

Effects of genotype on TENS effectiveness in controlling knee pain in persons with mild to moderate osteoarthritis. *N. Mukhopadhyay[1], D. Schutte[2], C. Vance[4], R. Walder[4], K. Sluka[4], B. Rakel[3], M. Govil[1].* 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) College of Nursing, Michigan State University, East Lansing, MI; 3) College of Nursing, The University of Iowa, Iowa City, IA; 4) Physical Therapy and Rehabilitation Graduate Program, College of Medicine, The University of Iowa, Iowa City, IA.

Evidence from both animal and human studies suggests that Transcutaneous Electrical Nerve Stimulation (TENS) can be an effective way to treat pain in a variety of acute and chronic conditions. The effectiveness of TENS in the treatment of osteoarthritis (OA) knee pain is less certain, and the role of genetic variants as modifiers of TENS effectiveness is relatively unexplored. The purpose of this study is to examine the extent to which genetic variability modifies the effectiveness of TENS in controlling knee pain in persons with mild to moderate OA. Seventy-five subjects (mean age 56.3 years, 61% females) diagnosed with medial compartment knee OA were recruited from the Orthopedic and Sports Medicine Department of a large Midwestern tertiary care center and were randomly assigned to three groups: 1) High Frequency TENS (HFT, 100Hz), 2) Low Frequency TENS (LFT, 4Hz), and 3) Transient Placebo TENS (TPT, current delivered for 30 sec, then ramped down to zero over 15 sec). Measures of pain were collected pre and post treatment and included subjective pain (VAS) at rest and with movement, cutaneous mechanical pain testing using von Frey filaments, heat pain threshold, and pressure pain threshold using a digital pressure algometer. Pain measures were obtained at the knee and anterior tibialis regions on both the ipsilateral and contralateral side, and the difference in pre vs. post treatment measures analyzed. On a 0-100 VAS pain scale, average reduction in intensity and distress at rest were 13.90 and 16.94 points for HFT, and 10.32 and 13.36 for LFT. TPT produced a placebo effect showing reduction of 16.84 and15.32 points. Subjects were genotyped in 11 candidate genes with a known or hypothesized role in central or peripheral pain pathways: NGFB, NTRK1, EDNRA, EDNRB, EDN1, OPRM1, TAC1, BDNF, BDKRB1, 5HTT, and COMT. Linear regression modeling, using PLINK, examined genotype effect on change in pain outcomes, comparing TPT vs. HFT and TPT vs. HFT+LFT. SNPs rs165599 (COMT) and rs6827096 (EDNRA) for heat pain threshold, and rs6715729 (TAC1) for the cutaneous mechanical test were at or below the bonferroni-corrected threshold of 0.002. The results from this study will help provide the basis for a clinically useful tool to predict TENS intervention outcomes and the targeting of subsequent interventions that are sensitive to both individual and environmental characteristics. GWAS Analysis of Autopsy Confirmed Late-Onset Alzheimer Disease Confirms Limited Effect Heterogeneity Among Known Loci. *A.C. Naj[1], G.W. Beecham[1], E.R. Martin[1,12], P.J. Gallins[1], R. Rajbhandary[1], K.L. Hamilton[1], R. Mayeux[2,3], L.A. Farrer[4,5,6,7,8], G.D. Schellenberg[9], J.R. Gilbert[1,12], J.L. Haines[10,11], M.A. Pericak-Vance[1,12], The Alzheimer's Disease Genetics Consortium.* 1) Hussman Inst for Human Genomics, Univ Miami, Miami, FL; 2) Taub Institute on Alzheimer's Disease and the Aging Brain, Department of Neurology, Columbia University, New York, NY; 3) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 4) Department of Biostatistics, Boston University, Boston, MA; 5) Department of Medicine (Genetics Program), Boston University, Boston, MA; 6) Department of Ophthalmology, Boston University, Boston, MA; 7) Department of Neurology, Boston University, Boston, MA; 8) Department of Epidemiology, Boston University, Boston, MA; 9) Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA; 10) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 11) Vanderbilit Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 12) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL.

Alzheimer Disease (AD) is a highly genetic and complex neurodegenerative disease. Until recently, only *APOE* variation has been consistently associated with late-onset AD (LOAD); recent GWAS have identified additional risk loci (*CLU*, *PICALM*, *CR1*, *BIN1*, *CD2AP*, *EPHA1*, *ARID5B*, *MS4A4/6E*, *ABCA7*, and *CD33*). However, phenotypic heterogeneity may obscure the true effects of these loci. We investigated a potential source of heterogeneity, autopsy confirmationby comparing association results between autopsy-confirmed (AC) cases (n=1,472) and clinically-identified (CI) cases (n=2,693) versus all controls (n=4,752) using data from 5 ADGC datasets.). Furthermore, as misclassification may have weakened signals at truly associated variants, we examined 2,324,879 SNPs genotyped and imputed among autopsied cases and all controls for undetected novel LOAD associations. Analyses were performed with multinomial logistic regression, stratifying cases by autopsy confirmation of AD clinical diagnosis using the mlogit function of SAS (v9.2). While we confirmed associations with chromosome 19 SNPs in/near *APOE* (rs2075650- AC P=1.6×10^{-22}; CI P=3.2×10^{-29}), several other loci demonstrated differential patterns of association in stratified analyses; *CR1* SNP rs6701713 was more strongly associated among AC cases (OR=1.21, P=8.1×10^{-4}) than CI cases (OR=1.15, P=0.0026), as was *ABCA7* SNP rs3752246 (AC OR=0.82, P=0.0017; CI OR=0.88, P=0.01). Conversely, some SNPs were more strongly associated in the CI cases: *PICALM* SNP rs561655 (AC OR=1.10, P=0.041; CI OR=1.18, P=1.29×10^{-5}), and *CLU* SNP rs1532278 (AC OR=1.11, P=0.041; CI OR=1.16, P=3.5×10^{-4}). Examining only AC-control associations for novel signals, the most statistically significant associations (P<10^{-5}) included SNPs in *CR1*, such as a known missense variant, rs2296160 (OR=1.20, P=7.6×10^{-6}) and the intronic SNP rs1051029 (OR=0.72, P=5.8×10^{-7}) in the gene *ITPR1*, which is in the calcium-signaling pathway and has been shown to be down-regulated with increasing AD severity (Ravetti et al. 2010). Our stratified analyses of autopsy-confirmation status found that associations differed modestly among some but not all of the most significantly-associated SNPs in our original study, suggesting that clinical diagnosis is an excellent proxy for autopsy confirmation in genetic studies of LOAD.

The NCBI dbGaP database of genotypes and phenotypes provides resources for genome-wide association studies and medical resequencing. *S. Sherry, M. Feolo, Y. Jin, M. Kimura, K. Tryka, R. Bagoutdinov, J. Paschall, L. Hao, A. Sturcke, L. Phan, N. Popova, S. Pretel, L. Ziyabari, M. Lee, Z. Wang, M. Kholodov, G. Godynskiy, N. Sharopova, S. Stefanov, M. Shumway, J. Ostell.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

The dbGaP database of Genotypes and Phenotypes (www.ncbi.nlm.nih.gov/dbgap) archives and redistributes comprehensive data sets from genome-scale biomedical research studies. Public displays of study results include data object summaries, phenotype collection documents, data browsers, analysis results and connections to other information resources. For authorized investigators, dbGaP distributes all submitted de-identified, individual-level phenotype and genetic data, and aggregate-level association results. As of June 1, 2011, 132 dbGaP studies provide individual-level data for 257,331 study participants including 125,698 phenotype measures,141 billion genotypes, and 52 terabases of sequence data in over 7000 BAM files. Any Principal Investigator (PI) registered in the NIH Federated Commons (eRA) system may request access to individual level data through the dbGaP controlled access system. In the past 12 months, 3733 access requests were submitted by 647 PIs. Completed applications are automatically routed to the PI's institutional signing official (SO) for approval, and then forwarded for review and an approval decision by an NIH Data Access Committee. 2498 were approved, with a mean time to approval of 18.8 days. Submission of the data access request constitutes agreement and acknowledgment to the terms of use for the requested data sets. These terms are detailed in the “Data Use Certification” documents and generally include agreements to adhere to indicated limitations of use; not redistribute the data; not attempt to identify or contact study participants; acknowledge intellectual property principles; and adhere to publication embargo policies. Public data in dbGaP includes study descriptions, documents, variable summaries, descriptions of controlled-access components and limited aggregate data. NCBI provides a growing collection of tools to **browse** catalogs of published association results, and **examine** multiple GWAS association results simultaneously in genome coordinates. dbGaP content is connected when possible to other public information resources, including NHGRI's Genome Wide Association Catalog, PubMed, Gene, SRA and dbSNP. The dbGaP FTP site provides all public content. There you will find study release notes, documents in XML markup and PDF formats, a report describing all of the components available through controlled access, and phenotype variable summary data.

Exploiting modern computer architectures to accelerate genetic linkage analysis. *A. Medlar[1], D. Glowacka[2], H. Stanescu[1], R. Kleta[1].* 1) Department of Medicine, University College London, London, United Kingdom; 2) Department of Computer Science, University College London, London, United Kingdom.

Exact algorithms to perform genetic linkage analysis scale exponentially with the size of input. Beyond a critical limit the amount of work to do exceeds both available time and memory. Software derived from the Elston-Stewart algorithm cannot be used to analyse many genetic markers simultaneously, whereas Lander-Green-derived algorithms are limited by pedigree complexity. In circumstances beyond these limits, we are forced to either abbreviate the input in some manner (relevant to the algorithm/software employed) or else use an approximation algorithm based on stochastic sampling. Simplifying the pedigree by removing family members or the degree of consanguinity can dramatically reduce the power of the linkage study and produce ambiguous results. Approximation by stochastic simulation, greatly extends what can feasibly be analysed, but can take an immense amount of time to converge to a final result. Convergence problems are compounded by software implementations which are mostly single-threaded and, as computer processors are manufactured with increasing numbers of physical processing cores, cannot take full advantage of processing power readily available. To a limited degree we can already exploit some parallelism. Each chromosome within each pedigree is independent. In addition, we could analyse a pedigree in batches of markers using a sliding window, however this introduces error where batches meet. From another perspective, even batching limits the level of parallelism due each batch needing to be large enough to make a multi-point analysis worthwhile. A modern desktop computer (as of June 2011) can have a quad-core processor, with each core capable of running two independent threads, and a graphics cards with up to 512 stream processors. We want to better understand the workload that linkage analysis provides and how best to combine this with both the more general-purpose multi-core processor architecture versus the specialist many-core graphics processing unit (GPU) architecture. We aim to build upon existing work of descent graph samplers, by experimenting with both implementing parallel samplers for single markov-chain monte-carlo (MCMC) chains and parallel methods to combine multiple chains to understand what provides the biggest win on our target platforms.

703F

Association of COL2A1 Gene Polymorphisms with the Development of Myopia. *S. Annamaneni[1], H. Chintala[1], V. Satti[1], P. Kasu[2].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Maxivision Eye Hospital, Hyderabad, Andhra Pradesh, India.

Myopia (near-sightedness) is a common, sight threatening, multifactorial ocular disorder exhibiting genetic heterogeneity, in which retinal defocus results in impaired vision. Collagens are major extracellular glycoproteins of scleral ECM of the eye and the unsual disruption, degradation or accumulation of several collagens result in altered scleral fibril architecture and loss of tissue integrity. Collagen type II (COL2A1) gene is an important positional candidate gene for myopia, the mutant forms of which are associated with connective tissue disorders and syndromes with ocular abnormalities like high myopia. In view of its functional implication, the present case-control association study (205 high myopia cases, 96 low myopia cases and 248 control cases) analysed two intronic polymorphisms of this gene (COL2A1-Hind III polymorphism in intron 33 and dinucleotide insertion/deletion polymorphism in intron 50) through PCR followed by RFLP analysis and PAGE. The genotype distribution of Hind III polymorphism (H or h allele) of COL2A1 gene in high myopia patients revealed significant increase in the frequency of hh homozygotes (48.1%) as compared to control group (38.3%) and low myopia group (20.8%). The association of hh genotype was observed with male sex in high myopia, females in low myopia, early onset high myopia, late onset low myopia, patients in vegetarian diet group, non-familial and consanguineous groups of both high and low myopia suggesting that the presence of h allele might confer risk to the development of myopia through altered scleral-collagen interactions.The genotype distribution of intron 50 polymorphism (L1 or L2 allele) among high myopia cases revealed decreased frequency of L2L2 genotype (6.34%) as compared to controls (11.3%) but showed slight elevation in comparison to low myopia (4.12%). The genotype distribution in relation to other epidemiological variables demonstrated elevated frequency of L1 allele in males with high myopia, myopia patients on vegetarian diet, high myopia cases with early age at onset and low myopia with later age at onset 10-20 yrs, familial cases of low myopia, and consanguineous group in both types of myopia. In conclusion, our results indicate that h allele of Hind III polymorphism and L1 allele of intron 50 polymorphism of COL2A1 gene might confer risk to the development of high myopia through its role in scleral remodeling.

704F

Comparing variant calling methods in target exons of a worldwide sample of 14,000 individuals. *Y.Y. Lo[1], C. Sidore[1], J. Li[2], Y. Li[3], S.L. Chissoe[4], M.R. Nelson[4], M.G. Ehm[4], G. Abecasis[1], S. Zollner[1].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Genetics, Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 4) GlaxoSmithKline, Department of Genetics, RTP, NC.

In the past years, exome sequencing studies have been shown valuable in identifying rare variants that contribute to complex phenotypic traits. The success of these studies has resulted from their ability to generate large amount of reads at high coverage and large sample size. Critical steps to understanding the contribution of rare polymorphisms to phenotypic variation include generating precise genotype calls and identifying sources of error. There are many ways of generating genotype calls, based on how information is aggregated across samples and across sites. It is important to locate possible sources of error arising from each method when sample size increases, especially at the sites with local low coverage. Here we perform a comparative analysis on a dataset consisting of the exons of 202 genes sequenced to an average depth of 27x in a sample of >14,000 individuals. In addition, SNP data from previous genome-wide association studies are available for 10,500 individuals. After careful data cleaning and read mapping, we apply several methods for calling genotypes. We use individual based and population based calling algorithms, as well as LD based methods. For calling genotypes based on LD patterns, we combine exon sequences from target genes with flanking genotype data in a 1Mb window. We evaluate the quality of the variants generated by each method and compare across methods by calculating heterozygote concordance. Also, several independent sources of data were available to measure genotype accuracy, including eight genes sequenced in 993 individuals using conventional capillary methods, 150 sample duplicates, 30 trios, and 2 trios sequenced deeply by the 1000 Genomes Project. We quantify error as a function of multiple covariates such as the underlying coverage, allele frequency and sample size. Since over 50% of the variants called are singletons, we assess in particular the quality of singletons in each method. Preliminary results show that while individual based caller generates most number of singletons, at least 25% of them are false positives. By pooling information across samples, population based and LD based algorithms have significantly better sets of singleton calls. We also find that LD based method improves most of the low-quality genotypes called by individual based or population based methods. The results of our study provide important guidelines for the design and interpretation of resequencing based association studies.

Evaluation of POWERPLEX ESI 17® Amplification kit STR loci in an admixed hispano-amerindian population sample of Valparaíso, Chile. *G. Molina[1], MO. Yañez[2], J. Manríquez[1], S. Rojas[1].* 1) Unidad de Genética Forense, Servicio Médico Legal, Valparaiso, Región de Valparaíso, Chile; 2) Instituto de Química, Facultad de Ciencias, Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile.

The PowerPlex ESI 17® (PP17, PROMEGA) amplification Kit was designed for applications in forensic genetics analysis using short tandem repeats loci (STR) polymorphism in European population (ENFSI and EDNAP recommendations). In our population, routinely, forensic genetics testing was performed using the STR loci included in AmpFℓSTR® Identifiler® PCR Amplification kit (ID, Applied Biosystems), that includes the 13 CODIS loci (FBI recommendations). Our population is an admixture between Hispanic and Amerindians. In the literature, population genetics analysis for PP17 STR loci are scarce and mainly from Europe. To obtain population genetics data and evaluate the usefulness of the loci included in PP17, we analyzed 150 unrelated individuals' samples obtained with previous informed consent, who attend to paternity testing in our unit. The sample size was calculated according to Chakraborty (1992) to obtain frequencies higher than 0.1 ((=0.95). The DNA extraction was automated performed and the STR loci was PCR amplified using PP17 and ID amplification kits, according to manufacture recommendations. Population genetics data analysis was determined using Arlequin (University of Geneva). Power of exclusion (PE) and Match Probability (MP) were calculated using PowerStats v1.2 software (PROMEGA). The SE33 loci MP was the lowest (2.20 x 10-2) and the PE (0.788) was the third highest. The other 5 new loci ((D10S1248, D22S1045, D2S441, D12S391 and D1S1653) have similar informativeness than CODIS loci. The combined MP and PE for PP17 were 3.71 x 10-19 and 0.9999998 respectively, while for ID the parameters were 5.93 x 10-17 and 0,9999993. This study showed a high percentage of heterozigocity in PP17 loci in the population studied, despite being designed for European population. In conclusion, the use of the PP17 system has better performance than ID for forensic genetics porpoises. The combined use of these two systems could resolve complex DNA testing, where ID alone is not sufficient to get a strong conclusion.

706F

Genetic Variant Of COMT (Catechol-O-methyltransferase) Associated With Risk For Dementia. *P.A. Pereira[1], M.A. Romano-Silva[1], M.A.C. Bicalho[1,2], L.A. De Marco[1], H. Correa[1], S.B. Campos[1], E.N Moraes[1,2], K.C.L. Torres[1], I.C.R.S. Bozzi[1], G.J.G.S. Pimenta[1], M.P. Mello[1], L.B. Rodrigues[1], B.R. Souza[1], D.M. Miranda[1].* 1) UFMG, Belo Horizonte, Minas Gerais, Brazil; 2) Centro Jenny Faria de Assistência à Saúde do Idoso e da Mulher, Hospital das Clínicas, Universidade Federal de Minas Gerais (UFMG), Brazil.

Objective The aim of the present study was to examine the association between polymorphisms in the COMT gene and dementia in the Brazilian population. Catechol-O-methyltransferase (COMT) catalyzes the transference of methyl group in catecholamines such as dopamine and norepinephrine in the process of metabolism of these neurotransmitters. COMT regulates the amount of dopamine in the prefrontal cortex (PFC). Substantial studies indicate a close relationship between COMT and several human psychotic disorders. The case-control method was used to study the association between dementia and genetic variants of COMT in the Brazilian population. Methods 8 tagSNPs (rs737866, rs933271, rs1544325, rs740603, rs4646312, rs740601, rs4646316 and rs165774) in the COMT gene were genotyped by PCR-Real Time in 113 outpatients with diagnosis of dementia and 118 individuals belonging to the healthy comparison group to investigate an association between the COMT gene and dementia. The participants were evaluated using the DSM-IV, MINI-PLUS and NINCDS-ADRDA. Results The statistical findings shown that seven of the remaining eight tagSNPs analyzed were found to be significantly associated with dementia at the allele level and all tagSNP at the genotype level present an association with dementia (table). Linkage Disequilibrium analysis also showed difference between cases and controls groups. Conclusion Our results support the hypothesis that the polymorphisms of COMT gene may be associated with risk/protection to development of dementia.

Heritability estimation for human height using GWAS-based studies in African-Americans. *F. Chen, G.K. Chen, C.A. Haiman, D.O. Stram, the Genome-Wide Association Studies of Breast and Prostate Cancer in African-Americans.* Preventive Medicine, University of Southern California, Los Angeles, CA.

Height has an extremely polygenic pattern of inheritance. Genome-wide association studies (GWAS) have revealed hundreds of common variants that are associated with human height at genome-wide levels of significance. Each of these common variants has a very modest effect, and only a small fraction of phenotypic variation can be explained by the aggregate of these common variants. In this large study of 12,567 African-American men and women, we genotyped and analyzed 985,415 autosomal SNPs across the entire genome, from which we selected random sets of SNPs (10k, 50k, 100k, 200k, 300k) and estimated the proportion of variance in human height that is explained by the patterns of heritability captured by each set of SNPs using a standard variance components approach. We found that 5.2% (standard error (SE), 1.2%), 19% (SE, 2.3%), 30% (SE, 2.8%), 36% (SE, 3.2%) and 37% (SE, 3.4%) of variation in height can be explained by the additive heritability captured by 10k, 50k, 100k, 200k and 300k SNPs, respectively. We noted that the estimate of heritability explained increases with the number of SNPs used in the estimation process but asymptotes at around 35-40 percent at SNP numbers lower than conventional estimates of the number of variants needed to capture genetic variation in this relatively low LD population. We conclude that the additive heritability estimate is therefore most likely reflecting long-range relatedness between nominally unrelated participants rather than the variance explained by a given set of SNPs. This is the first and largest study to date that investigates the inheritance property of human height in a population of African origin using GWAS samples. Future work on this subject includes analyses focusing on further dissecting the variation of height to the genetic architecture and simulation studies aiming at unveiling the statistical picture of the inheritance pattern of height in this population.

Disentangler: a visualization technique for linkage disequilibrium mapping using multi-allelic loci. *N. Kumasaka[1], Y. Okada[1], A. Takahashi[1], M. Kubo[1], Y. Nakamura[2], N. Kamatani[1].* 1) Ctr Genomic Med, RIKEN, Tokyo, JAPAN; 2) Human Genome Center, Institute of Medical Science, University of Tokyo, JAPAN.

Linkage disequilibrium (LD) mapping using multi-allelic genetic loci (such as HLA alleles) is occasionally required to identify susceptibility haplotypes for complex diseases. Here we propose a new visualization technique to map LD with multi-allelic loci. A statistical method to infer underlying haplotypes at those loci is developed and the multiple correspondence analysis (MCA, also known as homogeneity analysis) is further applied, which provides an optimal default of the inferred haplotypes on a display. Several practical examples of LD mappings with HLA alleles associated with ulcerative colitis and Crohn's disease are presented, which illustrate the potential usefulness of the method as an aid to the interpretation of disease susceptibility haplotypes at multi-allelic loci. The method is general thereby applicable for single-nucleotide polymorphisms and allele-specific copy number polymorphisms, or mixture of those in a single display.

709F

Model-based identification of pseudo-trio structures in population genomic data and application to haplotype phasing. *D. Xifara, G. McVean.* Statistics, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Experimental designs that include trio data or other familial structures lead to powerful and robust approaches for the analysis of population genomic data, for example in haplotype phasing and the detection of genetic association in the presence of population structure. However, even in cohorts of unrelated individuals it is often still possible to identify individuals that share extended identity and hence recent common ancestry at one or more loci. The long range phasing method of Kong et al (2008) uses such recent ancestry to reconstruct haplotypes. However, the authors also suggested that this approach may only apply to extremely large cohorts in populations with limited genetic diversity. We have developed a model-based approach for the identification of pseudo-trios in unrelated cohorts. By combining information across multiple `pseudo-parents' we achieve accuracy in haplotype phasing comparable to current state of the art algorithms for haplotype estimation in samples of as few as 50 individuals. Furthermore, the algorithm leads to marginal phasing of samples, hence ease of parallelisation, and can be applied to cohorts of arbitrary size. We also discuss the possible use of identifying and utilising extensive relatedness in the analysis of genetic association in weakly-structured populations.

The polymorphism rs642961 (IRF6) contributes differently to nonsyndromic cleft lip/palate susceptibility according to geographic regions of Brazil. *L.A. Brito[1], C.B.F. Silva[1], K.M. Rocha[1], D. Schlesinger[1], L.A. Cruz[1], L.K. Bárbara[1], M. Aguena[1], D.F. Bueno[1], N. Alonso[2], D.R. Bertola[1], D. Meyer[1], M.R. Passos-Bueno[1].* 1) Department of Genetics, University of São Paulo, São Paulo, Brazil; 2) Division of Plastic Surgery, School of Medicine, University of São Paulo, São Paulo, Brazil.

Nonsyndromic cleft lip with or without cleft palate (NSCL/P), the most common craniofacial birth defect, is a complex disease with multifactorial inheritance, with prevalence varying among populations (1:1000 in Europeans (EU), 0.3:1000 in Africans (AF) and 3.6:1000 in Amerindians (AI)). IRF6 (1q32) has been the locus of more replicated associations, with the marker rs642961 (G>A, within an IRF6 enhancer) presenting the strongest association signal in most of the studies and being appointed as a functional variant. As Brazilians constitute an admixed population mainly from EU, AF and AI populations, approaches such as structured association are recommended in order to avoid false correlations. In this study, this SNP was tested for association with NSCL/P in Brazilian population. We have also genotyped a panel of 40 biallelic insertion-deletion ancestry informative markers in 471 patients and 326 controls, in order to characterize the individual ancestry composition. Patients were from 5 different Brazilian locations (Rio de Janeiro, n=112; Maceió, n=62; Barbalha, n=52; Fortaleza, n=163 and Santarém, n=82). Ancestry contributions and association tests were performed with Structure 2.3.3 and STRAT softwares. Frequency of the at risk allele rs642961 was estimated as 0.19 (cases) and 0.13 (controls). Overall ancestry contributions were 60% EU, 22% AF and 18% AI for cases and 71% EU, 19% AF and 10% AI for controls. Individual admixture was used to stratify the association analysis and correct for effects of admixture in case-control comparison (structured association test). When the test was performed with the whole patient sample, no significant association was detected; however, analyzing each region separately, rs642961 was significantly associated only in Barbalha (P=0.005, ORhet=1.97 [95%CI 0.99-3.89], ORhom=4.85 [1.7-14.3]. The positive association found in Barbalha is consistent with the risk allele reported in other populations (A) and with the genetic contribution for NSCL/P, estimated in a previous genetic epidemiological study (heritability estimates: Barbalha=85%; Santarém=71%; Rio de Janeiro=70%, Fortaleza=64% and Maceió=45%); moreover, the higher risk conferred by the homozygous genotype suggests a recessive role for this locus. These results suggest that despite the positive association in a region of Brazil, it is not an important locus for cleft risk in our population. FAPESP, CNPq, MCT.

711F

A Novel Permutation Strategy to Correct for Population Stratification in Case-Control Studies of Rare Variation. *M.P. Epstein[1], Y. Jiang[1], K.N. Conneely[1], R. Duncan[1], A.S. Allen[2], G.A. Satten[3].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC; 3) Centers for Disease Control and Prevention, Atlanta, GA.

Many case-control tests of rare variation [Neale et al. PLoS Genet e1001322; Ionita-Laza et al. PLoS Genet e1001289; Li et al. AJHG 87: 728 among others] are implemented in statistical frameworks that prohibit straightforward correction for confounders such as population stratification. Confounding due to population stratification is possible in resequencing studies since rare variants likely are specific to particular ancestral groups. To correct for this confounding, we propose establishing the significance of a rare-variant test using a novel permutation procedure that preserves the population stratification within the sample. Using Fisher's noncentral hypergeometric distribution, we sample disease outcomes for subjects in a permuted dataset in a manner such that the probability a subject is selected as a case is dependent on his/her odds of disease conditional on ancestry. Our permutation framework allows for adjustment of different measures of ancestry and further can model other confounders of interest to researchers. Using simulated sequence data based on coalescent models, we demonstrate that our permutation strategy corrects for confounding due to population stratification that, if ignored, would inflate the size of a rare-variant test. As an example, we simulated case-control sequence data for African-American samples under a model where the odds of disease for a subject increased with increasing proportion of African ancestry and then applied the rare-variant test of Ionita-Laza et al. (which cannot model confounders) for analysis. When the odds ratio of disease given African ancestry was 1, 4, and 8, we estimated the type-I error rates of the naive test at nominal alpha=0.05 to be 0.051, 0.100, and 0.192, respectively. When we reanalyzed the datasets by applying our novel permutation strategy to the Ionita-Laza test (sampling subjects based on estimated odds of disease conditional on principal components), we obtained type-I error rates of 0.047, 0.053, and 0.045, respectively, which indicates our method was able to correct for the confounding. In addition to simulation results, we will also present results based on application of our approach to real sequence data from the FUSION study of type 2 diabetes. The permutation approach is applicable to any rare-variant association test used in a case-control study and is implemented in a modified version of the R package `BiasedUrn' for public use.

Population structure of Hispanics in the Multi-Ethnic Study of Atherosclerosis. *A. Manichaikul[1,2], W. Palmas[3], C. Rodriguez[4], C.A. Peralta[5,6], J. Divers[7], X. Guo[8], W.-M. Chen[1,2], Q. Wong[9], K. Williams[9], K.F. Kerr[10], K.D. Taylor[8], W. Post[11,12], M.O. Goodarzi[8], M.M. Sale[1,13], A.V. Diez-Roux[14], S.S. Rich[1], J.I. Rotter[8], J.C. Mychaleckyj[1].* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 2) Department of Public Health Sciences, Division of Biostatistics and Epidemiology, University of Virginia, Charlottesville, VA; 3) Department of Medicine, Columbia University, New York, NY; 4) Department of Medicine and Department of Epidemiology, Wake Forest University School of Medicine, Winston-Salem, NC; 5) Department of Medicine, Division of Nephrology, University of California San Francisco, San Francisco, CA; 6) Division of General Internal Medicine, San Francisco VA Medical Center, San Francisco, CA; 7) Department of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 8) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 9) Collaborative Health Studies Coordinating Center, University of Washington, Seattle, WA; 10) Department of Biostatistics, School of Public Health, University of Washington, Seattle, WA; 11) Division of Cardiology, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 12) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 13) Department of Medicine and Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville VA; 14) Department of Epidemiology, Center for Social Epidemiology and Population Health, University of Michigan, Ann Arbor, MI.

Using ~60,000 SNPs selected for minimal linkage disequilibrium, we perform population structure analysis of 1,374 unrelated Hispanic individuals from the Multi-Ethnic Study of Atherosclerosis (MESA), with self-identification corresponding to Central America (n=92), Cuba (n=50), the Dominican Republic (n=202), Mexico (n=669), Puerto Rico (n=190) and South America (n=107). By projection of principal components (PCs) of ancestry to samples from the HapMap phase III and the Human Genome Diversity Panel (HGDP), we demonstrate the first two PCs quantify the Caucasian; African; and Native American origins. The third and fourth PCs demonstrate a South-to-North axis that separates HGDP Native American samples with respect to known geographic location, and reveal corresponding differences in Native American ancestry among individuals from Mexico, Central and South America, and Puerto Rico. Using k-means clustering computed using the top PCs of ancestry, we define four subgroups of the MESA Hispanic cohort that show close agreement with self-identification, roughly labeling the clusters as primarily Dominican / Cuban; Mexican; Central / South American; and Puerto Rican. Genetic association of triglycerides with 33 SNPs in the LPL gene region, previously reported in GWAS of Caucasians but as yet unconfirmed in Hispanic populations, provides evidence of association in pooled analysis of the MESA Hispanic cohort: top SNP rs328 (Ser447Stop), P=8.1E-6. In stratified analysis, the Dominican / Cuban and Mexican subgroups had comparable estimated effects of -0.226 (SE=0.063) and -0.187 (SE=0.048) on log triglycerides (log mg/dL) per copy of the coded G allele, respectively, while estimated effects for Central / South American and Puerto Rican subgroups were closer to zero, with values -0.010 (SE=0.092) and -0.033 (SE= 0.095), respectively. Our findings highlight the genetic diversity of the MESA Hispanic cohort, and demonstrate the importance of considering this diversity in examining genetic association in the United States Hispanic population.

Admixture mapping for qualitative or quantitative traits when confounding covariates and gene-environment interactions are present. *B. Zhu[1,2], D. Dunson[1], M.L. Miranda[3,4], A.E. Ashley-Koch[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Statistical Science, Duke University, Durham, NC; 3) Nicholas School of the Environment, Duke University, Durham, NC; 4) Department of Pediatrics, Duke University Medical Center, Durham, NC.

Admixture mapping is a popular tool to identify regions of the genome associated with traits in a recently admixed population. Several methods have been introduced, primarily for dichotomous traits. We propose a two-stage approach for qualitative or quantitative traits and also consider the presence of confounding covariates and gene-environment interactions. In the first stage, the number of ancestral alleles at each selected locus is sampled across the entire genome based on a Hidden Markov Model (HMM) using a Markov chain Monte Carlo (MCMC) algorithm. The HMM is similar to the ones implemented in STRUCTURE and ANCESTRYMAP, with one key difference: we model the recombination process non-parametrically. Thus, the recombination rates are no longer homogeneous across the genome, and we can identify recombination hotspots. In the second stage, we investigate the association between the qualitative or quantitative trait with one set of ancestral allele estimates along with possible confounding covariates and gene-environment interactions, using a generalized linear model (GLM) with a shrinkage prior. The association results are combined across multiple sets of ancestral allele estimates to account for uncertainty in the ancestry estimates. This new approach is less vulnerable to false-positive discovery, since it investigates the association between the trait and all possible ancestral alleles across loci simultaneously, instead of using multiple tests each for one locus at a time as in previous approaches. Through simulation, we estimate the sensitivities and specificities of marker selection with our approach for a binary outcome with the true genetic locus imparting an odds ratio varying from 1.3 to 2.5 over a range of sample sizes from 500 to 2500. We show that, for a typical African American population (1000 subjects with an average of 80% African ancestry across the genome), our approach could identify the locus with an odds ratio 1.3 with sensitivity of 87% and specificity of 99%. Similar simulations are carried out for the continuous outcomes, although there is no direct comparison to ANCESTRYMAP for this approach. In summary, our approach provides increased flexibility for modeling in admixture analyses by allowing for continuous traits, and incorporation of covariates and higher order interactions.

714F

Multi-ethnic fine-mapping of cis expression-QTLs with fixed-effect meta-analysis. *C.P. Grace[1], J.C. Whittaker[2], J. Huxley Jones[2], A.P. Morris[1].* 1) Wellcome Trust Centre For Human Genetics, Oxford University, United Kingdom; 2) GlaxoSmithKline, Medicines Research Centre, Gunnels Wood Road, Stevenage, UK.

Genome-wide association studies (GWAS) have successfully identified novel loci contributing genetic effects to a range of complex human traits. However, localisation of the underlying causal genes and/or variants remains a challenge. One approach that may elucidate the functional basis of these findings is to integrate GWAS findings with gene expression data in relevant tissues. This is typically achieved through mapping of expression-QTLs (eQTLs) in publicly available data sets, and correlating these with signals of association from GWAS.

We have considered high-density genotyping data made available through the International HapMap Project for 270 samples across four populations: 30 CEPH trios from Utah with Northern European ancestry (CEU), 30 Yoruba trios from Nigeria (YRI), and 90 unrelated Chinese and Japanese individuals from Beijing and Tokyo (CHB/JPT). We have tested for association of up to 2.2 million SNPs with cis-expression of up to 18,000 transcripts (i.e. within 1Mb of transcription start site) in lymphoblastoid cell lines within each of these three broad ethnic groups. In the absence of heterogeneity in allelic effects on gene expression, we can increase power to detect eQTLs by combining results from the three ethnic groups through fixed-effects meta-analysis. Furthermore, differences in patterns of linkage disequilibrium between ethnic groups would be expected to improve the mapping resolution of causal variants within cis-eQTL signals.

Our trans-ethnic meta-analysis identified genome-wide significant ($p<1x10-12$) evidence of association for 4,368 cis-eQTLs. Of these, there was nominal evidence of heterogeneity (Cochran's Q-statistic $p<1x10-3$) at 513 cis-eQTLs, which is significantly higher than expected by chance (binomial test: expected: 4, 95% interval: 1 to 10). However, within many cis-eQTL signals with homogeneous effects across ethnic groups, there is a noticeable improvement in mapping resolution. For example through trans-ethnic meta-analysis, causal variants of the probe GI_21553312-S (CHURC1) (peak signal, $p = 3.85x10-304$ Cochran's Q p-value = 0.008) were localised to a 47kb interval, compared to 78kb in CEU alone.

Our results demonstrate the potential for trans-ethnic meta-analysis of cis-eQTL studies to improve mapping resolution, but also highlight the need for the development of novel methodology to take account of heterogeneity in allelic effects between distantly related populations.

715F

Independent genetic control of gene expression in whole blood and lymphoblastoid cell lines. *J.E. Powell[1], A.K. Henders[1], A.F. McRae[1], M.J. Wright[1], N.G. Martin[1], E.T. Dermitzakis[2], G.W. Montgomery[1], P.M. Visscher[1].* 1) Statistical Genetics, Queensland Institute of Medical Research, Brisbane, Qld, Australia; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva 1211, Switzerland.

The genetic control of gene expression has been well documented by a large number of studies, although, in the last few years, there has been much discussion as to the degree to which expression acts in a tissue specific manner. Given the aetiology of many complex diseases involve multiple tissues and cell types, understanding the extent of shared genetic control for gene expression between tissues is especially important. Most recent attempts to use data from multiple tissues have first mapped expression quantitative trait loci (eQTL) from individual tissues or cell types and then compared results among them, reporting the extent of eQTL overlap as an indicator of the level of common genetic control between tissues. Whilst these studies provide important information on the regulatory control of expression across tissues, their limited power means they can typically only detect eQTL with effects above a certain size, leading to studies usually only explaining a small proportion of genetic variation for gene expression. In a genetically informative design, narrow or broad sense heritability for gene expression can be estimated using the concept of identity by decent. These estimates of heritability refer to the combined effects of all causal variants that segregate in the population. Similarly, the genetic correlation between gene expression levels in different tissues can be estimated. These estimates quantify the combined effects of all causal variants on the genetic covariance. Here, we report results from a study using expression data from monozygotic twins to investigate the genetic control of gene expression in lymphoblastoid cell lines and peripheral blood mononuclear cells. We estimate the genetic correlation which is a measure of the level of common genetic control of gene expression between the two RNA sources. Our results show that, when averaged across the genome, mean levels of genetic correlation for gene expression in LCL and PBMC samples are close to zero. We support our results with evidence from gene expression in an independent sample of LCL, T-cells and Fibroblasts. In addition, we provide evidence that housekeeping genes, which maintain basic cellular functions, are more likely to have high genetic correlations between the RNA sources than non-housekeeping gene, implying a relationship between the transcript function and the degree to which a gene has tissue specific genetic regulatory control.

Association analysis of LRRC20 polymorphisms with aspirin exacerbated respiratory disease. *J. Kim[1], B. Park[2], C. Park[3], H. Shin[1,2].* 1) Sogang University, Seoul, Korea; 2) SNP Genetics, Inc., Seoul, Korea; 3) Soonchunhyang University Bucheon Hospital, Bucheon, Korea.

Aspirin exacerbated respiratory disease (AERD) is characterized by so-called aspirin triad consisting of aspirin hypersensitivity, bronchial asthma and chronic rhinosinusitis with nasal polyposis. The leucine-rich repeats containing domain has been known to be conserved in many proteins involved in the innate immunity. Recently, genetic polymorphism in leucine-rich repeat containing 20 (LRRC20) has been reported to be associated with increased interferon alpha in the serum. To investigate the association between LRRC20 polymorphisms and AERD, a total of 37 common single nucleotide polymorphisms (SNPs), with minor allele frequency (MAF) over 0.05, were genotyped in 166 AERD and 429 aspirin-tolerant asthma (ATA) subjects in a Korean population. Logistic analysis revealed that LRRC20 polymorphisms and haplotypes might be risk factors for the development of AERD ($P = 0.003-0.04$). In further addition of association with forced expiratory volume in one second (FEV1) decline by aspirin provocation, minor homozygote of rs4747011 showed about 2.5-fold increase in the FEV1 decline among asthmatics compared to other genetic modes ($P = 0.01$). Despite the needs for replications in large cohorts and further functional evaluations, our preliminary findings suggest that LRRC20 polymorphisms are potentially associated with aspirin hypersensitivity in asthma.

717F

Polymorphisms in genes participating in the oxidative stress pathway are associated with airway reactivity in patients with COPD. *N.M. Rafaels[1], I. Ruczinski[2], T. Murray[1,3], R.A. Mathias[1], L. Huang[1], V. Mantese[1], C. Vergara[1], L. Gao[1], A.E. Berger[1], J. Connett[4], P.D. Paré[5,6], D. Sin[5,6], A. Sandford[5,6], D. Daley[5,6], T.H. Beaty[3], K.C. Barnes[1], N.N. Hansel[7].* 1) Division of Allergy and Clinical Immunology, Johns Hopkins, Baltimore, MD; 2) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins, Baltimore, MD; 3) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins, Baltimore, MD; 4) Division of Biostatistics, School of Public Health, University of Minnesota, Minneapolis, MN; 5) Department of Medicine, St. Paul's Hospital, University of British Columbia, Vancouver, BC; 6) James Hogg Research Centre, Providence Heart and Lung Institute, University of British Columbia, Vancouver, BC; 7) Division of Pulmonary and Critical Care Medicine, Johns Hopkins, Baltimore, MD.

Rationale: Chronic obstructive pulmonary disease (COPD) is traditionally considered a disease of fixed airway obstruction and progressive loss of lung function contributing to significant morbidity and mortality worldwide. Airway reactivity (AR), a narrowing of stimulated air passages, in individuals with COPD from the Lung Health Study (LHS) has been associated with worse outcomes, including accelerated loss of lung function. **Methods:** We genotyped 559,660 SNPs using the Illumina Human660W-Quad v.1_A BeadChip in 4,251 European American patients with COPD from the LHS. The LHS was a randomized multicenter clinical trial designed to test the effectiveness of smoking cessation and bronchodilator administration in smokers with mild lung function impairment. AR was measured for 3,991 subjects at baseline and 3,510 subjects at year 5 of this longitudinal study and calculated as a quantitative measure, using the two-point slope then converted on the scale log10(0.681-AR). We ran a genome-wide association study (GWAS) on AR and subsequent pathway analysis using Ingenuity Systems Inc. on SNPs with a p<10-4. The most prominent pathway was the oxidative stress pathway. Here we tested the hypothesis that 340 single nucleotide polymorphisms (SNPs) in the 23 oxidative stress genes identified from the pathway analysis were associated with AR. SNP associations were tested under a linear regression model, adjusting for age, gender, height, weight, FEV1, FEV1/FVC, clinic site, and if the subject had quit smoking at year 5. The results were then combined using a correlated meta-analysis approach combining baseline and year 5 data. **Results:** Ten SNPs in the genes, *GSTM3* (rs1927328, rs1571858, and rs7483) *GSTM5* (rs929166), *ABCC4* (rs3765535, rs1729764, rs4148501, and rs1750996), and *MAP3K13* (rs12495216 and rs6803944), were associated with increased AR, after adjusting for Bonferroni correction (P = 0.00015). In addition, rs17111652 in *USP24* was significantly associated with decreased airway reactivity (P = 8.7E-8). There was a stronger association with AR at baseline for SNPs in *ABCC4* and *MAP3K13*, but stronger associations with AR at year 5 for SNPs in *GSTM3*, *GSTM5*, and *USP24*. **Conclusions:** Our findings suggest genes in the oxidative stress pathway may be a significant factor in regulating AR for patients with COPD. Analysis of imputed SNPs and additional populations is underway.

Examining the relationship between smoking history and genetic susceptibility on pancreatic cancer risk. *E.J. Childs[1], L. Wang[2], S. Chen[3], A. Blackford[2], G. Parmigiani[4,5], A.P. Klein[1,2,6].* 1) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA; 2) Oncology and Pathology, Johns Hopkins Medical Institute, Baltimore, MD, USA; 3) Department of Biostatistics, University of Medicine and Dentistry of New Jersey, Piscataway, NJ, USA; 4) Department of Biostatistics and Computational Biology, Dana-Farber Cancer Institute, Boston, MA, USA; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA; 6) The Sol Goldman Pancreatic Cancer Research Center, Johns Hopkins Medical Institute, Baltimore, MD, USA.

Pancreatic cancer is the 4th leading cause of cancer death. Its five-year survival rate of about 5% is the lowest of all major cancers. Prior segregation analysis suggests that pancreatic cancer is influenced by an autosomal dominant major gene inheritance. Well-established risk factors for pancreatic cancer include cigarette smoking and family history, with current cigarette smoking approximately doubling pancreatic cancer risk. While some studies have sought to examine the joint-effects of smoking and family history, these studies have jointly modeled both the effect of major gene inheritance and cigarette smoking. Using full pedigree data from the National Familial Pancreatic Tumor Registry, we formulated a semiparametric model incorporating autosomal dominant inheritance and estimated the independent and joint effects of major gene and cigarette smoking on the penetrance of pancreatic cancer using MCMC. Alternative models are compared using AIC and Bayes Factors. Full analysis will be presented. These data will provide the foundation for more detailed risk-assessment for high-risk pancreatic cancer families.

Influence of Genetic Variants on Response to Vitamin D Administration. *Z. Dastani[1], D. Goltzman[2], T. Wang[3], L. Fu[4], D.P Kiel[5], D. Cole[6], B. Richards[1, 7].* 1) McGill Univ, Department of Human genetics and Epidemiology and Biostatistics, Montreal, QC, Canada; 2) McGill Univ, Department of Medicine, Montreal, QC, Canada; 3) Cardiology Division, Massachusetts General Hospital, Boston, USA; 4) University of Toronto, Department of Laboratory Medicine & Pathobiology ON, Canada; 5) Institute for Aging Research Hebrew SeniorLife and Harvard Medical School, Boston, USA; 6) University of Toronto, Departrments of Laboratory Medicine & Pathobiology, Medicine, and Genetics, ON, Canada; 7) Department of Twin Research and Genetic Epidemiology, King's College London.

Introduction: Vitamin D deficiency, a common worldwide disorder, is associated with several chronic diseases including diabetes, cardiovascular disease, autoimmune disorders, and cancer. 25-hydroxyvitamin D (25OHD) levels are highly heritable and a recent meta-analysis of GWAS studies from the SUNLIGHT consortium identified three loci that strongly influence circulating vitamin D levels. However, whether these variants influence dose response to vitamin D levels is unknown; and this information could be clinically useful. We therefore sought to determine if variants decreasing 25OHD levels were associated with differences in response of 25OHD levels to vitamin D administration. Objective: In this study, we aimed to test whether the genome-wide significant SUNLIGHT SNPs (rs2282679, in the GC gene; rs12785878, near the DHCR7 gene and rs10741657, near the CYP2R1 gene) which influence 25OHD levels also influence the response of 25OHD levels to vitamin D administration in 2122 individuals from Canadian Multicentre Osteoporosis study. Methods: We first adjusted naturally log transformed 25OHD levels for age, sex, body-mass index, and season of blood draw. Then change in residualized 25OHD levels calculated in people taking 400 or more IU of vitamin D per day. The range of dose of vitamin D intake was between 400-5000IU Next, we assessed the additive effect of each 25OHD decreasing allele on baseline and dose response and created an overall genotypic risk score by summing the number of risk alleles weighted by their beta-coefficients from the SUNLIGHT meta-analysis. Results: Each SNP was significantly associated with 25OHD levels in 2084 individuals (rs2282679, pvalue=3.06e-05; rs12785878, pvalue=1.24e-06, and rs10741657, pvalue=1.08e-05). The overall weighted genotype risk score was also correlated with decreasing concentrations of 25OHD () =-0.99, pvalue= 1.35e-14). A higher genotypic risk score was associated with an increase in 25OHD response to vitamin D administration () =+1.70, pvalue= 0.007) in 149 individuals with available supplementary vitamin D intake. The association persisted after adjusting for dose of vitamin D intake. Conclusion: Individuals carrying risk alleles for lower 25OHD demonstrate an enhanced response to supplementary vitamin D intake. Therefore, identifying individuals at risk may provide clinical utility for the treatment of VitD deficiency. Currently we are confirming this finding in additional samples from European populations.

720F

Genome-wide linkage scan for QTL influencing quantitative ultrasound measures of bone strength in children from the Jirel ethnic group in eastern Nepal. *K.D. Williams[1, 2], J. Blangero[3], M.C. Mahaney[3], T.D. Dyer[3], J. Subedi[4], B. Jha[5], J.L. VandeBerg[3], S. Williams-Blangero[3], B. Towne[6].* 1) Department of Anthropology , Temple University, Philadelphia, PA; 2) Department of Pediatrics , Temple University, Philadelphia, PA; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) Department of Sociology and Gerentology, Miami University, Oxford, OH; 5) Tribhuvan University Institute of Medicine, Kathmandu, Nepal; 6) Department of Community Health, Boonshoft School of Medicine, Wright State University, Dayton, OH.

Most genetic studies of bone strength have been conducted in adults from Western countries using phenotypes obtained from dual-energy x-ray absorptiometry (DXA). Relatively few studies have been have been conducted in children, especially children from non-Western populations, and using phenotypic data obtained from other modalities. Here we present results from initial genome-wide linkage analyses of speed of sound (SOS) measures obtained from quantitative ultrasound (QUS) testing in healthy children from the Jirel ethnic group in Eastern Nepal who participate in the Jiri Growth Study. QUS SOS measures reflect properties of bone including cortical thickness, bone density, trabecular microstructure, and elasticity. In contrast to more commonly used calcaneal QUS measures that serve as proxies for skeletal bone strength and quality of the skeleton, this study presents results pertaining to properties of long bones. Specifically, axial QUS measures of load bearing and non-load bearing bones. In the total sample of 602 children (308 boys; 294 girls) aged 6 to 18 years, most belonging to one very large extended pedigree, the heritabilities of distal radius and midshaft tibia SOS measures were significant: SOS_{arm} h^2 = 0.33 ± 0.10, p<0.0001; SOS_{leg} h^2 = 0.36 ± 0.11, p<0.0001. Genome-wide linkage analyses were conducted in a subset of 247 children (126 boys; 121 girls) typed for ~400 STR markers spaced at an average density of 10 cM. Suggestive linkage of SOS_{arm} to markers on chromosome 10p was found (LOD = 2.03), and modestly suggestive linkage of SOS_{leg} to markers on chromosome 13q was indicated (LOD = 1.46). Because the genetic correlation between SOS_{arm} and SOS_{leg} was found in the total sample to be significantly greater than zero but significantly less than 1.0 (δ_g SOS_{arm};SOS_{leg} = 0.41 ± 0.21), bivariate linkage analysis of SOS_{arm} and SOS_{leg} was conducted. In this small initial sample of genotyped individuals, however, the joint linkage analysis of SOS_{arm} and SOS_{leg} did not yield notably different results than those observed in analyses of each trait separately. In sum, these preliminary results demonstrate significant heritabilities of QUS SOS axial bone measures in Jirel children, and the feasibility of localizing and eventually identifying in a larger study sample genes that influence these measures of bone strength.

Sliding-window based testing of rare variant associations. *A. Brisbin[1], K.A. Ellsworth[2], L. Wang[2], B.L. Fridley[1].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN.

Single-marker based tests are underpowered for detecting association between phenotypes and rare variants, leading to the development of methods for testing association of sets of rare variants. Previously, we introduced the Difference in Minor Allele Frequency (D-MAF) method, a method for analysis of rare variants which makes no assumptions about the direction of effects, and found that it outperforms most existing methods in simulations including protective variants. Here, because including markers with no effect can reduce power, we extend our method to a sliding-window approach, and examine the effect of window size on the power of several popular methods of rare variant analysis. In addition, we use the D-MAF to test for association between variants found by next-generation sequencing of the gene FKBP5 and response to the cytotoxic drug gemcitabine in a set of lymphoblastoid cell lines.

722F

Joint modelling of repeated measures and time-to-event data in genetic association analysis of type 1 diabetes. *Z. Chen[1], A.D. Paterson[2, 3], A.J. Canty[4], L. Sun[2, 5], S.B. Bull[1, 2].* 1) Samuel Lunenfeld Research Institute, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Department of Mathematics & Statistics, McMaster University, Hamilton, Ontario, Canada; 5) Department of Statistics, University of Toronto, Toronto, Ontario, Canada.

The longitudinal cohort design is attractive for genome-wide association studies (GWAS) of complex traits and diseases, as it enables investigation of environmental and genetic influences over time. In this design, it is typical to examine SNPs for association with multiple phenotypes of various types, e.g., repeated quantitative trait (QT) measures or time to a clinically-defined outcome. SNP associations with clinical phenotypes may be categorized as follows: (1) direct and independent of an intermediate QT, (2) indirect and induced by association with a QT, or (3) pleiotropic on both a QT and the clinical outcome. As an alternative to modelling each phenotype separately, we propose joint modelling of repeated QT measures and time to clinical outcome by an approach originally developed for HIV/AIDS clinical trials (Wulfsohn and Tsiatis, 1997), but novel to the GWAS setting. We apply it in a recent GWAS of the genetics of complications of type 1 diabetes (Paterson et al., 2010). To consider various scenarios for the relationship of a SNP with longitudinal repeated measures of HbA1c and time to diabetic retinopathy (TDR), we selected SNPs apparently associated with one or the other or both phenotypes. In each case, we compare estimates and hypothesis testing results from joint likelihood maximization to those from separate analyses, and within the joint model, we apply likelihood ratio tests (LRT) to help distinguish among direct and indirect SNP associations. For example, in separate analyses we first detected rs1358030 in the HbA1c GWAS () =0.05±0.01, p=6.7E-9), which was also associated with TDR () = 0.34±0.15, p=0.02). In joint analysis with strong global SNP association (p= 7.3E-8), rs1358030 retained association with HbA1c () =0.05±0.01, p=3.1E-8) but not with TDR () =-0.13±0.09, p=0.13). We interpret this as evidence of direct association for HbA1c and indirect for TDR. To reduce computational costs, we also applied a two-stage estimation method, in which a linear mixed model is fitted to the longitudinal HbA1c in the first stage, and in the second stage a Cox proportional hazards model is fitted to TDR with the predicted HbA1c treated as a time-dependent covariate, with similar conclusions but without a global LRT. Advantages of joint modelling include inference for joint SNP association with both phenotypes that can help to distinguish among alternative genetic architectures, and improved precision in estimation of QT association with time to event.

723F

A generalized pooled association statistic for analyzing rare variants. *A. Derkach[1], J.F. Lawless[2,3], L. Sun[1,2].* 1) Statistics, University of Toronto, Toronto, Ontario, Canada; 2) Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Statistics and Actuarial Science, University of Waterloo, Waterloo, Ontario, Canada.

There is a recent shift to analysis of rare variants due to the advances in sequencing technology and the realization that the common variants identified in many genome-wide association studies only explain a small proportion of the heritability estimated for complex human diseases and traits. Because of the limited statistical power available to detect an association between a trait and a single rare variant in studies of moderate size, the strategy of pooling variants into a composite test has been considered by several authors (e.g. Li and Leal, 2008; Madsen and Browning, 2009; Price et al., 2010). Instead of analyzing one variant at a time, the pooled approach considers multiple variants simultaneously, enriching a signal by aggregating information across variants within a gene or pathway. Most methods assume that all variants have the same direction of effect (e.g. all deleterious), but more recently, Neale et al. (2011) and Ionita-Laza et al. (2011) proposed alternative methods that directly model protective effect among the variants considered. Nevertheless, the pros and cons of each method are mostly argued in the context of ad-hoc simulation studies.

We show that previously proposed methods can be derived from the same statistical framework. More specifically, they can be constructed as a function of the same vector of statistics. One of the benefits of such a generalization is new statistics that take into account the possibility of both deleterious and protective variants. Another benefit of this generalization is it allows for theoretical calculations to facilitate the systematical evaluation of the validity and power of different methods. Lastly our generalization can handle categorical or quantitative traits, and can deal with phenotype-dependent sampling for either type of phenotype. We also compare performance of the proposed methods on the publicly available data from HapMap project. Particularly we are interested in the ability of the methods to detect population stratification with rare variants.

724F

Genetic associations of inflammatory diseases with the gene encoding septin 6. *M. Kong, Y. Kim, J. Ryu, C. Lee.* Soongsil University, Seoul, Korea.

Inflammation is a underlying protective mechanism in the body infected by foreign substances such as bacteria and viruses. Chronic inflammation, however, slowly arises when this response is not completely turned off or extinguished and can become a disease. In order to identify genes associated with a variety of inflammatory phenotypes, a genome-wide association study was conducted in a large scale cohort with 8,842 unrelated Korean individuals. Two intragenic single nucleotide polymorphisms (SNPs) of rs6603540 in Septin 6 (SEPT6, intron 1) and rs5949032 in acetylserotonin O-methyltransferase-like (ASMTL, intron 9) were associated with multiple inflammatory diseases such as degenerative arthritis, rheumatoid arthritis, and gout ($P < 0.001$). Associations of the SNPs with some inflammatory biomarkers including hematocrit were also observed ($P < 0.05$). Analysis with data partitioned by gender revealed male-specific associations of rs6603540 with rheumatoid arthritis and hyperlipidemia ($P < 0.05$). This might be attributed to a gender-specific transmission ratio distortion (TRD) considering a heterogeneity of its minor allele frequency by gender. Further analysis for their functional roles in alternative splicing showed that the rs6603540 might induce formation of cassette exon by altering splicing elements. This study suggested that SEPT6 might play a critical role in inflammatory responses by its cytokinetic function, an integral part of immune response.

725F

Combining SNP and HLA AIMs for Ancestry Analysis for an Immunogenetic Transplantation Outcome Association Study. *A. Madbouly[1], L. Gragert[1], M. Maiers[1], M. Malkki[2], E. Petersdorf[2].* 1) Bioinformatics Research, National Marrow Donor Program, Minneapolis, MN; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

The overall aim is to investigate the mechanisms through which at-risk non-HLA genetic markers e.g. immune response gene polymorphisms contribute to survival disparities in Hematopoietic Stem Cell Transplants (HSCTs). Several studies showed that survival after HSCTs depends on the patient's ethnicity, with a higher risk of post transplant mortality, relapse or graft-versus-host disease among minority patients. This led to the hypothesis that precise definition of the ancestry of transplant patients and donors will shed some light on post transplant survival disparities. In order to stratify by degree of shared ancestry a pilot study was performed to identify ancestry of transplant patients and donors genotyped for two types of ancestry informative markers (AIMs): HLA and SNPs. The cohort included 491 individuals (76 African-American (AFA), 48 Asian/Pacific Islanders (API), 243 Caucasian (CAU), 104 Hispanic (HIS) and 20 Native American (NAM)) genotyped for HLA-A, -B, -C, -DRB1 and -DQB1 and 30 autosomal SNPs from a published (Kosoy 2009) reference AIMs panel. 23 of the chosen SNPs had >40% allele frequency difference between AFA and CAU, 23 >40% difference between AFA and API, and 9 >40% difference between CAU and API. Out of the last 9 SNPs, only one had a difference >40% between CAU and South Asian (SAS) and three between East Asian (EAS) and SAS. Assignment of admixture proportions was determined using STRUCTURE v2.3.2. Preliminary results indicated high accuracy in recapturing ancestry of self-identified AFA, EAS and CAU individuals, however distinguishing SAS from CAU individuals proved challenging due to sample size disparities and the lack of sufficiently differentiating SNPs. When the pilot cohort was augmented with EAS and SAS individuals from the published reference cohort (Kosoy 2009) to balance sample proportions, SAS individuals emerged as a separate cluster distinct from EAS and CAU. We additionally used Bayesian inference to assign racial categories to the pilot cohort using HLA AIMs. The algorithm used reference haplotype frequencies and knowledge of population sizes within the Be The Match® Registry as priors to calculate the overall likelihood of a race assignment. Classifying race using HLA frequencies gave >80% recovery of self-identified race for AFA and API, with lower recovery for CAU, HIS, and NAM. We plan on using the results from the HLA ancestry classifier as a tie-breaker supplementing ancestry classification using SNP AIMs.

726F

A model that combines array and sequence data to improve genotype accuracy. *J. O'Connell[1], J. Marchini[2].* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom.

Data sets containing large cohorts of individuals who have been genotyped on microarrays as well as sequenced at low coverage are now becoming available. Genotypes are typically called from arrays independently of sequence data (and vice versa). Whilst the genotype calls coming from modern arrays are of high quality, accuracy and call rate can still be improved by incorporating sequence data into calls. This is particularly true for low frequency variants where very few observations are available to identify clusters for the rare genotypes. Higher quality genotype calls and better call rates will reduce time spent on quality control and decrease Type I and II error in genome wide association studies. To combine sequence and array data effectively, a model must be able to identify when one data source is spurious and discard this information, relying on the alternate source. We present a Bayesian mixture model for genotype calling from array allele signal intensities, with parameter estimation and calls augmented by genotype likelihoods from sequence data. The method successfully identifies and discards spurious data and is capable of handling individuals with missing values, for example, a subset of individuals may have only been assayed on an array and not sequenced. This results in genotype calls with greater accuracy and a higher call rate than standard array-only or sequence-only methods. The implementation requires similar computational time to standard software for array-only based genotyping, providing higher quality genotype calls for minimal extra time and effort. We demonstrate these capabilities on 1000 Genomes individuals which have been genotyped on the Illumina HumanOmni2.5S chip as well as sequenced at approximately 4X coverage.

727F

Making the most of case-sibling studies. *M. Shi, D.M. Umbach, C.R. Weinberg.* Biostatistics Br, NIEHS, Res Triangle Park, NC.

In genetic association studies, properly analyzed family-based designs are robust against bias from population stratification. The case-parents design is one of the most convenient such approaches. Parents, however, are not always available, especially for diseases with onset later in life. For those diseases, the case-sibling design, where cases and one or more unaffected siblings are studied, can be very useful. This design requires the analyst to account for dependencies, for example using conditional logistic regression (CLR). We here consider an alternative analysis, which treats the case-sibling design as a nuclear family study, but with all parents missing. Under the weak assumption of Mendelian inheritance in the source population, one can carry out maximum likelihood analysis by using the expectation maximization (EM) algorithm to account for missing parental genotypes. An additional issue for this design is that many cases may not have a sibling available. The EM-based approach can also incorporate singleton cases, while a traditional logistic regression analysis would discard them. We use simulations to compare performance of CLR and nuclear family analytical approaches for studies where cases have one or two unaffected siblings. We also assess power gained by incorporating singleton cases, under several risk scenarios.

728F

The role of thromboxane A2 receptor gene polymorphisms in lung function and severity in childhood-onset asthma. *K. Takeuchi[1], Y. Mashimo[1], S. Hattori[1], N. Shimojo[2], M. Tomita[2], T. Arima[2], Y. Morita[2], K. Sato[3], S. Suzuki[3], T. Nishimuta[3], H. Watanabe[3], A. Hoshioka[4], A. Yamaide[4], M. Watanabe[5], Y. Kohno[2], A. Hata[1], Y. Suzuki[1].* 1) Department of Public Health, Chiba University Graduate School of Medicine, Chiba, Japan; 2) Department of Pediatrics, Chiba University Graduate School of Medicine, Chiba, Japan; 3) Shimoshizu National Hospital, Yotsukaido, Japan; 4) Chiba Children's Hospital, Chiba, Japan; 5) Department of Pediatrics, Toho University School of Medicine, Tokyo, Japan.

We have been studying association of matrix metalloproteinase (*MMP*) genes in the *MMP* cluster region in chromosome 11 with adult and/or childhood asthma. We were also interested in whether genetic variations have impact on pulmonary function and severity in asthma patients. We thereby investigated association of SNPs of the *MMP*s and several asthma-related genes with pulmonary function and severity in childhood-onset asthma patients. We found that one *MMP13* SNP showed a significant association with severity in childhood-onset asthma. Among asthma-related genes investigated, a SNP of thromboxane A2 receptor (*TBXA2R*) gene (c.795T/C) showed association with both pulmonary function and severity in childhood-onset asthma. Thromboxane A2 is known to be involved in platelet aggregation and constrictor of vascular and respiratory smooth muscle, therefore, the *TBXA2R* gene is a good candidate for bronchial hyperresponsiveness and airway inflammation. Because the 795T/C polymorphism is synonymous and unlikely to influence the function of the receptor, other polymorphisms being in strong linkage disequilibrium (LD) with this SNP may affect the efficiency of transcription or translation. We comprehensively surveyed SNPs of this gene including the 5' upstream and 3' downstream regions, and found that four SNPs in the intron between exon 1 and exon 1b of the gene were in LD to 795T/C. We next performed luciferase reporter assay to evaluate the effect of these SNPs on gene expression. We transfected vector constructs containing 6 different haplotypes consisting of the 4 SNPs into HEK293 cells. After 24 hours of transfection, luciferase activities were measured using Dual-Luciferase Reporter Assay System. Three haplotypes (H1, H2, H6) showed higher transcriptional activity than the rest of the haplotypes (H3, H4, H5). No single SNP was precisely associated with the activity. These results suggest that the haplotype variation of this region affects *TBXA2R* gene expression and may affect pulmonary function and severity in asthma patients.

729F

Extensions of Bootstrap Bias-Reduction to Address the Winner's Curse in Genome-wide Association Analysis of Time-to-Event Phenotypes. *J. Taleban[1], L.L Faye[1,2], A. Dimitromanolakis[1], A.D. Paterson[2,3], L. Sun[2,4], S.B. Bull[1,2].* 1) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON; 2) Dalla lana School of Public Health, University of Toronto, Toronto, ON; 3) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON; 4) Department of Statistics, University of Toronto, Toronto, ON.

Adjustment of effect estimates for winner's curse inflation is critical for interpretation and replication of findings in the context of high-dimensional multiple testing, including genome-wide association studies and whole-genome sequencing. The effectiveness of a general non-parametric bootstrap bias-reduction method developed for association analysis and implemented in software (Faye et al. 2011, Sun et al. 2011) has been well demonstrated for disease status and quantitative traits in the GWAS setting. The method can adjust for both threshold and ranking selection effects arising from use of stringent genome-wide significance criteria and maximization of the association statistics over the genome, respectively. Motivated by genetic association analysis of complications in type 1 diabetes (Al-Kateb et al. 2008, Paterson et al. 2010), we extend use of the method to longitudinal study designs in which the phenotype of interest is time to observation of an event, as time to event data tend to have more power than other longitudinal measures. In this case, the phenotype is the time from baseline to clinical diagnosis of severe nephropathy in 1362 white participants of the Diabetes Control and Complications Trial (DCCT), the effect size parameter is the natural log of the hazard ratio (logHR), and the test statistic for association is the Wald statistic under additivity. In application to genetic association analysis of 1228 SNPs in 212 candidate genes with minor allele frequency (MAF) greater than 5 percent, using the freely available software BR-squared (Bias-Reduced estimates by Bootstrap Resampling), we observed 41.8-79.9 percent reduction of the logHR for 15 SNPs with nominal 1 percent significance. For the previously reported top SNP, rs17880135 in SOD1 (MAF=5.6 percent, p=8.2 x10-4, 95 percent logHR CI: 0.28-1.09), reduction in the logHR was 73.0 percent (from 0.69 to 0.19). With only 115 events observed, validity of the bootstrap in sparse data is a concern and warrants continued investigation. Using selected candidate gene SNPs, we further consider how the approach can be applied to a simple gene-based allele count for low MAF SNPs, similar to that current in sequencing applications. In principle the approach is applicable in high density genome-wide studies. The extension to survival-type models demonstrates potential for extensions to other phenotypes and to methods adapted for low frequency variants.

730F

Discovery and replication of gene-gene interactions in multiple independent Alzheimer's Disease Genetics Consortium datasets. *T.A. Thornton-Wells[1], K.D. Brown-Gentry[1], E.S. Torstenson[1], S.M. Dudek[1], L. Jiang[1], M.D. Ritchie[1], E.R. Martin[2], M.A. Pericak-Vance[2], J.L. Haines[2], Alzheimer's Disease Genetics Consortium.* 1) Center for Human Genetics Research, School of Medicine, Vanderbilt University, Nashville, TN; 2) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL.

Background. Alzheimer disease (AD) has a complex genetic etiology, involving heterogeneity and gene-gene interactions. Recent GWAS in AD have led to the discovery of novel genetic risk factors; however, the investigation of gene-gene interactions in GWAS has been limited. **Methods.** We conducted a gene-gene interaction analysis in one discovery dataset from University of Miami, Vanderbilt University and Mt. Sinai School of Medicine (UM/VU/MSSM) and two replication datasets: (a) the Translational Genomics Research Institute series 2 (TGEN2), and (b) the Alzheimer Disease Neuroimaging Initiative (ADNI). All cohorts were genotyped using Illumina or Affymetrix SNP microarrays, and each dataset was imputed using MaCH with HapMap Phase 2 CEU samples. We used a biological knowledge-driven approach (Biofilter) to select SNP-SNP models with a priori evidence that their genes interact or participate in common biological pathways or processes. (SNPs within 50kb of APOE were excluded.) We analyzed each SNP-SNP model using the multifactor dimensionality reduction (MDR) method and selected models with a testing balanced accuracy (testBA) ⁄ 55%. We then used a gene-centric approach for model replication. For each replication dataset, we ran MDR on all SNP-SNP models comprising genes from the selected discovery dataset models, and we selected all models with a testBA⁄ 55% in at least 2 of 3 datasets. **Results.** Six gene-gene models discovered in the UM/VU/MSSM dataset were replicated in both the TGEN2 and ADNI datasets, each with an average testBA⁄ 58% and a maximum testBA (for the best SNP-SNP model in a single dataset) of up to 72%. Seven gene-gene models replicated in only one dataset with average testBA⁄ 60% and a maximum testBA of up to 79%. ABCC9 appeared in 2 models that replicated in both datasets--one with ABCB1 (a major component of the blood-brain barrier that purportedly plays a role in A) clearance) and one with TF (which has been associated with iron overload and oxidative stress in AD). SMAD3 (which is bound by pTau in AD brain) appeared in 2 models, one of which replicated in both datasets. **Conclusions.** Using a biological knowledge-driven approach, we were able to identify SNP-SNP models of interest that replicated at the gene level across multiple datasets. Logistic regression analyses are ongoing to further characterize the models, and permutation testing will be used to obtain an unbiased estimate of significance.

731F

An evaluation of the informativeness of population genetics when making genotype calls in exome-captured next generation sequencing data. *S. Vattathil[1,2], F.A. San Lucas[1,2], Y. Fan[3], W. Yang[3], W. Wang[1], S.P. Hunger[4], M. Loh[5], M. Devidas[6], C-H. Pui[3], E. Mardis[7], M.V. Relling[3], P. Scheet[1,2].* 1) Epidemiology, University of Texas MD Anderson Cancer Center, Houston, TX; 2) The University of Texas Graduate School of Biomedical Sciences, Houston, TX; 3) St. Jude Children's Research Hospital, Memphis, TN; 4) The Children's Hospital and the University of Colorado Cancer Center, Aurora, CO; 5) Pediatrics, University of California, San Francisco, San Francisco, CA; 6) Biostatistics, University of Florida, Gainesville, FL; 7) The Genome Institute at Washington University, St. Louis, MO.

Most algorithms for making SNP and genotype calls from next-generation sequencing data do not rely solely on read counts, but incorporate additional sources of information to increase the accuracy of the calls. The use of population genetic data, such as population allele frequencies or patterns of linkage disequilibrium, helps when data quality is poor, or reads sparse. Accounting for technological artifacts, such as with sequencing error rates and base-specific quality scores, is important due to the relatively high error rates for current sequencing methods. These additional parameters may be defined in various ways. For example, allele frequencies may be calculated directly from the read data, estimated jointly with the genotypes, or measured in a larger reference population that may be somewhat genetically distinct. Technological error rates may be assumed a priori or estimated from the data. We tested several methods for defining the population and sequencing fidelity parameters within a simple calling algorithm based on allelic counts, and compared the genotype accuracies produced in each case. Our sample consisted of constitutional DNA collected from 27 individuals, with exome capture using the Nimblegen SeqCap EZ Exome v2.0 array and sequencing conducted via an Illumina HiSeq. We compared the sequence-based calls to genotypes inferred from an Affymetrix SNP 6.0 microarray experiment, and, because coverage was high (98% of sites in the target region were covered at 20x), we also assessed accuracy using the sequence data alone by “downsampling” the reads and comparing genotypes estimated from the full and reduced datasets. This allowed us to measure false-positive and false-negative rates for variant detection across multiple ranges of read depth and allele frequency.

Further replication of the TRAF1/C5 genetic association with radiological damage in patients with rheumatoid arthritis. *S. Viatte[1, 4], D. Plant[1, 4], M. Lunt[1], B. Fu[1], B. Parker[1], J. Galloway[1], C. Solymossy[2], J. Worthington[1], D. Symmons[1], J. Dixey[3], A. Young[2], A. Barton[1].* 1) Arthritis Research UK Epidemiology Unit, Manchester Academic Health Science Centre, The University of Manchester, Manchester, United Kingdom; 2) Rheumatology Department, St Albans City Hospital, St Albans, United Kingdom; 3) Department of Rheumatology, New Cross Hospital, Wolverhampton, United Kingdom; 4) Equal contribution.

Background: A rheumatoid arthritis (RA) susceptibility region between the TNF receptor-associated factor-1 and complement component 5 genes (TRAF1/C5) has previously been reported to associate with radiological damage in two studies. We aimed to investigate RA genetic susceptibility markers, including variants at the TRAF1/C5 locus, as determinants of disease severity in an independent inception cohort of UK RA patients and to combine this with a previous study in a UK population. Methods: Sixty-seven RA susceptibility variants, were genotyped in 474 patients from the Early Rheumatoid Arthritis Study (ERAS) using Sequenom MassArray technology. Correlation between genetic markers and Larsen score was assessed at baseline, year 3 and year 5 follow-up. Data were combined with previously published data from the Norfolk Arthritis Register (NOAR) and analysed using longitudinal statistical models to include repeat measurements in the same individual at different time points. All analyses were adjusted for symptom duration at baseline. Results: A correlation was observed between rs2900180 at the TRAF1/C5 locus and Larsen score at year 3 (coef. 4.27 95%CI 0.49, 8.04, p=0.03) and in the longitudinal regression analysis (coef. 3.80 95%CI 0.81, 6.79, p=0.01) in ERAS. Combined longitudinal analysis of NOAR and ERAS samples increased the statistical evidence for association at the locus (coef. 2.15 95%CI 0.80, 3.49, p=0.002). Conclusions: The genetic marker rs2900180 is associated with extent of erosions, as measured by the Larsen score in the ERAS cohort. This represents the third independent study correlating genotype at the TRAF1/C5 locus with radiologic severity in RA.

733F

Association of *matrix metalloproteinase-7* and *-12* genes polymorphisms with asthma: A case-control study of *MMP-7* and *-12* in a Japanese population. *F. Yamaide[1,2], Y. Mashimo[1], N. Shimojo[2], T. Arima[2], Y. Morita[2], T. Hirota[3], S. Doi[4], K. Sato[5], S. Suzuki[5], T. Nishimuta[5], H. Watanabe[5], A. Hoshioka[6], M. Tomiita[6], A. Yamaide[6], M. Watanabe[7], Y. Suzuki[1].* 1) Department of Public Health, Graduate School of Medicine, Chiba University, 1-8-1 Inohana, Chuo-ku, Chiba, Japan; 2) Department of Pediatrics, Graduate School of Medicine, Chiba University, 1-8-1 Inohana, Chuo-ku, Chiba, Japan; 3) Laboratory for Respiratory Diseases, Center for Genomic Medicine, RIKEN, 1-7-22 Suehiro-cho, Tsurumi-ku, Yokohama, Kanagawa, Japan; 4) Osaka Prefectural Medical Center for Respiratory and Allergic Diseases, 3-7-1 Habikino-shi, Habikino, Osaka, Japan; 5) Department of Pediatrics, National Shimoshizu Hospital, 934-5 Sikawatashi, Yotsukaido-shi, Chiba 284-0003, Japan; 6) Department of Allergy and Rheumatology, Chiba Children's Hospital, 579-1 Heta-cho, Midori-ku, Chiba, Japan; 7) The First Department of Pediatrics, Toho University Omori Medical Center, 6-11-1 Omorinishi, Ota-ku, Tokyo, Japan; 8) Department of Otorhinolaryngology and Head and Neck Surgery, Graduate School of Medicine, Chiba University, 1-8-1 Inohana, Chuo-ku, Chiba, Japan.

[Background] Genetic variants influencing lung function or immune system may be involved in the development of asthma and/or its symptoms. Matrix metalloproteinases (MMPs), a family of secreted or membrane-bound endopeptidases, contribute to both normal and pathological tissue remodeling and also act as regulatory molecules by processing cytokines or adhesion molecules. In animal models, growing evidences suggest that MMPs play important roles in asthma phenotypes. Some *MMP* genes (e.g. *MMP9*) have recently been shown to be associated with asthma in Caucasian populations. [Objectives] We investigated whether single nucleotide polymorphisms (SNPs) in *MMP7* and *MMP12* could affect the susceptibility to and clinical phenotypes of asthma in the Japanese population. [Method] We conducted a case-control study between SNPs in *MMP7* and *MMP12* genes and asthma-related phenotypes using childhood and adult Japanese populations (653 childhood asthma patients and 423 controls, and 428 adult asthma patients and 646 controls, respectively). To investigate the effects of amino acid substitutions by SNPs on MMPs' enzymatic activity, MMP activity assays were performed using commercially available kits based on fluorescence resonance energy transfer (FRET) peptide. We also evaluated the effect of 3'UTR SNP in *MMP7* on its mRNA stability and the effect of SNP in *MMP12* on its antimicrobial activity. [Result] We found that, in the Japanese population, SNPs of *MMP7* (rs10502001, G/A, Arg77His; rs14983, C/T, 3'UTR) (P = 0.006; odds ratio (OR), 1.46; 95 % confidential interval (CI), 1.126 - 1.903) and *MMP12* (rs652438, A/G, Asn357Ser) (P = 0.015; OR, 1.60; 95 % CI, 1.002 - 2.556) showed significant association with adult and childhood asthma, respectively. We also found that the SNP (rs652438) in *MMP12* was associated with severity in adult asthma (P = 0.010). Using supernatant from cultured HEK293 cells stably transfected with the pcDNA3.1(+)-MMP7 or MMP12 as MMP proteins, we evaluated activation kinetics, rate of proteolytic cleavage of FRET peptide, Michaelis constant, and substrate specificity of the enzyme. In this system, we couldn't detect the functional effects of amino acid substitutions by SNPs on the enzymatic activity. [Conclusion] Our association study suggested that genetic variants of *MMP7* and *MMP12* conferred risk for development of asthma in the Japanese population. We are now investigating the effect of the SNPs on mRNA stability and antimicrobial activity.

RVTests: Rare-variant test package. *X. Zhan[1,2], Y. Hu[1,2], G. Abecasis[1,2].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Center of Statistical Genetics, University of Michigan, Ann Arbor, MI.

Next-Generation Sequencing(NGS) technology brings scientific community unprecedented amount of data. Existing tools are not maturely developed to conveniently handle sequencing data and are inefficient in helping researcher study the association between rare variant and phenotypes. With these considerations in mind, we developed RvTests, an open sourced C++ statistical package, that focuses on speed, accuracy and flexibility in manipulate large sequencing data set and provides interfaces for statisticians to develop their own statistical methods. We have integrated well-known statistical procedures, including exact test, Li's CMC method, Madsen-Browning's weighted method and et al, in the logistic regression framework. We also ease the procedure of exporting sequencing data for mature GWAS analysis tools, including PLINK, Merlin, and VCF. We will describe typical work flows that can be simplified by our package and will illustrate several of the features currently under active development.

Combining Association Tests for Rare Variant Analysis. *H. Zhou, K. Hao, C. Molony.* Merck Research Laboratories, Boston, MA.

The fast advancement of the next-generation sequencing technology has enabled us to identify rare variants with large genetic effects, which otherwise could hardly be captured by previous genome-wide association studies. Due to the low frequency of rare variants, statistical methods used for common variant analysis might not have optimal performance in the next-generation sequencing studies. Several alternative strategies, such as collapsing approach (TC), weighted-sum method (TW), and variable-threshold approach (TV), have been proposed to jointly analyze a group of variants within a gene and test for associations. However, these methods may not be robust when non-causal variants are included or when both protective and risk variants are pooled in the analysis. Extending our previous method developed for multiple common variant analysis, we present a testing approach that combines single rare variant association test p values. This combination is based on the summation of single test p values, giving greater weight to those with smaller p values. The performance of the combining approach was evaluated using realistic sequence-level data generated by FREGENE. Two scenarios were modeled: one panmictic population and one population incorporating bottlenecks, periods of growth and subdivision. For each population, one neutral model and one complex selection model were simulated. We compared the combining method to alternative tests (TC, TW, and TV) in identifying susceptibility genes under these scenarios. It is shown that the combining method is preferred and robust against the existence of non-causal variants or causal variants with opposite effects. This study demonstrates that the proposed method can be an optimal test for rare variant analysis.

736F

Critical comparison of deep resequencing analysis methods in a population sample of over 3000 subjects. *L. Li[1], L. Warren[1], J. Shen[1], V.E. Mooser[2], D.M. Waterworth[2], J.C. Whittaker[3], M.R. Nelson[1].* 1) Statsitical Genetics, GlaxoSmithKline, Res Triangle Park, NC, USA; 2) GlaxoSmithKline, Upper Merion, PA, USA; 3) GlaxoSmithKline, Stevenage, UK.

Rare variants are widely believed to contribute to phenotypic variation independently from or in conjunction with common variants. However, the methods used for analysis of common variants lack the power to detect associations due to rare variants even in very large samples. The rapid development and adoption of next-generation sequencing technologies has spurred corresponding innovation in statistical methodology. More than 20 analysis methods have been proposed, most aimed at assessing the collective effect of multiple rare variants within genes or other genomic regions of interest. Within such a large pool of analysis options, there is no method that is universally most powerful, so how do we choose which methods to apply? How do we interpret conflicting association results from different methods? Although answers to these questions can be addressed in part through simulation, rigid assumptions strongly influence the results and limit our ability to draw general conclusions. Here we present insights gained from analysis of 202 drug target genes resequenced in over 3000 European and Indian Asian population samples from the CoLaus and LOLIPOP studies, extensively phenotyped for cardiovascular and metabolic-related continuous and binary traits. We analyzed 42 traits, including several previously known or suspected associations, with a broad range of newly developed methods and predictions of functionality from PolyPhen and SIFT. We found many examples of widely concordant and discordant inferences among the methods and have investigated their underlying differences. We will compare analysis results from the different methods, share our reflections on their relative strengths and weaknesses and discuss the challenges and opportunities in working with such deep resequence data.

Keloid susceptibility loci 1q41, 3q22.3, and 15q21.3 replicated in a Nigerian population. *S. Hooker Jr[1], P.B. Olaitan[2], O.M. Oluwatosin[3], S.A. Fadiora[2], S. Ademola[3], V. Odesina[4], S.M. Leal[1], E.J. Reichenberger[5].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Surgery, Ladoke Akintola University of Technology Teaching Hospital, Osogbo, Osun State, Nigeria; 3) Department of Surgery, University of Ibadan, Ibadan, Oyo State, Nigeria; 4) HIV Adherence Program, University of Connecticut Health Center, Farmington, CT; 5) Department of Reconstructive Sciences, University of Connecticut Health Center, Farmington, CT.

Keloids are overgrown scars that stem from abnormal wound healing, usually as a result of injury. Keloids have a higher incidence in darker-skinned individuals with the greatest prevalence being found in individuals of African ancestry. Although keloids were first described centuries ago their pathogenesis is poorly understood. To better understand the genetic etiology of keloids, recently a genome-wide association (GWA) study was performed using a Japanese population (Nakashima et al., Nat Genet 2010). This study identified four variants on chromosomes 1q41, 3q22.3 and 15q21.3 which were associated at GWA significance level p-values. Two of the significant SNPs in the 3q22.3 region are not in linkage disequilibrium and therefore represent two separate regions. Only one of the SNPs lies within a known gene, NEDD4 on chromosome 15. We genotyped 96 tagSNPs within these regions in 286 cases and 267 controls, all of whom are Yorubans that were ascertained in Nigeria. Analysis was performed within a logistic regression framework using an additive allelic effect model controlling for both age and sex. Within these regions multiple SNPS were found to be associated with Keloids, the most significant findings for each region were with markers rs753961 (chr1: 220.3 Mb) OR = 0.58 ($p = 3.45 \times 10^{-3}$); rs13064974 (chr3:140.1Mb) OR = 1.32 ($p = 2.6 \times 10^{-2}$) ; rs940187 (chr3:140.3Mb) OR = 1.33 ($p = 2.7 \times 10^{-2}$) ; and rs8031043 (chr15: 53.9 Mb) OR = 0.68 ($p = 2.82 \times 10^{-3}$). For the two polymorphic SNPs which were genotyped in both studies, rs873549 (1q41) and rs940187 (3q22.3), the minor alleles increased the risk of keloid development in both studies. This is the first study to characterize the genetic susceptibility of keloids in a sub-Saharan African population.

738F

Genotype at the NOS3 G894T SNP is not associated with acute mountain sickness upon ascent to 4380 m or during brief exposure to an equivalent normobaric hypoxia. *M.J. MacInnis[1, 2], E.A. Carter[1], M.S. Koehle[1, 2], J.L. Rupert[1].* 1) School of Kinesiology, University of British Columbia, Vancouver, British Columbia, Canada; 2) Division of Sports Medicine, University of British Columbia, Vancouver, British Columbia, Canada.

Introduction: Acute mountain sickness (AMS) develops upon exposure to altitude and normobaric hypoxia (simulated altitude), and evidence suggests that susceptibility to AMS is partially genetic. The endothelial nitric oxide synthase gene, *NOS3*, was previously associated with AMS; however, the association has not been replicated, and its physiological basis is unclear.

Methods: Subjects were recruited for two separate experiments. Nepalese subjects (n=77) were recruited and assessed at the 2010 Janai Purnima festival, Gosainkunda, Nepal (4380m), and Caucasian subjects (n=19) were recruited and assessed during a 6-hour exposure in a normobaric hypoxia chamber (12% O_2; ~4400m). The Lake Louise Score (LLS) was used to diagnose AMS (AMS+/AMS-) and to quantify AMS severity, and PCR-RFLP was used to determine genotype at the *NOS3* G894T SNP. Heart rate (HR) and oxygen saturation (SpO_2) were measured in both conditions, and exhaled NO was measured in the normobaric hypoxia chamber using a NObreath analyzer (Bedfont Scientific, UK).

Results Variants of the NOS3 G894T SNP were not associated with susceptibility to AMS during exposure to altitude (p=0.84) or normobaric hypoxia (p=0.053). There was also no difference in genotype frequencies when the two populations were combined (p=0.34). Genotype was not associated with LLS, SpO_2, or HR during exposure to altitude (p>0.05) or normobaric hypoxia (p>0.05). Exhaled NO during normobaric hypoxic exposure was unrelated to the G894T genotype (p>0.05).

Discussion: The *NOS3* G894T SNP was previously associated with AMS in a Nepalese cohort, but we did not replicate this association in a separate Nepalese cohort at altitude or in a Caucasian cohort exposed to simulated altitude. The relatively small sample sizes resulted in too little power to detect the expected small-moderate effect; however, the overall distribution of genotypes was consistent with a protective role for the G allele, and the Caucasian cohort was near statistical significance. The discordance between the two Nepalese cohorts might be due to stratification resulting in unexpected heterogeneity, and we are currently using AIMs to investigate this possibility. The physiological basis of the previous association remains unclear.

739F

The Functional MICA-129 Polymorphism is Associated with Psoriatic Disease Independently of HLA-B and C. *R.A. Pollock[1], V. Chandran[1], J. Barrett[2], L. Eder[1], F. Pellett[1], C. Yao[1], M. Lino[1], S. Shanmugarajah[1], V.T. Farewell[2], D.D. Gladman[1].* 1) Psoriatic Arthritis Program, Toronto Western Research Institute, Toronto, Ontario, Canada; 2) MRC Biostatistics Unit, University of Cambridge Institute of Public Health, Cambridge, UK.

Objective: The major histocompatibility complex class I chain-related gene A (MICA) is located 47kb centromeric to HLA-B. MICA alleles can be classified into high and low-affinity binders of the natural killer/T-cell receptor NKG2D, based on a functional polymorphism at amino acid 129 (A/G>Met/Val). Our aim was to determine whether the high affinity MICA-129 Met allele is increased in psoriatic arthritis (PsA) patients compared to patients with psoriasis without arthritis and controls. Methods: 248 unrelated Caucasian PsA patients, 250 psoriasis subjects without arthritis, and 249 healthy controls were allelic typed for MICA using PCR-SSP and for HLA-B and C by PCR-SSO reverse line blot. All PsA patients satisfied CASPAR criteria and psoriasis subjects were examined by a rheumatologist to exclude PsA. MICA-129 Met/Val genotypes were assigned from allelic typing using DNA sequences available from the IMGT/HLA database (release 3.1.0). Univariate logistic regressions and chi squared tests were performed to determine the effect of MICA-129 genotype on group membership. Multivariate logistic regressions were also performed using the Val/Val genotype as the reference category, to adjust for the presence of risk alleles HLA-B*13, B*27, B*38, B*57, C*01, C*02, C*06, and C*12. Results: Univariate analyses showed that the presence of a Met allele significantly increased the risk of developing psoriatic disease (OR=1.6, p=1.5x10-3), psoriasis without arthritis (OR=1.7, p=5.3x10-3), and PsA (OR=1.6, p=7.7x10-3). Multivariate analyses showed that after adjustment for significant HLA-B and C alleles, homozygosity for the Met allele (genotype Met/Met) significantly increased risk of psoriatic disease (OR= 3.8, p= 1.0x10-4), psoriasis without arthritis (OR = 2.8, p= 6.1x10-3), and PsA (OR = 2.4, p= 2.7x10-2). Heterozygosity (Met/Val) did not affect risk. There were no significant differences in MICA genotypes between patients with PsA and psoriasis without arthritis. Conclusions: Individuals with a high-affinity Met residue at MICA-129, particularly those who are homozygous for the Met allele (Met/Met), have an increased risk of developing psoriatic disease, psoriasis without arthritis, and PsA independently of the presence of HLA-B and C risk alleles. This study is currently being validated in independent cohorts of patients and new results will be presented.

Polygenic and SNP-specific Genotype x Age Interaction Effects on Telomere Length. *J.W. Kent[1], S. Kumar[1], M. Carless[1], T.D. Dyer[1], V.P. Diego[1], J. Charlesworth[2], M.P. Johnson[1], A.G. Comuzzie[1], M.C. Mahaney[1], L. Almasy[1], J.E. Curran[1], E.K. Moses[1], H.H.H. Goring[1], J. Blangero[1], S. Williams-Blangero[1].* 1) Dept Gen, Tx Biomed Res Inst, San Antonio, TX; 2) Menzies Tasmania Res Inst, Hobart, TAS, Australia.

Genotype x environment interaction may contribute to differential risk of age-related physiological decline and progression of diseases of senescence. Telomeres are terminal chromosomal structures consisting of a repeated DNA sequence and its associated proteins; age-related reduction in telomere length is associated with genomic instability and cell senescence/death. We have previously reported GWA and linkage analysis of telomere repeat/single-copy sequence ratio (TSR), an efficient measure of telomere length, in peripheral blood mononuclear cells in 1,232 Mexican Americans in ~40 extended families. Here we compare these results to those for TSR measures in 1,089 Nepali Jirel in a single highly extended pedigree. TSR is heritable in both cohorts (Mexican Americans: h2 = 0.25 +/- 0.05, p = 5.2x10-12; Jirel: h2 = 0.22 +/- 0.05, p = 1.0x10-7. Family data permit polygenic genotype x age (GxA) analyses, with age taken as a proxy for lifetime exposure to environmental and physiological stressors. There is significant evidence of polygenic GxA in both cohorts (Mexican Americans, p = 0.00025; Jirel, p = 0.024), suggesting that at least some genes responsible for variation in TSR are differentially affected by environmental stress. We further compare GWA and linkage evidence from both ethnically distinct cohorts, as well as evidence for SNP-specific GxA for TSR.

741F

Gene polymorphisms associated with optic nerve vertical cup-to-disc ratio are risk factors for primary open angle glaucoma. *F. Mabuchi[1], Y. Sakurada[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1], S. Tsukahara[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: To assess whether the gene polymorphisms associated with optic disc vertical cup-to-disc ratio (VCDR) are risk factors for primary open angle glaucoma (POAG). Methods: Four hundred and twenty-five Japanese patients with POAG, including normal tension glaucoma (NTG, n = 213) and high tension glaucoma (HTG, n = 212), and 191 control subjects without glaucoma were analyzed for 7 gene polymorphisms associated with VCDR; rs1063192 (*CDKN2B*), rs10483727 (*SIX1*), rs17146964 (*SCYL1*), rs1547014 (*CHEK2*), rs1900004 (*ATOH7*), rs1926320 (*DCLK1*), and rs12015126 (*RERE*). The allele frequencies were compared between the patients with NTG or HTG and the control subjects. A logistic regression model was used to study the effects of the risk alleles when comparing the POAG patients with control subjects. Demographic and clinical features, including maximum intraocular pressure (IOP), in patients with POAG were compared between the genotypes. Results: The T allele frequency of rs1063192 (*CDKN2B*) and the A allele frequency of rs1900004 (*ATOH7*) were significantly higher (p = 0.0023 and p = 0.028 respectively) in patients with NTG than in the control subjects (86.2% vs. 77.7% and 39.4% vs. 31.9% respectively). Adjusted for age, gender, refractive error, and IOP, an almost 1.7 and 1.6 times increased risk of POAG was found with the T allele of rs1063192 (P = 0.032, odds ratio 1.73, 95% confidence interval 1.05 to 2.87) and the A allele of rs1900004 (P = 0.012, odds ratio 1.64, 95% confidence interval 1.12 to 2.41) respectively. The ages at diagnosis of the NTG patients with the TT genotype of rs10483727 (*SIX1*) and the CT or TT genotypes of rs1926320 (*DCLK1*) were significantly younger (P = 0.017 and P = 0.040 respectively) than those of the NTG patients without these genotypes. The ages at diagnosis of the HTG patients without CC genotype of rs12015126 (*RERE*) were significantly younger (P = 0.037) than those of the HTG patients with the CC genotype. There were no significant associations between the maximum IOP and the genotypes in patients with POAG. Conclusions: *CDKN2B* and *ATOH7* gene polymorphisms are considered to be non-IOP related genetic risk factors for POAG. *SIX1*, *DCLK1*, and *RERE* gene polymorphisms influence the phenotypic features in patients with NTG or HTG, and may contribute to POAG risk.

742F

A rare penetrant mutation in CFH confers high risk of age-related macular degeneration. *S. Raychaudhuri[1,2,3], O. Iartchouk[3], K. Chin[4], P.L. Tan[5], A. Tai[6], S. Ripke[2,7], S. Gowrisankar[3], S. Vemuri[3], K. Montgomery[3], Y. Yu[4], R. Reynolds[4], D.J. Zack[8], B. Campochiaro[8], P. Campochiaro[8], N. Katsanis[5], M.J. Daly[2,7], J.M. Seddon[4,9].* 1) Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Partners HealthCare Center for Personalized Genetic Medicine, Boston, MA; 4) Ophthalmic Epidemiology and Genetics Service, New England Eye Center, Tufts Medical Center, Tufts University School of Medicine, Boston, MA; 5) Center for Human Disease Modeling and Departments of Cell Biology and Pediatrics, Duke University, Durham, NC; 6) Study Center on the Immunogentics of Infectious Disease, Department of Pathology, Tufts University School of Medicine, Boston, MA; 7) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 8) McKusick-Nathans Institute of Genetic Medicine, Department of Ophthalmology, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD; 9) Department of Ophthalmology, Tufts University School of Medicine, Boston, MA.

Two common variants within CFH, the Y402H variant and the intronic rs1410996 SNP explain 17% of the total variance of age-related macular degeneration (AMD) liability. However, definitive proof for the involvement of CFH, as opposed to a neighboring transcript, as well as information about the potential mode of action of susceptibility alleles are lacking. Under the premise that rare functional variants might establish the causality of CFH and provide mechanistic insights, we used genotype and high throughput sequencing data to query the CFH region in a large cohort of AMD patients. We discovered a rare high-risk CFH haplotype. Sequencing introns, exons, and flanking regions of the CFH gene (100kb) in 84 individuals, including heterozygotes for the rare high-risk haplotype, revealed the presence of an R1210C mutation on that haplotype. This allele has been implicated previously in atypical hemolytic uremic syndrome, and results in loss of C-terminal ligand binding. We genotyped the R1210C mutation in 2,423 AMD cases and 1,122 controls with a TaqMan assay and found this rare allele to be associated with disease ($p=7.0x10^{-6}$), to exhibit high penetrance (present in 40 cases versus 1 control), and to track significantly with a six year earlier onset of disease ($p=2.3x10^{-6}$). This result suggests that loss of function alleles at CFH likely drive AMD risk. To our knowledge, this finding represents one of the first instances where a common variant for a complex disease has led to the discovery of a rare mutation with a large effect.

743F

Interaction between genetic and epigenetic variation affects regulatory mechanisms at the asthma-associated locus 17q12-q21. *S. Moussette[1,2], S. Berlivet[2], M. Ouimet[3], D.J. Verlaan[4,5,3], V. Koka[4], A. Al Tuwaijri[2,5], D. Sinnett[3,6], T. Pastinen[4,5], A.K. Naumova[1,2,5].* 1) The Research Institute of MUHC, Montreal, Quebec, Canada; 2) Department of Obstetrics and Gynecology, McGill University, Montreal, Quebec, Canada; 3) Sainte-Justine University Health Centre, Montreal, Quebec, Canada; 4) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 5) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 6) Department of Pediatrics, University of Montreal, Montreal, Quebec, Canada.

Phenotypic variation results from variation in gene expression, which may be modulated by genetic and/or epigenetic factors. To understand the molecular basis of human disease, interaction between genetic and epigenetic factors needs to be taken into account. The asthma-associated region 17q12-q21 harbors three genes, *ZPBP2*, *GSDMB* and *ORMDL3*, that show allele-specific differences in expression levels in lymphoblastoid cell lines and CD4+ T-cells. Genetic association between *cis*-regulatory polymorphisms and expression levels of *GSDMB* and *ORMDL3* reaches genome-wide significance, whereas the genetic *cis*-effect associated with *ZPBP2* expression has lower significance level[1]. Here we report the molecular dissection of allele-specific transcriptional regulation of the genes within the chromosomal region 17q12-q21 using *in vitro* transient transfection, formaldehyde-assisted isolation of regulatory elements, chromatin immunoprecipitation and sodium bisulfite DNA methylation assays. We found that a single nucleotide polymorphism produces an allelic effect on the activity of *ZPBP2* promoter region *in vitro*, and also leads to nucleosome repositioning on the asthma-associated allele. Analysis of epigenetic states shows that variable methylation of exon 1 of *ZPBP2* masks the strong genetic effect on *ZPBP2* promoter activity. In contrast, the *ORMDL3* promoter is fully unmethylated, which allows detection of genetic effects on its transcription. We conclude that the *cis*-regulatory effects on 17q12-q21 gene expression result from interaction between several polymorphisms and epigenetic factors. Moreover, our data suggest that GWAS studies are more likely to detect association for genes whose regulatory elements are not methylated.

1.Verlaan, D.J. *et al*. Allele-specific chromatin remodeling in the *ZPBP2*/*GSDMB*/*ORMDL3* locus associated with the risk of asthma and autoimmune disease. *Am J Hum Genet* **85**, 377-93 (2009).

Epigenetic changes subsequent to fetal exposure to dioxin. *A. Paoloni-Giacobino[1,2], E. Somm[3], C. Stouder[1].* 1) Dept Gen Med & Development, Geneva Univ Med Sch, Geneva 4, Switzerland; 2) Swiss Center for Applied Human Toxicology, University of Geneva Medical School, 1211 Geneva 4, Switzerland; 3) Department of Pediatrics, Geneva University Hospital, 1211 Geneva 14, Switzerland.

The endocrine disruptor dioxin, a by-product of numerous industrial processes that, being resistant to degradation, accumulates in the environment, is a potent reproductive and developmental toxicant. Paternal exposure to relatively low doses of dioxin was reported to decrease the sex ratio and maternal exposure during pregnancy to decrease ano-genital distance, prostate weight and sperm count in the male offspring. Dioxin might act by interfering with hormone secretion and/or action. Its toxicity might also be mediated by epigenetic changes in DNA methylation. This study addressed possible effects of dioxin on the methylation pattern of imprinted genes. Pregnant female mice were administered daily between days 9 and 19 of gestation 2 different doses of dioxin (2 or 10 ng/kg) and possible methylation changes in the differentially methylated domains of 2 maternally- (Snrpn and Peg3) and 1 paternally- (Igf2) imprinted genes were investigated in of 8-week-old male F1 offspring. The tissues analyzed were the sperm, the liver and the skeletal muscle. No change was observed in the level of methylation of Snrpn, whereas that of Peg3 was decreased in the liver at both dioxin doses and that of Igf2 was decreased in the sperm and in the liver but only at the higher dose of dioxin and increased in the muscle at both dioxin doses. Interestingly, the hypermethylation of Igf2 in the muscle was paralleled by a decreased mRNA expression of this promyogenic gene. The possibly direct toxic effects of dioxin on somatic cells might in particular affect muscle growth in the offspring, whereas an effect of dioxin on the imprinted gene Igf2 in the sperm, suggests a mechanism for transgenerational effects of this toxicant and possibly of other compounds with endocrine disrupting properties.

745F

Measures of global DNA methylation in post-mortem Alzheimer's disease brain. *Y.G. Patel[1], J. Mill[2], J.F. Powell[1].* 1) MRC Centre for Neurodegeneration Research, Institute of Psychiatry, Kings College London, UK; 2) Psychiatric Epigenetics Group, MRC SGDP Research Centre, Institute of Psychiatry, Kings College London, UK.

A role for epigenetics in the complex aetiology of the neurodegenerative disease Alzheimer's disease (AD) has been proposed. The most studied epigenetic mark is DNA methylation (the addition of methyl groups to cytosine located in CpG dinucleotides) and is known to change over time with aging and may also reflect more subtle changes in gene expression. An increasing number of measures of global DNA methylation have become available in recent years from ELISA (Enzyme-Linked ImmunoSorbent Assay) based assays to those adapted to quantitative analysis by pyrosequencing at CpG dinucleotides. Furthermore methylation status of repetitive elements (i.e. Alu and LINE1) is a major contributor to global DNA methylation patterns and has already been investigated in a variety of human diseases including cancers.

We have studied both global DNA methylation (by ELISA) and the more specific CpG dinucleotide based methylation of repetitive elements (at LINE1 and Alu elements) in post-mortem brains of AD cases and controls (20 AD cases and 20 controls). Preliminary results from comparing affected (Superior Temporal Gyrus) and unaffected (Visual Cortex) areas of AD brain and age-matched cognitively normal controls show a trend for a decline in global methylation and a significant decline at LINE1 CpGs in both affected and unaffected tissue. These changes in global methylation may reflect changes in tissue composition as a consequence of the neurodegenerative process and/or an affect of the oxidative and the inflammatory processes active in the degenerating Alzheimer's brain.

746F

The effects of alcohol and smoking on genome wide methylation patterns in women. *R. Philibert[1], J. Plume[2], S. Beach[3].* 1) Psychiatry, University of Iowa, Iowa City, IA; 2) Neuroscience and Genetics Programs, University of Iowa, Iowa City, IA; 3) The University of George, Athens, GA.

Smoking is associated with a wide variety of adverse health outcomes including depression, diabetes and heart disease. Unfortunately, the molecular mechanisms through which these effects are conveyed are not clearly understood. To examine the potential role of epigenetic factors in this process, we examined the relationship of smoking to both genome wide methylation patterns and gene expression in lymphoblast DNA from 165 female subjects from the Iowa Adoption Studies with respect to current smoking status using the Illumina 450 Methylation Bead Chip. We found that current smoking status was associated with significant genome wide changes in methylation at the single CpG residue and multi-residue resolution. Pathway analysis of differentially methylated genes demonstrated that the differentially methylated transcripts mapped to gene pathways known to involved in smoking related disease. Expression analysis of selected differentially methylated transcripts was informative and suggests that expression analyses will be necessary for the rigorous interpretation of methylation results. We conclude that smoking is associated with genome wide changes in DNA methylation and that the understanding of this area of epigenetics will shed new insight into smoking related disease.

747F

Disease-associated epigenetic changes in monozygotic twins discordant for schizophrenia and bipolar disorder. *R. Pidsley[1], E.L. Dempster[1], L.C. Schalkwyk[1], S. Owens[2], A. Georgiades[2], F. Kane[2], S. Kalidin[2], M. Picchioni[2], E. Kravariti[2], T. Toulopoulou[2], R. Murray[2], J. Mill[1].* 1) SGDP Centre, Institute of Psychiatry, London, United Kingdom; 2) Psychosis Studies, Institute of Psychiatry, London, United Kingdom.

Studies of major psychosis (schizophrenia and bipolar disorder) have traditionally focused on genetic and environmental risk factors, although recent research indicates a role for epigenetic processes in mediating susceptibility. Because monozygotic (MZ) twins share a common DNA sequence, the study of discordant twins represents an ideal design for investigating the contribution of epigenetic factors to disease etiology. We performed a genome-wide screen of DNA methylation on peripheral blood DNA obtained from a sample of MZ twin-pairs discordant for major psychosis (n=22 twin-pairs, 44 individuals). Numerous loci demonstrated disease-associated DNA methylation differences between twins discordant for schizophrenia and for bipolar disorder, and jointly for twins discordant for major psychosis. Pathway analysis of our top loci highlighted a significant enrichment of epigenetic disruption to biological networks and pathways relevant to disease and neurodevelopment. The top psychosis-associated DMR is located in the promoter of ST6GALNAC1, overlapping a previously reported rare genomic duplication observed in schizophrenia. This region was significantly hypomethylated in affected twins (p=4.03E-04). We subsequently assessed this region in post-mortem brain tissue from schizophrenia patients and controls finding marked hypomethylation across an extended region in ~13% of schizophrenia patients tested. Overall, our data provide further evidence to support a role for DNA methylation differences in the etiology of both schizophrenia and bipolar disorder.

Germline *KILLIN* (*KLLN*) mutations or epimutations in *PTEN* mutation-negative Cowden syndrome and in patients with apparently sporadic renal and breast cancers. *E. Pontzer[1], K. Bennett[1], P. Funchain[1], J. Mester[1], H. Neumann[2], C. Eng[1].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Section of Preventive Medicine, University of Freiburg Medical Center, Freiburg, Germany.

KLLN and *PTEN*, on 10q23, share a bidirectional promoter and are transcribed in opposite directions. Like PTEN, KLLN plays a role in the cell cycle and is transactivated by p53. Autosomal dominant Cowden syndrome (CS) is characterized by hamartomas and high risk of breast, thyroid and other cancers. While *PTEN* is believed to be the major CS gene, our recent study of 3042 probands with classic CS or CS-like (CSL) phenotypes revealed 25% of CS and 5% of CSL probands with germline pathogenic *PTEN* mutations. Linkage studies which pointed to 10q23 indicated no genetic heterogeneity. Our pilot study revealed *KLLN* germline hypermethylation (epimutation) in 37% of 123 *PTEN* mutation negative CS/CSL patients (Bennett JAMA2010) and in 56% of 41 sporadic clear cell renal cell cancer (ccRCC) patients (Bennett GCC2011). We hypothesized that both germline *KLLN* epimutation and mutation play roles in cancer predisposition. Mutation analysis of 136 *PTEN* mutation negative CS/CSL individuals, revealed a single germline *KLLN* mutation p.V17I. Through bisulfite sequencing and COBRA analysis of 154 *PTEN* mutation negative CS/CSL patients, 50 (32%; 95% confidence interval [CI] 24.63%-39.37%) were found to have germline *KLLN* epimutation, not seen in 50 controls. We demonstrated that *KLLN* promoter epimutation decreases *KLLN*, but not *PTEN*, expression 250-fold which can be reversed by demethylating agents. We also found that CS/CSL patients with *KLLN* epimutation have >2-fold increased prevalence of breast and renal cancers but without differences in thyroid or endometrial cancer prevalence. Because of the increased frequencies of breast and renal cancers in CS/CSL patients with *KLLN* epimutation, we analyzed *KLLN* for mutations and epimutations in individuals with apparently sporadic breast cancer (BC) or ccRCC. Of 52 patients with ccRCC, 2 (3.8%) had germline *KLLN* p.G44R mutations; of 67 ccRCC patients, 26 (39%; 95%CI27.32%-50.68%) were found to have *KLLN* epimutation. Of 20 patients with sporadic BC, one had a *KLLN* p.G44R mutation. No *KLLN* mutations were found in 57 controls. Our observations suggest that germline *KLLN* epimutation may be a new mechanism for CS/CSL with a high risk of breast and renal cancers. Further, germline *KLLN* epimutation may represent a low penetrance predisposition mechanism for ccRCC. These etiomechanisms not only will help in diagnosis, risk assessment and predictive testing, but also suggest future exploration of demethylating agents for prevention.

Differential CpG site methylation classifies psoriatic and normal skin. *EDO. Roberson[1], Y. Liu[1], C. Ryan[2], C. Joyce[1], S. Duan[1], L. Cao[1], A. Martin[3], W. Liao[4], A. Menter[2], A. Bowcock[1,3].* 1) Dept of Genetics, Washington University, St. Louis, MO, U.S.A; 2) Dept of Dermatology, Baylor University Medical Center, Dallas, TX, U.S.A; 3) Dept of Medicine, Division of Dermatology, Washington University School of Medicine, St. Louis, MO, U.S.A; 4) Dept of Dermatology, University of California, San Francisco, CA, U.S.A.

Psoriasis is a chronic, inflammatory, immune-mediated disorder primarily affecting the skin as well as other organs, including joints. Psoriasis is relatively common in Caucasian populations with a prevalence of 1% or more, less common in Asian populations (0.1%) and very rare in African populations. Differential gene expression studies have identified over 1,300 transcripts altered in psoriatic involved skin compared to normal skin. However, a global epigenetic profile of psoriatic skin has not been described. We have performed the first genome-wide study of altered CpG site methylation in psoriatic skin. We determined the methylation levels at 27,578 CpG sites in skin samples from individuals with psoriasis (12 involved, 8 uninvolved) and 10 unaffected individuals using Illumina methylation beadarrays. CpG methylation of involved skin significantly differed from normal skin at 1,108 sites. Twelve of these CpG sites mapped to the epidermal differentiation complex, upstream or within genes that are highly up-regulated in psoriasis. Hierarchical clustering of 50 of the top differentially methylated (DM) sites separated psoriatic from normal skin samples, and also performed well at classifying psoriatic involved from psoriatic uninvolved skin. For some of the analyzed samples expression arrays had previously been performed, and correlation between methylation and expression was calculated. Sites with inverse correlations between methylation and nearby gene expression include those of KYNU, OAS2, S100A12, and SERPINB3, whose strong transcriptional up-regulation are important discriminators of psoriasis. We observed a small number of CpG sites with differential methylation in psoriatic uninvolved skin versus normal. We confirmed CpG methylation differences by pyrosequencing CpG sites in the region of three DM CpG sites. Multiple clinical trials have demonstrated the efficacy of TNF blockade for the treatment of psoriasis. When we examined the effect of this treatment on global CpG methylation we observed that after a month, methylation levels had started to change in the direction seen in uninvolved skin. Hence, psoriasis diagnosis and treatment response might be predicted by methylation changes in skin of patients.

DNA methyltransferases expression and methylation status in adult offspring of hyperhomocysteinemic dams supplemented with methionine. *V.C. Silva[1], E.J. Haseyama[2], M.T.C. Muniz[3], V. D'Almeida[2].* 1) Pediatrics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Psychobiology, Universidade Federal de São Paulo, São Paulo,São Paulo, Brazil; 3) Universidade de Pernambuco, Recife, Pernambuco, Brazil.

Aim: Epigenetic regulation is crucial in the development of organisms, since it is required to achieve either stable genes expression or repression at various stages of development. DNA methylation is the most studied epigenetic mechanism and it is accomplished through specific enzymes called DNA methyltransferases, which transfer a methyl group to the cytosine of CpG dinucleotides. Human epidemiologic and animal model data indicate that nutrition and other environmental stimuli influence prenatal epigenetic development pathways and thereby induce permanent changes in metabolism and chronic disease susceptibility. As methionine-homocysteine cycle alterations are described in some disease and could have a role on fetal programming through changes on S-adenosylmethionine (SAM) levels, the aim of this study was to investigate the effects of methionine supplementation, during gestation and lactation, on expression of methyltransferases and global methylation pattern. Methods and Results: One month before pregnancy, 13 Swiss female mice were distributed into 2 groups: control (CT=6) group and methionine supplemented (MS=7) group (1% of methionine in water ad libitum). After 20 days, plasma homocysteine levels from MS group were approximately 50% higher than CT group (CT= 4.45 μmol/L, MS= 8.71 μmol/L; p=0.0001). Three months old male offspring (CT=15, MS=11) were euthanized by decapitation, the liver was harvested and DNA and mRNA isolated by Wizard® Genomic DNA Purification Kit and Trizol® method, respectively. Gene expression of *Dnmt1*, *Dnmt3a* and *Dnmt3b* was quantified by real time PCR using *Gapdh* as the housekeeping gene and data were analyzed by 2-ΔΔCT method. Hepatic DNA global methylation was measured by Imprint® Methylated DNA Quantification Kit. T-test was used to compare the results considering significant $p<0.05$. Our results demonstrated that the treatment with methionine throughout the pregnancy and lactation had no significant effect on the hepatic male expression of *Dnmt1* (p=0.844), *Dnmt3a* (p=0.794) and *Dnmt3b* (p=0.963), and neither on hepatic DNA global methylation (p=0.183). Conclusion: Despite dams hyperhomocysteinemia, we can suggest that the organism develops compensatory mechanisms during high methionine intake which results on similar methyltransferases gene expression and also global methylation in exposed adult offspring compared to controls. Sources of research support: FAPESP, CNPq and AFIP.

Neonatal DNA Methylation Patterns Associate with Gestational Age. *A.K. Smith[1,2], J.W. Schroeder[2], K.N. Conneely[3], J.C. Cubells[1,2,3], V. Kilaru[1], D.J. Newport[3,4], B.T. Knight[3,4], Z.N. Stowe[3,4,5], P.A. Brennan[6], J. Krushkal[7], F.A. Tylavsky[7], R.N. Taylor[5], R.M. Adkins[8].* 1) Psychiatry & Behavioral Sciences, Emory University, Atlanta, GA; 2) Genetics and Molecular Biology Program, Emory University, Atlanta, GA; 3) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 4) Emory Women's Mental Health Program, Emory University School of Medicine, Atlanta, GA; 5) Department of Gynecology and Obstetrics, Emory University School of Medicine, Atlanta, GA; 6) Department of Psychology, Emory University, Atlanta, GA; 7) Department of Preventive Medicine, University of Tennessee Health Science Center, Memphis, TN; 8) Department of Pediatrics, University of Tennessee Health Science Center, Memphis, TN.

There is an increased risk for adverse neonatal outcome with declining gestational age (GA), and epigenetic alterations, including changes in DNA methylation, may contribute to the relationship between GA and adverse health outcomes in these offspring. To test this, we evaluated the association between GA (range: 32.3-43.4 weeks) and methylation patterns in neonatal DNA extracted from umbilical cord blood. DNA methylation at >27,000 CpG sites was examined in two prospectively-characterized cohorts: 1) a clinical cohort consisting of 259 neonates from women with a history of neuropsychiatric disorders, delivered between 2000 and 2010 and 2) a population-based cohort consisting of 197 neonates of uncomplicated mothers, delivered between 2007 and 2010. GA was determined by obstetrician report and maternal last menstrual period. The associations between proportion of DNA methylated and GA were evaluated by fitting a separate linear mixed effects model for each CpG site, adjusting for relevant covariates including neonatal sex, race, birthweight percentile and chip effects. CpG sites in 39 genes were associated with GA (false discovery rate <.05) in the clinical cohort. The same CpG sites in 18 genes replicated in the population-based cohort, with each association in the same direction. Notably, these CpG sites were located in genes previously implicated in labor and delivery (e.g., *ESR1*, *AVP* and *OXT*) or that may influence the risk for adverse health outcomes later in life (e.g. *DUOX2*, *CAPS2* and *CASP8*). All associations were independent method of delivery or induction of labor. The current results suggest that neonatal DNA methylation varies with gestational age even in term deliveries. The consequences of these changes warrant further investigation of their potential contribution to clinically significant postnatal adverse outcomes.

Causal relationships between genotype, methylation and expression in whole blood of healthy controls. *K.R. van Eijk[1,2], S. de Jong[1,2], T. Langeveld[1], E. Strengman[1], E. Janson[1], J.H. Veldink[3], L.H. van den Berg[3], R.S. Kahn[2], C.G.F. de Kovel[1], M.P.M. Boks[2,4], S. Horvath[5], R.A. Ophoff[1,2,5,6].* 1) Department of Medical Genetics, University Medical Center Utrecht, The Netherlands; 2) Department of Psychiatry, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands; 3) Department of Neurology, Rudolf Magnus Institute of Neuroscience, University Medical Center Utrecht, The Netherlands; 4) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, The Netherlands; 5) Department of Human Genetics and Biostatistics, University of California, Los Angeles, USA; 6) Center for Neurobehavioral Genetics, Neuropsychiatric Institute, University of California, Los Angeles, USA.

Epigenetic mechanisms are important for regulating the cellular machinery including gene expression. DNA methylation is one form of epigenetic control that is most commonly studied. However, little is known about the complex relationship between DNA methylation and gene expression. This study is an effort to decipher the causal relationship between DNA methylation and gene expression. For this study we used (Illumina) array-based genome-wide DNA methylation and gene expression data obtained in whole blood of 148 healthy controls. To examine the association of DNA methylation and gene expression a linear regression was performed with DNA methylation as a predictor of gene expression levels. Age and gender were used as covariates. Significance thresholds were adjusted for cis (maximum distance of 500 kb between the probes) and trans (genome-wide). Available genome-wide SNP data was used to investigate the genetic control of DNA methylation and gene expression at these loci. Finally the edges (links) between the top 25 DNA methylation probes and corresponding gene expression probes were oriented by using underlying cis-acting SNPs as causal anchors. Specifically, the network edge orienting (NEO) software was used to calculate Local Edge Orienting (LEO) scores based on local structural equation models. We observed both positive and negative associations between gene expression probes and DNA methylation probes. For cis 3,617 significant associations were found, of which 1,934 negative (53.5%) and 1,683 positive (46.5%). Of the methylation and expression probes associated with each other 239 methylation probes and 219 expression probes are regulated by SNPs. After calculating LEO scores for 159 probe/SNP combinations, 50 combinations (31%) have a LEO score above 0.8, indicating good model fit, for the model SNP>Methylation>Expression and 12 combinations (7.5%) have a LEO score>0.8 for the model SNP>Expression->Methylation. Patterns in causality were found to coincide with LD blocks of genetic markers. Overall the results show that DNA methylation levels and gene expression levels are both positively as well as negatively correlated. In addition, about 10 percent of the DNA methylation and gene expression probes are regulated by genetic variants. For some relationships a causal direction could be assigned. These results provide insight into the complex and diverse relationship between DNA methylation and gene expression.

Epigenetic regulation at the NR3C1 gene promoter and PTSD. *V. Vukojevic[1], A. Papassotiropoulos[1], D. de Quervain[2].* 1) Molecular Neurosciences, Biozentrum/University of Basel, Basel, Switzerland; 2) Cognitive Neurosciences, Faculty of Psychology/University of Basel, Basel, Switzerland.

Background: Human memory is a genetically complex trait. Candidate gene and genome-wide studies (GWAS) led to the identification of gene loci associated with human memory capacity. Despite the success of this approach a significant amount of phenotypic variation remains to be explained. The study of epigenetic mechanisms, such as DNA methylation, is expected to improve our understanding of the molecular underpinnings of this complex trait. Methods: Via direct bisulfite sequencing and SMART qPCR we investigated the promoter methylation of NR3C1 (nuclear receptor subfamily 3, group C, member 1), which is known to be important for cognitive processes related to post-traumatic stress disease (PTSD). Genetic variability of the NR3C1 locus was tested with the Affymetrix 6.0 SNP array. Results: Human emotional memory performance and brain activation during emotional memory tasks are associated with NR3C1 promoter methylation profiles. DNA methylation of the NR3C1 promotor 5' CpG NGFI-A factor-binding site is negatively correlated with such PTSD-related phenotypes as severity of intrusions and total PDS score in survivors of the Rwandan genocide. Conclusion and outlook: We conclude that DNA methylation of the NR3C1 gene promoter is associated to PTSD-related phenotypes. Currently we are expanding our search to the epigenome-wide level to identify additional and -possibly- interacting epigenetic loci.

Pharmacoepigenetic impact of Chronic systemic steroid use on genome-wide DNA methylation in the International COPD Genetics Network. *E.S. Wan[1], W. Qiu[1], B.J. Klanderman[1], D.A. Lomas[2], S.I. Rennard[3], A. Agusti[4], A. Baccarelli[5], W.H. Anderson[6], E.K. Silverman[1], D.L. DeMeo[1].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Cambridge Institute for Medical Research, University of Cambridge, Cambridge,UK; 3) University of Nebraska, Omaha, NE; 4) Hospital Clinic Universitat De Barcelona, Barcelona, Spain; 5) Harvard School of Public Health, Boston, MA; 6) GlaxoSmithKline, Research Triangle Park, NC.

Rationale: DNA methylation can reflect both endogenous factors, such as aging, & exogenous factors, such as smoking, diet, and medication use. Systemic steroids are a powerful class of medications administered therapeutically for a variety of indications in medical practice, often for protracted courses. Despite widespread use, the mechanisms of action of systemic steroids are not fully understood. We hypothesize that chronic systemic steroid use may be associated with distinct genome-wide DNA methylation patterns. Methods: We examined probands (n=382) enrolled in the International COPD Genetic Network (ICGN): subjects were 45-65 y.o., had ⁄ 5 pack-years of smoking, and a post-bronchodilator FEV_1 <60% predicted with an FEV_1/FVC <90% predicted. Genome-wide DNA methylation data was obtained using the Illumina HumanMethylation27 BeadChip on DNA isolated from peripheral blood leukocytes. We conducted an analysis comparing probands who reported chronic systemic steroid use (n=60) with probands who did not (n=322) using beta regression as implemented in R. All analyses were adjusted for age, sex, batch, and FEV_1 % predicted. Results: Using a Bonferroni adjusted p-value cutoff of 1.88×10^{-6} to denote genome wide significance, 2,322 CpG sites were differentially methylated in probands who reported chronic systemic steroid use compared to probands who did not report steroid use. CpG sites in the low density lipoprotein receptor related protein 3 (*LRP*), lymphotoxin alpha (*LTA*), & aldehyde dehydrogenase 3 family member B1 (*ALDH3B1*) were among the most highly associated differentially methylated loci. We conducted a gene set enrichment analysis in DAVID which demonstrated significant enrichment in extracellular & plasma membrane components, defense, inflammatory, and wound healing response, cytokine activity, cellular adhesion & communication, signal transduction, coagulation, platelet activation, cell migration & chemotaxis related processes. Conclusions: Chronic systemic steroid use in subjects with moderate to severe COPD is associated with variable DNA methylation patterns throughout the genome. Gene set enrichment analysis identified both expected and novel pathways impacted by differential methylation and may lend insight into the mechanism of action of & variable responses to this commonly administered medication. Funding: T32 HL007427 (S.T.Weiss), R01 HL089438 (D.L.D.)& the Doris Duke Clinical Scientist Development Award (D.L.D.).

Genome-wide DNA methylation changes in fragile X syndrome. *T. Wang[1,2], R. Alisch[1], P. Chopra[1], J. Mowrey[1], B. Lynch[1], V. Patel[1], C. Collins[1], K. Conneely[1,3], J. Visootsak[1], B. Coffee[1], S. Warren[1].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Genetics and Molecular Biology Graduate Program, Emory University, Atlanta,GA; 3) Department of Biostatistics, Emory University, Atlanta,GA.

Fragile X syndrome (FXS) is the most common form of inherited intellectual delay and is caused by an expansion of a CGG repeat located in the 5' untranslated region (UTR) of FMR1, leading to hypermethylation and gene silencing of this locus. While the dynamic methylation patterns of this full mutation allele are well characterized, DNA methylation changes elsewhere in the genome has not been examined. Here, we quantitatively profiled whole blood-extracted DNA from six full mutation FXS patients and 170 controls for their methylation levels at 485,764 CpG dinucleotides throughout the genome. Following a differential methylation analysis, we find 79,330 loci with a significant differential methylation at an FDR of 0.05 . Of these differentially methylation loci (DML), only the FMR1 locus is hypermethylated. The remaining DML show statistically significant but subtle hypomethylation, suggesting that the hypermethylation of FMR1 full mutation may act as a `methylation sink,' reducing methylation of methyl-sensitive alleles throughout the genome. In addition, considerably more homogeneous cells-induced pluiripotent stem (iPS) cells derived from two Fragile X fibroblasts and two normal fibroblasts exhibit hypermethylation at four genomic regions distinct from the FMR1 locus. Together, these data indicate that, depending upon the cell type and/or differentiation status, the full mutation allele of FMR1 may influence DNA methylation elsewhere in the genome.

756F

Nicotine dependence-associated DNA methylation changes measured by a methylation array-based approach. *H. Zhang[1,3], A.I. Herman[1,3], H.R. Kranzler[4], R.F. Anton[5], H. Zhao[2], W. Zheng[2], J. Gelernter[1,3].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) Department of Biostatistics, Yale University School of Public Health, New Haven, CT; 3) VA Connecticut Healthcare System, West Haven, CT; 4) Department of Psychiatry, University of Pennsylvania School of Medicine and Philadelphia VAMC, Philadelphia, PA; 5) Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, SC.

Tobacco use, including cigarette smoking, may increase the risk for cardiovascular and pulmonary disease and cancer in part through epigenetic modification of genes. We investigated peripheral blood DNA methylation levels of 384 CpGs in promoter regions of 82 candidate genes (mainly involved in dopaminergic, serotonergic, opioidergic, GABAergic and glutamatergic neurotransmission) in 285 African Americans [AAs; 122 cases with nicotine dependence (ND) and 163 controls] and 249 European Americans (EAs, 115 ND cases and 134 controls) using Illumina GoldenGate methylation array assays. Effects of ND on DNA methylation were analyzed using multivariate linear regression with sex, age, ancestry proportion and alcohol or drug dependence as covariates. The q-value method was applied to control the false discovery rate in multiple testing. Six CpGs in AAs and nine CpGs in EAs showed a nominally significant difference in DNA methylation levels between ND cases and controls (6 CpGs in AAs: $0.018 \le P \le 0.034$, $q>0.05$; 7 CpGs in EAs: $0.015 \le P \le 0.043$, $q>0.05$). Additionally, there were sex effects on DNA methylation. In male AAs, six CpGs (GRIN1^2, GRIN1^4, MBD1^1, SLC6A1^3, HTR1A^8, and OPRD1^6) were hypermethylated in cases ($1.7\times10^{-8} \le P \le 0.009$, $6.5\times10^{-6} \le q \le 0.594$) compared to controls. In particular, CpG GRIN1^2, which is located in the promoter region of GRIN1 and the potential binding site (GGCGCG) of transcription factor ZF5, was more highly methylated in AA male cases (mean±SEM: 0.174±0.008) than in AA male controls (mean±SEM: 0.011±0.019) ($P=1.7\times10^{-8}$, $q=6.5\times10^{-6}$). In female AAs, two CpGs (GABRG2^5 and GRIN2B^5) were more highly methylated in cases than in controls ($P=0.004$, $q=0.743$ for both sites). However, in male EAs, 11 CpGs (HTR1B^9, SLC6A4^5, CHRNB4^7, DRD1^8, GRIN2C^5, GRIN2B^3, POMC^5, OPRK1^2, GABRB1^2, MECP2^1 and MAOA^4) were less highly methylated in cases than in controls ($0.0007 \le P \le 0.008$, $0.077 \le q \le 0.158$). In contrast, in female EAs, seven CpGs (HTR1A^2, OPRD1^3, OPRL1^4, POMC^5, GABRB1^3, DNMT3A^2 and GAD2^5) were more highly methylated in cases ($0.003 \le P \le 0.010$, $q>0.050$) than in controls. In summary, DNA methylation levels were found to be influenced by ND, race and sex. These preliminary findings need to be verified using independent sample sets and methods which can measure methylation levels of denser CpG sites in the promoter region of genes.

Epimutations and transcriptional dysregulation of SHANK3 in brains associated with autism spectrum disorder. *L. Zhu[1], X. Li[1, 6], A. Towers[2], X. Wang[1], J. Goldstein[1], H. Yang[5], Y. Jiang[1, 2, 3, 4].* 1) Pediatrics, Duke University, Durham, NC., U.S; 2) Program in Genomics and Genetics, Duke University, Durham, NC., U.S; 3) Program in Cell and Molecular Biology, Duke University, Durham, NC., U.S; 4) Duke Institute for Brain Science, Duke University, Durham, NC., U.S; 5) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC., U.S; 6) Molecular Genetics department, Shanghai Jiao Tong University, Shanghai, China.

Although a genetic component is strongly implicated in the etiology of autism spectrum disorders (ASD), the molecular basis is poorly understood in the majority of cases; single gene mutations and chromosomal microdeletions or duplications are found in about 10% of idiopathic ASD cases. Microdeletion and de novo frame shift mutations of the synaptic protein gene SHANK3 have been strongly implicated as a cause of ASD. We hypothesize that epigenetic dysregulation of the SHANK3 gene in brain contributes to ASD susceptibility. We performed DNA methylation profiling of 5 SHANK3 CpG islands (CGI-1 to CGI-5) in cerebral cortex and cerebellum tissues from 52 ASD patients and 32 controls. Compared to controls, ASD cerebellum samples had a significantly higher percentage of methylation in CGI-2 (control: 4.1±6.6%; ASD: 10.1±18.3 %, p=5.03e-13), CGI-3 (control: 45.6±10.1%; ASD: 52.4±12.6%, p= 5.45e-09), and CGI-4 (control: 2.1±5.8 %; ASD: 9.4 ± 14.9 %, p=1.11e-43) using the t-test. In the cerebral cortex, ASD samples had a significantly higher percentage of methylation in CGI-2 (control: 4.5±7.6%; ASD: 24.3±19.6%, p= 5.82e-64) using t-test; no difference was found for the other CGIs. Heat map analysis revealed significantly increased methylation of CGI-2 and CGI-4 in 12 to 15% of ASD brain tissues. In Silico analysis, RNA expression, and luciferase reporter assay revealed that SHANK3 has 5 intragenic promoters and extensive alternative splicing of coding exons. The CGI-2, CGI-3, and CGI-4 correspond to promoter 3, 5, and 6 respectively. The pattern of alternative splicing and expression of different isoforms of SHANK3 were altered in ASD brains with increased methylation. The chromatin immunoprecipitation (ChIP) assay revealed that the active chromatin marker H3K4me3 is significantly decreased but the repressed chromatin marker H3K27me3 is significantly increased in the CGI-4 region in ASD samples with increased methylation. Aberrant methylation at global level and other candidate ASD candidate genes were not found in these ASD brain tissues. This study is the first to show that epimutations of SHANK3 are strongly associated with susceptibility to ASD. We propose that isoform-specific transcriptional dysregulation of synaptic protein genes in brain, due to epimutation, may contribute significantly to the molecular basis of ASD.

MicroRNA-Regulated Gene Networks in Human. *S. Banfi[1,2], V.A. Gennarino[1], G. D'Angelo[1], G. Dharmalingam[1], S. Fernandez[3], G. Russolillo[4], R. Sanges[5], M. Mutarelli[1], A. Ballabio[1,6], P. Verde[3], M. Sardiello[1,6].* 1) TIGEM, Fondazione Telethon, Naples, Naples, Italy; 2) Medical Genetics, Department of General Pathology, Second University of Naples, Naples, Italy; 3) Institute of Genetics and Biophysics “A. Buzzati Traverso”, CNR, Naples, Italy; 4) CNAM - Laboratoire Cédric & Chaire de Statistique Appliquée, Paris, France; 5) Bioinformatics, Animal Physiology and Evolution, Stazione Zoologica Anton Dohrn, Villa Comunale, Naples, Italy; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, Texas USA.

Transcriptional regulatory networks control proliferation, differentiation and metabolism of eukaryotic cells through two main classes of regulators: transcription factors (TFs) and microRNAs (miRNAs). However, while the contribution of TFs is well established, our current understanding of the processes regulated by miRNAs remains limited. Here, we carried out a comprehensive analysis of human miRNA regulatory networks based on Co-expression Meta-analysis of miRNA Targets (CoMeTa). CoMeTa integrates expression data from hundreds of cellular systems and multiple tissues, to capture the relationships between the regulatory dynamics of genes. The CoMeTa analysis of 675 human miRNAs provided a dramatic improvement in our ability to pinpoint their bona fide target genes, as compared to first-generation methodologies, which were based solely on sequence and evolutionary analyses. CoMeTa outputs were used here to correlate miRNAs to specific biological pathways. This analysis revealed that many critical biological processes are controlled by miRNAs through regulation of specific networks of co-expressed target genes. CoMeTa data were also used to build a global map of miRNA communities based on gene co-targeting, which revealed synergistic regulation of cohorts of genes involved in similar processes. The use of CoMeTa, coupled to experimental in vitro assays, allowed us to identify three novel putative regulators of TGF) signalling, which represent potential therapeutic targets for treatment of invasive tumours. Based on our findings, we propose CoMeTa as a general paradigm for second-generation procedures to infer targets, biological roles and network communities of miRNAs.

Comprehensively Functional Studies of miR-199a in Testicular Germ Cell Tumors. *S. Gu[1], Y.K. Suen[1], H.H. Cheung[2], W.Y. Chan[1,2].* 1) School of Biomedical Sciences, The Chinese University of Hong Kong, HKSAR, Hong Kong; 2) Lab of Clinical and Developmental Genomics, NICHD, NIH, Bethesda, MD.

microRNAs (miRNAs) regulate gene expressions by pairing to the mRNAs of protein-coding genes to direct their posttranscriptional repression. Previous studies showed that hypermethylation silences the expression of miR-199a-2 in testicular germ cell tumors (TGCTs). It has been shown that miR-199a-2 is a tumor suppressor, normally modulating a spectrum of genes involved in TGCTs, and PODXL (podocalyxin-like protein) is one of such targets. We aim to find other downstream target(s) of miR-199a-2 besides PODXL and examine their roles in tumorigenesis. In addition, the relationship among these targets of miR-199a-2 and the overall regulation of tumorigenesis by miR-199a-2 will be studied. In order to find potential targets of miR-199a-2 in TGCTs, two stably transfected testicular tumor cell strains (NT2), one with an expression vector carrying control marker GFP and one with a vector carrying miR-199a-2 precursor downstream of the marker GFP were used as in vitro models. Total cellular proteins of the cells were analyzed by two-dimensional gel electrophoresis. Differentially expressed proteins were isolated and subjected to mass spectrometry analyses. Difference in gene expression was investigated using expression chips. In addition, target prediction programs were employed to identify target candidates of miR-199a-2. Combining the results of these methods, several potential targets of miR-199a-2 were obtained for further verification by Western Blot and qPCR. One of such targets is involved in chromatin modification. We are in the process of verifying direct interaction between miR-199a-2 and the potential targets by luciferase receptor assay. The effects of silencing of the potential targets on the behavior of TGCT cells will also be examined.

Comprehensive evaluation of genome-wide SNP, mRNA expression and microRNA expression relationships in human cell lines. *RS. Huang[1], HK. Im[2], D. Ziliak[1], B. LaCroix[1], ME. Dolan[1], NJ. Cox[1], E. Gamazon[1].* 1) Dept Med, Univ Chicago, Chicago, IL; 2) Dept Health Studies, University of Chicago, Chicago, IL.

Given the major role of gene and microRNA (miRNA) expression in biological, physiological and pathological processes, we set out to comprehensively and systematically evaluate the relationship between miRNA expression, mRNA expression and genetic variation. Genome-wide miRNA and mRNA expression were characterized in Phase I/II unrelated 54 CEU (Utah residents with northern and western European ancestry) and 55 YRI (African from Ibadan, Nigeria) HapMap lymphoblastoid cell lines (LCLs) using the Exiqon miRCURYTM LNA arrays and the Affymetrix GeneChip® Human Exon 1.0 ST array, respectively. Genome-wide analysis identified 100 and 114 miRNAs whose expression levels are negatively correlated with 558 and 633 mRNA expression phenotypes in CEU and YRI samples, respectively ($p<10^{-4}$). A large number of these potential miRNA-mRNA binding relationships are also predicted by miRbase. We then investigated the role of genetic variation in mediating these relationships. First, we identified SNPs that are located in the 3'UTR regions of genes and may affect miRNA bindings. Importantly, 25 and 25 SNPs located in the 3'UTR of target genes were identified as cis-acting eQTLs ($p<0.01$) to 16 and 18 of their neighboring genes in CEU and YRI, respectively. Replication studies for the cis-acting eQTL and miRNA-mRNA relationships were conducted in an independent set of Phase III HapMap CEU and YRI samples. Functional study was then performed on selected miRNA/mRNA pairs to confirm the differential miRNA binding affinity due to the presence of these SNPs. Secondly, we mapped miRNA expression levels to 7,458 and 12,413 SNPs as miRNA-eQTLs ($p<10^{-8}$) in CEU and YRI, respectively through a genome-wide association study. Of these miRNA-eQTLs, 47 and 12 were also found to be mRNA-eQTLs for 318 and 150 genes in CEU and YRI ($p<10^{-4}$), suggesting that either genetic variation is mediating the observed relationship between miRNA and mRNA or a SNP may regulate miRNA expression thereby regulating mRNA expression. This study extends our understanding of the genetic regulation of the transcriptome and suggests that genetic variation may influence interactions between miRNAs and mRNAs greater than has previously been appreciated.

A parallel study of mRNA and microRNA profiling of peripheral blood in young adult women. *C. Huang[1], S. Simone[2], S. Gadd[3], N. Jafari[4].* 1) Preventive Med, Northwestern Univ, Chicago, IL; 2) Dept. of Pediatrics, Northwestern Univ, Chicago, IL; 3) Dept. of Pathology, Northwestern Univ, Chicago, IL; 4) Center for Genetic Medicine, Northwestern Univ, Chicago, IL.

Backgound: Aging is a complex process that involves the interplay of genetic, epigenetic, and environmental factors. Identifying aging-related biomarkers holds great potential for improving our understanding of complex physiological changes, thereby providing a means to investigate the mechanism by which aging influences various diseases. Method and Results: We performed a parallel study of microRNA and gene expression profiling of peripheral blood in a group of healthy young adult women, among which 13 were aged 22-25 and 9 were aged 36-39 years old. We identified a significantly distinct pattern of microRNA, but not gene expression profiling, between these two young adult women groups. We also performed correlation analysis of expression levels between all pairs of age-associated microRNAs and genes and identified a weak global correlation between these two types of expression levels. A significant involvement of estrogen regulation was observed by pathway analysis of the most differentially expressed microRNAs that included miR-155, -18a, -142, -340, -363, -195, and -24. Conclusion: Our results suggest that the change in global microRNA expression in the peripheral blood is associated with normal aging in young adult women. This change may precede global gene expression changes. The association of differentially microRNAs with estrogen regulation may inform future studies to investigate the regulatory mechanism of these microRNAs on estrogen-associated diseases.

762F

Epigenetic Regulation of Ocular Growth: Genome-wide Profiling of Scleral micro-RNAs, Potential Role and Implications for Myopia. *R. Metlapally[1], P. Gonzalez[2], F.A. Hawthorne[3], K. Tran-Viet[3], C.F. Wildsoet[1], T.L. Young[2,3].* 1) School of Optometry, UC Berkeley, CA, USA; 2) Duke Eye Center, NC, USA; 3) Duke Center for Human Genetics, NC, USA.

Ocular growth during myopia development is driven by a retino-scleral signaling cascade with the sclera (outer coat) ultimately guiding ocular elongation via active extracellular matrix remodeling. Micro-RNAs are small non-coding RNAs that can regulate gene expression by base pairing with the 3' UTR of target sequence/s, and serving as nodes of signaling networks. To date, there are no studies of micro-RNAs in the sclera. We hypothesized that the sclera, like most tissues, expresses micro-RNAs, some of which play an active role in modulating genes during ocular growth regulation. We profiled micro-RNAs in the human sclera from rapidly growing human fetal eyes and stable adult donor eyes using high-throughput microarray and quantitative PCR analyses. Scleral samples from normal human fetal (24 wk gestation) and age-matched adult donor eyes (n=3, each group) were obtained, and RNA extracted using the miRVANA kit. Genome-wide micro-RNA profiling made use of the Agilent Human miRNA Microarray platform. miRNA target predictions were obtained using Microcosm, TargetScan and PicTar algorithms. Follow-up experiments using TaqMan® MicroRNA Assays targeting micro-RNAs showing either highest significance, detection, or fold differences, and collagen specificity, were applied to tissue from posterior and peripheral regions (n=7, each group). Microarray data were analyzed using miRInform, and quantitative PCR data with 2^-deltaCt method. Approximately 300 micro-RNAs were found to be expressed by human sclera (298 & 353 detected in at least one adult and fetal sclera sample respectively), with several micro-RNAs showing differential regulation ($p<0.01$, min $p=1.5 \times 10^{-6}$). In follow-up experiments, mir-214, let-7c, let-7e, mir-103, mir-107, and mir-98 showed increased expression in fetal tissue (fold changes 1.5 to 4, $p<0.01$). No significant differences were observed in micro-RNA expression between posterior and peripheral regions within either age group. This is the first study of micro-RNA expression in human sclera. The sclera expresses several micro-RNAs, some of which show age-related differential regulation, higher in rapidly growing fetal eyes, consistent with a role in ocular growth regulation. A link between these scleral micro-RNAs and myopia, which also involves accelerated eye growth is plausible but yet to be established. Genome-wide mRNA profiling is underway to understand the pathways involved and the correlation with micro-RNA signatures.

Identification of the chromatin regions coated by non-coding *Xist* RNA. *H. Kugoh[1], K. Murakami[2], E. Ohshiro[1], T. Ohhira[1], M. Oshimura[1].* 1) Biomedical Science and Chromo., Regenerative Medicine, yonago city, Tottori, Japan; 2) Laboratory for Pluripotent Cell Studies, RIKEN Center for Developmental Biology (CDB), Kobe, Japan.

The non-coding RNA (ncRNA) genes, which did not encode proteins, produce functional RNA molecules that play an important role of gene regulation, including X chromosome inactivation (XCI) and RNA interference (RNAi). Of these, the non-coding XIST RNA has been particularly well characterized. XIST RNA is known to act as a regulatory molecule in XCI, which accomplishes dosage compensation in mammals. *XIST* RNA coats and spreads along the X chromosome; recruits the silencing complexes, including histone deacetylase, histone methyltransferase, and the polycomb group protein complex; and eventually establishes X chromosome inactivation by induction of heterochromatin formation. Although the majority of X-linked genes in mammalian cells indicate loss of expression by silencing of the entire chromosome on XCI, some genes were expressed in both active and inactive X chromosome. However, it was incompletely defined how *XIST* RNA actually affects on silencing genes and genes escaped from inactivated X chromosome, respectively. We developed a modified RNA tagging and recovery of associated proteins (TRAP) method to study the association between *Xist* RNA and its target genes. In mouse cells, *Xist* RNA was detected on the *Ube1x* gene, but not on Jarid1c and *Utx* genes, which escape from XCI. Using this technique we were able to show that the *Xist* RNA molecule is not present on active genes that escape from XCI, but is present on genes inactivated by XCI, suggesting that this method is a powerful tool for functional analysis of ncRNA.

764F

Evidence for genetic, epigenetic and exogenous regulation of Inflammasome and related genes. *A.A. Awomoyi[1], A. Papp[2], G. Smith[2], W. Sadee[2], M. Wewers[3].* 1) 6209, Lone Oak Dr, Bethesda, MD; 2) Pharmacology Dept, Ohio State University Medical Center, Columbus, OH; 3) Davis Heart and Lung Res. Inst and Internal Medicine, Ohio State University Medical Center, Columbus, OH.

Multiprotein complexes, termed inflammasome and related genes, which are assembled in a stimulus dependent manner, are central to the innate host response. Dysregulated inflammasome functioning is associated with numerous diseases and disorders. Naturally occurring genetic variations within any of the inflammasome genes have the potential to modulate the activation and assemblage of this complex. One important variation that, to our knowledge, has not yet been systematically investigated in the context of inflammasome function is that regulatory polymorphisms in specific inflammasome genes may result in altered mRNA expression. This is detectable as an allelic mRNA expression imbalance in subjects heterozygous for a marker SNP in the transcribed exonic region of the genes. To search for regulatory mechanisms influencing inducible gene expression, we selected 6 of these genes; NLRP1, NLRP3, PYCARD, MEFV, CASP1 and CASP12. We searched public databases and identified TagSNPs in exonic regions with high frequency of heterozygosity within these genes. We used a single base extension technique (SNaPshot) to measure allele mRNA expression ratios in human blood monocytes and MCSF differentiated macrophages in the presence or absence of LPS from heterozygous individuals. Allele mRNA expression was compared to the corresponding genomic allele ratios measured in the same subjects. A relative deficit in one allele compared to the alternate allele suggests a cis acting regulatory element within the gene locus of interest. Using this approach, we predict that specific inflammasome genes will be shown to be regulated at least in part by cis-acting genetic elements. We show that similar genotypes were expressed differently. Out of 20 human healthy volunteers 4 heterozygotes exhibit monoallelic expression of Pyrin at the exon 2 SNPID rs224225. This we found to be due in part to promoter DNA hypermethylation. This genomic region is known to be excised from full length transcript during or following gene transcription. Those monoalleleic expressions that are not found to be due to promoter region DNA hypermethylation, extracellular stimulus such as LPS is able to restore the heterozygous state. We demonstrate for the first time the multiple interacting affects of genetic, epigenetic and exogenous factors on a biological process such as Inflammasome Complex activity. This finding has profound implications for interpretation of genetic linkage and association studies.

765F

sFRP1 and sFRP2 epigenetic association with osteoblastic differentiation of mesenchymal stem cells. *M. Mahmoodinia Maymand[1], M. Norouzinia[2,3], S. Rezaei[1], M. Farshdousti Hagh[3].* 1) Stem cell Dept, Sarem Cell Research Center, Tehran, Ekbatan, Iran; 2) Department of Medical Genetics, Tarbiat Modaress University, Tehran, Iran; 3) Department of Hematology, Tarbiat Modaress University, Tehran, Iran.

Mesenchymal stem cells (MSCs) have an extensive potential to proliferate and differentiate into osteoblasts. Wnt/) -catenin signaling pathway play key role in osteogenesis. Wnt inhibitors on the other hand can result in osteoporosis. The role of gene expression regulation of Wnt signaling in osteoblast differentiation has been shown in several studies. However, the exact mechanism of this regulation remains to be cleared in this study we sought to investigate the role of epigenetic regulation at the DNA level in promoter regions of sFRP1 and sFRP2 during osteoblastic differentiation of mesenchymal stem cells. Expression pattern of these genes has also been studied in relation to methylation changes. MSC from bone marrow was isolated, expanded and characterized in vitro by flowcytometry, differentiation potential and culture characteristics. Osteoblastic differentiation factors such as Dexamethasone and ascorbic acid were used to induce differentiation. Osteoblastic markers such as ALP and osteocalcin as well as Alizarin red immunostaining showed the success of differentiation. sFRP1 and sFRP2 promoter methylation status was determined using Methylation Specific PCR in multipotent state and during different stage of osteoblastic differentiation. We show that sFRP1 and sFRP2 promoters are totally unmethylated in MSC. Methylation pattern during osteoblastic differentiation shown no de novo methylation. RT-PCR confirms the result of MSP on sFRP1 and sFRP2. It has been shown that Canonical Wnts and BMPs cooperatively induce osteoblastic differentiation through a GSK3) -dependent and) -catenin-independent mechanism. Mesenchymal stem cells seem to be mainly unmethylated in the indifferentiated state. However we have shown before that some genes like as ROR2 are epigenetically methylated at DNA level during the differentiation. In tis research show that sFRP1 and sFRP2 are expressed and its expression maintained through osteoblastic differentiation through mechanisms other than methylation of DNA. Histone modifications and transcription factor based regulation of gene expression seem to be good candidates for further research.

Regulation of chromatin structure on human subtelomeres during cellular senescence. *P.E. Thijssen[1,2], P.E. Slagboom[2], B.T. Heijmans[2], S.M. van der Maarel[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Department of Molecular Epidemiology, Leiden University Medical Center, Leiden, Netherlands.

Telomeres erode due to successive rounds of DNA replication in cycling cells and stochastic damage of oxygen radicals. *In vivo* telomere lengths roughly correlate with donor age, but show high inter- and intra-individual variability. *In vitro*, progressive telomere loss is one of the triggers of the tumor suppressive mechanism of cellular senescence. More recently it has been reported that the chromatin structure of telomeres and the adjacent subtelomeres changes with telomere length reduction. Fifth generation $Terc^{-/-}$ mice show dramatic telomere loss, a reduction in heterochromatin markers H3K9me3, H4K20me3 and CpG methylation, and an increase in acetylation of lysine residues. The effect of telomere dynamics on subtelomeric chromatin make-up in human cells is less well understood. Subtelomeric chromatin changes can have phenotypic consequences as implicated by the loss of compaction leading to improper expression of a subtelomeric retrogene in the progressive muscular dystrophy FSHD. To gain more insight in the interplay between telomere shortening, cellular senescence and subtelomere chromatin structure, we set out to map chromatin changes on two subtelomeres in senescing WI-38 human primary fibroblasts. Using ChIP followed by Q-PCR, we systematically interrogated the chromatin make-up at 7qter and 11qter up to 250 kb proximal from the telomere. On both subtelomeres and telomeres we observe a ± 2 fold decrease in the heterochromatin marker H3K9me3, concurrent with a 2-3 fold increase in the transcriptional regulator H3K27me3. H4K16ac, implicated in yeast telomere biology and chromatin higher order compaction, shows a steep decrease with cellular senescence. In the studied 250 kb window we did not observe a clear effect of distance to the telomere on the chromatin changes. In addition, we did not observe uncontrolled spreading of the shelterin component TRF2 onto the subtelomere. In summary, the subtelomeres of chromosome 7q and 11q show relative opening by a loss of H3K9me3, possibly compensated by a gain in transcriptional repressor H3K27me3 and a decrease in H4K16ac. We are currently interrogating the expression of transcripts from the region studied, including TERRA transcripts emanating from 7q and 11q.

PARP-1 and SATB-1 bind to the TT>A SLE associated regulatory downstream of TNFAIP3. *F. Wen[1], M. Kinter[2], J.M. Guthridge[1], P.M. Gaffney[1].* 1) Arthritis and Clinical Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Free Radical Biology and Aging, Oklahoma Medical Research Foundation, Oklahoma City, OK.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by dysregulated interferon responses and loss of tolerance of self-antigens resulting in systemic inflammation and organ failure. The tumor necrosis factor alpha inducible protein 3 (TNFAIP3) gene encodes the ubiquitin-modifying enzyme A20, which negatively regulates NF-2B activity. We recently described a functional TT>A polymorphic dinucleotide, 42kb downstream of the TNFAIP3 promoter, as a prime candidate causal polymophism responsible for association with SLE in subjects of European and Korean ancestry that demonstrates reduced affinity for a nuclear protein complex that includes NF-2B. In order to further characterize this nuclear protein complex we affinity purified proteins from LPS stimulated THP-1 cells using oligonucleotide probes specific for the wild type (TT) or polymorphic (A) sequence followed by mass spectrometry. Two primary proteins poly (ADP-ribose) polymerase 1 (PARP-1) and special AT-rich sequence binding protein 1 (SATB-1) were isolated. The identities of these proteins were confirmed by Western blotting in independent experiments. PARP-1 functions in DNA replication and chromatin remodeling, and also facilitates diverse inflammatory responses by promoting pro-inflammatory gene expression. SATB1 functions in tethering chromatin to the nuclear membranes at matrix attachment regions thus facilitating long-range regulation of gene transcription. These results suggest that the TT>A polymorphism may predispose to SLE through the recruitment of chromatin modifying proteins that modulate long-range transcriptional regulation of A20.

768F

Can repetitive element methylation be used as a surrogate measure of gene promoter-region methylation? *E.M. Price[1,2], M.S. Penaherrera[2], D.E. McFadden[2,3], M.S. Kobor[2], W.P. Robinaon[2].* 1) Obstetrics and Gynaecology, University of British Columbia, Vancouver, British Columbia, Canada; 2) Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 3) Pathology, University of British Columbia, Vancouver, British Columbia, Canada.

Two repetitive elements (REs) - LINE1 (L1) and Alu make up close to 50% of the human genome and are hypothesized to modulate gene expression and genomic evolution in beneficial, neutral and detrimental ways. Hundreds of thousands of REs are present throughout the human genome and generally maintain a stable level of methylation through life, which is thought to prevent their transposition. Recently, studies of human disease and environmental exposure have capitalized on these characteristics and used methylation of L1 and/or Alu elements as surrogate measures for global DNA methylation. However, there has been little evidence to support this claim and no investigation for whether it holds true across different tissues. We assessed L1 and Alu DNA methylation by bisulfite pyrosequencing as indirect measures of global DNA methylation and compared them to an average methylation of promoter regions across the genome as assayed by the Illumina Infinium HumanMethylation27 BeadChip array (measuring 27,578 CpGs in 14,475 genes). These measures were evaluated in villi from 41 control placentae (20 1st trimester; 11 2nd trimester; and 10 3rd trimester) in addition to organ tissues from 11 control 2nd trimester fetuses (11 brain, 11 kidney, 10 muscle samples) and 10 adult female control blood samples. Statistical analyses of associations were carried out using Spearman rank-order correlation and Mann-Whitney tests. L1s in 1st, 2nd and 3rd trimester placenta were significantly less methylated than in all other tissue types ($p<0.001$). There was a trend for increased average gene promoter methylation with gestational age, while L1 methylation remained stable. Illumina average DNA methylation was correlated with L1 methylation ($R_s=0.51$, $p<0.001$) but not Alu in highly methylated tissues (fetal organ and female blood samples) but not moderately methylated tissues (placental samples). Specifically, there was a strong correlation between L1 and Illumina average methylation in 2nd trimester placenta ($R_s=0.77$, $p<0.01$) and brain tissue ($R_s=0.76$, $p<0.01$). Thus, L1 methylation may be a better reflection of methylation at gene promoters across the genome. However, we caution that even though L1 methylation is correlated with Illumina DNA methylation in some of our study groups, each of L1, Alu and Illumina DNA methylation is a different and distinct measure of genomic methylation. Thus, all three may be influenced by environmental factors in different or complementary ways.

Skewing of X-chromosome inactivation in tissues: is HUMARA assay in blood a reliable proxy? *M. Hrebicek, J. Minks, J. Sikora, D. Musalkova, R. Dobrovolny, E. Richterova.* Inst Inherited Metabolic Disor, Charles Univ, Prague 2, Czech Republic.

X-inactivation, the mechanism by which females compensate double dosage of X-linked genes, leads to transcriptional silencing of one X chromosome in each somatic cell. In some females, one of the X chromosomes is preferentially inactivated. Such a "skewing" of X-inactivation, routinely measured in peripheral blood leukocytes by HUMARA assay, may be associated with adverse phenotypes and therefore serves as a useful diagnostic parameter. To expand the limited literature, we have tested the fidelity with which HUMARA assay in blood captures skewing in different tissues as well as allelic expression ratios of X-linked genes. Skewing of X-inactivation in whole blood and 20 other tissues in five elderly females revealed that mean standard deviation of X-chromosome inactivation ratios among the assayed tissues was 8.2 percent. Of note, as much as 16 percent variation was observed between pairs of specimens collected from the same tissue. Segregation of skewing of XCI ratios with the germ layer from which the tissues were derived was not observed as mean standard deviation (S.D.) of skewing of XCI ratio among all tissues (8.0) was comparable to the mean S.D. calculated within tissues originating from ectoderm (8.3), mesoderm (7.7) and entoderm (5.1). We further probed allelic expression ratios of 10 X-linked genes in 63 females in blood. In 94.6 percent of samples, the results differed from the HUMARA-based results by <20 percent. While the departure of an individual gene or tissue from skewing measured by HUMARA assay in blood can be substantial and cannot be excluded unless probed in situ, this assay usually provides a fair estimate of the inactivation of other genes in other tissues. We conclude from our data that HUMARA assay in blood, often the only feasible approach for testing X-inactivation skewing, is a useful surrogate for skewing of X-inactivation in tissues. Research was supported by Internal grant Agency of Ministry of Health, Czech Republic grant NR 8361-3 and received also institutional support from VZ MŠM CR 0021620806.

770F

The Role of Cohesin in Imprinting and Escape from X-inactivation. *J. Kalish[1], S. Lin[2], M. Bartolomei[2].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA.

Cohesin genes are associated with human disease. Specifically, mutations in cohesin subunits and related proteins (SMC1A, SMC3, and NIPBL) are seen in patients with Cornelia de Lange Syndrome (CdLS). The pathogenesis of CdLS does not appear to be related to sister chromatid cohesion and chromosome segregation, but is likely due to the role of cohesin in gene regulation. Cohesin co-localizes with CTCF and other factors and may help mediate transcriptional regulation at several imprinted loci. CTCF has been shown to bind at the boundaries of several genes that escape X-inactivation, acting as a chromatin insulator. Liu et al demonstrated increased cohesin binding on the X chromosome at hypomethlyated regions compared to autosomes in normal patients but in CdLS patients less cohesin is present at hypomethylated regions on the X chromosome. This suggests a role for cohesin in gene regulation specifically on the X chromosome. Renault et al reported linkage of SA2, a cohesin component located on the X chromosome, with familial skewing of X-inactivation, suggesting a role for cohesin in X-inactivation choice. We have shown that RNAi targeting of CTCF and cohesin leads to elevated mRNA expression of imprinted genes while maintaining imprinted expression, suggesting a non-allelic role for CTCF and cohesin in imprinting. We are currently using siRNA knockdown of CTCF and cohesin to test the hypothesis that these genes have a role in gene escape from X-inactivation.

771F

Elucidating the role of noncoding RNAs in initiation of mouse imprinted X chromosome inactivation. *E. Maclary, M. Hinten, M. Freedman, M. Pedraza, E. Buttigieg, C. Harris, S. Purushothaman, S. Kalantry.* Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

In XX female mammals, genes along one of the two X-chromosomes are transcriptionally silenced in order to equalize the dosage of X-linked genes to that expressed in XY males in a process known as X-chromosome inactivation. Classically, initiation of X-inactivation in the mouse model system is thought to be controlled in cis by two noncoding RNAs: Xist and Tsix. Xist is expressed only from the inactive-X, and is proposed to trigger epigenetic silencing by recruiting protein complexes that alter chromatin structure. The antisense partner of Xist, Tsix, is exclusively expressed from the active-X, and is thought to forestall inactivation of the active-X by inhibiting Xist transription. We have recently shown, however, that the initiation of imprinted mouse X-chromosome inactivation, a process during which the paternally-derived X-chromosome is preferentially inactivated, is not globally disrupted in the absence of Xist. Analysis of X-linked gene expression in early mouse embryos lacking Xist on the paternally-derived X-chromosome show that these embryos still initiate silencing of paternal X-linked genes. This Xist-independent silencing calls into question the cascade of epigenetic events that characterize the two Xs, including the role of Tsix. We therefore set out to test if Tsix expression is also dispensable during the initiation phase of imprinted mouse XCI. Preliminary results, employing RNA fluorescence in situ hybridization and allele-specific RT-PCR, suggest that Tsix is not required to prevent inactivation of the maternally-derived X-chromosome during the initiation phase of imprinted X chromosome inactivation. Our data therefore argue that alternate mechanisms, including novel X-linked noncoding transcripts, regulate the initiation of imprinted mouse X chromosome inactivation. To discover novel noncoding X-linked transcripts that are candidates to trigger or prevent imprinted X-inactivation, we plan to use RNA-seq technology.

772F

Assessing patterns of placental development using X-chromosome inactivation (XCI) and gene methylation profiling. *M.S. Peñaherrera, L. Avila, R. Jiang, R.K.C. Yuen, C.J. Brown, W.P. Robinson.* Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada.

A considerable degree of within-placenta variability in DNA methylation level has been reported for a number of loci. X-chromosome inactivation (XCI) skewing has also shown considerable site-to-site variability within a placenta. In an attempt to understand the three dimensional growth and development of the placenta, we utilized chorionic villi samples collected from a set of 4 control placentas for which 3-7 sites divided into 4 different placental depths were collected. First, we assessed XCI skewing using the assay for the Human Androgen Receptor gene (HUMARA). We found a significant degree of variability for XCI skewing between sites within each placenta; however, there was a high degree of correlation of skewing values for samples obtained from the same site but spanning the different placental depths (fetal to maternal side of the placenta). This demonstrates that placental development is highly clonal by depth and that cells within a villous tree are likely derived from a small number of precursors. To determine if methylation patterns associated with other genes/regions would also show a greater degree of between-site than within-site differences, we studied methylation at genes/regions previously found to show variable methylation within a placenta including: *H19/IGF2* ICR1; the promoters of *KISS1*, *CASP8*, *PTPN6*, and *APC*; and indicators of global genome methylation such as LINE-1 elements. Methylation at these sites was quantified using pyrosequencing. ANOVA analysis of the methylation results showed that both LINE-1 and *APC* have greater between-than within-site variation, while *PTPN6* and *H19/IGF2* ICR1 show no effect of site or depth on methylation. The promoter methylation of some genes such as *KISS1* and *CASP8* shows significant between-site differences in some, but not all, placentas. Methylation levels that vary to a greater degree between sites but are highly correlated at different placental depths of the same site may reflect that, to some degree, methylation in those genes/regions is stably maintained during the growth phase of the placental villous trees. On the other hand, for genes/regions that do not follow this pattern, such as *H19/IGF2* ICR1, it is possible that methylation is modified post-differentiation or is perhaps more subject to variation through environmental influences.

773F

A conserved role of (-adducin (ADD-1) in memory, synaptic plasticity, and in AMPA-type glutamate receptor dynamics. *V. Vukojevic D.[1], L. Gschwind[2], C. Vogler[1], P. Demougin[1], D.J.-F. de Quervain[2], A. Papassotiropoulos[1], A. Stetak[1].* 1) Molecular Neurosciences, Biozentrum/University of Basel, Basel, Switzerland; 2) Cognitive Neurosciences, Faculty of Psychology/University of Basel, Basel, Switzerland.

Identifying the molecular mechanisms that underlie learning and memory are one of the major challenges in neuroscience. Taken the advantages of the nematode C. elegans, here we investigated the role of (-adducin (add-1) in associative learning and memory. We found that loss of add-1 selectively impairs short- and long-term memory. Furthermore, (-adducin is required in vivo for long-term consolidation of synaptic plasticity, and sustained increase of AMPA-type glutamate receptor (GLR-1) content in the synapses but also plays an important role in long lasting changes of GLR-1 turnover dynamics. The role of ADD-1 is splice-form and tissue specific and it controls the storage of memories likely through capping of the fast growing barbed end of actin. In addition to C. elegans, genetic variability of the human ADD1 gene was significantly associated with episodic memory performance. Taken together, our findings support a common molecular role for (-adducin in memory from nematodes to humans and may provide a powerful clinical approach for the treatment of memory related diseases.

Expression of Claudin-3 on Perineurial fibroblasts of Sporadic Neurofibroma. *M.H. Sulaiman[1], A. Dodson[2], C.A Kudi[1], J.O Hambolu[1], S.A Ojo[1].* 1) Vet Anatomy, Ahmadu Bello University, Zaria, Nigeria; 2) School of Cancer studies, Division of Surgery and Oncology, University of Liverpool.

INTRODUCTION; Neurofibromatosis type 1 (NF1) is one of the common autosomal disorders in human with an estimated birth incidence of 1/3500 people worldwide. Schwann cells are reported to constitute the major cell type (40-80%) in neurofibromas because they exhibited biallelic mutation of the NF1 gene. Its protein product, neurofibromin negatively regulate Ras. Therefore, in Schwann cells loss of function of neurofibromin may promote cell proliferation. In peripheral nerves, Schwann cell-axon relationship is thought to be isolated from the adjacent tissues by the perineurium, which creates a diffusion barrier formed by the tight junction. Tight junctions (TJ) are specialized cell-cell point of adhesion at the apical region of epithelial and endothelial cells. These junctions create a barrier that regulate paracellular transport of solutes (barrier function) between cells and also restrict lateral diffusion (fence function) of molecules so as to maintain cell polarity. Tight junction proteins have been suggested to constitute an essential part of this barrier in perineurial and endothelial cells. AIM OF THE STUDY; This study was undertaken in to demonstrate the functional integrity of the perineurial fibroblasts tight junction in sporadic neurofibromas using rabbit anti claudin-3 polyclonal antibody. METHODS; Prior informed patient consent was obtained, and the study has and ethical approval (06/1505/137) that was granted by the Liverpool Research Ethics Committee. Standard immunohistochemistry method was used. Briefly, routine histological procedures(haematoxylin and eosin staining) was first carried out followed by staining using cell markers and tight junctions antibody staining using commercially prepared antibodies (Claudin-3) on experimental and control tissues. RESULTS; The sporadic benign neurofibromas exhibited an immunolabelling pattern with anti-claudin-3 that was intensely positive for membranous staining of perineurial fibroblasts as was recorded for the normal peripheral nerve. Additionally, nuclei staining were observed in Schwann cells of the sporadic neurofibromas. CONCLUSION; We suggests that the perineurial fibroblast tight junctions in sporadic neurofibroma is not disrupted and may be intact due to full compliments (lack of haplo) of the NF-1 gene in sporadic neurofibroma.

Expression of PPARbeta, C/EBPalpha and C/EBPbeta in Psoriasis. *S. Emre[1], N. Unver[1], F. Sarikaya[1], G. Erkin[2], A. Karaduman[2].* 1) Medical Biology, Faculty of Medicine, Ankara, Ankara, Turkey; 2) Department of Dermatology, Faculty of Medicine, Hacettepe University, Ankara-TURKEY.

Psoriasis is a disorder with genetic and immunologic background. Abnormal epidermal proliferation and differentiation characterize the inflammatory skin disease psoriasis. The important roles of PPAR) and C/EBPs transcription factors in regulating overlapping pathways in keratinocyte strongly suggest that both families of transcription factors closely interact to regulate the differentiation program of the skin. This work examined the expression of PPAR) in lesional and nonlesional psoriatic skin compared to normal skin by immunohistochemical analyses . It also aimed to investigate whether the expression of PPAR) and C/EBPs were altered in lesional and nonlesional psoriatic skin compared to normal skin by using quantitative real time RT-PCR methods. Our results analyzed that PPAR) are strongly expressed in interfollicular epidermis. In particular, PPAR) is localized to nuclei throughout the entire subrabasal part of lesional psoriatic skin. The results also showed that the expression of hyperproliferation marker Keratin 6A and late keratinocyte differentiation marker Involucrin are upregulated in psoriatic skin. Next, it demonstrated the expression of PPAR) is significantly upregulated in hyperproliferative lesional skin from psoriasis patients. It also showed that the expression of C/EBP(and C/EBP) are decreased in lesional psoriatic skin. This study reveals the importance of the regulatory interplay among PPAR) , C/EBPs in the control of proliferation and differentiation in keratinocyte cell during psoriasis pathogenesis. .

Tissue Inhibitor of Metalloproteinases-4 gene expression is enhanced in human osteoarthritic synovial membranes and is upregulated by TGF-) in Chondrocytes. *M. Zafarullah[1, 2], W. Huang[1], M. El Mabrouk[1], J. Sylvester[1], F. Dehnade[2].* 1) Medicine, University of Montreal, Montreal, Quebec, Canada; 2) CHUM Notre-Dame Hospital, Montreal, Quebec, Canada.

INTRODUCTION: Tissue inhibitors of metalloproteinases (TIMPs) inhibit matrix metalloproteinases (MMPs) implicated in arthritic cartilage destruction. TIMPs also have anti-angiogenic, growth-promoting and proapoptotic activities in diverse systems. TIMP-4 gene therapy diminishes experimental arthritis and periodontitis in rats. TIMP-4 gene polymorphism is associated with osteoarthritis in Korean population. We studied the previously unknown status of TIMP-4 gene expression in human joint tissues and its regulation by arthritis-associated cytokines. METHODS: RNA from human knee synovial membranes and synovial fibroblasts or chondrocytes was extracted by homogenization in guanidinium isothiocyanate solution. TIMP-4 mRNA expression was measured by semi-quantitative RT-PCR analysis in comparison with glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA. TIMP-4 protein levels from cytokine-treated chondrocytes were measured by western blotting. Chondrocytes were also treated with extracellular signal-regulated kinase (ERK) pathway inhibitor, U0126 or Sp1 inhibitor, mithramycin alone or with transforming growth factor beta (TGF-) 1). Total cellular proteins (20 μg/lane) were separated by SDS-PAGE and Western blots reacted with rabbit Anti-carboxy terminus human TIMP-4 polyclonal antibody (Chemicon AB816) that detects a ~29-kDa band, which co-migrates with the purified human TIMP-4 protein. RESULTS: TIMP-4 RNA expression originating from synovial fibroblasts was significantly (2.4 fold; $p<0.001$) elevated in 8 osteoarthritic (OA) versus 7 non-arthritic synovial membranes. Non-arthritic and OA femoral head and knee chondrocytes displayed substantial but variably constitutive expression of the TIMP-4 mRNA. In articular chondrocytes, TGF-) 1, oncostatin M (OSM) and interleukin 17 (IL-17) upregulated TIMP-4 RNA or protein expression while interleukin-1 beta (IL-1)) and tumor necrosis factor alpha (TNF-( ) did not, suggesting differential regulation by arthritis-associated cytokines. TGF-) 1 induction of TIMP-4 expression was inhibited by U0126 and mithramycin. CONCLUSIONS: Increased TIMP-4 gene expression in OA synovial membranes and cartilage may be due to induction by TGF-) 1, OSM and IL-17 suggesting its pathophysiological role in tissue remodeling in human joints. TGF-) 1 induction of TIMP-4 expression is mediated partly by ERK signalling pathway and Sp1 transcription factor.

777F

Molecular characterization of phenotypes associated with PEX7 deficiency: Rhizomelic Chondrodysplasia Punctata type 1 (RCDP1) and adult Refsum disease (ARD). *S. Jiralerspong[1], G. Nimmo[1], A. Moser[2], S. Steinberg[2], N. Braverman[1].* 1) Dept. of Human Genetics, McGill University-Montreal Childrens Hospital Research Institute, Montreal, Quebec, Canada; 2) Dept. of Neurogenetics and Neurology, Kennedy Krieger Institute, Johns Hopkins Med. Ctr., Baltimore, Maryland, USA.

RCDP1 is a peroxisome biogenesis disorder caused by defects in PEX7, the peroxisome receptor for PTS2 targeted matrix proteins: thiolase, phytanoyl-CoA hydroxylase (PhyH) and alkylglycerone-phosphate synthase (AGPS). We previously reported severe, intermediate and mild phenotype groups based on residual tissue plasmalogens and reflecting amounts of AGPS imported into the peroxisome. In the mild group, plasmalogens are near normal and the phenotype resembles ARD, due to deficient PhyH import. Here we evaluated intraperoxisomal amounts of AGPS, PhyH, thiolase and PEX7 proteins by immunoblotting in 24 PEX7 deficient fibroblast lines, representing all 3 phenotype groups. We show that 30-60% of AGPS is correctly targeted inside the peroxisome in the mild patient group, was absent in the severe group, but also appeared absent in the intermediate group. We propose that AGPS import in the intermediate group accounts for residual plasmalogen levels observed in patients, but may be below the sensitivity of western analysis. For PhyH, 10-20% is imported into the peroxisome in both mild and intermediate groups, but negligible in the severe group. Thiolase import was undetectable in nearly all severe patients, but showed a high level of variability (0-75%) in our set of intermediate and mild patients, indicating additional, unknown factors that influence thiolase import. We found reduced amounts of PEX7 protein generated by the majority of alleles in each group. The highest recovery of AGPS and PhyH import occurred in an ARD patient, shown to express residual amounts of wild type PEX7 transcript from a `leaky' splice site mutation. Treatment with trimethylamine chemical chaperones to encourage conformational correction of PEX7 missense proteins failed to increase PTS2 protein import. Filipin staining showed accumulation of perinuclear cholesterol in patient fibroblasts with absent AGPS import, an increase not observed in fibroblasts from our PEX7 hypomorphic mice with 30% residual AGPS import, even after loading with LDL. We conclude that certain PEX7 missense alleles, as well as residual amounts of wild type PEX7, can rescue the RCDP phenotype by restoring sufficient (⁄ 30%) AGPS import. These same PEX7 alleles, although associated with some PhyH import, cannot prevent the development of ARD over time.

***RET* mutational spectrum in Hirschsprung's disease: evaluation of 601 Chinese patients.** *S.S. Cherny[1], M.M. Garcia-Barceló[2], T.Y.Y. Leon[2], M.T. So[2], P.C. Sham[1], P.K.H. Tam[2].* 1) Psychiatry, Univ Hong Kong, 21 Sassoon Road, Hong Kong; 2) Surgery, Univ Hong Kong, 21 Sassoon Road, Hong Kong.

Hirschsprung's disease (HSCR) is a developmental disorder characterized by the absence of ganglion cells in the lower digestive tract. Aganglionosis is attributed to a disorder of the enteric nervous system (ENS) whereby ganglion cells fail to innervate the lower gastrointestinal tract during embryonic development. There is significant population variation in the incidence of the disease, and it is most often found among Asians (2.8 per 10,000 live births). HSCR most commonly presents sporadically (80% of the cases), with a recurrence risk of 4%, and more males than females affected (4:1). Both rare (<1% in the population) and common germ line variants of the RET gene, acting either alone or in combination, are the main cause of the disease. Yet, while *RET* common variants are strongly associated with the commonest manifestation of the disease (male, short segment, and sporadic forms), rare coding sequence (CDS) variants are more frequently found in the lesser common and more severe forms of the disease (females, long or total colonic aganglionosis, and familial). Here we present a rare variant (RV) screening of the CDS and intron/exon boundaries of the *RET* gene in 607 Chinese sporadic HSCR patients, the largest number of patients ever reported. We have found a total of 61 different heterozygous RVs (50 novel) distributed in 100 patients (16.64%). These include 14 silent, 29 missense, 5 nonsense amino-acid changes, 4 frame-shifts, and one in-frame amino-acid deletion in the exonic region and two splice-site deletions, 4 nucleotide substitutions and a 22 bp deletion in intronic or untranslated regions. The exonic variants were mainly clustered in the sequence encoding the extracellular domain of the RET protein. All RVs were predicted to alter the protein function. The highest frequency of rare variants was found among those patients with the most severe form of the disease (24% in long or total vs 15% in short-segment). Phasing of the RVs with the *RET* risk-haplotype suggested that *RET* RVs do not underlie the undisputable association of RET common variants with HSCR. None of the variants was found in 250 Chinese controls.

Looping Interactions and Noncoding Transcription Support Complexity of Distant *Bmp2* Enhancers in Bone. *E.M. Broeckelmann[1], S. Pregizer[1], G.E. Crawford[2], D.P. Mortlock[1].* 1) Vanderbilt University, Nashville, TN; 2) Duke University Medical Center, Durham, NC.

Bmp2 is a member of the TGF-) superfamily of secreted signaling molecules that not only plays a critical role in pattern formation and morphogenesis during embryonic development, but also promotes osteoblast differentiation and bone formation throughout life, thus making it a vital factor in the maintenance of bone health. Association studies have implicated *Bmp2* polymorphisms in the pathogenesis of osteoporosis and osteoarthritis, and BMP2 is indispensable for the initiation of fracture repair, which is illustrated by the fact that *Bmp2* conditional knockout mice have significantly reduced bone mass and exhibit spontaneous fractures that are unable to heal. Previously, our transgenic analyses in mice have shown that *Bmp2* gene expression is controlled by numerous distant cis-regulatory elements in a tissue- and time- specific manner and further identified a 656bp evolutionarily conserved element (ECR1) 156kb downstream of the promoter, which specifically functions as *Bmp2* enhancer in osteoblasts. However, while ECR1 drives robust transgene expression in most endochondral bones, it exhibits remarkable anatomical specificity in that it is inactive in cranial intramembranous bones, suggesting the existence of (an) additional osteoblast enhancer(s). In order to further examine the specific role of ECR1 *in vivo*, we deleted ECR1 from a *Bmp2*-containing BAC transgene. Transient transgenic analysis in mouse embryos shows that ECR1 enhancer activity is essential for transgene expression in all bones, although in isolation it is only sufficient to drive expression in a limited subset of osteoblasts. Additional evidence suggesting an active role for multiple enhancers in the regulation of osteoblast-specific *Bmp2* expression was obtained in Chromosome Conformation Capture (3C) assays in MN7 cells (a murine osteoblast cell line), which reveal looping interactions of the *Bmp2* promoter with not only the ECR1 locus, but also with a new candidate locus ~120kb upstream of *Bmp2*. This corresponds to the location of a long noncoding RNA that could also be shown to be expressed in MN7 cells. Lastly, DNase hypersensitivity data from human osteoblasts have been mapped onto the murine *Bmp2* locus and serve as an independent tool to identify additional candidate enhancer loci, some of which overlap with previously identified regions of interest.

A novel functional, regulatory PPAR. polymorphism. *M. Claussnitzer, V. Glunk, H. Hauner, H. Laumen.* Else Kröner-Fresenius-Centre for Nutritional Medicine, Technical University Muenchen, Freising, Germany.

Introduction: Obesity and type 2 diabetes result from a complex interaction of environmental factors acting on a susceptible genetic background. The PPAR. 2 variant Pro12Ala has been reproducibly associated with improved insulin sensitivity and BMI variability, although the Ala12 allele results in reduced PPAR. 2 transcriptional activity. This might be explained by a counteracting regulatory SNP in strong linkage disequilibrium (LD) to the PPAR. tagSNP. **Methods:** 13 HapMap SNPs in LD (r^2 = 0.8) with the PPAR. Pro12Ala tagSNP were bioinformatically analyzed by Genomatix software. Using luciferase assay and electrophoretic mobility shift assay (EMSA) the transcriptional regulatory function of the SNP was assessed. PPAR. mRNA levels were analyzed in homozygous EBV-LCL cells by RT-PCR. **Results:** Based on a bioinformatic approach the SNP rs4684847(C>T) was selected for functional characterization. This polymorphism is located 6 kb upstream of the PPAR. 2 promoter in perfect LD to the Pro12Ala variant. The minor T allele drove a significantly higher relative luciferase expression compared to the major allele in 3T3-L1 adipocytes and C2C12 myocytes. EMSA experiments revealed an allele-specific DNA-protein binding. Specificity of this complex was confirmed by competition experiments. Allele- and isoform-specific regulation of endogenous mRNA expression in homozygous EBV-LCL cells was exclusively evident for PPAR. 2, but not for PPAR. 1. **Conclusion:** The contradictory finding that the Ala12 allele results in reduced transactivation capacity though it is associated with increased insulin sensitivity and altered BMI might be partially explained by this cis-regulatory polymorphism.

Time Course for Production of the Putative Inducer of MYOC Transcription (IMT) Protein. *C. Marrs[1], K. Scott[1], F. Rozsa[1], M.I. Othman[1], J.E. Richards[1,2], H. Pawar[1].* 1) Ophthalmology & Visual Sciences, Kellogg Eye Center, University of Michigan, Ann Arbor, MI; 2) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI.

Purpose: Induction of myocilin (MYOC) transcript and protein is known to occur in human trabecular meshwork (TM) cells in response to long term dexamethasone (DEX) treatment, and excess MYOC protein is seen in TM in about 50 percent of primary open-angle glaucoma (POAG) cases (Lutjen-Drecoll et al. IOVS 1998;39:517). This raises important questions about the role of increased MYOC in POAG, one of the leading causes of blindness worldwide, and the circumstances under which MYOC can be induced. It has previously been shown by Shepard and colleagues (IOVS 2001;42:3173) that the use of cycloheximide to block protein translation results in failure to induce increased transcription of the MYOC gene by DEX treatment in TM cells. This implies the existence of an intermediate protein, which we refer to as Inducer of MYOC Transcription (IMT), that is necessary for induction of increased MYOC transcript. The goal of this project was to identify the time period during which the putative IMT protein is synthesized. Methods: Primary culture human TM cells were grown to 75 percent confluence and induced with DEX as previously reported (Rozsa et al. Mol Vis 2006;12:125). Cells from DEX treated and untreated wells were harvested at 0, 0.1, 2, 6, 10, 12, 18, 24, and 48 h time points. Total RNA was extracted using the Trizol® Reagent, quantified using Nanodrop spectrophotometer, reverse transcribed, and then the MYOC transcript was quantified by TaqMan® assay. Results: Using MYOC expression normalized to a beta-actin control, we observed that DEX treatment of primary culture TM cells led to a slight, brief drop in MYOC transcription at 0.1 h, followed by a return to baseline level up until about 10 h. MYOC gene transcription first showed signs of induction by a 1.6-fold at 12 h, followed by continued increases of ~3.4-fold by 18 h, ~ 4.8-fold by 24 h, and ~8.6-fold at 48 h. Conclusion: Even though elevation of intraocular pressure in response to DEX takes weeks to manifest, we find that induction of transcription begins between 10 h and 12 h of exposure to DEX. This implies that the putative IMT protein required for DEX induction of MYOC must be expressed within that first 12 h period.

Identification of a sciatic-nerve specific enhancer regulating expression of the PMP22 gene. *P. Patel[1], S. Choi[1], D. Hawkins[2], B. Ren[3].* 1) Inst Gen Med, Univ Southern California, Los Angeles, CA; 2) Dept. of Medicine/Medical Genetics, University of Washington, Seattle, WA; 3) Ludwig Institute for Cancer Research, Univ of California, San Diego, CA.

Charcot-Marie-Tooth is the most common inherited peripheral neuropathy in humans with an estimated prevalence of 1 in 2,500. Defects in at least 39 genes lead to CMT. CMT1A is characterized by slowly progressive distal muscle atrophy and weakness, absent deep tendon reflexes, and deformity of the feet. A 1.5Mb duplication including the peripheral myelin protein gene (PMP22) underlies CMT type 1A (CMT1A) in >70% of CMT patients making it the most frequent sub-type. Animal models over-expressing PMP22 recapitulate the disease. Thus, reducing expression of PMP22 could be a therapeutic strategy for CMT1A. We have therefore, sought to dissect the regulation of the gene as a first step towards discovering small molecules that may be useful in modulating expression of the gene in CMT1A patients. Chromatin immunoprecipitaion (ChIP) is a powerful method to identify binding sites on genomic DNA for proteins such as transcription factors, or to assess modifications of genome structure by histone-binding in a region of the genome, which is now known to influence gene transcription epigenetically. DNA regions bound by histone 3 methylated at lysine 4 (H3K4me1) and acetylated at lysine 27 (H3K27ac) are regarded as putative enhancer elements. We therefore, conducted ChIP analysis of an ~200kb region encompassing the PMP22 gene using chromatin purified from rat sciatic nerve to identify putative enhancers. The immunoprecipitated chromatin was hybridized to a custom NimbleGen 385K chip array on which 87 rat genes, 10 mouse genes, and 9 human genes related to myelination and their flanking sequences were tiled. The input DNA was labeled with Cy-3 and the test DNA was labeled with Cy-5 and after hybridization, the respective signals obtained by scanning and analyzed using NimbleScan. Fourteen regions were identified as candidate enhancer elements and along with two negative control regions from other regions of the genome. These regions were cloned into a luciferase reporter vector, pGL3-basic and pGL3-TK (herpes virus thymidine kinase promoter) and evaluated for expression in a rat Schwann cell line, S16 to determine if they can enhance luciferase expression. These studies have identified an enhancer element within the first intron of the gene that is currently being characterized. These results will be presented.

Abnormal quantitative Real-Time PCR (qPCR) Quantification in *TSC1/TSC2* genes: Results in a Cohort of Patients with Tuberous Sclerosis. *N. Lannoy[1], JF. Durant[2], I. Abinet[1], T. Corbisier[1], A. Jansen[3], K. Pelc[4], MC. Nassogne[5], K. Keymolen[6], JL. Gala[2], B. Delle Chiaie[7], S. Gaillez[8], Ch. Verellen[1], Y. Sznajer[1], N. Lannoy is supported by a grant from "Michelle stichting, scientific foundation.* 1) Centre de Génétique Humaine, Cliniques Universitaires Saint-Luc U.C.L, Brussels, Belgium; 2) Centre de Technologies Moléculaires Appliquées , Cliniques Universitaires Saint-Luc U.C.L, Brussels, Belgium; 3) Pediatric Neurology, UZ Brussel, V.U.B, Brussels, Belgium; 4) Pediatric Neurology, Hôpital Universitaire des Enfants Reine Fabiola, U.L.B, Brussels, Belgium; 5) Pediatric Neurology, Cliniques Universitaires Saint-Luc U.C.L, Brussels, Belgium; 6) Centrum for Medische Genetica, UZ Brussel, V.U.B, Brussels, Belgium; 7) Centrum for Medische Genetica, UZ Gent, Gent, Belgium; 8) Centre de Génétique Humaine, CHU Sart-Tilman, Liège.

Introduction Tuberous sclerosis complex (TSC) represents an inherited autosomal dominant condition characterized by progressive occurrence of skin lesions and multisystemic hamartoma. Mutation or rearrangement in *TSC1* or TSC2 gene encoding hamartin and tuberin has been identified in patients who fulfilled the clinical criteria (Roach 2004). Despite systematic sequencing of all coding exons, splice site junctions and search for large genomic rearrangements, a causative mechanism is not found in up to 20 percent; suggesting genetic heterogeneity or that maybe other regulatory regions modification inside these two genes might be responsible for the disease.In order to test this last hypothesis, qPCR quantification of TSC mRNA was performed in 17 unrelated patients with TSC phenotype. Methods Patients referred for molecular diagnosis of TSC were enrolled based on the validated clinical criteria. In patients where first line of investigation did not allow to identify mutation (sequencing of all 21/41 exons, respectively) nor deletion/duplication (MLPA) in *TSC1 or TSC2* gene, RNA sample was collected for determining gene expression variations on a LightCycler® 480 System. Relative mRNA quantification was applied to determine the amount of target mRNA in samples. Relative comparison between each sample was achievable using the 2-+;+Ct method and)-actin housekeeping gene for normalization of gene expression. Additionally, TSC genes promoters and UTR regions were analysed on DNA patients by sequencing. Results On the initial cohort of 91 index patients diagnosed with TS, 17 were eligible for RNA expression studies. Abnormal level (decreased, increased or complete absence) of expression in either one or in the two genes was identified in 15 affected patients. 6 patients were identified with expression anomaly in both genes; 6 in *TSC1* and 3 in *TSC2* gene. In two families, expression in both genes was comparable to normal population. Sequencing of promoter and 5'/3'UTR regions of TSC genes did not reveal any sequence distortion. Conclusion Expression anomalies in TSC genes were evaluated in 17 unrelated families with a clinical diagnosis of tuberous sclerosis after mutation in coding sequences and del/dupl were rule out. This complementary molecular investigation allows postulating for a causative role of so far unidentified regulatory regions important for tuberin and hamartin expression. *Ref: Roach S. J Ped Neurol 2004;19:644.*

Mutations in *LRP5* cause primary osteoporosis without features of OI by reducing Wnt signaling activity. *J. Korvala[1], H. Jüppner[2], O. Mäkitie[3], E. Sochett[4], D. Schnabel[5], S. Mora[6], D. Deraska[7], W.G. Cole[8], H. Hartikka[1], L. Ala-Kokko[1,9], M. Männikkö[1].* 1) Oulu Center for Cell-Matrix Research, Biocenter and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Oulu, Finland; 2) Departments of Medicine and Pediatrics, Massachusetts General Hospital and Harvard Medical School, USA; 3) Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland; 4) Hospital for Sick Children, University of Toronto, Canada; 5) Department for Pediatric Endocrinology and Diabetes, Otto-Heubner-Centrum für Kinder- und Jugendmedizin, Charite, University Medicine Berlin, Germany; 6) Laboratory of Pediatric Endocrinology, BoNetwork, Division of Metabolic and Cardiovascular Sciences, San Raffaele Scientific Institute, Milan, Italy; 7) Department of Medicine, Winchester Hospital, Winchester, MA, USA; 8) Division of Orthopaedic Surgery, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 9) Connective Tissue Gene Tests, Allentown, PA, USA.

Primary osteoporosis is a rare childhood-onset skeletal condition whose pathogenesis is largely unknown. We have previously shown that primary osteoporosis can be caused by heterozygous missense mutations in the *LRP5* gene. The role of *LRP5* was further investigated by analyzing the gene in 18 children and adolescents who had evidence of osteoporosis (manifested as reduced BMD, recurrent peripheral fractures and/or vertebral compression fractures), but who lacked the clinical features of osteogenesis imperfecta (OI) or other known syndromes linked to low BMD. Fifty-one controls were also analyzed. Methods included direct sequencing and MLPA. *In vitro* studies were performed to examine the effect of two novel and three previously found primary osteoporosis mutations on the activity of the canonical Wnt signaling and on expression of Tph1 and 5-Htr1b. Two novel *LRP5* mutations (c.3446T>A; p.L1149Q and c.3553G>A; p.G1185R) were identified in two patients and their affected family members. *In vitro* analyses showed that one of these novel mutations and two previously reported mutations (p.C913fs, p.R1036Q) significantly reduced the activity of the canonical Wnt signaling pathway. Such reductions may lead to decreased bone formation, and could explain the bone phenotype. Gut-derived Lrp5 has been shown to regulate serotonin synthesis by controlling the production of serotonin rate-limiting enzyme, Tph1. *LRP5* mutations did not affect Tph1 expression, and only one mutant (p.L1149Q) reduced expression of serotonin receptor 5-Htr1b ($p < 0.002$). Our results provide additional information on the role of *LRP5* mutations and their effects on the development of juvenile-onset primary osteoporosis, and hence the pathogenesis of the disorder. The mutations causing primary osteoporosis reduce the signaling activity of the canonical Wnt signaling pathway and may therefore result in decreased bone formation. The specific mechanism affecting signaling activity remains to be resolved in future studies.

Tissue-specific loss of gene expression mediated by a common upstream SNP. *K. Lower, C. Derry, J. Hughes, D. Garrick, D. Vernimmen, H. Ayyub, R. Gibbons, D. Higgs.* MRC Molecular Haematology Unit, Weatherall Institute of Molecular Medicine, John Radcliffe Hospital, Oxford, UK.

It is estimated that approximately 30% of genes are differentially expressed from each allele, and that the majority of this allele-specific expression occurs in a tissue-specific manner. Studies have shown that this observed allele-specific expression can primarily be explained by genetic variation, such as SNPs, within cis-acting regulatory elements. Whilst a functional effect can be predicted when a SNP is found within a known transcription factor recognition site, it is not yet clear to what extent sequence variation within the local area of transcription factor binding sites can affect the regulation of gene expression. Elucidating the functional effect of sequence polymorphisms, hundreds of which have now been linked to common human diseases through genome-wide association studies, is integral to reconciling these studies with the pathology of disease. We have previously shown that in humans the gene NME4, contained on the short arm of chromosome 16, has acquired a non-conserved, functional erythroid-specific transcription factor (GATA-1) binding site. The presence of this site results in recruitment of erythroid-specific transcription factors, and results in the production of not only an alternative erythroid-specific transcript, but also mediates an interaction with the evolutionarily conserved upstream (globin regulatory elements (REs), which lie approximately 300kb upstream of NME4. The physical interaction between these two GATA-1 binding sites ((globin REs and NME4) results in an ~8-fold upregulation of both the erythroid-specific transcript (eNME4) and full length NME4. Here we describe in detail the functional effect of a common SNP within NME4, which results in both the complete loss of expression of eNME4 and the loss of upregulation of NME4. One variant of this polymorphism completely abrogates GATA-1 binding in vivo, despite lying 65 base pairs upstream of the predicted canonical GATA-1 binding site. Importantly, the presence of this SNP has no effect on NME4 expression in non-erythroid tissues. This provides an example of the potentially dramatic, tissue-specific effects, which can arise from common variation, and may account for a significant proportion of normal variation and disease risk within the human population. In addition, this study highlights the importance of carrying out functional characterisation of common non-coding polymorphisms, associated with disease risk, in clinically relevant tissues.

786F

TNF-alpha-308A allele is associated with the risk of Hepatitis B infection. *M. Mansoori[1], A. Tahmasebifar[2], R. Abdolmohammadi[1], M. Shahbazi[3].* 1) Golestan University of Medical sciences, Advanced Biomedical Faculty & Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MSc; 2) Golestan University of Medical sciences, Advanced Biomedical Faculty & Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MD-PhD; 3) Golestan University of Medical sciences, Advanced Biomedical Faculty & Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MSc-PhD.

TNF-alpha-308A allele is associated with the risk of Hepatitis B infection Background and aim: Tumor necrosis factor-alpha (TNF-a) plays a vital role in host immune response to HBV. The cytokine production in individuals has a capacity that contains a major genetic component. The researches showed the evidences that suggest TNF-a gene polymorphisms associated with resistant to or susceptibility of chronic HBV infection. The purpose of this study was to examine whether TNF-a promoter polymorphisms are associated with the resistant to HBV infection or not. Methods: A total number of 744 Iranian people were classified in two different groups; HBV infected cases (n=261), who were HBS-Ag-positive, and healthy controls (n=483). TNF-a promoter polymorphism at position -308G>A was determined and the distribution of genotypes in HBV infected cases and healthy controls were compared. Results: The frequency of TNF-a-308GG genotype in healthy controls was 47.2 percent, significantly higher than 28 percent in HBV infected patients ($p<0.05$). While the frequency of TNF-a-308A (A/A and A/G)genotype in healthy controls was 52.8 percent, significantly lower than 72 percent in HBV infected patients ($p<0.05$). The frequency of TNF-a-308A allele in Iranian people was remarkably higher in comparison to the world population. Conclusion: TNF-a-308 G/G polymorphism was associated with HBV resistant, whereas TNF-a-308A (A/A or A/G) polymorphism was associated with chronic HBV infection. It is probably that, the -308 G/G polymorphism of TNF-a gene promoter region plays an important role in the resistant to HBV infection in Iranian population.

Identification of genetic variations in human Glycine N-acyltransferase using 454® pyrosequencing. *F.H. O'Neill, C. Herfurth, A.A. van Dijk.* Biochemistry, North-West University, Potchefstroom, South Africa.

Humans are continuously exposed to harmful compounds. These compounds may be of xenobiotic, e.g. pharmaceutical drugs, or endogenous origin. Detoxification is the process by which these harmful compounds are neutralised and excreted from the body. Glycine N-acyltransferase, (EC 2.3.1.13; GLYAT) is a key enzyme in the second phase of detoxification and detoxifies compounds containing a carboxylic acid group by conjugating them with glycine. The conjugation renders the compound more water soluble and allows for its excretion in urine. It is believed that, similar to what has been observed for the Cytochrome P450 group of enzymes, variations within the GLYAT gene may lead to altered enzyme activity that can affect the efficacy of detoxification. The aim of this study was to identify genetic variations within the GLYAT gene of a cohort of individuals whose GLYAT activity has been biochemically screened.

A number of potential participants were identified via screening of their phase I and II biochemical detoxification profiles. Eighteen of the identified individuals, all of whom were of Caucasian origin, agreed to participate in the study. DNA, isolated from blood samples obtained from the participants, was used as a template to amplify the GLYAT gene via PCR. The 23.2kb GLYAT gene was amplified in four parts and the amplicons sent for GS FLX Titanium (Roche) pyrosequencing at Inqaba Biotec (Pretoria, South Africa). The sequencing results were analysed with the Lasergene software package (DNAStar). A minimum depth of coverage of 20 times was a prerequisite for an area to be analysed for variants.

Analysis of the sequence data revealed 94 variations within the GLYAT gene, 29 of which were novel variations. The novel variations consisted of 10 nucleotide changes, seven insertions and 12 deletions. Four of the novel variations occurred within the 3' untranslated region of exon six while the rest were all located within the introns. Identification of these variants is an important step towards establishing a correlation between variations within the gene and altered enzyme activity.

TNF-alpha-238A allele is associated with the risk of Hepatitis B infection. *A. Tahmasebifar[1], M. Mansoori[2], R. Abdolmohammadi[3], M. Shahbazi[4].* 1) Golestan university of Medical sciences, Advanced Biomedical Faculty and Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MD-PhD; 2) Golestan university of Medical sciences, Advanced Biomedical Faculty and Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MSc; 3) Golestan university of Medical sciences, Advanced Biomedical Faculty and Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, MSC; 4) Golestan university of Medical sciences, Advanced Biomedical Faculty and Cellular and Molecular Medicine Research Center, Taleghani Hospital, Gorgan, Iran, Ms-PhD.

TNF-alpha-238A allele is associated with the risk of Hepatitis B infection Background and aim: Chronic hepatitis B virus (HBV) infection is a global health problem with an estimated 350 million people chronically infected worldwide. The virus itself, environment factors, ethnic differences and genetic susceptibility have also been reported to have some influences on the progression of this liver disease. Interestingly, the clearance of HBV infection is associated specifically with HLA-DR13 in several ethnic groups. Several cytokines have been identified to participate in the process of viral clearance via host immune response to HBV. In particular, Tumor necrosis factor-((TNF-( ) is an important cytokine in the pathogenesis of HBV infection. The gene of TNF-(is located 850 kb telomeric of the class II HLA-DR locus of the short arm of chromosome 6. The amount of cytokine production seems to be affected by the polymorphisms in the regulatory region. There have been a number of studies on the association between chronic HBV, HBV clearance, HBV resistance and HBV susceptibility and TNF- promoter polymorphisms (-1031T/C, -863C/A, -857C/T, -308G/A, and-238G/A).We hypothesize that genetic variation in the TNF-(promoter polymorphisms may affect the resistance and clearance of HBV infection. Methods: A total number of 744 Iranian people were classified in two different groups; HBV infected cases (n=372), who were Hepatitis B Surface-Antigen-positive (HBS-Ag-positive), and healthy controls (n=372). TNF-a promoter polymorphism at position -238G>A was determined and the distribution of genotypes in HBV infected cases and healthy controls were compared. Results: The frequency of TNF-(-238GG genotype in healthy controls was 57.6 percent, significantly higher than 37.7 percent in HBV infected patients ($p<0.05$). While the frequency of TNF-(-238A (A/A and A/G) genotype in healthy controls was 42.4 percent, significantly lower than 62.3 percent in HBV infected patients ($p<0.05$). The frequency of TNF-(-238A allele was remarkably elevated in Iranian population as compared to the other groups throughout the world reported in literature. Conclusion: TNF-(-238 G/G polymorphism was associated with HBV resistant, whereas TNF-(-238A (A/A or A/G) polymorphism was associated with chronic HBV infection. Therefore, the -238 G/G polymorphism of TNF-(gene promoter region may play an important role in the resistant to HBV infection.

Extensive variation in U4atac snRNA, a minor spliceosome component that is mutated in the severe human developmental disease MOPD I. *D.E. Symer[1,2,3,4], K. Akagi[1,2], H. He[1,2], R.C. Dietrich[5], A. Robertson[6], W. Li[1,2], J. Li[1,2], J.A. Westman[3], C.B. Burge[6], A. de la Chapelle[1,2], R.A. Padgett[5].* 1) Human Cancer Genetics Program, Ohio State Univ Comp Cancer Center, Columbus, OH; 2) Department of Molecular Virology, Immunology and Medical Genetics, Ohio State University, Columbus, OH; 3) Department of Internal Medicine, Ohio State University, Columbus, OH; 4) Department of BIomedical Informatics, Ohio State University, Columbus, OH; 5) Department of Molecular Genetics, Lerner Research Institute, Cleveland Clinic, Cleveland, OH; 6) Department of Biology, Massachusetts Institute of Technology, Cambridge, MA.

We recently showed (ref. 1) that mutations in human U4atac small nuclear RNA (snRNA), a component of the U12-dependent spliceosome, are responsible for the devastating developmental disorder, microcephalic osteodysplastic primordial dwarfism (MOPD I). Functional splicing studies showed that this disease is caused by biallelic mutations in the mature RNA region of U4atac snRNA, reducing minor splicing function to between 3 and 8% of normal activity. MOPD I patient-derived fibroblasts show defective U12-dependent splicing but normal U2-dependent splicing, while introduction of a wild type *RNU4ATAC* snRNA gene into such cells restores U12-splicing. We sequenced the *RNU4ATAC* snRNA gene from a large number of healthy, diverse individuals, revealing a surprisingly high frequency of single nucleotide polymorphisms (SNPs) within and adjacent to it. We also found extensive variation in and near three other U12-dependent spliceosomal snRNA genes, *RNU11*, *RNU12* and *RNU6ATAC*, in diverse human genomes. Each variant identified in healthy adults appears to occur in heterozygosity and at low allele frequencies. Analysis of transcriptome datasets and functional testing both demonstrated that each of these minor snRNA genes is encoded by a single functional copy in the human genome. Numerous pseudogene copies of these snRNAs display significantly less variation within human populations than do the snRNA genes themselves. Of the many naturally occurring SNPs identified in U4atac snRNA, several are predicted to disrupt basepairing to different extents. An assay of in vivo function confirmed that many of these variants can disrupt U12-dependent splicing, in some cases at similar levels seen for the MOPD I disease-associated mutations. These results suggest that functionally deleterious variants can occur at unexpectedly high frequency in essential snRNA components of the minor spliceosome, and provide new insights into the ongoing evolution of RNA splicing. They also suggest that additional disease-associated mutations in snRNAs remain to be identified. 1. He et al. (2011) Science 332, 238-240.

Quantitative analysis of the human beta cell transcriptome. *A.C. Nica, J.C. Irminger, S.E. Antonarakis, P.A. Halban, E.T. Dermitzakis.* Genetic Medicine & Development, University of Geneva, Geneva, Switzerland.

Gene expression shapes phenotypic differences among cell-types, individuals and populations. Immediately affected by DNA sequence variation, transcript abundance provides a direct link between genotype and organismal phenotypes, helping thus interpret some of the currently known disease-predisposing loci. As most phenotypes manifest themselves only in certain tissues, it has become apparent that mRNA profiling is most informative in the context of a trait-relevant cell-type. Towards this end, we provide here the first detailed description of the human beta cell transcriptome using deep coverage RNA sequencing (RNA-seq). We employ a unique method described previously (Parnaud G et al, Diabetologia 2008) to obtain a highly purified (approx 90%) population of beta cells from a mixed preparation of islets derived from human cadaveric pancreata. We sequence each sample in one Illumina HiSeq 2000 lane, providing thus an unbiased transcriptome characterisation at unprecedented resolution, down to even just one transcript copy per cell. We quantify and catalogue all beta cell expressed genes, both coding and non-coding (including microRNAs) at the exon, transcript and gene level. In addition, we identify novel alternatively spliced variants. While the limited sample size does not allow proper association mapping of expression quantitative trait loci (eQTLs), we will determine allele-specific expression (ASE) signals in each heterozygote site. These, in combination with haplotype homozygosity information, enable us to detect rare eQTLs and assess the overall properties of proximal (cis) effects. We shall further make use of the observed inter-individual variation in beta cell expression levels by integrating and interpreting diabetes-associated loci. Altogether, the fine structure and properties of the human beta cell transcriptome constitute a powerful resource aiding our understanding of diabetes genetics.

Detection and validation of MCF7 fusion transcripts, chimeric transcripts and novel proteins using paired end RNA Seq with the 5500 Genetic Analysis System. *R. Nutter, C. Barbaraciou, O. Sakarya, A. Siddiqui.* Life Technologies Applied Biosystems, Foster City, CA.

Our understanding of the structure and function of RNAs is rapidly expanding due to the implementation of the high throughput sequencing application termed RNA Seq. We have used RNA Seq to study in great detail the transcriptome of MCF7, a well studied breast cancer cell line. We have constructed cDNA libraries from polyA RNA isolated from the MCF7 cell line and used high throughput, paired end sequencing using the 5500xl Genetic Analysis System to study the transcriptome in depth. The data generated was analyzed using Lifescope™ v2.0 software followed by the publicly available software programs Cufflinks and SIFT to find novel RNA forms not present in normal human cells. Our approach has identified a number of novel RNA forms and predicted proteins from a large paired end dataset. We found a total of 25 fusion transcripts in our dataset, some are known but many have not previously been reported. All novel fusion transcripts have been validated using custom TaqMan® assays. When we compared our results to RNAs from a number of other cancer lines, we found examples of recurrent fusions in a number of lines. Deep analysis of the fusion transcripts suggests specific regions of transcripts are more favored than others as sites where fusions occur. Cufflinks and SIFT were used in addition to Lifescope™ software to identify alternative splicing events and chimeric transcripts and predict novel proteins from this large dataset. This is the first demonstration of the potential power of using very large datasets with these software tools to more fully describe the transcriptome of a cancer cell line and reliably predict novel transcripts as well as proteins derived from these transcripts. For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.

The creation of BAC transgenic mice to explore the transcriptional and behavioral effects of a putative functional polymorphism in the human dopamine) -hydroxylase gene. *D. Perdomo[1, 2], T. Berg[5], K. Mercer[4], P. Szot[3], C.L. Liles[2], D. Wenshenker[2], J. Cubells[2,4].* 1) Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA 30322; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322; 3) 3. Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA 98108; 4) Department of Psychiatry and Behavioral Sciences, Atlanta, GA 30322; 5) 5. Ce-M-M-Research Center for Molecular Medicine of the Austrian Academy of Sciences, Lazarettgasse 14, AKH BT 25.

BACKGROUND: Dopamine beta-hydroxylase (D) H) is the catecholamine biosynthetic enzyme that converts dopamine to norepinephrine, and is expressed specifically in noradrenergic cells. Serum D) H activity is a stable heritable phenotype that is highly variable across individuals, and a large fraction of this variability appears to be controlled by rs1611115, a single nucleotide polymorphism 1021 bp upstream of the translational start site of the DBH gene 1 The “T” allele of rs1611115 associates with low serum D) H activity, but transient transcription experiments with reporter constructs suggested the “T” allele associated with greater transcriptional activation2. Here, we report initial results of our efforts to create a mouse model capable of supporting analysis of the functional effects of rs1611115 on DBH gene regulation. METHODS: We are generating human BAC transgenic mice bearing either the “C” or “T” allele at -1021C-T, in the context of greater than 100 kb of human sequence. Those lines are then crossed with mice completely lacking endogenous mouse D) H (Dbh -/-). RESULTS: We have successfully generated two lines of mice with the low activity “T” allele of human DBH and crossed them onto a Dbh -/- background. In situ hybridization results reveal that human DBH is specifically expressed in the locus coeruleus, the major brain noradrenergic nucleus, indicating that all regulatory elements necessary for cell type-specific expression in the brain are present in the BAC. Furthermore, the transgene rescued the embryonic lethality, delayed growth, and ptosis phenotypes of Dbh-/- mice. We are currently generating lines of mice with BACs bearing the “C” allele of DBH, and will compare DBH transcription, catecholamine neurochemistry, and behavior with the “T” allele BAC transgenic mice.

IMPLICATION OF THE ESE TRANSCRIPTION FACTORS (EPITHELIUM-SPECIFIC ETS-LIKE FACTORS) IN CFTR GENE EXPRESSION. *A.T. de Becdelièvre[1,2,3], A. Hinzpeter[1], N. Martin[1], B. Costes[1], P. Fanen[1,2,3].* 1) U955, INSERM, Créteil, France; 2) Université Paris-Est, Faculté de Médecine, UMR-S 955, Créteil, France; 3) Service de Génétique, Hopital Henri Mondor, APHP, Créteil, France.

Cystic fibrosis (CF) (MIM#219700), the most common lethal autosomal recessive disease in Caucasians, is caused by the dysfunction of an epithelial chloride channel encoded by the *CFTR* gene (OMIM*602421). CF affects respiratory, digestive and reproductive systems with a variable severity, correlated to the amount of functional CFTR in each organ system. Of the 1800 mutations identified so far, less than 1% are located in *CFTR* regulatory regions and only a few transcription factors has been shown to regulate *CFTR* gene expression. ESE transcription factors are tissue-specific proteins which are up-regulated in bronchial epithelial cells in response to inflammation (1), a characteristic feature in the lungs of CF patients.**Aim**: We aimed to evaluate the influence of members of the ESE transcriptions factors on CFTR expression. **Methods**: Different sizes of the *CFTR* promoter subcloned upstream of the luciferase reporter gene were co-transfected in IB3-1 epithelial cells (CF cells) with either ESE-1, ESE-2 or ESE-3. Endogenous CFTR expression was measured by qRT-PCR after over-expression of the ESE proteins and interaction between ESE-1 and the *CFTR* promoter was assessed by chromatine immunoprecipitation (ChIP) in Calu-3 cells. **Results**: Whereas ESE-2 and ESE-3 over-expression did not affect promoter activity, ESE-1 had a 2 to 6 fold enhancer activity depending on the tested construct. Bioinformatic tools and direct site mutagenesis enabled to identify the major binding site of ESE-1 at position -37 bp of CFTR promoter, which was validated by ChIP. Finally, over-expression of ESE-1 in Calu-3 cells doubled endogenous *CFTR* expression while over-expression of ESE-2 or ESE-3 had no significant effect. **Discussion - Conclusions**: Members of the ESE protein family appear of special interest in cystic fibrosis, as a recent GWAS associated the locus of *ESE-3* (*EHF*) with lung disease severity in CF patients (2). We showed that ESE-1, a transcription factor induced by pulmonary inflammation, increases *CFTR* gene transcription. Sequence variations within its binding site or altering ESE-1 functional level could affect *CFTR* expression in patients, possibly accounting for phenotype variability. Deciphering ESE and *CFTR* interactions mechanisms could participate to a better understanding of the CF pulmonary disease. (1)Wu et al, Cell Research, 2008 (2)Wright et al, Nature Genet, 2011. Analysis of HSP70B' as a potential direct target gene of the FOXC1 transcription factor. *Y.A. Ito[1], F. Berry[1,3], M.A. Walter[1,2].* 1) Department of Medical Genetics, University of Alberta, Edmonton, AB, Canada; 2) Department of Ophthalmology, University of Alberta, Edmonton, AB. Canada; 3) Department of Surgery, University of Alberta, Edmonton, AB. Canada.

FOXC1 mutations cause human Axenfeld-Rieger Syndrome (ARS), an autosomal-dominant disease that affects the anterior segment of the eye. ARS patients have an elevated risk to develop earlier-onset glaucoma, a progressively blinding condition that is usually associated with increased intraocular pressure (IOP). Structures of the anterior segment of the eye, such as the trabecular meshwork (TM), are important in maintaining the aqueous flow pathway and thus, regulating IOP. The TM outflow pathway tissue is subjected to constant stress. Healthy TM cells have protective mechanisms to cope and adapt to various stresses, including oxidative stress. However, chronic exposure to stress may overwhelm cellular defense mechanisms, resulting in progressive diseases such as glaucoma. The identification and characterization of direct target genes of FOXC1, specifically those genes that are stress-responsive, are essential in understanding how disruptions in FOXC1 can result in ARS and glaucoma. Previous work in our laboratory using microarray technology has led to the identification of potential genes that are regulated by FOXC1. Heat shock protein 70 (HSP70B') is one gene identified in the microarray as a potential FOXC1 target. Although the function of HSP70B' is largely unknown, HSP70 proteins are typically involved in protecting cells during stress response. HSP70B' was an interesting gene to further study because there is increasing evidence that a variety of stresses, including oxidative stress, may contribute to the development of glaucoma. First, HSP70B' was further confirmed as a FOXC1 target gene by examining HSP70B' RNA levels in human trabecular meshwork (HTM) cells. HSP70B' RNA levels are decreased by 1.6 fold when FOXC1 is knocked down using siRNA technology ($P<0.05$). Under H_2O_2-induced oxidative stress conditions, there is at least four times as much HSP70B' RNA compared to non-oxidative conditions, suggesting that HSP70B' is stress-responsive. HTM cells are less resistant to oxidative stress when FOXC1 is knocked down, suggesting that FOXC1 is involved in the cellular stress pathway. Interestingly, FOXC1 knockdown resulted in a 1.6 fold increase in HSP70B' protein levels ($P<0.05$) in oxidatively stressed HTM cells. In fact, the highest level of apoptosis was observed in cells expressing the highest level of HSP70B'. Thus, these experiments suggest that FOXC1 regulation of HSP70B' protein is important in mediating the cellular stress response pathway.

Host factors associated with LINE-1 and its retrotransposition. *J.L. Goodier, L. Cheung, P.K. Mandel, H.H. Kazazian.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

LINE-1 retrotransposons constitute one-fifth of human DNA and have helped shape our genome. A full-length L1 encodes a 40 kD RNA-binding protein (ORF1p), and a 150 kD protein (ORF2p) having endonuclease and reverse transcriptase activities. Despite the immense significance of L1s for genome evolution, much about their biology remains unknown, including cellular factors involved in the complex process of retrotransposition. By means of immunoprecipitation of tagged L1 ORF1p or ORF2p expressed from full-length retrotransposition-competent L1 constructs followed by MS sequencing, we identified proteins associated with the L1 ribonucleoprotein particle. These included helicases, RNA transport proteins, chaperone proteins, and splicing factors. We have assessed the co-localization of these cellular proteins with L1-enoded proteins and RNA. Employing a well-established GFP-reporter retrotransposition assay, as well as a novel retrotransposition assay based on secreted luciferase, we also assayed the effects of overexpression or siRNA-suppression of these proteins on cell culture retrotransposition. These studies suggest candidate cofactors that interact with the L1 to modulate its activity, and increase our understanding of the means by which the cell coexists with these genomic “parasites”.

796F

Retrotransposition of marked SVA elements by human L1s in cultured cells. *D. Hancks, J. Goodier, P. Mandal, L. Cheung, H. Kazazian Jr.* Institute for Genetic Medicine, The Johns Hopkins School of Medicine, Baltimore, MD.

Human retrotransposons generate structural variation and genomic diversity through ongoing retrotransposition and non-allelic homologous recombination. Cell culture retrotransposition assays have provided great insight into the genomic impact of retrotransposons, in particular, LINE-1(L1) and Alu elements; however, no such assay exists for the youngest active human retrotransposon, SINE-VNTR-Alu (SVA). Here we report the development of an SVA cell culture retrotransposition assay. We marked several SVAs with either neomycin or EGFP retrotransposition indicator cassettes. Engineered SVAs retrotranspose using L1 proteins supplemented in trans in multiple cell lines, including U2OS osteosarcoma cells where SVA retrotransposition is equal to that of an engineered L1. Engineered SVAs retrotranspose at 1-54 times the frequency of a marked pseudogene in HeLa HA cells. Furthermore, our data suggest a variable requirement for L1 ORF1p for SVA retrotransposition. Recovered engineered SVA insertions display all the hallmarks of LINE-1 retrotransposition and some contain 5' and 3' transductions, which are common for genomic SVAs. Of particular interest is the fact that 4 out of 5 insertions recovered from one SVA are full-length, with the 5' end of these insertions beginning within 5nts of the CMV promoter transcriptional start site. This assay demonstrates that SVA elements are indeed mobilized in trans by L1. Previously intractable questions regarding SVA biology can now be addressed.

797F

THE TRANSMEMBRANE PROTEIN 126A GENE (OPA7), A MITOCHONDRIAL LOCATED mRNA, ENCODES A MITOCHONDRIAL INNER MEMBRANE PROTEIN. *S. HANEIN[1,2], M. GARCIA[3], V. SERRE[1,2], L. FARESTAIE[1,2], I. PERRAULT[1,2], S. GERBER[1,2], J. COTTINEAU[1,2], N. DELPHIN[2], A. SCHMITT[3,4], J.-M. MASSE[3,4], A. ROTIG[1,2], F. DEVAUX[3], A. MUNNICH[1,2], J. KAPLAN[1,2], J.-M. ROZET[1,2].* 1) Genetics and epigenetics of neurometabolic diseases and birth defetcs, INSERM U781-Paris Descartes University & Institute of genetic diseases IMAGINE, Necker - Enfants Malades University Hospital, Paris, France; 2) Genetics Department, Necker - Enfants-Malades University Hospital, Paris, France; 3) Structure, dynamique et évolution des réseaux génétiques, UMR 7238 CNRS-Université Pierre et Marie Curie, Paris, France; 4) Inserm, U1016, CNRS, UMR8104, Institut Cochin - Paris Descartes University, Paris, France.

Purpose: Hereditary optic neuropathies are a heterogenous group of inherited disorders affecting the retinal ganglion cells and their axons which form the optic nerve. To date, four modes of inheritance were described: autosomal dominant, autosomal recessive, mitochondrial and X-linked. Leber hereditary optic neuropathy (MIM 535000) and autosomal-dominant optic atrophies (adOA, MIM165500) are by far the two main forms. Nonsyndromic autosomal-recessive optic atrophies (arOA) are rare conditions which existence has been long debated. Recently, we have identified the first gene, to our knowledge, responsible for this condition, TMEM126A (OPA7, MIM612988) in four families originating from the Maghreb. TMEM126A is highly conserved in higher eukaryotes, strongly expressed in retinal cellular compartments enriched in mitochondria suggesting that TMEM126A may be a mitochondria-localized mRNA (MLR) protein and might be essential in the early nucleation process of large mitochondrial complexes. TMEM126A is supposed to encode a mitochondrial transmembrane protein but its function remains to be elucidated. In an effort to further understand the physiopathologic mechanisms of arOA and to investigate the mechanism of action of TMEM126A protein we address the sub-cellular localization of both TMEM126A mRNA and endogenous protein. Methods: A polyclonal antibody targeting the TMEM126A protein has been generated and its specificity was validated. Fluorescent in situ hybridation, cellular fractionation, mitochondrial membranes association study, mitochondrial sub-compartmentalisation analysis by both proteolysis assays and transmission electron microscopy were carried out. Results: We present molecular and biochemical evidences showing that TMEM126A is translated in the vicinity of mitochondria and encodes a mitochondrial protein strongly associated to the mitochondrial inner membranes. Transmission electron microscopy approach further localizes TMEM126A protein to the inner mitochondrial membrane likely close to the cristae. Conclusion: OPA7 gene encodes a mitochondrial inner membrane protein close to cristae. This result is a first step toward to a better understanding of the mechanism of action of this crucial protein for retinal ganglion cells and provides further arguments to support the importance of mitochondrial dysfunction in the pathogenesis of inherited optic atrophies.

A rare deletion of *IKBKG/NEMO* promoter B in Incontinentia Pigmenti patient reveals the role of *IKBKG* promoterA during embryonic development. *F. Fusco[1], A. Pescatore[1], M.I. Conte[1], M. Paciolla[1,2], M.B. Lioi[2], M.G. Miano[1], M.V. Ursini[1].* 1) IGB-ABT-CNR, Naples, Italy; 2) University of Basilicata, Potenza, 85100, Italy.

Nuclear factor-kB (NF-kB)is a key transcription factor that regulates innate and adaptive immunity as well as ectodermal development. Mutations in the coding region of the *IkBKinaseG/NF-kB Essential MOdifier* (*IKBKG/NEMO*)gene cause X-linked Ectodermal Dysplasia with Immunodeficiency (EDA-ID,MIM300291) in male and Incontinentia Pigmenti (IP,MIM308300) in female. This gene, in Xq28,overlaps *G6PD* gene by a conserved bidirectional CpG promoter (promoterB) ubiquitously expressed. In addition, *IKBKG* gene has its own promoter, promoterA, at long distance to its coding region. We identified a promoterB deletion in one IP patient and we showed the IP skin pathogenesis in that case is due to the absence of promoterB and to physiological downregulation of promoterA in keratynocites differentiation. The observation that promoterA is more active in the stem cells prompted us to investigate on its role during embryonic development. We predicted by bioinformatic analysis the conserved human-mouse transcription binding sites typically expressed in embryonic stem cells, and we observed that most of them were involved in hematopoietic development. We focalized our attention on Prep1 homeodomain transcription factor belonging to the TALE superclass that includes Meis1-3, Prep2 and Pbx1-4. *TALE* genes in mouse show to be essential for hematopoietic stem cells,and *Prep1* is responsible for protecting the embryo very early in development. We performed functional studies by co-trasfecting the promoterA with Prep1 and Pbx proteins in HeLa cells and, using luciferase reporter assay, we observed activation of the *IKBKG* promoterA expression only in presence of both TALE factors. ChIP assay on the factor Prep1 protein extracts of fetal liver of mice at the embryonic E14.5 stage, indicated that *IKBKG* is a direct *in vivo* target of Prep1 during the hematopoiesis. We suggest that a coordinate regulation between promoterA and promoterB in early embryogenesis is required for proper *IKBKG* gene expression during the immunosystem development. On the other hand, such a role of IKBKG in immunosystem is strongly supported by the severe immunodeficiency observed in EDA-ID patients carrying mutations of *IKBKG*. This study demonstrates how a rare genomic rearrangement responsible for IP can give the cue to uncover novel mechanisms controlling the *IKBKG* gene expression.The study is supported by Telethon GGP08125 and AssociationIncontinentia Pigmenti France (http://www.incontinentiapigmenti.fr).

A Challenge to Genotype to Phenotype Relationships: What are the Implications of the Discovery that Post-Genomic Events can Influence Phenotypic Expression? *C. Alvarado[1,3], B. Gottlieb[1,2,3], L.K. Beitel[1,2,3,4], M. Trifiro[1,2,3,4].* 1) Lady Davis Institute for Medical Research, Montreal, Quebec, Canada; 2) Segal Cancer Centre, Jewish General Hospital, Montreal, Quebec, Canada; 3) Dept of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) Dept of Medicine, McGill University, Montreal, Quebec, Canada.

A central dogma of modern genetics has been that phenotypic expression can be predicted by genomic sequencing. This principle has been the basis for much of our understanding of disease ontogeny. Up until now the concepts of variable expressivity and penetrance have been used to explain problems in genotype to phenotype relationships. However, possible mechanisms involved in these concepts have remained unidentified. The assumption has been that any such variation in the relationship is within the `normal' parameters of the relationship. To test this assumption, we decided to examine the genetics of the androgen receptor (AR) gene, a locus-specific gene, in which mutations are responsible for the rare condition known as androgen insensitivity syndrome (AIS). We examined a total of 140 patients with a clear AIS phenotype, and found that in over 40% a mutation in their AR coding exons could not be identified. Further, similar results have been reported in two other AIS databases. In the absence of any other gene being identified as causing AIS to date, the question arises as to whether post-genomic events may play a critical role in determining AIS phenotype. Over the past few years a number of such events and factors have indeed been identified that can significantly affect the relationship between genotype and phenotype. These include DNA and RNA editing, alternative splicing, DNA methylation and interactions involving coactivators and corepressors. In particular, the discovery of widespread RNA editing in over 10,000 genes in normal individuals has suggested that the belief that a specific genotype will result in a specific phenotype needs to be carefully reexamined. Clearly, our reliance on genomic information to predict disease phenotype, such as in genome wide association studies, needs to be reconsidered, which is perhaps why until now, such studies have failed to produce the breakthroughs originally predicted. In light of all the possible post-genomic sources of phenotypic variation and the apparent disconnect between genotype and phenotype in many diseased individuals, we have proposed a new model of the genotype to phenotype relationship that we believe more accurately reflects the actual complexity of this relationship. The term `personalized medicine' has become a key concept of many in discussing the future approaches in treatment of disease, however, it seems unlikely that such a goal can be achieved relying solely on genomic analysis.

Retrotransposition of a unique piece of LCR7 played a key role in the generation of Williams-Beuren syndrome-associated LCR during the primate evolution. *A. Shimizu[1], S. Minoshima[2], N. Shimizu[3].* 1) Department of Molecular Biology, Keio University School of Medicine, Tokyo, Japan; 2) Department of Photomedical Genomics, Basic Medical Photonics Laboratory, Medical Photonics Research Center, Hamamatsu University School of Medicine, Hamamatsu, Japan; 3) Advanced Research Center for Genome Super Power, Keio University, Tsukuba, Japan.

Background: Segmental duplications (SDs) are thought to accelerate the diversity of genome organization during evolution. The SDs in general form repeats of DNA fragments with various sizes, facilitating the birth-and-death event of creating new genes. However, the SDs occurred at a remote location often mediate large hemizygous deletions at meiosis. This is often caused by the unequal nonallelic homologous recombination (NAHR), giving rise to several genetic disorders. Williams-Beuren syndrome (WBS; OMIM 194050) is characterized by distinct facial changes, growth deficiency, mental retardation, and congenital heart defect, in association with infantile hypercalcemia. The WBS is caused by the large hemizygous deletion (1.6 Mb or 1.8 Mb) at 7q11.23 including several contiguous genes. These deletions were mediated by the chromosome 7 specific low copy repeats (LCR7s). Many studies have proposed the mechanism of LCR-mediated deletion or duplication in the primates, however, how these LCRs have evolved from ancestral loci and how they spread over the mammalian genome is still unclear. Results: Here, we present examined an evolutional history of the WBS chromosomal region in the mammalian genome, and defined twenty-six homologous sequence units (LCR7-a~LCR7-z) in the WBS region of human genome. This The unique piece of LCR7 (LCR7-k) flourished during the primate evolution (Chimpanzee, Orangutan, Baboon, Macaque and Gibbon), and it was repeated twenty-one times in the human genome. Interestingly, one particular gene or its paralogs were found in every piece of LCR7-k. Moreover, at least seven of 21 are considered active gene although their functions are not yet clear. The Ka/Ks ratio of those active genes for human vs chimpanzee was as high as 3.29. Conclusions: Our observations suggest that retrotransposition of a unique piece of LCR7-k, played a key role in the generation of WBS-associated LCR in the human lineage. As an evolutionary consequence, only human was given the risk for causing the congenital disorder WBS.

Genome-wide signatures of `rearrangement hotspots' within segmental duplications in humans. *M. Uddin, M. Sturge, D.D. O'Rielly, L. Peddle, P. Rahman.* Faculty of Medicine, Discipline of Medicine and Genetics, Memorial University, St. John's, Newfoundland, Canada.

The catalogue of segmental duplications comprises approximately 5% of the human genome where specific regions are prone to genomic rearrangements. Evidence suggests involvement of multiple events in the origin of rearrangements such as non-allelic homologous recombination (NAHR), non-homologous end joining (NHEJ), fork stalling and template switching (FoSTeS), and microhomology-mediated break-induced replication (MMBIR). The primary objective of this study was to create a genome-wide high resolution map (i.e., >100bp) of `rearrangement hotspots' to facilitate the identification of regions capable of mediating pathogenic deletions or duplications in humans. A hierarchical method was employed to fragment segmental duplications into multiple smaller segmental duplication (SD) units. Combining an end space free pairwise alignment algorithm with a `seed and extend' approach, an exhaustive search of 409 million alignments was performed to detect complex structural rearrangements within the reference guided assembly of NA18507 human genome with 18x coverage. This included previously identified 4.8 MB novel sequence from de novo assembly within this genome. The results of this study revealed that intra-chromosomal recombination is enhanced in genic compared with agenic duplicated regions. We have identified 1,963 rearrangement hotspots within the duplicated regions overlapping 166 genes. Furthermore, duplicated gene nucleotide variants (DNVs) were enriched within the hotspots region. These regions show increased NAHR event frequency as the origin of copy number variations (CNVs) and pathogenic duplications/deletions. Among the detected hotspots, 20% were clustered within the proximal and distal segmental duplications breakpoints flanked by the pathogenic deletions/duplications that have been mapped for 24 NAHR mediated genomic disorders. FISH Validation of selected complex regions shows >90% concordance with in silico localization of the highly homologous derivatives. The generation of genome-wide signatures of `rearrangement hotspots' likely serve as templates for NAHR and may provide a powerful approach towards the understanding of the underlying mutational mechanisms for development of constitutional and acquired diseases.

CAGI: The Critical Assessment of Genome Interpretation, a community experiment to evaluate phenotype prediction. *S.E. Brenner[1], S. Repo[1], J. Moult[2].* 1) Department of Plant and Microbial Biology, University of California, Berkeley, CA 94720; 2) IBBR, University of Maryland, Rockville, MD 20850.

The Critical Assessment of Genome Interpretation (CAGI, `kā-jē) is a community experiment to objectively assess computational methods for predicting the phenotypic impacts of genomic variation. In this assessment, participants are provided genetic variants and make predictions of resulting phenotype. These predictions are evaluated against experimental characterizations by independent assessors. The CAGI experiment culminates with a community workshop and publications to disseminate results, assess our collective ability to make accurate and meaningful phenotypic predictions, and better understand progress in the field. A long-term goal for CAGI is to improve the accuracy of phenotype and disease predictions in clinical settings.

At the first CAGI workshop in December 2010, Pauline Ng, Iddo Friedberg, Sean Tavtigian, Gad Getz, and Sean Mooney made detailed assessments of 108 prediction entries from 8 countries. The CAGI 2010 datasets included rare variants identified from resequencing in cancer cases and controls; nonsynonymous point mutations within a human metabolic enzyme; clinical phenotypes associated with complete human genomes and exomes; cancer cell-line pharmacogenomics; effects of double-mutants in reactivation of p53; and mechanisms underlying GWAS disease associations. The meeting revealed the relative strengths of different prediction approaches, showing some that worked consistently well, while other classes worked only on special types of problems. Even with the simplest dataset, involving nonsynonymous mutations in a human metabolic enzyme, yielded great variability of the results: the best groups had a Spearman rank correlation of ~0.5 with the correct results, while predictions submitted by some groups were only as good as random or worse. Several predictions for the cancer case / control dataset significantly segregated the individuals into their respective cohorts, and some methods performed better than the method initially applied by the dataset author. Overall, CAGI 2010 highlighted the need for customized approaches for specific problems. We are currently completing further analysis of the prediction quality. The CAGI 2011 prediction season runs during summer 2011, with assessment in the fall, and a meeting to be held in the Bay Area in December 2011. We continue to welcome new experimental datasets for CAGI and all predictors. Current information is at the CAGI website at http://genomeinterpretation.org.

Refining susceptibility loci for chronic obstructive pulmonary disease with lung eQTLs. *M. Lamontagne[1], C. Couture[1], M. Laviolette[1], Y. Bossé[1,2], The Merck-Laval-UBC-Groningen Lung eQTL consortium.* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Quebec, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

Chronic obstructive pulmonary disease (COPD) is the fourth cause of chronic morbidity and mortality in the United States and Canada. COPD is characterized by airflow obstruction that is not fully reversible. Recent genome-wide association studies (GWAS) have identified robust susceptibility loci associated with COPD and lung function. However, the genetic mechanisms mediating the risk within these loci remain to be found. The goal of this study is to identify causal variants and genes within susceptibility loci associated with COPD and lung function measurements. Genome-wide gene expression profiles of 500 non-tumor lung specimens were obtained from patients undergoing lung surgery. Blood-DNA from the same patients were genotyped for 1,2 million SNPs. Following genotyping and gene expression quality control filters, 409 samples were analyzed. The first step of the analyses was to identify SNPs affecting gene expression in the lung or lung expression quantitative trait loci (eQTLs). The second step was to overlay lung eQTLs to susceptibility loci of COPD and lung function derived from previous GWAS. The first step of the analyses is now completed. A total of 49,667 cis and 1,713 trans eQTLs were identified. Analyses are ongoing to link these eQTL results with published GWAS. Preliminary results suggest that lung eQTLs are located in susceptibility loci of lung function and COPD. Notably, an eQTL on chromosome 5q33.1 governing the expression levels of FBXO38 was identified. This locus was previously associated with abnormal lung function (i.e. FEV1/FVC ratio) and our results suggest that the risk is mediated through the regulation of FOXO38 in the lungs. In summary, the results of this study suggest that lung eQTLs reside in genomic regions previously associated with COPD and lung function, which is an important step to understand the molecular basis of COPD. This study also supports the use of eQTLs in a relevant tissue to prioritize causal genes within loci identified as harboring susceptibility gene variants in GWAS.

Stimulation effects on eQTLs in peripheral blood leukocytes in peripheral blood leukocytes. *K. Löytynoja[1], E. Dukes[1], M. Zucchelli[2], J. Vendelin[1,3], A. Parmar[1], E. Einarsdottir[1], J. Kere[1,2,3,4], D. Greco[1], P. Saavalainen[1].* 1) Dept Medical Genetics and Research Program for Molecular Medicine, University of Helsinki, Helsinki, Finland; 2) Dept Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 3) Clinical Research Centre, Karolinska University Hospital, Huddinge, Sweden; 4) Folkhälsan Institute of Genetics, Helsinki, Finland.

BACKGROUND: Expression quantitative trait loci(eQTLs) are loci of genetic variation that control gene expression by proximal (cis) or distal (trans) effects, and may contribute to phenotypic differences. Previous studies have identified multiple such loci and revealed differences between cell types and tissues. Our aim was to identify eQTLs potentially relevant in immune related traits using primary human leukocytes under immunological stimuli. MATERIALS AND METHODS: Spearman rank correlations were calculated for Agilent whole human genome (44K) expression data of in vitro LPS-stimulated (6h) peripheral blood mononuclear cells (PBMCs) and anti-CD3/CD28 stimulated (6 h)CD4+ T cells, along with unstimulated controls, and Illumina 610 quad SNP data of 39 healthy blood donors (17 males, 22 females). Exact p-values were computed for eQTLs with p 1.0E-8 and sex specific eQTLs. RESULTS AND CONCLUSIONS: Preliminary results show highest number of eQTLs for unstimulated cells, and lower number of eQTLs after stimulation. In line with previous studies we found females to show higher number of eQTLs in comparison to males, and ciseQTLs in general to have lower p-values than the more numerous trans eQTLs. Males had higher number of eQTLs in T cells than in PBMCs, whereas females had no difference in eQTL counts between the cell types or conditions. Most of the eQTLs found in more than one subset were shared between females and the combined data set. We have successfully replicated several previously reported indicating enough power of the sample size for common alleles. However, we expect 10 % of the variation in expression to result from SNPs in probe binding sites. Our data provides information of global interactions within genome in immune stimulated and unstimulated PBMC and T cells, and sheds light on sex specific shared between females and the combined have successfully replicated several previously reported eQTLs, indicating enough power of the sample size for common alleles. However, we expect 10 % of the variation in expression to result from SNPs in probe binding sites. Our data provides information of global interactions within genome in immune stimulated and PBMC and T cells, and sheds light on sex specific eQTLs in humans.

Comprehensive NextGen Clinical Sequencing of the Human Mitochondrial Genome (mtDNA) with Low Level Heteroplasmy Analysis: 1+ Years of Diagnostic Experience Highlights the Clinical Importance of Homoplasmic as well as Heteroplasmic Variants. *C. Buzin[1], R. Boles[2], W. Scaringe[1], C. Boysen[1].* 1) MEDomics, LLC, Azusa, CA; 2) Los Angeles Childrens Hospital.

BACKGROUND: Disorders of the mitochondrial DNA (mtDNA) differ clinically from most genetic diseases due to maternal inheritance and the presence of hundreds to thousands of genome copies within a cell (heteroplasmy). Most “classical” mtDNA disorders are often thought to be caused by heteroplasmic mutations, and heteroplasmy is often screened for when evaluating patients for mtDNA disorders. Previous evidence suggesting that mtDNA has a mutation rate roughly 18x higher than nuclear DNA, would predict that low heteroplasmy levels could be common in normal individuals, and thus significantly confound clinical interpretation of mtDNA heteroplasmic variants found in patients with suspected mitochondrial disease. In addition, homoplasmic mtDNA mutations are also established as the cause of some clinical conditions, although differentiation from the multiple homoplasmic polymorphisms found in nearly all humans can be challenging. RESULTS: Heteroplasmic and homoplasmic variants were detected by comprehensive clinical NextGen sequencing of the mitochondrial genome derived from blood and saliva; each sample was sequenced thousands of times. Surprisingly, analysis of the first 50 consecutive clinical samples reveals that about half are without any heteroplasmic variants at levels of 1% or more. In addition, most of the heteroplasmic variants seen are unlikely to be of functional significance. Thus some previous patients who were candidates for painful and expensive muscle sampling (biopsy) for biochemical analysis, were reevaluated for mitochondrial genome diseases by the referring physician, and subsequently tested by blood sampling for nuclear mitochondrial diseases or for other diseases in the differential diagnosis. In addition, some muscle biopsies were eliminated because genomic sequencing demonstrated homoplasmic mutations that likely contribute to, or drive the clinical phenotype, analogous to the manner in which homoplasmic mutations can cause diseases like Leber's Hereditary Optic Neuropathy or hereditary deafness. CONCLUSIONS: While some cases may illustrate how current ignorance is more profound than knowledge, comprehensive NextGen sequencing (or massively parallel sequencing) and deep heteroplasmy analysis of the mitochondrial genome derived from blood is often clinically useful and sometime eliminates the need for muscle biopsies.

Whole-genome definitive haplotypes of SNPs and CNVs determined by genotyping duplicated haploid genomes. *T. Tahira[1], Y. Kukita[2], K. Yahara[3], M. Sonoda[1], K. Yamamoto[1], N. Wake[4], K. Hayashi[1].* 1) Div. Genome Analysis, Med Inst Bioreg, Kyushu Univ. Fukuoka, Japan; 2) Research Inst., Osaka Medical Center for Cancer and Cardiovascular Diseases, Osaka, Japan; 3) Div. Life Science System, Fujitsu Kyushu Systems Inc. Fukuoka; 4) Dpt. Gynecology and Obstetrics, Graduate School of Medical Sciences, Kyushu Univ.

The majority of the variation of human genome, in terms of the extent genomic regions are involved, is accounted for by copy number variations (CNVs), and some of them are implicated in the disease susceptibility. Finding such disease-responsible CNVs requires detailed knowledge of haplotype structure of CNVs and SNPs for the ethnic groups to which the study subjects belong. However, delineating such haplotype structures is difficult if diploid cells without pedigree information are studied. We have been determining definitive haplotypes of Japanese by analyzing complete hydatidiform moles (CHMs), using high-density DNA arrays. CHMs are tissues carrying duplicated haploid genomes derived from single sperms. This makes CHMs more advantageous as materials over conventional diploid cells in detecting CNVs, because greater signal to noise ratios in hybridization signals are expected, and data interpretation is not bothered by possible heterozygosities of overlapping CNV segments. We genotyped 84 CHM genomes using Affymetrix SNP 6.0 and Illumina 1M-duo, and obtained a definitive haplotype map that included 1.7 million SNPs. For 1.1 million common SNPs (MAF ／ 0.05), we calculated linkage disequilibrium and created the map of LD-bins in which strongly correlated SNPs (pairwise r^2／ 0.8) were grouped and represented by tagSNPs. Genotype data (signal intensities) were analyzed for CNVs using the Circular Binary Segmentation algorithm. Segments were then filtered based on their mean log-ratios. Number of segments defined as CNV were 8002 (Affymetrix) and 3715 (Illumina). These segments were merged based on mutual overlap and 2258 CNV region (CNVR) were identified. We compared 1030 CNVRs detected in at least 2 samples in our study with 436 CNPs (MAF>0.02) identified by HapMap 3 project. One fourth of our CNVRs overlapped with HapMap CNPs. Most of our CNVR (83%) overlapped with structural variation registered in the Database of Genomic Variants (v10). Whole-genome definitive haplotype of SNPs and CNVs determined in this study (D-HaploDB: http://orca.gen.kyushu-u.ac.jp/) provide a useful resource to relate genome variations to complex diseases.

Detailed Metabolic Studies Identify Endophenotypes in Rare Obesity and Overgrowth Disorders. *W. Gibson[1, 2], J. Sou[1, 2], S. Gyawali[3], A. Fam[1, 2], R. Billings[1, 2], S.L. Babich[1, 2], L. Musa[1, 2], J. Friedman[1], S. Lear[3], S. Jones[4,5], D.D. Weaver[6], K. Boycott[7], P. Eydoux[1, 8] FORGE Consortium Canada.* 1) Dept Medical Genetics, BC Children's Hospital, Vancouver, BC, Canada; 2) Diabetes Research Program, Child and Family Research Institute, Vancouver, BC; 3) School of Kinesiology, Simon Fraser University, Vancouver, BC; 4) Michael Smith Genome Sciences Centre, Vancouver, BC; 5) BC Cancer Agency; 6) Dept Medical & Molec Genetics, Indiana University, Indianapolis; 7) Dept Medical Genetics, Children's Hospital of Eastern Ontario, Ottawa; 8) Cytogenetics Laboratory, BC Children's Hospital.

Recent advances in genome-wide analysis have identified previously-unknown metabolic pathways that control body weight. Study of patients and families with monogenic obesity and overgrowth disorders typically finds rare DNA variants that confer a high risk for obesity, whereas genome-wide association studies identify variants that confer a high population-attributable risk for increased adiposity (i.e. % body fat). We have been studying patients with rare overgrowth, obesity and lipodystrophy syndromes with a combination of genome-wide methods (Affy 6.0 SNP arrays and Whole Exome Sequencing in selected families). Because these disorders perturb the normal relationship between lean mass, fat mass and metabolic risk, we believe that Body Mass Index should be supplemented with direct quantitation of food intake, lean tissue mass, metabolic rate and activity level, as well as measurement of total and depot-specific fat mass. We have recruited several individuals with “paradoxical endophenotypes” - persons in whom metabolic risk appears abnormally high despite low adiposity. Our data on healthy adults (N=19, Age range 24-60) has found a mean resting energy expenditure (REE) of 30.6 kilocalories per kilogram of lean body mass per day (kCal/kgLBM; 95% CI 26-35). We have found several people whose REE is elevated after adjusting for lean body mass (range: 37-90 kCal/kgLBM/d). In lean individuals with low muscle mass and normal food intake, this may indicate a long-term risk for wasting and sarcopenia, as has been reported in Amyotrophic Lateral Sclerosis. In lipodystrophic individuals with high muscle mass and normal/elevated food intake, such a finding may indicate the body's attempt to dispose of excess intrahepatic and intramuscular fat by oxidation. Thus, data on body composition and metabolic rate may add value to the clinical delineation of patients with rare disorders of body weight. These data could assist in medical management, by showing a response to pharmacological and/or dietary interventions. For example, high-calorie supplements might be prescribed to build muscle in patients with low lean mass and elevated metabolic rate. Alternatively, a lowering of resting energy expenditure might be an early marker of metabolic benefit from dietary manipulation in patients with lipodystrophies. Supported by CIHR's Institute of Nutrition, Metabolism & Diabetes (OG PCN-102990), by the BC Clinical Genomics Network and by the FORGE consortium.

Functional genomic study on circulating B cells underlying defects in bone quality in postmenopausal Caucasian women. *V.S. Hanumanthu, L. Li, X.H. Peng, Y. Wang, R.R. Recker, P. Xiao.* Osteoporosis Research Center, Creighton University, Omaha, NE.

The commonly used measurement BMD (bone mineral density) is not the only real-life factor and may not even be the most important factor that determines skeletal fractures. Bone quality (BQ) describes the more important determinant of fractures. BQ can be defined in a hierarchical cellular, tissue, and structural levels. Excessive osteoclastogenesis may be one important mechanism that regulates bone quality. B cells play an important role in osteoclastogenesis via secretion of osteoclast-related factors, such as RANKL (receptor activator of NF-2B ligand), OPG (osteoprotegrin) and TGF-) 1 (transforming growth factor). Our previous functional genomic study also found importance of circulating B cells in the etiology of postmenopausal low BMD. However, little is known about circulating B cells in the etiology of defects in BQ. In the present study, we aim to screen functional genes in circulating B cells associated with defects in BQ in postmenopausal Caucasian women. We recruited 50 postmenopausal Caucasian women at age 45-70 with osteopenia, 25 with fragility fractures during the previous 5 years and 25 non-fracture controls with age, sex and BMD matched. We isolated circulating B cells and extracted their total RNA. Expression profiling for RNA sample from each subject was performed by Affymetrix Human Gene 1.0 ST array to identify genes that are differentially expressed. Significance of gene expression was measured using paired t-test. We found 223 genes that were differentially expressed among the two groups. Among them, chemokine ligand 17 (CCL17) ($p = 0.017$) and TYRO3 protein tyrosine kinase (TYRO3) ($p = 0.048$) were up-regulated in the fracturing group and found to have functional significance in osteoclastogenesis upon reviewing existing literatures. Studies found that increased secretion of CCL17 in human peripheral blood monocytes stimulated osteoclastogenesis and activated TYRO3 in mouse mature osteoclasts increased bone resorption. Further data analysis and qRT-PCR will be conducted to verify the findings. This is the first study to elucidate the role of circulating B cells in regulating human BQ.

809F

Exome sequencing of extended late-onset Alzheimer's disease (LOAD) families identifies rare variants associated with AD risk. *M.A. Kohli[1], A.C. Naj[1], E.R. Martin[1], G.W. Beecham[1], K.L. Hamilton[1], P.L. Whitehead[1], J.R. Gilbert[1], J.L. Haines[2], S. Zuchner[1], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Over the past five years, identifying risk genes for Alzheimer's disease (AD) has focused on testing the `common disease-common variant' (CDCV) hypothesis, in part because the tools to do so (e.g., large-scale SNP genotyping chips) have become widely available. While common variants like the , 4 allele of *APOE* clearly play a role in AD, there is a growing realization that the CDCV hypothesis is unlikely to explain all the genetic effect underlying AD. One alternative hypothesis invokes multiple rare variants (RV) in one or more genes, each with stronger individual effects than common variants in genes identified under CDCV. We identified a subset of 5 pedigrees from 61 extended multi-generational, late-onset AD (LOAD) families to attempt identification of rare variants. The five pedigrees average six AD-affected individuals, and have been screened to exclude known familial AD mutations in *APP*, *PS1*, and *PS2* genes. No *APOE* , 4/, 4 individuals were included. All affecteds in the five pedigrees underwent genome-wide genotyping (Illumina OMNI 2.5 arrays). Whole-exome sequencing was performed on 2-4 affected individuals per pedigree comprising 2-6 cousin or avuncular pairs. Based on genotyping results we calculated extended identity-by-descent (IBD) haplotypes per pedigree and determined that 0.7% to 18.1% of the genome fell within regions of >80% IBD sharing among affected relatives making these regions the most likely to harbor variants that lead to the LOAD burden. Novel missense variants in *FBXL22* and *G6PC2* were observed within the IBD sharing regions of each pedigree and were specific to each family. Neither gene has been associated with LOAD. Both variants were confirmed by Sanger sequencing and showed nearly complete segregation. Moreover, missense variants were identified that fell in genes recently associated with LOAD ($P<10^{-5}$) in a large genome-wide association study (GWAS, Naj et al. 2011). These changes include a rare missense variant in the *PTPRD* gene and a common missense change in *CD33*. We have identified unique rare variants that segregate with LOAD in these large families. Our results validate that combing genome-wide genotyping to determine IBD sharing with whole exome sequencing data in extended families can identify candidate rare variants in both known and novel LOAD genes. This approach holds promise for any complex disease where such families can be identified.

PHARMACOGENOMICS AND DRUG METABOLIMS. *A.Patricia. lozano Medellin.* pharmaceutical chemistry, National university, bogota, Colombia.

Pharmaceutical chemistry is a discipline that has enabled to provide the necessary medicines and vaccines for human welfare through the development of the human genome project has opened a window for using pharmacogenomics and pharmacogenetics get closer to the development of new drugs pharmacological targets which are detected with great precision with thanks to the techniques of medicinal chemistry.Several genetic causes and at different levels in the mechanism of action of a drug may be responsible for inter-individual variations in response to drug treatment. These include, first, differential pharmacokinetics due to genetic variations in the processes of absorption, distribution, metabolism, pro-drug activation, inactivation of the active generation of biologically active metabolites), and excretion of a particular drug. The rapid metabolism of certain drugs is caused by duplication, or multiduplicatión amplification of genes coding for CYP2D6. To date we have identified 2, 3, 4, 5 and 13 copies of these genes in tandem. These allelic variants confer a phenotype “ultra-rapid metabolizer” on their hosts. The rapid scientific progress has identified the key enzymes responsible metabolism occurred in phases I and II. One of the biggest obstacles is presented in pharmacological treatment currently is for the extensive interindividual variation is observed in drug metabolism. These variations may lead to different situations, such as treatment failure of drug therapy, onset of effects adverse or even toxic effects. The incidence of fatal adverse effects triggered by drugs cause over 100,000 deaths per year in the United States, placing between 4 and 6 cause of death in recent times.

Identification of the genetic and molecular basis of adult neuronal ceroid lipofuscinosis (NCL4) using novel genomic methods. *L. Noskova[1,2], V. Stranecky[1,2], H. Hartmannova[1,2], A. Pristoupilova[1,2], H. Hulkova[1,2], M. Elleder[1,2], H. Jahnova[1], K. Hodanova[1,2], S. Kmoch[1,2].* 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General Teaching Hospital, Prague, Czech Republic, Ke Karlovu 2, Prague 2; 2) Center for Applied Genomics, Prague.

Neuronal ceroid lipofuscinoses (NCLs) are heterogenous group of most common inherited neurodegenerative disorders with incidence of between 1 and 5 per 100 000 in different countries. They are characterized by neurodegeneration and accumulation of autofluorescent lipopigments in both neural and peripheral tissues. Most of NCLs presenta as infantile or juvenile forms, to date approximately 280 NCL causing mutations have been found in eight genes.Adult NCLs either recessive (Kufs` disease) or dominant (Parry disease) are considered rare and their genetic and molecular basis is still unknown. We identified Czech family with autosomal dominant ANCL presenting with myoclonic epilepsy, generalized tonic clonic seizures, progressive cognitive deterioration and depressive symptomatology starting in a third decade of life, normal activity of palmitoylthiosterase 1 in leucocytes and characteristic neurolysosomal storage of autofluorescent material with ultrastructural appearance of granular osmiophilic deposits (GRODs) in brain. To map the disease loci, we used Affymetrix GeneChip® Mapping 10K 2.0 Arrays, genotyped available family members and performed linkage analysis. We also performed gene expression analysis in leucocytes isolated from four patients using Illumina HumanRef-8 v2 Expression BeadChips and exome sequencing on SOLID™ 4 System in one proband. By combination of these approaches and several methods of bioinformatic analysis of exome data, we obtained list of unique changes in candidate regions. Sequencing verification and segregation of found changes with the fenotype is in progress. This study was supported by the grant from the Ministry of Education of the Czech Republic (MSM0021620806) and by the grant of Charles University GAUK 299911.

Identifying Common and Infrequent Genetic Risk Variants in Type 1 Diabetes in a Family Based Study. *S. Onengut-Gumuscu[1], W.M. Chen[1], M. Szpak[1,2], J.C. Mychaleckyj[1], P. Concannon[1], S.S. Rich[1], the T1DGC.* 1) Center for Public Health Genomics, University of Virginia, Charlottesville, VA, USA; 2) Faculty of Biology, University of Warsaw, Warsaw, Poland.

Type 1 Diabetes (T1D) is a complex disease that results from the immune mediated destruction of the insulin secreting beta-cells of the pancreas. We have recently reported the results of a genome-wide association (GWA) study in T1D and a meta-analysis of these data in combination with two prior GWA reports. The total sample set included 7,514 cases and 9,045 controls. We identified 18 novel genomic regions that were associated with T1D in our meta-analysis. In conjunction with those from previous linkage and association studies, there are now more than 40 confirmed genomic regions harboring risk loci for T1D. Aiming to fine map all reported T1D risk loci in a systematic approach, we have densely genotyped all T1D regions in 2,835 affected sib pair (ASP) families and 494 T1D trio families (total of 12,983 samples) previously recruited by the Type 1 Diabetes Genetics consortium (T1DGC) using a custom genotyping panel (ImmunoChip). The ImmunoChip content focused not only on known T1D risk loci but also on risk loci from other immune-mediated diseases, and included 186 risk loci. Common and infrequent SNPs included on the ImmunoChip were chosen from the 1000 Genomes Project pilot CEU population variants as well as those contributed by investigators through disease specific resequencing projects. After completing Illumina design metrics, a total of 196,524 SNPs were included on the ImmunoChip. On average, 643 SNPs were genotyped in each non-HLA T1D risk locus (over 6,000 SNPs covered the HLA region). Approximately 12 % of the SNPs genotyped had minor allele frequencies (MAF) between 0.01 and 0.05 (less frequent) and 14 % of the SNPs were rare (MAF < 0.01). A total of 35 of the previously reported T1D risk loci exhibited strong evidence of association in the ASP and trio T1D families where 22 of the risk loci had P-value < 1×10^{-4} and 13 of the risk loci had P-values between $1x\ 10^{-4}$ and 1×10^{-3}. The ImmunoChip platform has allowed us to refine associations in T1D risk loci simultaneously and lead to identification of independent common and infrequent T1D risk variants contributing to disease development. The biological influence and detailed functional role of each risk variant will need to be further elucidated in future functional studies.

Copy Number Variants of GSTM1 gene in Rheumatoid Arthritis. *E. Petit-Teixeira[1], M.S. Ben Kilani[1], L. Michou[1], T. Bardin[2], F. Cornelis[1,2,3,4].* 1) GenHotel-EA3886 Laboratory, University of Evry-Val d Essonne, Evry , France; 2) Federation of Rheumatology, Lariboisiere Hospital, APHP, Paris, France; 3) Clinical Genetics Unit, Lariboisiere Hospital, APHP, Paris, France; 4) Adult Genetics Unit, CHSF, Corbeil, France.

Rheumatoid Arthritis (RA) is a chronic inflammatory disease that affects primarily joints manifesting as pain, stiffness and synovitis leading in turn to articulation destruction. This autoimmune disease has a complex etiology not entirely elucidated. The major genetic factor, HLA-DRB1 gene, is characterized by several shared epitope (SE) alleles associated with RA. Part of environmental component in RA is explained by tobacco exposure. Detoxifying process of carcinogen components from tobacco is a key step under control of several genes. Among them, glutathion S-transferases (GST) family genes encode peroxydases acting on secondary cytotoxic metabolites for cell protection. One member of this family, GSTM1 gene, is characterized by Copy Number Variations (CNV). Our aim was first to analyze CNVs of GSTM1 gene in relation with tobacco exposure among RA patients. Second, genetic, clinical and biological data (presence of erosion and of autoantibodies) were considered to analyze the relationship between CNVs and RA. Finally, we studied transmission of CNVs in trio families. CNVs identification was performed using fluorescent specific probe and dedicated analysis (Applied Biosystems). Results were confirmed by specific amplifications. Relation between CNVs, tobacco and others factors in 240 RA patients was determined by Odds Ratio with 95% Confidence Interval and with logistic regression. Transmission disequilibrium and genotype relative risk were tested in trio families with one RA patient and its two healthy parents. Homozygous GSTM1 deletion was observed in 52% of RA patients. This deletion is not associated with tobacco exposure (TE+) in RA patients (43% TE+ versus 53% TE-, OR = 0,69 [0.41-1.15]), but with presence of the HLA-DRB1 SE in the subgroup of RA patients TE+ (56% HLA-DRB1 SE positive versus 14% HLA-DRB1 SE negative, OR = 2.87 [1.15-7.17]). A trend of transmission disequilibrium in trio families was observed for GSTM1 deletion. Furthermore, CNVs characterization revealed several cases of GSTM1 copy loss through transmission. Several studies described associations of GSTM1 deletion with RA considering tobacco exposure and severity of the disease. Our study is the first to characterize CNVs GSTM1 in RA trio families. The familial material could highlight mechanisms of deletion for this gene and the association with RA. CNVs characterization should be the next step to elucidate new genomic factors in complex diseases such as RA.

VAR-MD: Advanced analysis of whole exome sequencing for detection of hemizygosity. *M. Sincan[1,2], D.R. Simeonov[1], T.C. Markello[1], D.A. Adams[1], C. Toro[1], C. Tifft[1], W.A. Gahl[1], C.F. Boerkoel[1].* 1) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD; 2) NIH Undiagnosed Diseases Program, NIH, Bethesda, MD.

Whole Exome Sequencing (WES) is increasingly used in diagnoses of rare Mendelian diseases, but methods are required to comprehensively analyze and prioritize huge numbers of variants. We have developed a tool that can evaluate WES variants and produce a ranked list of potential causative mutations in the family. This tool 1) employs a simple, tab-delimited input file containing the annotated variants shared within the family; 2) utilizes family structure and affected status, 3) makes use of public data sets for further annotation and analysis; 4) makes use of the short read alignments of the exomes in bam format for additional analyses; and 5) for the first time, detects hemizygosity. This tool was highly successful in prioritizing and ultimately identifying pathological mutations causing spinocerebellar ataxia type 28, GM1-gangliosidosis, and spastic paraplegia type 35 (SPG35) in different patients enrolled in the NIH Undiagnosed Diseases Program. Of particular interest was the case of a boy with SPG35. Previous WES analytical tools read the mother's genotype as homozygous for the normal FA2H allele while the father was found to carry a point mutation. However, the maternal allele actually carried a deletion of exons 3-7. Since monoallelic deletions cause continuous loss of heterozygosity across the deletion, we interrogated the BAM alignment files of the family for unusual runs of homozygosity. We confirmed that this was indeed the case for this family, and incorporated this process into our WES filtering analysis. This advanced tool for WES analysis (VAR-MD), which has broad applicability and includes the innovation of detecting copy number variants, is available to the public at http://research.nhgri.nih.gov/.

Large-scale transcriptome analysis using RNA-seq reveals new insights into psoriasis biology. *L. Tsoi[1], R. Nair[2], B. Li[1], J. Ding[1], J. Gudjonsson[2], P. Stuart[2], T. Tejasvi[2], H. Kang[1], G. Abecasis[1], J. Elder[2,3].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Dermatology, University of Michigan, Ann Arbor, MI; 3) Ann Arbor Veterans Affairs Hospital, University of Michigan, Ann Arbor, Mi.

Psoriasis is a genetically determined chronic inflammatory disease of the skin and joints that affects ~0.2-2% of the world's population. To further our understanding of the biology of psoriasis, we utilized high-throughput RNA sequencing technology (RNA-seq) to assay the transcriptomes of lesional and normal skin. We sequenced 92 lesional and 82 normal punch biopsy samples of human skin, each with an average of ~38 million single-end 80-bp reads. Comparison of 42 samples examined with both RNA-seq and our recent microarray-based studies showed systematic differences in estimated expression levels. Based on RNA-seq data, we identified 3,577 differentially expressed genes between the two tissues, and further investigation showed that the genes identified only by RNA-seq have markedly lower expression than those also identified by microarray, indicating that RNA-seq has higher resolution for low abundance transcripts. Pathway analyses revealed differentially expressed genes were enriched for genes involved in cytokine-cytokine receptor interaction and immune system processes. Furthermore, cytokine genes that are functionally important for psoriasis, such as IFNG, IL17, IL22 and IL24, which were not detected as differentially expressed by microarray analyses, were all identified as differentially expressed using RNA-seq. Using a specially tuned variant calling algorithm, we also performed variant calling using the RNA-seq data. Among the nonsynonymous, synonymous, and nonsense polymorphisms identified, 49%, 63%, and 33% of them overlap with the records in dbSNP respectively. The transition to transversion ratios (Ts/Tv) for the novel variants found are comparable to the known variants and, comparing individual genotypes with previous GWAS data, we obtained an average of 98.4% concordance rate, indicating the high accuracy of variant discovery and genotype calling from RNAseq. The increased resolution and power provided by RNA-seq will allow a more comprehensive view of global gene regulation and interaction in psoriasis, and the ability to identify novel disease-associated expressed variants should provide new insights into its pathogenesis.

Identification of the gene causing IFTDC. *M. Weterman[1], P. Barth[2], G. Nuernberg[3], O. Milanesi[4], P. Nuernberg[3], B. Poll-The[2], F. Baas[1].* 1) Neurogenetics/LVGA, K2-213, AMC/UvA, Amsterdam, Netherlands; 2) Pediatric Neurology, Emma Children's Hospital, AMC, Amsterdam, Netherlands; 3) Cologne Center for Genomics, Koln, Germany; 4) Pediatrics, University of Padova, Padova, Italy.

Infantile Fiber Type Disproportion and Cardiomyopathy (IFTDC) is a rare pediatric muscular disorder, characterized by general muscle weakness with onset shortly after birth and dilated cardiomyopathy. It was initially reported in six apparently unrelated Dutch families. All patients died between 4 and 6 months of age. Muscle biopsies of four of the patients showed small type I and normal type II fibers. An extensive search for defects related to disturbances in energy metabolism, respiratory chain defects and disorders of mitochondrial fatty acid metabolism, in frozen muscle biopsies and cultured fibroblasts, was negative. We therefore tried to identify the cause of this disease using a genome wide approach. Genomic DNA was used for linkage analysis on an Affymetrix 250K SNP microarray. Parametric analysis, initially with a reduced marker panel of 20K SNPs markers, assuming consanguinity with a second cousin marriage, and autosomal recessive inheritance with full penetrance and low frequency led to the identification of a homozygous region of 2.2 Mb on chromosome 12 that was shared between all patients. Detailed analysis of the region using all markers gave a LOD score of 10.82. Sequence capture of the region of interest followed by next generation 454 sequencing only yielded homozygous changes within the coding regions of genes that were already reported as polymorphisms. Although over 95% of the coding regions were covered, 31 of 398 exons had a coverage that was either too low or totally absent. Sanger sequencing of these gaps yielded three homozygous changes, one was a known polymorphism, one was located in the untranslated region of the corresponding mRNA, and the third mutation was a splice site mutation in a myosin gene, making this gene a strong candidate for the disease. Identification of compound heterozygosity for frame shift mutations in the same gene in an Italian patient with the same clinical phenotype, supports the pathogenic role of this gene in IFTDC.

817F

Deep sequencing of the human TCR. and TCR) repertoires provides evidence that TCR) rearranges after () , .+ T-cell commitment. *C.S. Carlson[1], A. Sherwood[2], C. Desmarais[2], R.J. Livingston[2], J. Andriesen[2], M. Haussler[3], H. Robins[1].* 1) Pub Hlth Sci, Fred Hutchinson Cancer Res Ctr, Seattle, WA; 2) Adaptive TCR Corporation, Seattle, WA; 3) Faculty of Life Sciences, University of Manchester, Manchester,United Kingdom.

The two main lineages of T lymphocytes develop from multi-potent precursors in the human thymus. The most common type in blood are () T cells, which bind to antigenic peptides displayed on the surface of cells by human leukocyte antigen (HLA) molecules. Far less well understood are .+ T cells, which do not bind HLA:peptide complexes and are more prevalent in the gut mucosa. For both lineages, their ability to recognize a diverse array of antigens is mediated by a rearranged receptor on their surface, the T cell receptor (TCR), composed and of an (and) chain for () T cells or a . and + chain for .+ T cells. The canonical model for commitment from the precursor to one these two lineages assumes that . , +, and) chains rearrange prior to commitment to () or .+ fate. A crucial step towards better understanding the role of .+ T cells is to work out the developmental process. To test the standard model and to understand the .+ TCR repertoire, we use high-throughput sequencing to catalog millions of TCR. and TCR) chains from peripheral blood () and .+ T cells, from three unrelated individuals. Almost all sampled () and .+ T cells have rearranged TCR. sequences. While sampled () T cells have a diverse repertoire of rearranged TCR) chains, less than 10% of .+ T cells in peripheral blood have a rearranged TCR) chain. Our data indicate that TCR. rearranges in all T lymphocytes, consistent with TCR. rearranging prior to T cell lineage commitment, while rearrangement of the TCR) locus is restricted, and occurs after T cell precursors commit to the () T cell lineage. This result explains the conundrum in T cell leukemia and lymphoma that TCR. is almost always rearranged and TCR) is only rearranged in a subset of cancers. As high-throughput sequencing of TCRs is translated into the clinic for monitoring minimal residual for leukemia/lymphoma, our data suggests the sequencing target needs to be TCR . .

Measurement of T cell repertoire diversity in the peripheral blood by novel multiplex PCR and next-generation sequencing methods. *J. Han, C. Gunter, C. Sanders, Q. Yang, C. Wang.* HudsonAlpha Institute for Biotechnology, Huntsville, AL.

An individual's collection of B and T cells determine their ability to respond to infection and malignancies; each cell contains one of millions of possible combinations of V, D, and J gene segments, comprising an immune repertoire. Studies from our lab and others suggest that immune repertoire diversity might be an effective indicator for determining overall health status and disease prognosis. We have previously developed an ARM-PCR/HTS (amplicon rescued multiplex PCR/high throughput sequencing) method allowing us to semi-quantitatively and comprehensively analyze the TCR repertoire[1]. Using this technology, we sequenced TCR) CDR3 fragments amplified from cDNA molecules isolated from three T cell subsets: regulatory (Tr, CD4+CD25+), helper (Th, CD4+CD25-), and cytotoxic (Tc, CD8+) cells from peripheral blood samples. Based on these, we propose a diversity index called D50 as a measure of the diversity of a sequenced immune repertoire. In simple terms, D50 is the minimum percentage of distinct CDR3s accounting for at least half of the total CDR3s.

We compared D50 values between lung, colon, and breast cancer samples to age-matched healthy individuals, who had no known illnesses at the time of blood donation, and found that the D50 values in all three T cell subsets are lower by a statistically significantly amount ($p<0.05$) in comparison to their healthy control counterparts. In addition, D50 values of Tr cells were better able to distinguish normal from cancer samples than those of either Tc or Th cells. Given that loss of immune repertoire diversity is associated with various diseases, we suggest that the D50 test could be used as a screening test to evaluate health status. In addition, the expression profile of disease-specific CDR3s may be used as biomarkers for early diagnosis, prognosis, or disease management.

Background: Systemic lupus erythematosus is a sexually dimorphic autoimmune disease which is more common in women, but affected men often experience a more severe disease. The genetic basis of sexual dimorphism in lupus is not clearly defined. Here, we examine sex-specific genetic effects among lupus-susceptibility loci. Methods: A total of 18 lupus-associated autosomal genetic loci were genotyped in a large set of lupus patients and controls of European descent, consisting of 5,932 female and 1,495 male samples. Sex-specific genetic association analyses were performed. Sex-gene interaction was further validated using both a parametric (logistic regression) and non-parametric (multifactor dimensionality reduction) methods. We examined aggregate differences in sex-specific genetic risk by calculating a cumulative genetic risk score for lupus in each individual and comparing average genetic risk between men and women. Results: We observe a significantly higher cumulative genetic risk for lupus in men than in women. We report significant sex-gene interaction in the HLA region and IRF5 genes whereby male lupus patients possess a significantly higher frequency of risk alleles than their female counterparts. We also report that the genetic effect observed in KIAA1542 is specific to female lupus patients, and does not seem to play a role in lupus in men. Conclusions: Our data indicate that men require a higher cumulative genetic load to develop lupus compared to women. This observation suggests that the higher prevalence of lupus in women, and the more severe lupus phenotype in men could be related to autosomal genes.

Identification of novel genes in human primary immunodeficiency diseases using exome sequencing. *S. Khan[1], B. Wakeland[1], C. Liang[1], N. van Oers[1], M. De la morena[2], E. Wakeland[1].* 1) University of Texas Southwestern Medical Center, Dallas, Texas; 2) Children's Medical Center, Dallas, Texas.

Severe immunodeficiencies are rare in the human population (less than 1 in 70,000) and their genetic etiology is very difficult to decipher. More than 150 genes have been linked to various forms of primary immunodeficiencies and most of these are the consequence of a monogenic defect and hence follow a simple mendelian inheritance. In this study we utilized whole exome sequencing strategy to identify the causative genetic lesions in patients with severe immunodeficiencies of unknown etiology. This strategy has proven to be a powerful, efficient strategy for identifying genes underlying rare Mendelian disorder. We subjected five families with one or more children who have severe PID with an unknown genetic basis to whole exome sequencing using SureSelect Human All Exon Kit from Agilent technologies and sequenced in a single lane of an Illumina GAIIx. On average 4.5 Gbp of sequence data was generated per sample of which 2.54 Gbp of the sequence mapped specifically on the tiled exons. On average individual genomes differed from the reference sequence by 64,449 total SNVs. To distinguish potentially deleterious mutations from other variants, only nonsynonymous, variants and short coding region insertions or deletions were considered. We will present the analysis for one of the probands with severe combined immunodeficiency with no detectable peripheral T cells at ASHG 2011. The causative variants for the PID exhibited by the proband was sought using several filtering strategies that led to a list of 29 candidate variations that were novel, deleterious mutations that were homozygous or compound heterozygous only in affected child within a PID family. Based on the functional impact of SNV on the gene and a consideration of the expression of these genes within immune cell lineages or relevant tissues, a final list of 6 potential genetic mutations that could cause this specific SCID has been generated. These mutations are now being validated using standard Sanger sequencing. The future studies will characterize the impact of these variants on their expression in T cells and other tissues by RNA-SEQ analysis of PBMC from the parents and or siblings that are heterozygous for the candidate variant. We hope that these data will identify novel genes and their functional role within the human immune system.

821F

A genetical genomics approach to understanding the regulatory mechanisms of host-pathogen interactions in humans. *M.N. Lee[1,2,3], C. Ye[1], A.C. Villani[1], P. De Jager[1,3], A. Regev[1], N. Hacohen[1,2,3].* 1) Broad Institute, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA.

While naturally occurring genetic variants are known to modulate gene expression (e.g. eQTL), limited studies have evaluated the influence of these variants on pathogen responses using relevant human primary immune cells. Results from such gene-environment studies will be crucial to further understand disease etiology of a variety of disorders including infectious diseases, autoimmune diseases, and cancer. We will present a systematic study evaluating variation of gene expression responses across a healthy cohort of 30 individuals using monocyte-derived dendritic cells (MoDCs) activated through bacterial and viral sensors that mediate innate immune responses to pathogens. The cohort consists of equal numbers of Caucasians, Asians and African-Americans; half female and half male for each ethnicity. We will describe a combined information-theoretic and functional genomics strategy to identify key components of the pathogen response with natural genetic variants that may be associated with disease susceptibility.

822F

Identification of Novel Imprinted Genes Expressed in Mouse Frontal Cortex Using RNA-Sequencing. *K. Wigg[1], E. Dempster[2], C. Barbacioru[3], L. Gomez[1], Y. Feng[1], P. Monnier[1], R. Logan[1], J. Eubanks[1], C. Barr[1,4].* 1) Genetics and Development, Toronto Western Hosp, Toronto, ON, Canada; 2) Institute of Psychiatry, Kings College London, London UK; 3) Applied Biosystems (Life Technologies), Foster City, California, USA; 4) Program in Neurosciences and Mental Health, Hospital for Sick Children, Toronto, Ontario, Canada.

Current data support approximately 90 validated imprinted genes in mice, but recent estimates indicate that this number may be well over 1,000. Many of the genes are imprinted in a tissue/cell type specific pattern and little is known of these genes. Previous evidence indicates that imprinted genes influence the development of specific brain regions and we sought to identify imprinted genes contributing to the development of the frontal cortex. We developed a strategy using crosses and reverse crosses of mouse strains to determine the parent-of-origin of expressed genes. We used next generation sequencing of RNA (RNA-seq) from the frontal cortex of the adult F1 mice to identity transcripts differing in expression between the crosses. RNA from the two parental lines was also sequenced to determine strain specific polymorphisms and determine the parent-of-origin of the transcripts. We identified transcripts that were differentially expressed between the crosses showing parent-of-origin effect in the frontal cortex including known imprinted genes (e.g. Meg3, Snurf/Snrpn, Ube3a, Rasgrf1) and genes with no prior evidence for parent-of-origin effects. Using a FDR of 0.01, and requiring that the same parent-of-origin bias was evident in 3 biological replicates, we identified 109 transcripts with parent-of-origin effects. The finding of novel imprinted genes indicates that the number of imprinted genes with tissue specific effects is underestimated and requires further studies to identify the full complement of imprinted genes in brain. The understanding of parent-of-origin effects in specific brain regions will make a significant contribution to our understanding of the role of imprinting in brain function and behavior.

823F

Genetic analysis of the Th17-related genes in cerebral malaria. *S. Marquet[1], B. Poudiougou[2], U.E Ndoumbe[1], A. Traore[2], A.A Oumar[3], S. Cabantous[1], O. Doumbo[2], A.J Dessein[1].* 1) INSERM U906, Université de la Méditerranée, Marseille, France; 2) Department of Epidemiology of parasitic disease, University of Bamako, Bamako, Mali; 3) Centre des oeuvres universitaires, University of Bamako, Bamako, Mali.

The pathogenic mechanisms of cerebral malaria (CM) are unclear but are thought to involve cytokine-mediated inflammation enhanced by parasite sequestration in microcirculation. In previous work, we have shown that Interferon-. and Interleukin-12 protect against CM whereas IL-4 may be a risk factor for severe malaria. By conditional logistic regression analysis, three genotype combinations of two IL4 polymorphisms influencing IL-4 levels are associated with different risk of severe malaria. Actually, our research is focus on the recently discovered Th17 cytokine response which is shown to play a crucial role in regulating tissue inflammatory reactions. To investigated the contribution of Th17-related genes in susceptibility to CM, 96 Tag SNPs have been selected in IL1B, IL6, TGFB1, IL23A, IL17A, IL17F, IL22, IL6ST, IL17RA, and IL27RA genes and tested by Illumina Golden Gate genotyping Assay. The univariate analysis in the first cohort of 152 nuclear families was performed using the Family-based association test package (FBAT). The analysis revealed significant or suggestive associations with disease for 18 polymorphisms. To follow-up these results, study of 87 additional families, who were independent of the initial study sample and were from the same population, are ongoing. When the association will be confirmed, additional polymorphisms in linkage disequilibrium with associated SNPs could be tested. Finally, functional analysis will be performed to determine the molecular role of these markers in disease development.

824F

Significance of polymorphisms within the *SLC11A1* (*NRAMP1*) gene that is associated with *Mycobacterium avium* complex infection. *B.R. Sapkota[1,2], M. Hijikata[1], I. Matsushita[1], G. Tanaka[3], A. Mabuchi[2], K. Tokunaga[2], N. Keicho[1].* 1) Department of Respiratory Diseases, Research Institute, National Center for Global Health and Medicine, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Department of Respiratory Medicine, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

Background: *Mycobacterium avium* complex (MAC) disease is caused by the infection with a group of microorganism in nontuberculous mycobacteria (NTM) *viz. Mycobacterium avium* and *Mycobacterium intracellulare*. Pulmonary MAC infection is a rare disease manifested with common respiratory symptoms and typical radiographic findings. Although genetic variants in the *SLC11A1* (*NRAMP1*) gene have been associated with mycobacterial diseases, these finding have not been extensively validated in pulmonary *Mycobacterium avium* complex (MAC) infection. This study investigates linkage disequilibrium (LD) pattern within the *SLC11A1* gene and its association with pulmonary MAC infection. **Methods and Findings:** Altogether, 19 polymorphic loci in *SLC11A1* were genotyped to define LD blocks and haplotype structures in European descendents and Japanese population, and Tag SNPs were chosen. A total of 6 polymorphic sites were genotyped in 111 pulmonary MAC cases and 211 controls from Japan. Furthermore, allelic expression imbalance of mRNA of *SLC11A1* gene was evaluated in peripheral blood cells from Japanese heterozygous individuals. Frequencies of major haplotypes were different between these two populations. One unique haplotype accounting for 4% was observed only in the Japanese population with a variant (allele 7) of 5' GT repeat. We observed an association between T allele of rs2279014 and protection from MAC disease when comparing allele frequencies with an odds ratio of 0.582 (95% CI 0.379 - 0.894, p = 0.013). In subgroup analysis, this SNP was associated with late onset (> 50 age group) of disease (p = 0.029) and also associated with patients without co-morbidity (p = 0.028). Of the haplotypes carrying three loci (rs17235409, rs17235416 and rs2279014), haplotype `GIC' was significantly associated with the MAC disease (Permutation p value = 0.008). However, no significant difference in allele-specific expression levels of mRNA was observed. **Conclusion:** Haplotype frequency differences were observed between European descendents and Japanese population, and Tag SNPs were selected in the Japanese population. A significant association of rs2279014 with pulmonary MAC infection was observed. To our knowledge, rs2279014 SNP has not been reported in association with any other diseases. The statistical significance was modest and will require further study for conclusive validation.

Analysis of de novo genomic events implicates a zinc-finger protein in controlling chilhood carcinogenesis. *J. Hussin[1,2], V. Bruat[2], Y. Idaghdour[1,2], F. Casals[1,2], V. Saillour[2], J.F. Spinella[2], M. Larivière[2], S. Busche[3], B. Ge[4], T. Pastinen[3,4], D. Sinnett[1,2], P. Awadalla[1,2].* 1) Faculty of Medecine, University of Montreal, Quebec, Canada; 2) Ste-Justine Hospital Research Centre, Montreal, Quebec, Canada; 3) Department of Human Genetics, McGill University, Montreal, QC, Canada; 4) Genome Quebec Innovation Centre, Montreal, QC, Canada.

Cancer is the leading cause of death by disease among children in western countries, with nearly 15,000 new pediatric cases diagnosed each year in North America. While the overall incidence rate of cancer in children continues to rise steadily, its etiology remains elusive. In particular, little is known about the contribution of *de novo* events, occurring during meiosis, to the genetic instability that drives pediatric cancer. To characterize the importance of these genetic events in controlling carcinogenesis in children, we used a family-based analytical framework, coupled with cohort validation studies, to identify new variants and recombination breakpoints using genomic data. Through the in-depth analysis of a unique case, a family with two siblings having hyperdiploid childhood acute lymphoblastic leukemia (ALL), we called *de novo* point mutations and indels from high-throughput sequencing data, performed fine-scale dissection of meiotic recombination events and examined tumor-specific mitotic recombination patterns and chromosomal breakpoints. We successfully identified candidate *de novo* mutations, having predicted deleterious phenotypic impact, and we located recombination events in genes known to be involved in cancer, which could be indicative of potential driver mutations in childhood ALL. Furthermore, the abnormal placement of maternal meiotic recombination events allowed us to discover the presence, in the mother, of a rare allele of a chromatin-modifying gene, encoding a C-terminal tandem array of C2H2 zinc fingers (ZnF). This meiosis-specific gene has been identified as a key player in regulating recombination in mammals. We further observed an excess of rare alleles at that locus in a cohort of parents with children having childhood ALL. Since variation in the ZnF array domain in humans has been shown to influence meiotic instability and to be implicated in some pathological genome rearrangements, it may therefore play an important role in childhood tumorigenesis.

Title: Linkage disequilibrium analysis of polymorphisms of FRAS1 Related Extracellular Matrix 1 (*FREM1*) in susceptibility to HIV-1 infection in a Sub Saharan African female sex worker cohort. *J.F. Tuff[1], N. Kaplonski[1], V. Ly[1], B. Liang[1], S. Tyler[1], J. Kimani[3], M. Luo[1,2], F.A. Plummer[1,2].* 1) National Microbiology Laboratory, Winnipeg, MB, Canada; 2) University of Manitoba, Medical Microbiology, Winnipeg, MB, Canada; 3) University of Nairobi, Medical Microbiology, Nairobi, Kenya.

Objective: A genome wide association study of the Pumwani Sex Worker (ML) cohort identified a single nucleotide polymorphism (SNP; rs1552896) in *FREM1* to be significantly correlated with the HIV-exposed Seronegative (HESN) phenotype. In this study, our goal was to identify polymorphisms within *FREM1* that are in linkage disequilibrium (LD) with rs1552896 and characterize causative genetic variants contributing to HESN phenotype. Design: Twenty-two overlapping PCR amplicons were designed to span *FREM1* (176,330 bp) and amplified in 69 ML members. The amplicons were sequenced with Genome Sequencer FLX™ (Roche) and assembled with Sequencher 4.8 (Gene Codes). Statistical measures of LD (Logarithm of the Odds (LOD) score, D', and r2) between polymorphisms were determined with Haploview v 4.2. Results: We identified 918 *FREM1* polymorphisms in this cohort, 447 of which are newly discovered. Twelve of these polymorphisms were in LD with rs1552896, within a 32Kbp LD block. These polymorphisms consisted of 8 intronic SNPs (rs112356286, rs74549063, rs2818932, rs12337418, rs62537679, rs1889050, rs62537685, and rs11788565), 3 novel microsatellite variations, and a non-synonymous exonic SNP (rs2779500). *FREM1* SNP rs2779500 results in a leucine residue replacing a valine residue in the second CSPG domain of FREM1 splice isoform 1 and 2. Conclusions: It is possible for a polymorphism to be associated with a disease phenotype not because it is biologically causal, but because it is in LD with a causal polymorphism. We therefore sought to identify all polymorphisms in LD with *FREM1* SNP rs1552896, a SNP previously shown to be highly associated with the HESN phenotype. In doing so, we have identified 12 additional polymorphisms whose possible contribution to the HESN phenotype in the ML cohort warrants future investigation.

Genome-wide Linkage Scan in an Indian Family with Split-hand/foot Malformation narrowed down the SHFM3 region to 10q25.1-q25.3. *A. Ali[1], R. Raman[2].* 1) Centre for Genetic Disorders, Banaras Hindu University, Varanasi, India; 2) Department of Zoology, Banaras Hindu University, Varanasi, India.

Split-hand/foot Malformation is a complex disorder with considerable variable expressivity and genetic heterogeneity. However, its inheritance pattern mostly indicates autosomally dominant monogenic pattern. Recently, examples of X-linked and autosomally recessive patterns have been seen where involvement of more than one interactive genes has been speculated. Genome-wide linkage scan of a 5-generation SHFM family, using 10K SNP arrays (Affymetrix, USA), shows a single peak with LOD score 3.01 at the region 10q25.1-q25.3. A few earlier reports have also identified 10q24-q25 as one of the critical regions for SHFM3. Recombination in one of the affected children between SNPs rs1361356 and rs952965 enables us to narrow down the critical locus to a 0.46 cM region, which falls upstream of the gene SORCS1 which has not yet been shown as a candidate gene for SHFM. The study was supported by a grant from the Department of Biotechnology, New Delhi to RR.

Genome-wide linkage analysis for longevity in European nonagenarian siblings: Genetics of Healthy Ageing Study (GEHA). *M. Beekman[1,2], P.E. Slagboom[1,2], H. Blanche[3], M. Perola[4], A. Hervonen[5], V. Bezrukov[6], E. Sikora[7], L. Christiansen[8], S. Schreiber[9], A.J.M. De Craen[1,2], T.B.L. Kirkwood[10], I.M. Rea[11], M. Poulain[12], J.M. Robine[13], S. Valensin[14], M.A. Stazi[15], G. Passarino[16], L. Deiana[17], S. Gonos[18], O. Törnwall[4], Q. Helmer[1], F. Martella[1], R.G.J. Westendorp[1], M. Lathrop[3], J.W. Vaupel[19], K. Christensen[8], J. Gampe[19], A. Nebel[9], J.J. Houwing-Duistermaat[1,2], C. Franceschi[14] On behalf of the GEHA consortium.* 1) Leiden University Medical Centre, LUMC, Leiden, The Netherlands; 2) Netherlands Consortium for Healthy Ageing, The Netherlands; 3) Foundation Jean Dausset, CEPH, France; 4) The National Institute for Health and Welfare, THL, Helsinki, Finland; 5) Tampere School of Public Health, Tampere, Finland; 6) Institute of Gerontology, Kiev, Ukraine; 7) Nencki Istitute for Experimental Biology, NENCKI, Warszawa, Poland; 8) Epidemiology, Institute of Public Health, University of Southern Denmark, Odense, Denmark; 9) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel (CAU), Germany; 10) Newcastle University, UNEW, United Kingdom; 11) Queens University of Belfast, QUB, United Kingdom; 12) Catholic University of Louvain, UCL, Belgium; 13) INSERM, Health & Demography, CRLC, France; 14) University of Bologna, Interdepartmental Centre "Luigi Galvani" CIG, UNIBO, Italy; 15) Istituto Superiore di Sanità, ISS, Rome, Italy; 16) University of Calabria, UNICAL, Italy; 17) University of Sassari, UNISS, Italy; 18) National Hellenic Researcher Foundation, NHRF, Athens, Greece; 19) Max Planck Institute for Demographic Research, MPIDR, Rostock, Germany.

Nonagenarians and their first degree family members have a life-long survival advantage that can be attributed to a lower risk of coronary artery disease and type-2 diabetes despite the fact that they carry as many GWAS-identified disease risk alleles as the general population. We hypothesized that long-lived families carry alleles that lower disease susceptibility. To identify such longevity alleles, we performed a genome-wide linkage scan among 2118 nonagenarian Caucasian sibling pairs that have been recruited in fifteen study centers of eleven European countries in the Genetics of Healthy Ageing (GEHA) Study. In the joint nonparametric linkage analysis we observed four regions that show linkage with longevity; chromosome 14p11.2 (LOD=3.47), chromosome 17q21.32 (LOD=2.95), chromosome 19p13.2 (LOD=3.76) and chromosome 19q13.32 (LOD=3.57). Since the 19q13.32 region spans the *APOE* gene, known to contribute to longevity and mortality, we analyzed whether the APOE, 2, 3, 4 alleles contributed to the linkage. An analysis in which association and linkage were additively modeled, using LAMP, showed that together the APOE, 2 ($P \leq 0.0001$) and the APOE, 4 ($P=0.020$) alleles explain the linkage at 19q13.32. To fine map these linkage results at the 14p11.2, 17q21.32 and 19p13.2 loci we used GWAS data in the nonagenarian siblings that contributed to the linkage results to test for associations explaining the linkage. For the association analyses 1058 unrelated nonagenarian cases were compared with 8776 younger controls of similar geographical origin as the cases. At 14p11.2 we tested 1023 SNPs for association, at 17q21.32 2969 SNPs, at 19p13.2 1850 SNPs and at 19q13.32 3805 SNPs. Using a fixed effect meta analysis approach, rs2075650 at 19q13.32 appeared the only SNP within these four linkage regions significantly associated with longevity. This SNP is in linkage disequilibrium with the APOE, 2, 3, 4 polymorphisms and is known to reflect the effect of the *APOE* gene on longevity. We conclude that besides the effect of the *APOE* gene on longevity, at least three other loci play a role located at 14p11.2, 17q21.32 and 19p13.2. Since the linkage results are not explained by common variants, we suggest that rare variants at these regions contribute to human familial longevity.

829F

Genetic mapping of loci regulating transcripts related to stress responses. *A. Jasinska, N. Freimer.* Dept Psychiatry, Univ California, Los Angeles, Los Angeles, CA.

The genetic component of individual vulnerability to stress and stress-related disorders remains unclear. Genetic differences among individuals underlie individual responses to environmental stressors at both molecular (gene expression) and higher organismal (behavioral and cognitive) levels. Identification of stress gene expression traits and their regulatory expression quantitative trait loci (eQTL), may contribute to understanding individual differences in stress response. Here we report genetic mapping of eQTL related to the regulation of these responses. We investigated gene expression levels before and after a severe stressor which was evenly applied to all members of an extended pedigree of about 500 vervet monkeys, the Vervet Research Colony (VRC). In 2008 the entire pedigree was relocated from UCLA to Wake Forest University. We analyzed linkage for pre-move and post-move expression levels, as well as for change in expression levels between these time points. We identified two loci, ANXA11 and TFE demonstrating cis and trans regulation respectively.

Copy-Number Variation In Finnish Multiple Sclerosis Families. *V. Leppa[1,2,3], O. Pietilainen[1,2], L. Peltonen[1,2,4], A. Palotie[1,4], J. Saarela[1].* 1) Institute for Molecular Medicine FIMM, University of Helsinki, Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Helsinki Biomedical Graduate School, University of Helsinki, Helsinki, Finland; 4) The Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Multiple sclerosis (MS) is a debilitating complex disease of the central nervous system. It is characterized by multifocal demyelination, inflammation and neuronal degeneration. Both environmental factors and genetic background affect the development of the disease. The etiology of MS remains largely unknown. Prevalence of MS is 1/1000 in Finland, but roughly 2-fold in the Southern Ostrobothnia (SO) region and shows familial clustering. This is likely to be caused by long lasting isolation of this region. Genome-wide association studies (GWAS) have revealed over 50 common SNPs with modest odds ratios that are associated with MS. These SNPs are thought to be in linkage disequilibrium with the potential causative variants. Copy-number variants (CNVs) are larger and thought to be more likely causative themselves. CNVs have not yet been intensively studied in MS. Our aim is to study CNVs in the Southern Ostrobothnian MS families and to determine if the CNVs are inherited and co-segregate with the disease. We have genotyped 157 samples (41 cases and 116 family members) from 10 multiplex families and 36 regional control samples using the Illumina HumanHap670 chip. CNVs were called using PennCNV and QuantiSNP softwares. 89% of regional controls and 91% of family samples passed QC, and six family members were retyped and passed subsequent QC (raising family success rate to 95%). CNV calls from PennCNV and QuantiSNP were compared and only CNVs that were detected using both methods were included (81% of initial PennCNV calls on average). The family-based QC has not yet been completed. In addition to families, we have data available from 600 Finnish MS cases and 3000 Finnish cohort samples to verify our initial findings and to monitor for CNV population frequencies. All putatively associated CNVs will be confirmed using traditional methods and tested for association in the whole Finnish MS material. We will study the expression of genes within and surrounding the CNV in individuals carrying different amounts of copies to assess the functional relevance. In case of *de novo* variations, we will use public databases (e.g. Genome Variation DB) to identify the potential segmental duplications or similar repetitive sequences potentially predisposing to CNVs. In addition to CNV analysis we will use the GWAS SNP data to assess the genetic load of known MS associated variants within the multiplex families.

Exome sequencing identifies novel candidates for familial combined hyperlipidemia. *A.C.Y. Mak, P.L.F Tang, R. Deo, C.R. Pullinger, M.J. Malloy, J.P. Kane, P.Y. Kwok.* Cardiovascular Research Institute, University of California, San Francisco, CA.

Familial combined hyperlipidemia (FCH), the most prevalent hyperlipidemia, is a complex metabolic disorder characterized by variable occurrence of high low-density lipoprotein (LDL) and high triglycerides - a condition that is commonly associated with coronary artery disease (CAD). Over the years, numerous studies have contributed to the elucidation of the genetic basis of FCH, which is still largely unknown. The need to search for additional genetic variants remains due to the highly variable and complex genetic profile specific to each affected family. Exome sequencing provides a fast and comprehensive study of genetic variants that are associated with this disorder. Using the Illumina HiSeq2000 platform and the TruSeq exome enrichment protocol, we performed exome sequencing on 3 affected individuals from a large 60-member family with history of FCH and low levels of high-density lipoprotein cholesterol. The data obtained had a high target coverage of 94%, including 422 genes or loci previously found to be associated with lipid metabolic pathways, blood cholesterol (HDL and LDL) or triglycerides concentrations, or risk of CAD. On average, 31,000 variants were found within target regions in each individual. After removing synonymous and non-frameshift variants, 862 variants in regions conserved in 44-species were identified to be common in all three affected individuals. This includes 32 nonsynonymous variants in genes related to lipid metabolism. Among the 862 variants identified, 4% are novel non-synonymous or premature stop variants that possibly represent rare variants responsible for the FCH phenotype. Verification and exome sequencing of additional individuals from this family are underway. This partly includes the sequencing of a normal daughter of the current affected mother. This work will further help identify specific variants that provide protective functions against lipid disorders.

832F

A pipeline of targeted resequencing data analysis applied to a family with hearing loss. *J. Cai, J. Samanich, D. Moskowitz, R. Calder, J. Greally, B. Morrow.* Genetics, Albert Einstein College of Medicine, New York, NY.

Re-sequencing of exonic regions of human genome has become a popular strategy to discover variants associated with human disease. To efficiently provide interpretation of data, we developed an automatic pipeline for SNP/InDel identification and annotation that is added to WASP (http://wasp.einstein.yu.edu/index.php/Main_Page). The SNP/InDel identification module starts from alignment using BWA algorithm, de-duplication with Picard tools to the GATK framwork (including local re-alignment, base quality recalibration, per-base alignment quality adjustment and Unified Genotyper). For the SNP/InDel annotation module, basic functional annotation of SNPs/InDels is performed by ANNOVAR software, which implements regional classification (e.g. exon vs intron) and lists related genes. If the variants are within exons, functional consequences are appended, including nonsynonymous/synonymous SNP, stopgain/stoploss and frameshift/nonframeshift insertion/deletion. For a nonsynonymous SNPs, the effect of amino acid change is predicted to be benign or damaging using BLOSUM62, SIFT and Polyphen2. For a known SNP/InDel from the 1000 Genomes project or dbSNP, the alternative allele frequency or heterozygosity is added respectively. We applied this pipeline to a targeted resequencing of hearing loss genes (roughly 1 Mb) from one family with two deaf children and normally hearing parents. Based on Call Quality (>=30), Read Depth (>=5 per sample) and filtering SNPs around InDels, we identified 9957 SNPs and 1099 Indels. We evaluated the presence of recessive mutations and we found compound heterozygous variants in the gene TRIOBP, a known deafness gene (DFNB28). One was a nonsynonymous SNP (c.C5224T:p.L1742F), Leucine to Phenylalanine change (damaging) at chr22:36466887 (hg18) and the other was a frameshift deletion (c.1613_1615del) at chr22:36450122-chr22:364501224. Neither were in dbSNP131. The nonsynonymous SNP was not in the 1000 genome project sequences either and the other mutation was reported allele frequency 0.037 (InDel release, 2010.07).

Novel Features of Neural Retina Transcriptome Revealed by High-throughput RNA-Sequencing. *E. Gamsiz, S. Nagpal, E. Morrow.* Molecular Biology Cell Biology Biochemistry, Brown University, Providence, RI.

Neural retina is a favorable model to study neurogenetic disorders as there are greater than 100 genes in which mutations cause Mendelian forms of visual impairment. The transcriptome is the full set of transcripts expressed in a specific cell or tissue at a certain stage. RNA-Sequencing (RNA-Seq) on Next Generation Sequencing (NGS) platform is a promising technology to profile the transcriptome providing thorough and sensitive information on expression levels and alternative splicing events. In this study, we have applied high-throughput RNA sequencing to the whole set of mRNAs isolated from 21 day old murine neural retina. Isolated two cDNA libraries were sequenced by paired end chemistry via Illumina Genome Analyzer IIx. In average, 50 million of 60 bp paired end reads were obtained from each library. Using a pipeline of Bowtie, TopHat, Cufflinks and custom-made scripts, we identified 15251 genes and 20558 transcripts expressed in both libraries. Of the 15251 genes, 3665 were found to have alternative splicing events. Gene abundances were quantified in Fragments Per Kilobase of exon model per Million mapped fragments (FPKM) and exhibited a range between 0.125 and 2481.5. Rhodopsin was identified as the most abundant gene of all expressed in our samples. We also demonstrated interesting features of retinal disease genes. 159 genes in total associated with retinal diseases were taken from Retinal Information Network (RetNet) (http://www.sph.uth.tmc.edu/retnet/sum-dis.htm). Retinal disease genes were found to be among the most abundant expressed genes in the transcriptome (Chi-Square 72.07, DF=1, p<0.0001). We also studied genes from several gene ontology (GO) groups such as axonogenesis, neuron development, neurite morphology, neurotransmitter secretion, synaptic vesicles, synapse part and voltage-gated channel activity in neural retina transcriptome and demonstrated some other remarkable features. For example; we demonstrated that neural retina expresses a specific and restricted set of synaptic vesicle genes and large percentage of genes related with voltage-gated ion channels were highly expressed in both replicates. Our study presents the most comprehensive view of the transcriptome of the murine neural retina to date using novel, massively-parallel sequencing technologies. These data may also serve as a resource for the community of researchers investigating gene expression in the neural retina in mouse.

Extensive transcriptional diversity identified through massively parallel DNA and RNA sequencing of eighteen Korean individuals. *Y. Ju[1,2], J. Kim[1], S. Kim[1], D. Hong[1], H. Park[3], S. Lee[1], C. Lee[3], J. Seo[1,2].* 1) Genomic Medicine Institute, Medical Research Center, Seoul National University College of Medicine, Seoul, Korea; 2) Macrogen Inc., Seoul 153-023, Korea; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts 02115, USA.

Massively parallel sequencing technologies have identified broad spectrum of diversity of human genome. Here, we sequenced and correlated 18 genomes and 17 transcriptomes of unrelated Korean individuals. To prevent misalignment of RNA short-reads bearing splicing junctions, which increases error rate in RNA sequencing, we aligned the short-reads onto a set of cDNA sequences, generated using ~160,000 mRNA sequences obtained from Refseq, UCSC and Ensembl databases. We identified 4,414 regions as final unknown transcripts, which do not overlap any known genes or pseudogenes. Of these, 111 were detected from all the 15 samples. These transcripts cover 2.74 Mb of the human genome, and are located 4.7 kb from the nearest gene and the median length of these 4,414 unknown transcripts was 360 bp. Of the 4,414 novel RNA-derived genic regions, 19.5% (862) showed homology (≥ 20 amino acids long with ≥ 80% identity) to known protein sequences. We then examined gender differences in expression level of X chromosomal genes to explore X-inactivation profiles. We found 23 genes, including XIST, PNPLA4, HDHD1A, NGFRAP1 and GPR34, that show higher levels of gene expression in females compared to males. Interestingly, 5 genes that appear to be escaping X-inactivation had not been previously shown to escape X-inactivation in human fibroblasts. To investigate nucleotide change during transcriptional processes, we looked for evidence of RNA variants that did not correspond exactly with their derived genomic sequence. Applying conservative filter criteria to genome and transcriptome sequences of the same individuals, we identified 1,809 sites of such transcriptional base modifications (TBMs). On average, the lymphoblast cell lines of each individual showed ~ 500 sites of TBM variants. Of these 1,809 TBMs, 74.1 % (N=1,341) were nucleotide transition. 81.7% (N=1,096) of the transitions were A to G (N=985) and C to T (N=111) modifications on the coding-strand, which could be explained by previously known molecular mechanisms of A to I and C to U RNA editing. Next, to investigate allele-specific expression, or allelic expression imbalances, we compared the allele-specific read-counts from genome and transcriptome sequence data of individuals heterozygous in a tested SNP. From our dataset, we found 580 nsSNP sites that show preferential expression of one allele compared to the other.

Massively parallel sequencing and High-throughput of sorted human chromosomes 21 and Y. *Y. Kuroki[1], A. Toyoda[2], S. Kondo[1], Y. Nishida[3], O. Ohara[1], A. Fujiyama[2, 4].* 1) Laboratory for Immunogenomic, RIKEN Research Center for Allergy and Immunology, Yokohama, Japan; 2) Comparative genomics laboratory, National Institute of Genetics, Mishima, Japan; 3) United Centers for advanced Research and Translational Medicine, Tohoku University School of Medicine, Sendai, Japan; 4) Principles of Informatics Research Division, National Institute of Informatics, Chiyoda-ku, Japan.

Previous studies revealed striking differences of the genomic constitution and evolutionary aspect between autosomal chromosome 21 and male-specific chromosome Y, in addition to the differences identified the between human and chimpanzee genomes (Watanabe et al., 2004, Kuroki et al., 2006). In these works, we demonstrated that the nucleotide differences between human and chimpanzee were 1.5 times higher in chromosome Y than that of chromosome 21, and that the numbers and contents of the retrotransposons, the frequency of the genome rearrangements such as insertion/deletion and inversion, and the degree of the conservation in the syntenic regions were different between Chrs 21 and Y. To further clarify the fundamental characteristics in the genome structure and function between autosome and sex chromosome (Y chromosome) during the course in the evolution of human genome, we started extensive comparative analysis for the chromosomes 21 and Y among primates and other mammals. At first, we constructed pipeline for the sequencing of purified whole chromosomes and bioinformatics analyses. Roughly three million each of flow-sorted Chrs 21 and Y were subjected for sequencing by using Solexa/GAII analyzer. The average read depth for each chromosome exceeded more than 50X coverage, and these data enabled us to identify the SNVs, indels, and the sequences which did not included in the current version of the human reference genome assemblies, Build 37 or hg19. The strategy and the analytical pipeline for the chromosome-based genome analysis, and the novel findings will be presented.

837F

Candidate gene analysis in Behcet's disease using massively parallel sequencing. *S. Lee[1], S. Kim[5], H-G. Yu[5], J-I. Kim[1,2,3], J-S. Seo[1,2,3,4].* 1) Biomedical Sci, Seoul National Univ, Seoul, Korea; 2) ILCHUN Genomic Medicine Institute, Medical Research Center, Seoul National Univ, Seoul, Korea; 3) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea; 4) Macrogen Inc., Seoul, Korea; 5) Department of Ophthalmology, Seoul National University Hospital, Seoul, Korea.

Behcet's disease is thought to be triggered by environmental factors in patients with presidposing genetic background. HLA-B51 has shown strong association with Behcet's disease with relative risk of 5 to 20. As the contribution of HLA-B51 to the pathogenesis of Behcet's disease is less than 20%, the other genetic factors remain to be proven. Many candidate genes including TNF-alpha, ICAM-1, IL-1, CTLA-4, SUMO4, etc. were studied to identify associations with Behcet's disease. Recently, genome-wide association studies (GWASs) using more than 300K SNP chips identified association at IL10 and IL23R-IL12RB2 locus. However, recently performed GWASs based on SNP genotyping in many complex diseases have identified only a small fraction of the heritable variation. One possible explanation is that many rare variants, which are difficult to identify via GWASs, contribute substantially to the genetic variation of these diseases. Therefore, it has been suggested that sequencing candidate genes may be an efficient methods to investigate the contribution of rare variants to the phenotype. We performed targeted exon sequencing of 145 candidate genes using exon capture array followed by massively parallel sequencing in 32 Behcet patients and 32 controls. We called more than 100 SNPs with significant differences in frequency. These SNPs are located in FCGR3A, NOD1, IL25, IL12RB2, etc. We also identified several rare variants, including nonsynonymous rare variants which are predicted to be harmful by SIFT analysis. In conclusion, target enrichment and massively parallel sequencing technologies seem to provide valuable information on genetic predisposition in Behcet's disease.

838F

Non-coding and coding mutations associated with Kabuki syndrome identified by comprehensive, massively parallel sequencing of the 50 kilobase locus around *MLL2*. *S. Ng[1], K. Buckingham[2], M. McMillin[2,3], M. Bamshad[1,2,3], J. Shendure[1].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Pediatrics, University of Washington, Seattle, WA; 3) Seattle Children's Hospital, Seattle, WA.

We report on the identification of potential coding and non-coding mutations associated with Kabuki syndrome, both at and beyond the mixed lymphoid leukemia (*MLL2*) locus. By sequencing the entire locus (coding, intronic and flanking regions) using targeted capture and massively parallel sequencing, we can efficiently screen for both coding and non-coding variants, and gain a comprehensive picture of all variation within the region. This is informative for finding causal mutations, and also for identifying samples that are truly mutation negative, which in turn are useful to search for additional causative loci.

Previously, we had used exome sequencing to implicate *MLL2* in Kabuki syndrome[1], and also screened the coding exons of this gene (26 kb) using Sanger sequencing[2]. Likely causal mutations were found in 82 patients, but not in 22 others (21%). It is uncertain if the latter are actually *MLL2*-mutation-negative and hence effective candidates for a second locus search; they may instead harbor non-coding, structural or missed coding mutations at the *MLL2* locus. Using probes against the whole *MLL2* locus, including regulatory regions (50 kb total), we subjected sample libraries (100 ng gDNA starting) to 48-plex target enrichment and massively parallel sequencing. Initial results show high sensitivity: all causal mutations from sufficiently sequenced positive controls were recovered (78%, >90% bp passing filter). Also, 8 mutations were identified in 13 other well covered mutation-unknown samples - 1 nonsense, 1 missense, 2 coding indels), 2 variants in splice-sites and 2 in introns (GERP > 3). The remaining 5 samples had no potential pathogenic mutations despite >90% coverage, and represent samples that are most likely to be *MLL2*-mutation-negative. Based on this success, we are using this approach in lieu of Sanger sequencing to ascertain mutation status in a further 57 previously unscreened samples. The *MLL2*-mutation-negative samples are being used to identify additional loci for Kabuki syndrome through exome sequencing to find shared genes with mutations, and we are also sequencing a single parent-child trio to pinpoint *de novo* mutations. 323 potential mutations have been found in the proband of the trio (none in *MLL2*), and filtering by parental data will further reduce this list considerably.

Agilent Technologies SureSelect™ Human All Exon v3: High Performance Target Enrichment System for Human Exome Sequencing on Illumina and SOLiD platforms. *C. Pabón-Peña[1], E. Lin[1], B. Novak[1], M. Hamady[1], F. Useche[1], M. Visitacion[1], A. Giuffre[2], H. Ravi[2], S. Joshi[2], J. Ong[2], B. Arezi[3], S. Happe[2], D. Roberts[1], E. Leproust[1].* 1) Agilent Technologies, Genomics Research and Development, Santa Clara, CA; 2) Agilent Technologies, Genomics Research and Development, Cedar Creek, Texas; 3) Agilent Technologies, Genomics Research and Development, La Jolla, CA.

The introduction and widespread adoption of next generation sequencing technologies have reduced high-throughput sequencing costs by several orders of magnitude and enabled numerous whole-genome analyses. Nevertheless, the expense and operational capacity necessary for large scale whole genome studies is still prohibitive for many laboratories. Since large portions of the genome consist of repeat elements and regions of unknown phenotypic value, targeted exome capture combined with massively parallel sequencing has become one of the most viable options to gain novel insights into the genetic causes of inherited disorders. By focusing on the protein-coding regions of the human genome, scientists are now able to more efficiently identify both common and rare polymorphisms that are more likely to result in cellular dysfunction and exhibit significant penetrance in disease association studies, such as those implicated in the etiology of Mendelian disorders and complex diseases like cancer or neurological pathologies. We hereby describe our latest SureSelect Human All Exon design developed in collaboration with the Broad Institute. Performance improvements of multiplexed samples are demonstrated with respect to capture efficiency, uniformity, reproducibility of enrichment, and ability to detect SNPs, insertion/deletions, and CNVs on Illumina (Genome Analyzer IIx and HiSeq2000), and Life Technologies SOLiD platforms. The high specificity, accuracy, and excellent cross-platform sequence coverage demonstrates the utility of the SureSelect All Exon v3 for a wide variety of research and clinical applications that demand the most comprehensive view of functionally relevant regions of the human genome.

840F

High-throughput sequencing of a neuromuscular disorder panel for application on diagnostic testing: a 2x2 comparison between target enrichment methodologies and sequencing platforms. *S.L. Pereira[1], B. Baskin[2], E. Cheran[1], Z. Hu[1], K. Ho[1], L. Lau[1], S.W. Scherer[1], P.N. Ray[2].* 1) The Centre for Applied Genomics and Division of Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Molecular Genetics, Dept Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada.

Current diagnostic method for targeted gene re-sequencing is PCR amplification and Sanger sequencing. This procedure is labor intensive, expensive and time consuming, thus not economically feasible as a diagnostic test where many genes need to be analyzed. We investigated the sensitivity and specificity of two targeted enrichment methods (RainDance Technologies (RD) and Agilent SureSelect (SS)) to be used as comprehensive clinical diagnostic test for neuromuscular diseases using Next Generation Sequencing (NGS) platforms. We selected a panel consisting of 803 exons from 44 genes for target enrichment and high throughput sequencing of four individual affected by neuromuscular diseases. The target areas cover 198 Kb using RD, and 155 Kb using SS. Samples were sequenced on an Illumina GAII (2x76-bp), and SOLiD 4 (50-bp). The target coverage for the GAII and SOLiD was 100-120X and 50-75X respectively, and solely reflects the comparison of paired versus single read data. The two capture methods performed similarly, with ⁄ 95% and 76-98% of the target-bases with 10X and 30X coverage, respectively. GC-rich (>80%) exons were under-represented in the sequenced data regardless of the NGS platform or capture method used. Between 187 and 234 SNPs were detected for the 4 samples, most of which concordant between sequencing platforms and capture methods. Among discordant SNPs, <7% of the calls are specific to a NGS platform or capture method. The neuromuscular disease test panel proposed here provides an excellent strategy to test the power of targeted enrichment for massively parallel sequencing and to translate this technology into clinical diagnostics. Although the two target methods and NGS platforms perform equally well for this purpose, other parameters needs to be taken into consideration: RD requires a higher initial capital investment and incurs higher costs for sample preparation compared to SS, but RD samples can be ready for sequencing 2-3 days earlier than SS samples. The costs of running the NGS instruments may be comparable for runs of similar read length, but the time required to generate the data may vary between 4 to 16 days depending on read lengths and if performing a single or paired end run. The amount of data and results created requires a bioinformatician to deal with the analysis, and trained technical and clinical personnel for data interpretation based on read depth, read quality, alignment scores, and other parameters used in the analysis.

Semiconductor Sequencing for Life. *J. Rothberg, J. Leamon.* Ion Torrent, South San Francisco, ca.

Ion Torrent has invented the first device—a new semiconductor chip—capable of directly translating chemical signals into digital information. The first application of this technology is sequencing DNA. The device leverages decades of semiconductor technology advances, and in just a few years has brought the entire design, fabrication and supply chain infrastructure of that industry—a trillion dollar investment—to bear on the challenge of sequencing. The result is Ion semiconductor sequencing, the first commercial sequencing technology that does not use light, and as a result delivers unprecedented speed, scalability and low cost. Ion Torrent sequencing uses only natural (label-free) reagents and takes place in disposable semiconductor microchips that contain sensors that have been fabricated as individual electronic detectors, allowing one sequence read per sensor. The system performance has been demonstrated by sequencing four bacterial genomes, ranging in genomes size and GC content from Vibrio fisheri (4.3Mb genome, 38% GC) to Escherichia coli K12 - (4.6Mb genome, 51%GC) and DH10b (4.7Mb genome, 51%GC) to Rhodopseudomonas palustris (5.5Mb genome, 65%GC). Besides comprising the first genomes sequenced with post-light technology, the genomes are remarkable in the lack of data bias, which is as good, or better, than existing commercial platforms. Ion's technological applicability to routine human sequencing has also been demonstrated by utilizing Ion chips to sequence a human genome. We will show how the technology has scaled in just a few months from 1.2 million sensors in the first-generation Ion 314 chips to 6.1 and 11 million sensors in the second-generation Ion 316 and 318 chips respectively—all while maintaining the same 1- to 2-hour runtime. Additionally, Ion has successfully accomplished design, manufacture and sequencing using chips possessing the smaller 1-micron diameter well, enabling further increases in well density and sequencing throughput in subsequent chip designs. Because the heart of the system is a novel, disposable sensor, built and assembled using standard semiconductor fabrication methodologies, able to sequence without the need for intermediate enzymes or the constraints of having to image using light, the cost of genome sequencing will continue to fall with each successive generation of denser chips according to Moore's law.

Assessing the Effects of Whole Genome Amplification on Exome Sequencing. *J. Smith, I. Stanaway, E. Turner, C. Igartua, K. Patterson, S. McGee, T. Shaffer, C. Poel, B. Paeper, Q. Yi, K. Sawatzki, B. Munson, I. Robertson, M. Mynsberge, S. Austin, C. Shepard, S. Paquette, M. Tackett, J. Furlong, P. Robertson, D. Siegel, E. Johanson, E. Johnson, E. Phillips, M. Rieder, D. Nickerson.* Genome Sci, Univeristy Washington, Seattle, WA.

Traditional approaches for exome sequencing require significant amounts of input DNA from 5 - 10 microgram to successfully produce high quality exome sequencing libraries. However, many stored samples have limited DNA quantities and these input amounts limit their usefulness for second-generation sequencing methods. Whole Genome Amplification (WGA) is a cost-effective method to increase the amount of input DNA, but the effects on exome library construction, which already uses an enrichment strategy, could lead to coverage and uniformity bias. We have conducted a systematic review of WGA compared to unamplified controls. We amplified 100 ng of genomic DNA and compared it with standard exome library preparation protocols using 5 ug of input DNA. Libraries were prepared using standardized Illumina adaptors and captured using the Roche/Nimblegen EZ-Cap v2.0. We compared uniformity and read depth across exome target regions on multiple samples and assessed the ability to accurate call Single Nucleotide Variants (SNV), Indels, and Copy Number Variants (CNV). Interestingly, SNV and Indel variant calling was highly concordant between methods with rates > 99.99%, although read depths were lower and more variability of coverage was seen. The ability to accurately call CNVs from the WGA data was impaired by the large variance in the read depth and specificity was significantly reduced. Our results show that WGA has little effect on exome sequencing and SNV detection with caveat is that it will impact the ability to call structural variants, thus careful consideration should be made before utilizing this procedure.

843F

X-chromosome exome sequencing of a nonsyndromic intellectual disability family with multiple affected male sibs. *S. Kantarci[1,2], W.L. Donahue[3], P. Bayrak-Toydemir[3], L. Al-Gazali[4], N. Bissar-Tadmouri[5].* 1) Department of Pathology, Beth Israel Deaconess Medical Center, Boston, MA; 2) Harvard Medical School, Boston, MA; 3) Department of Pathology, University of Utah, ARUP Laboratories, Salt Lake City, UT; 4) Department of Paediatrics, United Arab Emirates University, Al-Ain, United Arab Emirates; 5) Department of Basic Medical Sciences, University Of Sharjah, College of Medicine, Sharjah, United Arab Emirates.

Intellectual disability (ID) is a lifelong condition with significant limitations both in intellectual functioning and in adaptive behavior, affecting ~1-3% of the general population. About 10-15% of ID is attributed to X-linked traits, with higher male to female ratio among milder cases. Non-syndromic intellectual disability (NSID) is characterized by intellectual impairment as the only feature without major physical abnormalities, dysmorphism, or neurological abnormalities. About 80% of known genes responsible for NSID reside on X-chromosome (>90 genes). In this study, we enrolled a nonconsanguineous Arab family with four affected male sibs and five unaffected female sibs. The affecteds have mild to moderate ID as the sole clinical feature. The affected sibs, with prior normal standard karyotype and Fragile-X molecular testing, were 15, 10, 8, and 6 years old at the time of recruitment. We utilized X-linked exome sequencing approach to identify a NSID-causing gene in this family. Using Agilent's SureSelect human X-chromosome kit, we captured the X chromosome genes (~7,674 exons) of one of the affected sibs for DNA sequencing. The captured region was sequenced as paired end with 50x coverage using Illumina HiSeq 2000. A total of 3,790 SNP and indel variants were annotated on this DNA sample using the GenomeQuest whole genome analysis software. After filtering, 66 novel variants (not reported in dbSNP database) were found to fall inside protein coding regions of 13 X-linked genes. We are in the process of further analyzing data. Deciphering the genetic basis of NSID is necessary for further understanding of human cognitive development. Revealing new pathways might allow improvements in diagnostic testing, genetic counseling, and future therapeutic interventions in families with NSID. Our study demonstrates the utility of next generation technology to help identify genes for genetics disorders of unknown etiology.

Whole-genome expression profiling of skeletal muscle reveals potential link between insulin resistance and diabetes in over weight west Africans. *H. Xu[1], A. Adeyemo[1], A. Elkahloun[5], J. Adeleye[2], W. Balogun[2], H. Huang[1], J. Zhou[1], G. Chen[1], D. Shriner[1], C. Adebamowo[3,4], S. Chandrasekharappa[5], C.N. Rotimi[1].* 1) Center for Research on Genomics and Global Health, National Institutes of Health (NIH), 12 South Drive, MSC 5635, Bethesda, MD 20892-5635; 2) Department of Medicine, College of Medicine/ University College Hospital, Ibadan, Nigeria; 3) Institute of Human Virology, Abuja, Nigeria; 4) Department of Epidemiology and Preventive Medicine, University of Maryland, Baltimore, Maryland; 5) Cancer Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland.

Obesity is one of the major risk factor for type 2 Diabetes (T2D). However we know very little about the changes in the transcriptome of the major tissue targets of insulin action (skeletal muscle and liver) in the early stages of obesity. Here, we used the Affymetrix HU-133 Plus 2.0 Arrays to examine genome-wide expression in skeletal muscle obtained by biopsy from West Africans. Twenty-one male non-diabetic subjects (mean age=56 years, mean body mass index (BMI)=23.8 kg/m^2, all Yoruba ethnicity) were enrolled from Ibadan, Nigeria. After controlling for covariates, 128 transcripts were correlated with log transformed BMI (partial correlation coefficient > 0.6, p<0.005). Seventy one transcripts were differentially regulated between overweight (BM⁄ 25 kg/m^2) and normal weight subjects (BMI<25 kg/m^2) at an absolute fold change>1.4 and a p<0.05. Principal component and cluster analyses showed clear separation of these two groups of subjects based on their gene expression profiles. Notably, 13 out of the 71 transcripts have been reported to influence the risk of developing diabetes (KCNQ5, HLA-DQA1, MEIS2, SPG7, PTGDS, TSPAN15, FAM78B, FAM102B, PMP22, SERPINA5, LPP, OSBPL3, HLA-DPB1).In addition, we examined the differences in gene expression profile between individuals with high HOMA_IR (a homeostatic model assessment of insulin resistance) and those with low HOMA IR index. We found that SERPINA5 was significantly differentially expressed between high compared to low HOMA_IR subjects. Interestingly, Elbein SC et al (2011) reported recently that, gene expression of SERPINA5 was associated with insulin resistance in skeletal muscle of European Americans. Furthermore, Gene Set Enrichment Analysis identified the G protein signaling pathway as the most significantly upregulated pathway in overweight subjects (p<0.001, FDR 0.03). To our knowledge, this study is the first to use expression profiling in skeletal muscle to identify genes that may underlie the well documented association between early weight gain, insulin resistance and diabetes in West Africans. We showed that, compared to normal weight, overweight subjects have notable changes in muscle gene expression in pathways that are dysregulated in T2D. By integrating these data with genetic association, it may be possible to identify novel biomarkers that may facilitate more robust understanding of early intervention targets in obesity, insulin resistance and T2D.

Whole Transcript Expression Microarray Profiling and Sequencing of Normal Colon and Adenocarcinoma Total RNA. *S. Fulmer-Smentek[1], B. Mullinax[2], E. Lin[1], J. Venneri[2], V. Kulkarni[1], C. Pabón-Peña[1], B. Novak[1], A. Bergstrom Lucas[1].* 1) Genomics R&D, Agilent Technologies, Santa Clara, CA; 2) Genomics R&D, Agilent Technologies, La Jolla, CA.

The ability to measure the alternative splicing of exons from RNA that leads to the translation of different proteins is useful for understanding biological mechanisms and classifying tissue and tumor types for research. Several methods are available to interrogate alternative RNA splicing, including exon microarrays, targeted RNA sequencing and whole transcriptome RNA sequencing. While all three methods provide the ability to identify alternative splicing between two samples, each brings distinct advantages. The SurePrint G3 exon microarray workflow includes catalog and custom microarrays, a whole transcript amplification method and tailored analysis software. Exon-level probes on the microarrays were designed from the highest quality content of public databases including RefSeq and Ensembl. Exon array data are analyzed for gene level and exon level expression using GeneSpring GX 11.5 software, enabling whole transcript profile comparisons within two days. Targeted RNA Seq methods allow for in depth analysis of a subset of transcripts of interest via RNA sequencing, while whole transcriptome RNA sequencing allows for hypothesis neutral discovery of alternative splicing, but at a relatively high cost and low throughput. We investigate here the correlation of exon microarrays with the various RNA sequencing methodologies, and demonstrate the high reproducibility and wide dynamic range of expression across a variety of RNA inputs for the exon microarrays. The whole transcriptome exon microarray workflow was further used to detect alternative splicing of exons between cancerous and normal cells resulting in gene and exon expression profiles consistent with the current literature. The results presented demonstrate the compatibility and utility of the various alternative splicing analysis methods.

846F

Deep sequencing of small RNAs from human skin reveals major alterations in the psoriasis miRNAome. *C.E. Joyce[1], X. Zhou[2], J. Xia[2], C. Ryan[3], B. Thrash[3], A. Menter[3], W. Zhang[2,1], A.M. Bowcock[1,4].* 1) Department of Genetics, Washington University School of Medicine, St. Louis, MO, 63110, U.S.A; 2) Department of Computer Science and Engineering, Washington University, St. Louis, MO, 63130, U.S.A; 3) Department of Dermatology, Baylor University Medical Center, Houston, TX, 77030, U.S.A; 4) Division of Dermatology, Department of Medicine, Washington University School of Medicine, St. Louis, MO, 63110, U.S.A.

Psoriasis is a chronic, inflammatory skin disease for which there is currently no cure. Transcriptome analyses have revealed ~1300 mRNA expression changes in psoriatic skin, but much less is known about the role of noncoding RNAs. Aberrant miRNA expression has been implicated in a number of human diseases, including cutaneous diseases such as psoriasis, atopic dermatitis, and melanoma. We have completed a comprehensive analysis of the miRNAome in normal, non-lesional psoriatic, and lesional psoriatic skin. We generated 6.7x10^8 qualified small RNA reads, representing the largest small RNA sequencing dataset derived from any human tissue to date. The global landscape of miRNAs in normal and psoriatic skin included 1) 717 known miRNAs and 176 cognate miRNA*s, 2) 284 novel miRNA loci, 3) miRNA variants that differ at the 3' or 5' termini, termed isomiRs, 4) a number of previously undescribed miRNA*s from known miRNA loci, and 5) a low frequency edited miRNAs. We validated the endogenous expression and processing of three novel miRNAs in skin and other human cell lines or tissues. Of particular note was the discovery and validation of a novel antisense miRNA derived from the miR-203 locus, which has a role in epidermal differentiation. The expression level of this novel antisense miRNA was 2.7-fold higher in psoriatic skin than normal skin. An additional 80 known and 17 novel miRNAs were two- to 42-fold differentially expressed in psoriatic skin. Differentially expressed miRNAs reflected defects in keratinocyte differentiation, immune cell quiescence, and angiogenesis, all processes which are known to influence psoriasis pathogenesis. In situ hybridization of differentially expressed miRNAs revealed stratified epidermal expression of an uncharacterized keratinocyte-derived miRNA, miR-135b, as well as the epidermal infiltration of the hematopoietic-specific miRNA, miR-142-3p, in psoriatic lesions. This study lays a critical framework for functional characterization of miRNAs in skin and therapeutic application of miRNAs for the treatment of cutaneous diseases.

Identification of trait- and disease-relevant genetic polymorphisms in miRNA target sites. *T. Kwan[1,2], S. Busche[1,2], B. Ge[2], S.H. Chen[2], L. Karemera[2], M. Georges[3], T. Pastinen[1,2].* 1) Human Genetics, McGill University, Montreal, PQ, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) Faculty of Veterinary Medicine, University of Liege, Belgium.

MicroRNAs (miRNAs) are ~22 nucleotide long noncoding RNAs that control the expression and function of eukaryotic genomes by acting as adaptors to specifically recognize and regulate targeted mRNAs. Candidate studies suggest that genetic polymorphisms in miRNA target sites (poly-miRTS) are associated with various disorders like Tourette's syndrome, hypertension, or the risk to developing breast cancer. We aim to create a genome-wide catalogue of poly-miRTS to provide the fundamental basis for the characterization of miRNA-related genetic alterations with an impact on human traits and disease, and to unravel the mechanisms of action of some causal poly-miRTS. To identify poly-miRTS on a genome-wide scale, we will monitor RNA levels and differences in allelic expression (AE) with and without active miRNA gene regulation. To shutdown miRNA-mediated gene regulation we interfere with the miRNA processing machinery by silencing Drosha, DGCR8, Exportin-5, and/or Dicer. Importantly, interference with any of these genes is not expected to prevent siRNA processing. Our present results show that silencing any single gene within the miRNA machinery does not substantially inhibit the level of mature miRNAs. However, successful silencing of Drosha, Exportin-5 and Dicer leads to an ~80 % reduction of mature miRNAs. RNA-sequencing and SNP genotyping experiments are currently ongoing. To circumvent off-target effects in assessing the global impact of silencing miRNA expression, we will monitor genome-wide differences in allelic rather than total gene expression. We anticipate that this will effectively eliminate non-specific effects and allows focusing on interaction of miRNA binding and genetic variants at binding sites.

High-throughput identification of direct microRNA targets. *H.C. Martin, S. Wani, A. Steptoe, S.M. Grimmond, N. Cloonan.* Queensland Centre for Medical Genomics, Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD, Australia.

Several studies have reported associations between SNPs in microRNAs or their predicted binding sites and human disease, and aberrant expression of microRNAs has been linked to multiple cancer types. In order to understand how dysregulation of a particular microRNA contributes to disease etiology, it is essential to know which mRNA transcripts it targets. Most of the existing high-throughput methods for elucidating these are confounded by the secondary effects of microRNA over-expression or repression, and the numerous computational algorithms for predicting targets have very high false positive rates. We optimized a protocol to capture direct microRNA-mRNA interactions, and applied this to ten human microRNAs known to play a role in cancer. Essentially, cells were transfected with synthetic biotinylated microRNA duplexes, the protein-microRNA complexes were purified out using streptavidin beads, and their associated mRNAs were analysed by microarray. We also extended the method to precisely locate the microRNA-binding site by combining an RNAse protection assay with massive-scale sequencing. Our results confirm that a single microRNA can directly bind to hundreds of transcripts. There was some evidence that many interactions were being mediated by the central region of the microRNA rather than the seed region, which is generally thought to be essential. The inferred targets were enriched in specific biological pathways, of which many were related to tumorigenesis, and our results further suggest several new avenues for investigation into the functional roles of these microRNAs. We have also found support for the hypothesis that isomiRs work in concert with their canonical partners to regulate the same molecular networks. This work is likely to improve our understanding of microRNA targeting and thus facilitate the characterization of normal microRNA function and annotation of GWAS hits, ultimately leading to a better understanding of the role of these molecules in disease.

849F

Whole exome resequencing reveals an unexpected amount of variability with possible functional consequences in human microRNAs. *J. Santoyo-Lopez[1,2,5], J. Carbonell[2], E. Alloza[2], S. Borrego[3,4], M. Ruiz-Ferrer[1,4], P. Arce[1], I. Medina[2], A. Vela[1], S. Perez[1], R. Fernandez[1], S.S. Bhattacharya[1,6], G. Antiñolo[1,3,4], J. Dopazo[1,2,5,7].* 1) Andalusian Center for Human Genomic Sequencing, Seville, Spain; 2) Department of Bioinformatics and Genomics, Centro de Investigación Príncipe Felipe (CIPF), Valencia, Spain; 3) Unidad de Gestión Clínica de Genética, Reproducción y Medicina Fetal. Instituto de Biomedicina de Sevilla (IBIS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Seville, Spain; 4) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Seville, Spain; 5) Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Valencia, Spain; 6) Andalusian Molecular Biology and Regenerative Medicine Centre (CABIMER), Seville, Spain; 7) Functional Genomics Node (INB), Valencia, Spain.

Targeted exome resequencing projects produce enormous amounts of data on protein coding sequences as well as other interesting functional elements of the genome, which includes microRNAs. These non coding RNAs are key components of the gene regulatory network in a wide range of species and operate by base complementarity. Due to this mode of action it is commonly believed that such regulatory elements were highly conserved. The analysis of the information available on 23 exomes from healthy southern Spain population, sequenced in the context of the Medical Genome Project, has uncovered an unexpected amount of variability in microRNAs. A total of 558 variants were found in 291 different miRNAs, 131 of which are known to be involved in almost 200 diseases. Among these, 487 (87%) variants were described for the first time in this study. This figure almost doubles the number of known variants in microRNAs and constitutes a remarkably high ratio of discovery. Different parts of the mature structure of the microRNA were affected by variants, which suggest a potential functional effect in the variability found. The average number of variants per individual found within miRNAs positions was of 118. Despite miRNAs were thought to be a highly conserved genomic element, our study has uncovered an unexpectedly high level of variability.

850F

Endothelium-derived Adropin is a Mediator Associated with oxLDL-Induced Endothelial Cells Dysfunction via Elevating microRNA-29a/b Levels. *M. Shen[1], K. Chen[1,3], M. Lu[2], S. Juo[1,3], T. Lee[1,3].* 1) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Graduate Institute of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Adropin, encoded by the Energy Homeostasis Associated (Enho) gene mainly expressed in the liver and brain, was originally thought to participate in maintaining metabolic homeostasis. It was also shown to exert direct effects and protective role on the vascular endothelium, including angiogenesis, anti-apoptosis, likely via VEGFR2 up-regulation and downstream eNOS activation through the VEGFR2-PI3K-Akt pathways. Due to its detectable expression in vascular endothelial cells such as HUVECs and implications in vascular function, we therefore investigated the patho-physiological significance of endothelium-derived, endogenous adropin in vascular endothelium. This endothelium-derived, endogenous adropin appears to function in regulating VEGFR2 signaling associated with vascular homeostasis. Whereas in the pathological case, pro-atherogenic oxidized LDL (oxLDL) was able to down-regulate adropin as well as VEGFR2 expression in HUVECs at mRNA and protein levels from qRT-PCR and Western blot analyses. Due to the presence of several putative microRNA binding sites in the adropin 3'UTR, we speculated whether microRNA-mediated silencing can account for the mechanism underlying oxLDL-triggered adropin down-regulation. Among the candidate microRNAs targeting to adropin 3'UTR, the levels of miR-29a and -b were elevated in response to oxLDL exposure. Additionally, co-transfection of either miR-29a or -b mimics abrogate the luciferase activity of luciferase reporter construct carrying adropin 3'-UTR. However this suppressive effect was not observed in the construct carrying mutated miR-29a/b binding site, which further supports the regulatory role of miR-29a/b. Furthermore, both miR-29a and -b mimics also down-regulate VEGFR2 expression in HUVECs. All these observations indicate that elevated miR-29a and -b upon oxLDL treatment contribute to the adropin down-regulation, which may in turns impair VEGF/VEGFR2 signaling and lead to endothelial cells dysfunction. Interestingly, the pull down assay indicated the directly physical interaction of adropin and VEGFR2 that probably affects the downstream VEGFR2 expression and activates VEGFR2 signaling. In this study we not only unravel the regulatory role of adropin in vascular endothelium but also provide a rational molecular basis for the pathogenesis of atherosclerosis.

851F

TaqMan®-based miRNA profiles classify expression in breast cancer and leukemia. *L. Wong, N. Mulakken, D. Ridzon, P. Brzoska, C. Chen.* Genomic Assays R&D, Life Technologies, 850 Lincoln Centre Drive, Foster City, CA, 94404, USA.

MicroRNAs (miRNAs) are small endogenous RNA molecules that play an important role in the regulation of developmental and physiological processes in animals and plants. Studies indicate that miRNAs are involved in the multilevel regulation of gene expression targeting a battery of mRNA genes. Researchers have discovered that miRNAs are efficacious biomarkers for the classification of tumors and other cell types, as well as prediction of outcome for many diseases because of their evolutionary conservation, unique expression signatures, relative stability, and abundance. To identify potential candidates involved in tumor progression in humans, we examined the expression of 750 miRNAs using Applied Biosystems TaqMan® MicroRNA Assays in five human breast cancer cell lines, and two human leukemia cell lines. Data from leukemia cell lines were compared to two cell lines of normal peripheral blood mononuclear cells (PBMC), and data from breast cancer cell lines were compared to normal breast tissue. In addition, the two groups of cancer samples were examined relative to the expression levels of 38 different normal tissues. We confirmed several miRNAs that were previously identified to be associated with cancer. For example, let-7 family showed significant differential expression between breast cancer cell lines and normal breast tissue. We also determined a group of miRNAs that were consistently differentially expressed relative to the normal samples in all cancer cell lines. In addition, we identified miRNAs that are uniquely expressed in breast cancer but not in Leukemia cell lines. Further, miRNA families that are represented frequently in the list of significant miRNAs in both types of cancers were determined. These findings provide insight into possible common and distinct pathways between breast cancer and leukemia and the role of miRNAs in human cancer.

Examining fine-scale dynamics of mitochondrial transmissions in humans. *B. Dickins[1], H. Goto[1], E. Afgan[2,5], I.M. Paul[3], J. Taylor[2,5], A. Nekrutenko[4,5], K. Makova[1].* 1) Department of Biology, The Pennsylvania State University, University Park, PA; 2) Department of Biology, Emory University, Atlanta, GA; 3) Department of Pediatrics, Penn State College of Medicine, Hershey, PA; 4) The Huck Institute for Life Sciences and Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 5) The Galaxy Project, http://usegalaxy.org.

Mitochondrial inheritance is unusual because it is uniparental and because, despite this, multiple alleles in varying proportions subsist in the populations of genomes present within a cell, tissue or individual: a situation defined as heteroplasmy. *De novo* mutations (DNMs) and heteroplasmy frequency shifts (HFSs) both contribute to the complex dynamics exhibited in this inheritance channel for which a thorough quantitative understanding is lacking. Given the uses to which mitochondrial DNA (mtDNA) sequence data is put, improving our knowledge would constitute a valuable contribution to fields as diverse as evolutionary biology, forensics and cancer diagnostics.

To this aim, we have sequenced mtDNA at high coverage from blood and buccal tissue of 19 individuals from six families with a total of 13 maternal transmission events. While massively parallel sequencing is, in principle, well-suited to the analysis of heteroplasmy (and polymorphism in general), we have strived to develop an analysis pipeline that is resistant to noise generated during sample amplification, library preparation, sequencing and mapping. Using simulations and re-sequencing of clonal DNA, we devised a broadly applicable set of criteria for detecting heteroplasmic sites above the 2% level and our analysis is easily repeatable through our Galaxy website where data and tools can be accessed, copied and modified.

Our analysis of data collected so far has revealed nine heteroplasmic sites and 15 mutation events (DNMs and HFSs) allowing us to describe the fine-scale dynamics of mitochondrial heteroplasmy. Because we have made use of DNA from more than one tissue, we are also able to infer patterns of change within individuals as well as within families. In general heteroplasmies appear to be relatively uncommon events while significant HFSs are more common.

853F

Characterization of the porcine imprinted and non-imprinted genomic domains orthologous to the human Prader-Willi syndrome chromosome region. *R.D. Nicholls[1,2], D.W. Lewis[2], K.L. Weichler[1], B.J. Henson[1], S.M. Gollin[2], R.S. Prather[3].* 1) Department of Pediatrics, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 2) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 3) Division of Animal Sciences, University of Missouri, Columbia, MO.

Prader-Willi syndrome (PWS) is a multisystem disorder caused by loss of function of a cluster of ~12 paternally-expressed, imprinted genes in human chromosome 15q11.2. Cardinal features of PWS include neonatal failure to thrive, abnormal body composition, short stature with growth hormone deficiency, and childhood-onset hyperphagia and obesity, among other endocrine and behavioral abnormalities. Although mouse models of PWS recapitulate some of the clinical components of the disorder, none develop early onset hyperphagia or the severe obesity of the human disease. Therefore, alternative animal models are needed to study the biomedical basis and therapeutic approaches for the eating disorder and obesity. Miniature pigs may provide an ideal model for PWS, since they have a more similar body size, physiology, anatomy, and genome to human than does the mouse, and hence may be more susceptible to development of obesity. Furthermore, technologies exist in the pig to produce genetic models of disease. While the pig genome sequence is close to being finished, nonetheless, the PWS-orthologous region is poorly represented. Using sequence databases to screen for phylogenetically conserved sequences from the PWS domain, we generated *in silico* a BAC contig spanning large portions of the pig PWS-homologous imprinted and non-imprinted domains. Ten of the imprinted genes have been identified from partially sequenced BACs and ESTs. We identified unsequenced BAC clones that span the ~150-kb *cis*-acting imprinting center (IC) or extend from partially sequenced regions towards the IC. Five of these BACs are being sequenced by the Wellcome Trust Sanger Institute. These new sequences will allow us to identify regulatory elements controlling genomic imprinting in this domain and that control neuronal gene expression of the *Snurf-Snrpn*-snoRNA bicistronic mRNA and downstream cluster of small nucleolar RNAs. Also, BAC clones for imprinted and non-imprinted regions are being FISH-mapped, with the IC-*Snurf-Snrpn* locus mapping to *Sus scrofa* chromosome 1q18. This work will identify the genetic structure, including imprinted genes, transcriptional and imprinting *cis*-regulatory elements, and the chromosome evolutionary breakpoints in the PWS-orthologous domain in pig, a region of significant biological, agricultural, and medical interest. *Supported by the Foundation for Prader-Willi Research and RAC (Children's Hospital of Pittsburgh)..*

Improved Base Calling for 5500 Series SOLiD Sequencers. *C. Yang, M. Jiang, E. Wang.* Life Technologies, Foster City, CA.

Recent advances in SOLiD systems have revolutionized genomics, making it possible to quickly produce huge amount of sequences at substantially lower costs than traditional Sanger sequencing. Improved probe and ligation chemistry have resulted in enhanced coverage with fewer sequencing gaps in both GC- and AT-rich regions. Meanwhile, there exist several challenging obstacles that have to be overcome in order to push sequencing accuracy even higher. For example, it has been a well known issue that later ligation cycles have much higher error rate than earlier ligation cycles. One of the factors contributing to such phenomena is through-cycle residual build-up, which results in the change of the bead intensities captured by the instrument camera. In this work, we developed an efficient algorithm to dynamically model and correct the residual effect to improve color call. Specifically, the bead intensity at a given cycle is modeled as the sum of three components: 1) the underlying theoretical intensity vector at the current cycle, 2) the residual effect from the immediate previous cycle as the product of the residual coefficients and the intensity vector of the previous cycle, 3) a vector term representing the background difference between the two cycles. Among the three terms, both the residual coefficients and the background difference terms are channel-dependent. Once the model is solved mathematically through least square fitting technique, the residual and the background difference are subtracted from the current cycle to recover the underlying intensity, from which more accurate color calls can be achieved. In practice, this complete workflow consists of three steps: 1) a chosen color caller feeds the initial color call values into the model; 2) the underlying intensity values are recovered by the model; 3) the recovered intensity values are feed into the color caller to refine the color calls. A subset of the beads are used for model fitting and the solved model parameters are applied to all the beads in the same panel for performance reason. The above algorithm has been implemented in 5500 series SOLiD sequencers and tested on multiple data sets. Compared with results obtained without residual correction, the new base caller showed about 10 percent of total and 50 percent of perfect matched throughput increase and it has been observed that such improvement resulted from lowering errors in later ligation cycles from cycle modeling correction.

Genome-wide mutation detection using the Mouse Diversity Genotyping Array: Evidence for a mutation signature associated with a premature aging phenotype. *S.T. Eitutis, A.E. Wishart, K.A. Hill.* Department of Biology, The University of Western Ontario, London, Ontario, Canada.

The somatic mutation theory of aging implicates mutation accumulation with aging-associated diseases. However, genome-wide analysis of mutation load in individual tissues of humans is limited by tissue availability. Mouse mimics of human disease permit direct hypothesis testing, and a new advance in single nucleotide polymorphism (SNP) array-based genotyping provides the first high-resolution and low-cost approach to genome-wide mutation detection. Using the Mouse Diversity Genotyping Array (MDGA) providing a 623,124 SNP probe mutation target, we report the first application of this array for somatic mutation detection in a mouse mimic of human aging-associated neurodegenerative disease. The *harlequin* (*hq*) mouse contains a hypomorphic mutation in the *Apoptosis-inducing factor* (*Aif*) gene resulting in a premature aging phenotype with mitochondrial dysfunction and neurodegeneration. The MDGA was used to determine the frequency and distribution of mutations between splenic and cerebellar DNA from two 8-month and two 15-month-old *hq* brothers and two 8-month-old AIF-proficient brothers. Putative mutations were detected as differences in SNP calls between two tissues of the same mouse. The *de novo* mutations in a tissue were identified as genotype calls different from the genetic background of the mice. Mutation frequency was higher in *hq* compared to AIF-proficient mice ($p<0.001$). Inter-animal variation in mutation frequency was lower in both tissues of the *hq* mice ($p<0.001$). Putative mutations in *hq* mice were over-represented on chromosomes 12, 13, and 14 in both tissues compared to AIF-proficient mice ($p<0.001$). These data suggest that the mutational mechanisms operating in the *hq* mouse appear to be similar in spleen and cerebellum and are suggestive of an endogenous mutagen with a specific signature or DNA sequence context yet to be identified. The postmitotic cerebellum in contrast to the highly replicative spleen may contribute to the degenerative phenotype of the mutation burdened *hq* cerebellum. To date, no disease phenotype has been observed for the *hq* spleen. Detailed searches for a preferred sequence context have ruled out common culprits: selectively neutral sequence, G+C content, single nucleotide composition, sequence repeats and CpG dinucleotides. Resequencing of chromosomes 12, 13 and 14 may reveal the mutation signature to help elucidate the role of accumulated mutations in this mouse model and perhaps with human aging and neurodegeneration.

Evidence for an altered profile of copy number changes in the cerebellum of the *harlequin* mouse mimic of human aging-associated neurodegeneration. *A.E. Wishart, S.T. Eitutis, K.A. Hill.* Department of Biology, The University of Western Ontario , London, Ontario, Canada.

An interesting paradox exists in the pursuit of understanding the genetic basis of complex phenotypes such as aging and neurodegenerative disease. In humans, technological advances and demand have fuelled low-cost, high-resolution methodologies including high-resolution SNP arrays and whole genome sequencing, but hypothesis testing is severely limited by tissue availability. In the mouse, array-based approaches were very low-resolution, and genome sequencing remains high-cost due to comparably lower demand, but hypothesis testing has the freedom of tissue availability and control over mouse genotype. The Mouse Diversity Genotyping Array (MDGA) is a new high-resolution 623,124 SNP array with over 900,000 additional probes for copy number detection capable of genome-wide assessment of associations between copy number variation and complex disease. We used the array for a novel approach to mutation detection and specifically to identify copy number changes (CNCs) across the genome with comparison between two somatic tissues of the same mouse. The burden and nature of CNCs were examined in two male *harlequin* (*hq*) mice deficient in *Apoptosis-inducing factor* (*Aif*) resulting in mitochondrial dysfunction, neurodegeneration and premature aging in comparison with with two AIF-proficient brothers. Genomic segmentation analysis using Partek® Genomics Suite identified different profiles in *hq* and AIF-proficient mice. Total CNC burden is similar between *hq* and AIF-proficient mice for both cerebellum and spleen. The *hq* mice have significantly more gains in copy number in the cerebellum ($p<0.001$). The *hq* mice have more similar profiles of CNCs in contrast to greater variation in the AIF-proficient mice. The occurrence of CNCs across chromosomes was similar to that expected for a uniform distribution. Our novel MDGA approach to CNC analysis has demonstrated success in identifying a potential mutation type associated with a tissue-specific disease phenotype.

Recent Natural Selection in Primate Non-coding Sequences. *B. Giardine, K. Chen, R. Harris, F. Chiarmonte, R.C. Hardison.* The Pennsylvania State University, Center for Comparative Genomics and Bioinformatics, University Park, PA, USA.

Non-coding regions under selective pressure indicate functional importance and can contribute to phenotypic diversity among species. To date few genome-wide studies have looked for signatures of selection outside of protein-coding regions. We employ a variation of the McDonald-Kreitman approach, using widely distributed ancestral repeats as the putative neutral mutation class, to detect recent selection in humans using two different time scales of hominoid evolution. The increasing availability of SNP data from more individuals and a variety of human populations supports more robust analyses of selection and diversity than were previously possible. Preliminary results show that the distribution of adaptive-selection signals varies among and along chromosomes; furthermore, regions showing strong deviations from neutrality tend to overlap with segmental and gene duplications that are enriched with other footprints of adaption. This genome-wide scan enables us not only to find signals of natural selection close to genes, but also those distal to coding regions. The resulting regions showing selection signatures can aid further studies to expand our understanding of the functional impacts of non-coding sequences under natural selection.

MTHFR and SCN1A genes polymorphism in Iranian patients with migraine. *M. Ansari[2], M.S. Fallah[1], AA. Owji[3], S. Saeidi[3], M. Moghadasi[4], A. Ebrahimi[1], N. Hatamnejadian[2], B. Sedaqati Khayat[2], F. Rezaei[1].* 1) Kawsar Human Genetics Research Center (KHGRC), Tehran, Iran, Islamic Republic of,; 2) Department of Clinical Biochemistry, Tehran University of Medical Sciences, Tehran, Iran, Islamic Republic of,; 3) Department of Biochemistry, Shiraz University of Medical Sciences, School of Medicine, Tehran, Iran, Islamic Republic of; 4) Department of Neurology, Iran University of Medical Sciences, Tehran, Iran, Islamic Republic of.

Introduction Migraine is a common debilitating neurologic disorder and familial clustering raises the probability that genetic factor might play a role in migraine susceptibility. Many genes including CACNA1A, ATP1A2, SCN1A and MTHFR seem to be involved and related to migraine susceptibility. This study performed to find the association between SCN1A and MTHFR polymorphism and migraine. Material and Methods Migrainous patient according to the international headache society criteria included in the study. Healthy people without any positive history of periodic headache and no family history of migrainous headache in the family recruited as control group. MTHFR C677T and A1298C polymorphisms and SCN1A gene polymorphisms (rs7601520 and rs2298771) were investigated using PCR-RFLP and direct sequencing method. Results: Seventy-five migrainous patient (18 males and 57 females) and 128 healthy controls (43 males and 85 females) were recruited in the study. MTHFR 677TT was more frequent in migrainous patients (17.1% vs, 3.1%, P<0.05) and were associated with higher risk of migraine (OR= 6.5, CI 95%; 2.03-20.76). 677T allele was also more frequent than 677C (38.0% vs. 25.8) ((P<0.001) (OR= 1.47, CI 95%; 1.10-1.97). 1298A and 1298C allele frequency doesn't differ in cases and controls. Substitution of wild type alleles in 3 out of 4 allele (677TT+1298AC or 1298CC+677TC) was more frequent in migrainous patients (20% vs 3.9%, P<0.0001). We didn't detect any cases with homozygote substitution of wild type allele in both SNPS. Genotypes for rs7601520 were AG, AA and GG in 23 (56.1%), 14 (34.15%) and 4 (9.76%) respectively. Allele frequency were A and G in 51 (62.2%) and 31 (37.8%) respectively. Genotypes for rs2298771 were AG, AA and GG in 26 (57.8%), 15 (33.3 %) and 4 (8.9%) respectively. Allele frequency were A and G in 56 (62.2%) and 34 (37.8%) respectively. Conclusion: It seems MTHFR polymorphism may predict the susceptibility to migraine attach. Genotype and allele frequency of rs7601520 and rs2298771 were in the range of other studies.

Exome sequencing in Charcot-Marie-Tooth disease. *M.A. Gonzalez[1], E. Powel[1], G. Montenegro[1], G. Shengru[1], S. Blanton[1], G. Beecham[1], F. Speziani[1], C. Siskind[6], J. Vance[1], M. Menezes[2], D. Herrmann[3], S. Scherer[4], M. Reilly[5], M. Shy[6], S. Zuchner[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) The Children's Hospital at Westmead, Sydney, N.S.W; 3) School of Medicine and Dentistry, University of Rochester Medical Center, Rochester, NY; 4) Department of Neurology, The University of Pennsylvania School of Medicine, Philadelphia, PA; 5) MRC Centre for Neuromuscular Diseases, The National Hospital for Neurology and Neurosurgery, London, UK; 6) Department of Neurology and Center for Molecular Medicine and Genetics, Wayne State University School of Medicine, Detroit, MI.

Charcot-Marie-Tooth (CMT) disease comprises a large number of genetically distinct forms of inherited peripheral neuropathies. The >40 known genes explain only 20-30% of the axonal forms of CMT. The Inherited Neuropathy Consortium has been formed to improve this situation by applying exome sequencing to dominant CMT2 families in order to identify rare known and novel CMT genes. As a novel and alternative approach, whole exome sequencing has recently been introduced. This method is capable of re-sequencing the near complete set of coding exons of an individual. We performed whole exome sequencing in 15+ CMT2 families that were previously excluded for changes in the gene MFN2. A bioinformatics pipeline was developed and, if applicable, linkage analysis performed. To date, we have produced and analyzed over 40 whole exomes from CMT patients. Depending on the sequence coverage we identified between ~9,000 and 11,300 non-synonymous variants per individual. Special consideration was given to variants in known CMT genes. Further variant filtering for segregation, presence in public databases, and potential functional significance resulted in between zero and several-dozen candidate genes in each family. In one family, we were able to establish significant two-point linkage of LOD>2.6 at a novel rare variant in the mitochondrial tryptophanyl tRNA synthetase gene at chr1:119Mb. In conclusion, we have developed an analysis pipeline for CMT gene identification in exome data. We have learned that exome analysis does not always lead to immediate resolve of a given dominant pedigree. While typically remarkably few genes remain after exome analysis the need for additional follow-up studies became apparent. Such approaches should include molecular studies, but also collaborative screening of additional CMT cases. Preliminary results and late-breaking findings will be presented and we will discuss strategies and pitfalls of the exome sequencing approach.

Whole-exome sequencing in a family with idiopathic generalized epilepsy. *E.R. Londin[1], M.A. Keller[2], A. Ertel[3], K. Delgrosso[3], S. Surrey[4], P. Fortina[3].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) American Red Cross, Philadelphia, PA; 3) Thomas Jefferson University Hospital, Department of Cancer Biology, Cancer Genomics Laboratory, Philadelphia, PA; 4) Cardeza Foundation for Hematologic Research, Department of Medicine, Thomas Jefferson University, Philadelphia PA.

Epilepsy is a heterogeneous group of seizure disorders and represents one of the most common neurological disorders affecting ~3% of the population at some point in their life. Epilepsy is characterized by recurrent, unprovoked episodes of seizures arising from a variety of symptoms; incidences peak in children and the elderly. While symptomatic epilepsies are introduced by outside sources such as brain malformations or trauma, idiopathic epilepsies have no known cause. To date, the study of rare monogenic forms of idiopathic epilepsies have been identified, but identification of genes associated with more common forms has remained elusive. Additionally, genome-wide associations studies of these common epilepsies have failed to identify any significant associations. We present the findings of the first next-generation sequencing project performed to identify potential candidates associated with epilepsy. Whole-exome sequencing was performed on a family consisting of parents and two siblings, one of which has idiopathic epilepsy. The proband has experienced generalized absence seizures since the age of 3 years. Using the Agilent SureSelect 38 Mb All Exome Kit, an average of 4.5 Gb of sequence at an average of 125x read depth per subject was achieved. Over 20,000 genetic variants (SNPs and indels) were identified. The variants were filtered based upon known and unknown function and presence within genes expressed in the brain as well as their presence within either dbSNP or the 1000 Genomes project. While our analysis did not identify novel variants, we identified five previously characterized non-synonymous SNPs in the affected sibling. These variants were present in the affected sibling and one of the parents, but not in the unaffected child. The five variants are within genes encoding neuronally-expressed ion channels not previously associated with epilepsy. We intend to determine the association of these SNPs with epilepsy in a larger study of affected and control subjects. This preliminary study demonstrates that exome sequencing of affected and unaffected family members can be used to identify variants that may be associated with a common form of epilepsy.

Gene expression profiling of both protein-coding and long non coding RNA transcripts from small amounts of total RNA using a single microarray design. *A. Bergstrom Lucas, E. Lin, V. Kulkarni, S. Fulmer-Smentek.* Genomics R&D, Agilent Technologies, 5301 Stevens Creek Blvd., Santa Clara, CA USA 95051.

Recently, thousands of long non-coding RNA (lncRNA) transcripts have been identified in mouse and human cells from genome-wide chromatin-state maps and RNA sequencing. The roles that the lncRNAs play in biology is under debate and vary widely from acting as scaffolds for chromatin remodeling to guiding complexes to the right locations in the genome to enhancing or activating protein-coding gene expression. As more researchers investigate the function of lncRNAs, there is a need for tools that can rapidly and accurately measure lncRNA expression along with mRNA expression. We have previously developed human and mouse SurePrint G3 microarrays comprised of all known protein-coding mRNAs and lncRNAs to enable systematic profiling of lncRNAs and protein-coding genes allowing for simultaneous detection of gene expression from a single sample. To demonstrate the utility of the arrays we used low nanogram amounts of matched tumor and adjacent normal RNA to produce cyanine-labeled cRNA. The labeled cRNA was applied to the arrays to detect differences in coding and non-coding gene expression profiles. Using the GeneSpring GX software we are able to identify differentially expressed lncRNAs and protein-coding RNAs in the tumor and normal samples in less than two days. Comparisons of probe signals from technical replicate samples demonstrated high reproducibility with wide dynamic ranges and high sensitivity. Data from the microarrays correlates well with whole transcriptome sequencing of the same matched tumor/normal samples. Using this approach we show that lncRNA expression coincides with key genes known to regulate biological processes involved in cancer progression and this work demonstrates how profiling mRNA and lncRNA from matched tumor and adjacent normal samples can allow researchers to further define the role of lncRNAs in gene regulation. As further discovery and definition of the structure of lncRNAs continue, new and updated content will be available on these arrays to further enable novel discoveries and understanding of the interaction between non-coding and coding RNAs.

DVWA, osteoarthritis-associated gene, is associated with joint destruction in patients with rheumatoid arthritis. *T. Suzuki[1,2], K. Ikari[1], K. Yano[1], Y. Toyama[2], A. Taniguchi[1], H. Yamanaka[1], S. Shigeki[1].* 1) Inst Rheumatology, Tokyo Women's Med Univ, Shinjuku, Japan; 2) Department of Orthopaedic Surgery, School of Medicine, Keio University, Tokyo, Japan.

Background:To date, a number of osteoarthritis (OA) susceptible genes have been reported. Since OA is characterized by cartilage loss leading to joint damage, it may share the genetic background of the joint destruction with rheumatoid arthritis (RA). The purpose of this study was to evaluate the genetic association of reported OA-susceptible genes and joint damage in Japanese RA patients. Methods:DNA samples of 1504 Japanese patients were collected from the IORRA (Institute of Rheumatology RA cohort) DNA collection. Of the patients, Sharp/ van der Heijde score (SHS) of the hands at 5-year disease duration, which represents joint destruction in RA, could be measured in 628 patients. Following polymorphisms were selected since they were reported to be susceptible to Japanese OA patients; ASPN (an aspartic acid [D] repeat), GDF5 (rs143383), CALM1 (rs12885713) and DVWA (rs7639618) (1-4). The D repeat polymorphism was genotyped using PCR with a fluorescent primer, and the SNPs were genotyped using the TaqMan assay according to the manufacture's instructions. Multiple regression analysis was performed with SHS as a dependent variable, and the number of the risk alleles of OA-susceptible genes and the known joint damage-associated factors as independent variables; the number of HLA-DRB1 alleles encoding the shared epitope (SE), sex, anti-CCP antibody (ACPA), rheumatoid factor and age of onset. We also examined the expression of the gene in RA cartilage tissues using RT-PCR when the association of severity is recognized. Results:Sex (female, P= 1.9x10-5), age of onset (younger, P= 6.4x10-5), ACPA (P= 0.047), the number of SE (P= 0.026) and DVWA (P= 0.023) had showed the impact on radiographic joint damage, while the other tested genes showed no association. DVWA transcripts were expressed in both OA and RA articular cartilage. Conclusions:DVWA was associated with joint destruction in RA patients. References 1. An aspartic acid repeat polymorphism in asporin inhibits chondrogenesis and increases susceptibility to osteoarthritis. Nat Genet.37:138- 44. 2. Meta-analysis of curated public genomic data provides evidence that tibolone induces breast cancer recurrence. *H.S. Wang, S. Weiman, A. Hsu, M. Shekar, I. Kupershmidt.* NextBio, Cupertino, CA.

NextBio's web-based tools and curated public genomic data can be used to investigate therapeutic regimens *in silico*. Here, we present a case study of tibolone, which is prescribed to treat vasomotor symptoms of menopause and has been used to treat vasomotor symptoms associated with breast cancer therapy. Tibolone was thought to interact selectively with estrogen receptors responsible for these symptoms without promoting proliferation and tumor growth. However, a 2009 report in The Lancet showed that tibolone significantly increased the risk of breast cancer recurrence to 15.2% from 10.7% in the placebo group—a discovery that prompted the study's premature termination. We propose that before initiation of clinical investigations, analysis of publicly available genomic data could have predicted this increased risk of recurrence and provided preliminary assessment of alternative treatment options. Our investigation of public genomic data curated by NextBio found positive correlations between tibolone-induced gene expression changes and those seen in breast cancer. We also found that the tibolone-induced gene expression profile resembles that of estradiol hormone replacement therapy (HRT), which has been contraindicated in breast cancer patients. Using NextBio's gene set enrichment analysis tools, we also found that gene expression profiles of tibolone treatment, HRT, and breast cancer were commonly enriched in genes related to the cell cycle, growth signaling, morphological changes, and cancer progression. These enrichment results suggest that tibolone may contribute to disease recurrence by similar mechanisms to HRT. Filtering tibolone expression profiles by ER receptor status in breast cancer revealed correlations with both ER+ and ER- subsets, consistent with literature reports that tibolone also interacts with other androgen receptors. A similar analysis in NextBio for gabapentin, which is also used to treat vasomotor symptoms, shows gene expression changes that are not correlated with breast cancer, HRT, or tibolone signatures, indicating its potential as a safer alternative than tibolone for breast cancer patients. Together, these analyses demonstrate that NextBio's web-based tools and integrative genomics data (including genome wide association studies, epigenetic, microRNA, resequencing, somatic mutation and DNA copy number data), can greatly aid applications such as the prediction of drug efficacy, adverse effects, and alternative therapies.

864F

Comparing methods for mapping *cis* acting polymorphisms using allelic expression ratios. *M. Santibanez-Koref[1], M.D. Teare[2].* 1) Institute of Human Genetics, University of Newcastle, Newcastle upon Tyne, United Kingdom; 2) School of Health and Related Research, University of Sheffield, 30 Regent Street, Sheffield, S1 4DA, U.K.

Genome wide association studies provide increasing evidence that modulation of transcription, in particular through changes acting in *cis*, plays an important role in modifying disease susceptibility. Differences in transcription between the two alleles at an autosomal locus can be used to test the association between candidate polymorphisms and modulation of gene expression in *cis*. This type of approach requires at least one transcribed polymorphism and one candidate polymorphism. In the past five years different methods have been proposed to analyse this type of data. Here we use simulations and real data sets to compare the power of some of these methods. The results show that when it is not possible to determine the phase between the transcribed and potentially cis acting allele there is some advantage in using methods that estimate phased genotype and effect on expression simultaneously. However when the phase can be determined, simple regression models seems preferable because of their simplicity and flexibility. The simulations and the analysis of experimental data suggest that in the majority of situations considered methods that assume a lognormal distribution of the allelic expression ratios are both relatively robust to a range of deviations from this assumption and more powerful than the alternatives that do not make these assumptions.

Association Analysis of Polymorphisms in Insulin Secretion Pathway Genes with T2D in North Indian Punjabi Population. *A.J.S. BHANWER[1], Y.P. SINGH[1], N. KAUL[1], K. MATHAROO[1], R.N.K. BAMEZAI[2].* 1) DEPARTMENT OF HUMAN GENETICS, GURU NANAK DEV UNIVERSITY, AMRITSAR, PUNJAB,INDIA; 2) SMVD UNIVERSITY, KATRA , J&K, INDIA.

Prevalence of T2D has rapidly increased in India and throughout the world during last two decades. The major cause of the disease in India is supposed to be changing life style, increasing stress, less physical activity, dietary pattern and ethnicity. The various clinical and anthropometric parameters have also contributed towards development of the diseases. Thus, environmental factors along with genetic factors influence predisposition to T2D. It is not yet clear after several studies carried out in various populations worldwide that how many confounding factors and which genes are genuinely responsible for development of this complex disease. The GWA studies have also revealed many loci in nuclear genome, most of which confront in the insulin secretion pathway. Present case-control study was initiated to analyse single nucleotide polymorphisms (SNPs) in genes of insulin secretion pathway such as KCNJ11 (rs5219), UCP2 (rs659366), PGC1-((rs8192678), SIRT1 (rs12778366), TCF7L2 (rs7903146), mt-ND3 (rs2853826) with susceptibility to T2D. PCR-RFLP and sequencing procedure was used for genotyping polymorphisms. The association of above mentioned polymorphisms in North Indian Punjabi population was investigated in 242diabetics and 251non diabetic age, sex and economic status matched controls. The participants for the study were recruited with informed consent from north Indian state of Punjab. Binary logistic regression was applied to test the association of risk factors with T2D after adjusting for age, sex and BMI. The polymorphism in UCP2 (rs659366) p=0.02, OR-0.638(0.437-0.933), PGC1-((rs8192678) p=0.001, OR-1.888(1.304-2.733) and mt-ND3 (rs2853826) p=0.00018, OR-0.480(0.327-0.705) showed significantly association under dominant model. Thus, we observed that variants in genes involved in insulin secretion pathway seem to play a role in increasing susceptibility in North Indian Punjabi population. The present investigation also concludes that differential pattern of association of polymorphisms is observed for different populations, suggesting the putative role of ethnicity. Thus, for risk calculation and proper medical intervention, knowledge of the ethnicity and nature of variation in risk factors need serious attention.

A Genomic Region on Chromosome 11q23.3 encompassing BUD13-ZNF259 and APOA5-A4-C3-A1 Gene Cluster Harbors Loci Contributing to Serum Triglyceride Concentrations in Asian Indians. *T.R. Braun[1], L. Been[1], S. Ralhan[2], G.S. Wander[2], J. Chambers[3], J. Kooner[3], D.K. Sanghera[1].* 1) Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Cardiology, Hero DMC Heart Institute, Ludhiana, Punjab, India; 3) National Heart and Lung Association, Imperial College London, London, UK.

Recent genome-wide association scans (GWAS) and meta-analysis studies conducted on European populations have identified many genes previously implicated in lipid regulation. Among these genes is the APOA5-A4-C3-A1 gene cluster. Validation of these loci on different global populations is important for their clinical relevance and particularly in developing novel drug targets for treating and preventing dyslipidemia and coronary artery disease (CAD). In an attempt to replicate GWAS findings on a non-European sample, we genotyped two GWAS SNPs (rs964184 and rs12286037) from BUD13-ZNF259 and APOA5-A4-C3-A1 gene clusters in an Asian Indian diabetes cohort comprising 3,781 individuals (2902 from Punjab and 879 from the US) from the Sikh Diabetes Study (SDS). Both SNPs were significantly associated with triglyceride (TG) levels; rs964184 (p=5.94x10-10) and rs12286037 (p=0.003) in this cohort. We further explored ~195 kb region on chromosome 11q23.3 encompassing BUD13-ZNF259 and APOA5-A4-C3-A1 clusters containing 45 SNPs using our preliminary lipid GWAS data from 8,280 individuals. Of these, 6,530 Asian Indians were from the LOLIPOP study (UK) and remaining from the SDS (USA). We identified eight SNPs to be significantly associated with TG in both the SDS and the LOLIPOP cohorts. Seven of these eight variants exhibited a strong association of genome-wide significance (p< 2x10-8) with TG levels in a joint meta-analysis performed on 8,280 individuals and the strongest signal was seen in rs964186 (p=3.06x10-45). Interestingly, other variants showing robust association signals (p< 3x 10-25) with TG in this population have not been identified in previous European studies. Future functional studies should enhance our understanding of clinical relevance of these genes in hyperlipidemia leading to pathogenesis of CAD.

The association between genetic variation in the vitamin D immunomodulatory pathway and susceptibility to severe influenza infection. *S. Malik[1], P. Aurora[1], M.A. Karmali[1], M. Phillips[2], A. McGeer[3], K. Green[3], K. Fonseca[4], M. Graham[5], B. Neupane[6], J. Beyene[6], V. Manning[7], P. Singh[7], M. Loeb[7].* 1) Office of Biotechnology, Genomics, and Population Health, Public Health Agency of Canada, Toronto, Ontario, Canada; 2) Pharmacogenomics Centre, Montreal Heart Institute, Montreal, Quebec, Canada; 3) Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Alberta Provincial Laboratory for Public Health, Calgary, Alberta, Canada; 5) National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg, Manitoba, Canada; 6) Department of Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, Ontario, Canada; 7) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

Influenza poses one of the greatest infectious threats to public health. Complications such as pneumonia and hospitalization, highest in those at the extremes of age, have a major impact on the healthcare system. The recent H1N1 outbreak indicated that obese persons, pregnant women and those with Type 2 diabetes were at particular risk for severe influenza, possibly due to the interplay between vitamin D and inflammation. Vitamin D related innate immunity may play an important role in the pathogenesis of influenza by eliciting rapid-acting antiviral defence mechanisms and/or dampening excessive virus-induced inflammation (cytokine storm) which may otherwise lead to severe infection. This study is a national multicenter collaborative effort to identify genetic variants in the vitamin D biosynthetic/immunomodulatory pathway associated with severe influenza. Innate immunity is critical for the early containment of the influenza virus. Recent evidence indicates that innate immunity to infectious agents is modulated by vitamin D, consistent with the observation that influenza infection follows a geographic and seasonal distribution of vitamin D-associated solar ultraviolet radiation. This observation has been substantiated by in vivo, in vitro, and RCT studies. We postulate that genetic variants within the vitamin D biosynthetic/immunomodulatory pathway are associated with severe outcomes of influenza infection. To this end, we have undertaken a candidate gene approach applying a population case-control design (413 cases and 285 controls). All participants are adults of European ancestry and laboratory confirmed carriers of the influenza virus. Cases are those admitted to hospital (severe outcomes); controls, those not admitted (mild outcomes). SNPs along the vitamin biosynthetic/immunomodulatory pathway were examined. We have currently identified three polymorphisms in the vitamin D biosynthetic/immunomodulatory pathway associated with severe influenza, however, the functional consequences of these SNPs is presently unknown. Further work is needed to characterize the role of these variants in the context of severe influenza infection. Results from this study can provide a better understanding into how vitamin D impacts the natural history of influenza infection and, further, can influence public health recommendations for vitamin D supplementation with a view to reduce the burden of severe influenza infection.

Polymorphisms in NFKB1 gene are associated with juvenile rheumatoid arthritis. *J. Ramírez Bello[1,2], O. Mendoza Nava[3], A. Gutierrez-Hernández[4], F. Espinoza Rosales[4], G. Escamilla[4], V. Baca[5], L. Orozco[1,2].* 1) Laboratory of Immunogenomics, National Institute of Genomic Medicine, SSa, DF, Mex; 2) PhD Genomics Science Program, Autonomous University Mexico City, DF, Mex; 3) Faculty of Chemistry, National Autonomous University of Mexico, DF, Mex; 4) Departament of Immunology, National Institute of Pediatric, SSa, DF, Mex; 5) Departament of Pediatric Rheumatology, CMN-Siglo XXI; IMSS.

Juvenile rheumatoid arthritis (JRA) is the most common rheumatic disease in childhood. Over time, evidence has accumulated implicating NFKB1 as a mediator of autoimmunity and potential therapeutic target for treating autoimmune diseases. This transcription factor is a major regulator of immune response, apoptosis and cell-growth control genes. On this way, the aim of this work was to determine whether SNPs located in the NFKB1 gene (NFKB1_1; rs3774933T/C, NFKB1_2; rs3774937T/C, NFKB1_3; rs3774938A/G, NFKB1_4; rs1587213C/T, NFKB1_5; rs1587214C/T) are associated to JRA in Mexican population. This study included 215 patients (127 female and 88 male) with JRA, which fulfilled the American College of Rheumatology (ACR) criteria for the diagnosis of JRA. All patients were <16 years of age at onset of disease. A group of 430 (254 female and 165 male) unrelated healthy controls were included. Genotyping was carried out by 5' exonuclease assay (TaqMan). The association test, Hardy-Weinberg Equilibrium (HWE) and haplotypes, were evaluated using EPIDAT, FINETTI and Haploview softwares, respectively. Both cases and controls were in HWE. Differences between cases and controls were observed when we compared the genotype and allele distributions (NFKB1_1T/C, OR 0.69, p= 0.004; NFKB1_2T/C, OR 0.67, p=.001; NFKB1_3A/G, OR 0.66, p=.0009; NFKB1_4C/T, OR 0.69, p=.004 and NFKB1_5C/T, OR 0.67, p=.001). As expected, the haplotype CCGTT, carrying all minor alleles showed protection to JRA (OR 0.66, p=0.002). Pairwise linkage disequilibrium (LD) between SNPs showed an r2 > 0.90. When we stratified by gender, similar results were obtained in females (data not shown). Analysis in silico showed that these five SNPs could have a biological implication affecting an intronic enhancer. In summary, our data suggest that SNPs with a potential biological function in NFKB1 gene are protector factors to JRA in Mexican population. It is possible that these SNPs can be important in the biological function of NFKB1.

Detection of Sample Contamination and Paralogous Sequence Misalignment Using Allele Balance Metrics Associated with Next Generation Sequencing. *I.B. Stanaway, J.D. Smith, E. Turner, C. Igartua, K. Patterson, S.R. McGee, T. Shaffer, C. Poel, J. Chin, B. Paeper, Q. Yi, K. Sawatzki, B. Munson, I. Robertson, M. Mynsberge, S. Austin, C. Shepard, S. Paquette, M. Tackett, J. Furlong, P. Robertson, D. Siegel, E. Johanson, E. Johnson, E. Phillips, M.J. Rieder, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

Recent advances in Next Generation Sequencing (NGS) have allowed the production of massive amounts of read data and the ability to process increasing numbers of samples in parallel. During sample preparation for NGS, there are many steps where low level sample cross-contamination could compromise data quality. We have found that allele balance (AB) is a useful metric for assessing sample contamination and detecting potential sequence paralogs. This metric measures the ratio of the two possible base calls (i.e. alleles) at diploid heterozygous variants. It is defined as the count of the reference allele mapped over a single base position divided by the total counts of bases mapped over that position. For high quality samples, the AB histogram ranges from 0 to 1.0 with a major peak ~0.5 and a second minor peak at ~0.8. We performed Nimblegen exome capture, Illumina sequencing, Burroughs-Wheeler alignment and called variants using the Unified Genotyper from the Genome Analysis Tool Kit (GATK) on 83 human Coriell DNAs. We show that low level sample contamination can be observed from the presence of a third peak in the lower quarter (<0.25) of the AB histogram. The variants falling in this third peak are predominantly common non-reference homozygotes where the reference allele from a second contaminating sample makes the variants appear to be heterozygous with an abnormal allele balance. The area under this peak grows linearly with the fraction of contaminating reads being sequenced. We define the lower limit of detection to be ~2% which allows adequate detection of low level contamination. Analysis of the other peak at ~0.8 shows variants with AB > 0.75 to have an excess of possible matches to other genomic regions. This suggests these are false variants derived from paralogous sequence mapping errors. This property is useful to identify potential novel copy number variants that have diverged in sequence identity from their paralog. Thus, AB is a useful and sensitive metric for assessing the quality of NGS data and subsequent variation calls.

An Integrated Analysis Framework for Detecting Human Genetic Variations from Next Generation Sequencing Data in Tumor Samples. *C. Xiao[1], A. Ward[3], T. Blackwell[2], A. Mnev[1], H. Kang[2], E. Garrison[3], G. Marth[3], G. Abecasis[2], S. Sherry[1].* 1) NIH/NLM/NCBI, 45 Center Drive, Bethesda, MD 20892, USA; 2) Department of Biostatistics, University of Michigan, 1420 Washington Heights, Ann Arbor, MI 48109, USA; 3) Boston College Biology Department, 140 Commonwealth Avenue, Chestnut Hill, Massachusetts 02467, USA.

Tumor mutation spectrum analysis can provide insight into molecular and genetic mechanism of tumorigenesis, thereby improving molecular diagnosis and therapy of cancer diseases. The advancements of high-throughput next-generation sequencing (NGS) technologies have provided researchers with unprecedented opportunities to address biomedical problems in cancer studies, but also imposed huge challenges for downstream analysis due to the volumes and complexities of the data. In order to establish a proper and efficient workflow and facilitate genetic research using NGS technologies, we have developed an integrated analysis framework with multiple read aligners and variant callers to profile genetic mutations from NGS data from various sequencing platforms (including ILLUMINA, LS454, and SOLiD) in a uniform manner. The framework manages parallel-computing resources, checks sample identities, aligns the reads to the reference genome sequences, refines the mapping of placed reads, calls SNPs, INDELs, and SVs, and performs functional annotation. This NIH-based pipeline has been used for detecting genetic variations (approximately 31 million consensus SNPs) from the 1000Genomes main project Phase I data, and currently is expanded to perform mutation profiling for large scale tumor resequencing projects.

Association of Tumor Necrosis Factor Gene Polymorphisms with Chronic Obstructive Pulmonary Disease: A case -control study from India. *N.A. Khan[1,2], N.L. Kamble[1], M.K. Daga[1], S.A. Husain[2].* 1) Medicine, Maulana Azad Medical College, New Delhi, Delhi, India; 2) Department of Biosciences, Jamia Millia Islamia University, New Delhi, India.

Background & Aim: Chronic Obstructive Pulmonary Disease is characterized by a chronic inflammatory process, in which the pro-inflammatory cytokine Tumor Necrosis Factor (TNF) Alpha is considered to play a role. We determined the common functional polymorphisms of TNF-a gene at -308, -863, and -1031 positions and explored the influence of each genetic variant on pulmonary function parameters, body mass index (BMI), serum TNF-a levels, and outcomes among heavy smokers with or without COPD in a case -control study conducted at Maulana Azad Medical College in New Delhi, India. Methods: Stable COPD Patients who were ever smokers and age and packs years smoked matched healthy controls (n= 230 in each group) were recruited. Allele and genotype frequencies of three tag single nucleotide polymorphisms (SNP) of the TNF-a gene promoter Region at -308, -863, and -1031 in all subjects was performed by polymerase chain reaction- restriction fragment length polymorphism technique on genomic DNA obtained from peripheral blood. Serum TNF Alpha level was measured by commercially available ELISA kit. Results: COPD patients had a significantly lower A allele frequency (9.7 vs. 15.1%, OR = 0.6, p = 0.048, false discovery rate q = 0.144) and a significantly lower A carrier genotype frequency (19.3 vs. 30.2%, OR = 0.52, p = 0.042, q = 0.135) than resistant smokers. The -863 CA genotype was associated with a better FEV1/FVC ratio (76 vs. 71.5%, p = 0.032), and higher BMI (25.9 vs. 23.6 kg/m2, p = 0.034). The -308 minor allele (A) had a higher odd ratio (OR) of being associated with COPD (Adjusted for age, sex, pack-yrs: OR 1.9) and was also associated with worse forced expiratory volume in one second/forced vital capacity. In addition, COPD patients with the -1031 C carrier genotype had higher serum TNF-a levels (20.9 vs. 16.2 pg/ml, p = 0.01). BMI (hazard ratio = 0.84, 95% CI = 0.74-0.96, p = 0.008) was the only independent predictor for mortality. Conclusion It is concluded that the TNF-a -863 A and -308A alleles may confer a degree of resistance to the susceptibility COPD among heavy smokers in Indian Population suggesting that tumor necrosis factor Alpha polymorphisms may play a role in the pathogenesis of COPD.

Genome-wide analysis of SNPs impacting methylation and gene expression in *cis*. *T. Pastinen[1,2], B. Ge[2], S. Busche[1,2], T. Kwan[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada.

DNA methylation is a frequent epigenetic modification which occurs almost exclusively in the context of cytosine methylation in CpG dinucleotides. It is fundamentally involved in the regulation of many cellular processes,including gene and microRNA expression, cellular differentiation, embryogenesis, and genomic imprinting. Methylation patterns are known to vary not only between cell types but also between individuals. Emerging evidence indicates that a fraction of population variation in methylation is heritable and due to common variants. We have assessed genome-wide methylation patterns in a panel of primary fibroblasts. In parallel, we have measured total gene expression, genome-wide allelic expression, and genetic variation at high density. The panel of 60 unrelated Caucasian individuals (and an additional set of offspring) were measured on Illumina's Infinium HumanMethylation450 BeadChips, which interrogates CpG-methylation at >450K sites. We filtered out CpG probes overlapping SNPs or potential cross-hybridization and then correlated SNPs ±250kb flanking each highly variable (top 25th percentile population variation) CpG-probe with methylation level in a regression test and normalized the methylation values. Approximately 2% of CpG-probes associated with local SNPs at high significance (P<1E-6, FDR<5%). The vast majority of the association signals for differential methylation lie in close proximity (distance <30kb) of measured CpG sites. Genetic variation in *cis*-regulation as determined by allelic expression mapping in these same cells was highly enriched among the SNPs governing differential methylation. Finally, we observe that nearly 100 common disease-associated SNPs are linked with methylation. Our results highlight new levels of diversity of functional variation in non-coding DNA, which may provide novel clues for the mechanistic basis of disease associations.

Nucleosome organisation and chromatin structure in the HapMap cell lines. *D.J. Gaffney[1], G. McVicker[1], Y. Fondufe-Mittendorf[2], A.A Pai[1], R. Pique-Regi[2], J. Degner[1], J. Widom[1], Y. Gilad[2], J. Pritchard[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Department of Molecular Biosciences, Northwestern University, Evanston, IL.

Nucleosomes are the basic unit of eukaryotic chromatin and determine the accessibility of the packaged DNA to protein. Nucleosome organisation, and the factors that control it, are therefore of central importance in understanding how genes are regulated. Here we use MNase digestion of chromatin followed by high-throughput paired-end sequencing to produce a genome-wide map of nucleosome organisation in two HapMap cell lines. We use a computational method to identify the most likely nucleosome phase in regions of active transcription factor binding, and align nucleosomes adjacent to transcription factor binding sites. Our method reveals a clear signature of positioning of nucleosomes surrounding most bound transcription factors, We demonstrate how this signature can be used to estimate the region of open chromatin surrounding a bound transcription factor. Combined with a high-coverage DNase1 hypersensitivity map, our approach allows us to visualize the chromatin structure of enhancers at very high resolution.

Large-scale analysis of heritable *cis*- and *trans*-regulation of gene expression across multiple tissues in twins. *E. Grundberg[1,2], K.S. Small[1,2], A.C. Nica[3], A.K Hedman[4], A. Buil[3], J.T. Bell[2,4], D. Glass[2], TP. Yang[1], A. Barett[5], J. Nisbett[1], A. Wilk[1], M. Travers[5], SY. Shin[1], J.L. Min[4], K.T. Zondervan[4], S. Ring[8], W. McArdle[8], G. Thorleifsson[6], A. Kong[6], U. Thorsteindottir[6,7], C.M. Lindgren[4], N. Soranzo[1,2], K.R. Ahmadi[2], K. Stefansson[6,7], G. Davey-Smith[8], M.I. McCarthy[3,5], P. Deloukas[1], E.T. Dermitzakis[3], T.D. Spector[2], the MuTHER consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 5) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Churchill Hospital, Oxford, UK; 6) deCODE genetics, Reykjavik, Iceland; 7) Faculty of Medicine, University of Iceland, Reykjavík, Iceland; 8) MRC Centre for Causal Analyses in Translational Epidemiology (CAiTE), School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom.

Genetic variation in gene expression is an important underlying mechanism in disease susceptibility, but the relative contribution of heritable *cis* and *trans* effects and how it differs across tissues remain largely unknown. Here we use genomic and transcriptomic (IlluminaHT-12) data in LCL, adipose and skin tissue from 856 twins collected as part of the MuTHER study (TwinsUK). We find an abundance of heritable expression traits across tissues (i.e. _40% of adipose transcripts having h^2>0.3). To map the underlying *cis*-effects we carried out eQTL analysis and find that the genetic variance of transcript levels in LCLs are more likely to be explained by a *cis*-SNP than in adipose or skin tissue. For transcripts with h^2>0.3, a single *cis*-SNP explains on average 12% (LCL), 8% (adipose) and 9% (skin) of the genetic variance (h^2>0.3) but the effect sizes are increasing as heritability increases. When studying the 20 most heritable transcripts (h^2>0.6), in most instances (75%) a single *cis*-SNP explains >50% of the genetic variance. Further on-going analysis includes utilizing the twin structure to estimate the total heritable *cis*-effect in order to delineate the contribution of both common and rare variants. Using continuous estimates of tissue-overlap and comparisons of the magnitude of eQTL effects we estimate that 39-58% of *cis*-SNPs act in a tissue-dependent fashion. However, as *cis*-effects seem to account for a minor proportion of the heritability we sought to study the architecture of *trans*-regulation. In general, *trans*-eQTLs seem to be almost exclusively tissue-restricted and contribute small effects. Notably, we find that 9-20% of the *trans*-eQTLs per tissue at P<5E-8 affect clusters of ⁄3 transcripts suggesting presence of master-regulators (MR). These putative MRs display enrichment for low P-values across all transcripts indicating they may regulate additional genes below the threshold. This is supported by estimation of the proportion of true positives (61) where MR are enriched for larger 61 values than non-MR (61_{MR}=0.23 vs. 61_{NMR}=0.14). Replication efforts of *trans*-effects in independent studies ($ALSPAC_{LCL}$: N=936, $Oxford_{LCL}$: N=331, $deCODE_{adipose}$: N=585, $GenCord_{fibroblast}$: N=68) are ongoing but initial findings indicate a 3-fold enrichment for replicated *trans*-eQTLs. In conclusion, we find that the majority of transcripts have complex genetic regulation highlighting the need for continued exploration of the architecture of *cis* and *trans* regulation.

Long-range regulatory elements identified using high-throughput chromosome conformation capture. *YC. Hwang[1], Q. Zheng[3,4], BD. Gregory[1,3,4], LS. Wang[1,2].* 1) Genomics and Computational Biology Graduate Program, University of Pennsylvania, Philadelphia, Pennsylvania, PA; 2) PENN Center for Bioinformatics, University of Pennsylvania, Philadelphia, PA; 3) Department of Biology, University of Pennsylvania, Philadelphia, PA; 4) PENN Genome Frontiers Institute, University of Pennsylvania, Philadelphia, PA.

In mammals, genes are not only regulated by their proximal promoters, but can also be affected by distal and orientation-independent elements such as enhancers. As enhancers can be distal from the genes they regulate, identifying possible enhancer elements is extremely laborious, and more comprehensive methods of detection are only recently being developed. Chromosome conformation capture (3C) is a technique that allows the interaction between DNA regions, both proximal and distal, to be analyzed. Lieberman-Aiden et al. combined 3C with high-throughput sequencing technology (Hi-C) to comprehensively identify the spatial organization of chromatin for human lymphoblastoid and erythroleukemia cell lines. Here, we have used this Hi-C data in conjunction with a de novo suite of algorithms to identify candidate enhancer elements genome-wide. To do this, we use a geometric distribution-based model with bias correcting to identify DNA interacting `hotspots', thereby ensuring that all subsequent analyses are performed with extremely significant datasets. For the lymphoblastoid cell line, we identified 81125 DNA interacting hotspots using this approach. A non-mutually exclusive categorization of these hotspots revealed that 97.2%, 48.2%, and 43.8% of the hotspots are overlapped with transposable elements, tandem repeats, and Refseq genes, respectively. Identification of interaction partners for the hotspots demonstrated that 78447 of the 81125 regions are contacting other hotspots, resulting in a total of 753541 chromosome connections. Of these hotspot-hotspot interactions we identified those where one interaction partner made contact with a gene promoter region, as these are potential enhancer elements. When overlapping this list of candidate enhancers with ENCODE histone modifications, we found that hotspots paired with promoter regions are 3.37 to 4.73 fold more likely to be near any of the three known activating histone modifications (H3K27ac, H3K4me1, and H3K4me3) (chi-square test p-value << 0.01). Meanwhile, we found no discernable enrichment for H3K27me3, a known repressing modification. These findings provide strong evidence that many of our promoter-associated hotspots are bona fide enhancers. In total, we have found that our novel analysis of the Hi-C data comprehensively identifies enhancers in the human genome. Future work includes experimental validation and identifying disease-linked polymorphisms that lie within our newly identified enhancers.

876F

Variation in transcription factor activity inferred by DNase-seq assays provide a trans-acting mechanism for gene expression variation in humans. *R. Pique-Regi[1], J.F. Degner[1], A.A. Pai[1], J.B. Veyrieras[3], D.J. Gaffney[1,4], J.K. Pickrell[1], G.E. Crawford[2], M. Stephens[1], Y. Gilad[1], J.K. Pritchard[1,4].* 1) Department of Human Genetics, University of Chicago; 2) Departments of Pediatrics, Division of Medical Genetics, Duke University; 3) BioMiningLabs, Lyon, France; 4) Howard Hughes Medical Institute, University of Chicago.

Variation in gene regulation plays an important role in evolution and disease. Changes in gene expression can occur at different stages but an important transcriptional mechanism is through DNA-binding proteins (i.e., transcription factors, TF) that recognize specific sequences. DNase-seq is a powerful tool for identifying regions of open chromatin which are often bound by transcription factors. Furthermore, bound transcription factors protect the DNA sequence within a binding site from DNaseI cleavage and produce recognizable ``footprints'' that can also contain information about the binding strength or affinity of the TF. In order to better understand the different genetic and non-genetic mechanisms through which transcription factors affect gene expression in a human population, we used DNaseI sequencing to measure genome-wide chromatin accessibility in 70 Yoruba lymphoblastoid cell lines (LCLs), for which genome-wide genotypes and expression levels from RNA-sequencing are also available. We measured chromatin accessibility in 100bp non-overlapped windows across the genome and extracted a set of 1.5 million locations that varied in chromatin accessibility. We find that inter-individual variation in chromatin accessibility for distinct locations in the region surrounding each gene's transcription start site (TSS) are highly correlated with inter-individual variation in gene expression. These accessible chromatin locations that regulate gene expression contain many distinctive TF ``footprints''. The largest fraction are associated in `cis' to genetic variants that affect both the local chromatin accessibility (caQTL) and gene expression (eQTL). However, about ~2000 chromatin accessibility windows are not significantly associated with any local genetic variation and are regulated in a `trans' mode through genetic variation (trans-eQTL) or environmental changes that may be affecting TF's availability, protein structure or DNA-binding domain. The most intriguing potential trans-signal that we identified is from a SNP (rs8106495) that is a weak eQTL for two neighboring genes (NFKBID and HCST). Our data suggest that this SNP may play a role in regulating chromatin accessibility of a large number of hypersensitive windows that have binding sites for NFKB, a factor which is known to be regulated by NFKBID.

877F

Deciphering the vertebrate regulatory code using short synthetic DNA sequences that drive enhancer activity. *R.P. Smith[1,2], A.K. Holloway[3], S.J. Riesenfeld[3], K.S. Pollard[2,3,4], N. Ahituv[1,2].* 1) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco; 2) Institute for Human Genetics, University of California, San Francisco; 3) Gladstone Institutes, University of California, San Francisco; 4) Division of Biostatistics, University of California, San Francisco.

A wide variety of clinical and molecular data indicate that noncoding regulatory sequences contribute significantly to human diversity and disease. However, our limited understanding of the vertebrate regulatory code makes it challenging to annotate functional regions and interpret the effects of nucleotide variation within them on gene expression and downstream phenotypes. Most studies seeking to decipher this code have taken a top-down approach, mutating known regulatory elements, experimentally characterizing individual transcription factor binding sites (TFBS) or searching for enriched sequence motifs near co-expressed genes. Here, we have pioneered a novel bottom-up approach, using pseudo de Bruijn sets to design 184 short (15bp) oligonucleotides encompassing all possible 6bp sequences (the shortest average TFBS length, 6-9bp). The regulatory potential of these sequences was tested in zebrafish at 24 and 48 hours post fertilization using a transgenic enhancer assay. Thirty-three sequences produced consistent expression in >50% of embryos, with many expressing in a tissue specific manner. Six of these 15bp sequences, each driving specific expression in a different tissue (somitic muscles, epidermis, forebrain, notochord, heart and spinal cord), were selected for further experiments. Deletion series revealed that in multiple cases, shorter 6-9bp regions within these sequences were responsible for the expression pattern observed. Concatenation of 5 copies of the same 15bp sequence resulted in stronger enhancer activity in some of the constructs, consistent with the observation that homotypic clusters can enhance gene expression. However, in other cases, the expression pattern was abolished, suggesting that the syntax (e.g. spacing, order) of transcription factor binding sites is an important factor in their function. Conservative genome-wide alignments demonstrate that the 15bp sequences appear in the zebrafish genome an average of 128 times, often near genes that function in the same tissues as observed in the enhancer screen. Through this work, we are building and functionally translating a regulatory language from scratch, providing a better annotation of functional elements in the genome and improving our understanding of the regulatory code. These results will also enable researchers from numerous biological fields to engineer regulatory elements that can act as drivers to specific tissues and time points.

878F

Co-localized transcription factor binding sites explain gene expression and disease-associated variants. *D.Y. Wang[1], A. Rendon[2], L. Wernisch[1].* 1) MRC Biostatistics Unit, University of Cambridge, Cambridge, United Kingdom; 2) Dept. of Haematology, University of Cambridge, Cambridge, United Kingdom.

Increasingly more regulatory regions are being cataloged at a genome wide scale by large consortium, such as ENCODE. ChIP-Seq experiments for detecting transcription factor binding sites allow for elucidation of potentially functional regulatory regions. Transcription factor occupancy at a proximal gene locus has been shown to correlate with the gene expression level. Yet, models describing the relationship between the dynamics of multiple transcription factors and gene expression levels have never been introduced for human cell types. Here, we show that information from multiple co-localized transcription factors can be used to explain human cell type-specific gene expression. By mapping combinatorial patterns of binding sites from 11 different transcription factors, we can elucidate K562 and GM12878 specific gene expression. In primary hematopoietic cells that are closely related to the K562 cell line, the amount of gene expression variation explained by the 432 distinct combinatorial patterns can be as high as 48%. In GM12878, 22% of co-localization regions have a different pattern compared to those in K562. The degree of dissimilarity between combinatorial binding patterns in K562 and GM1287 is surprisingly correlated with the amount of target gene expression explained. Generally, the level of gene expression explained is lower for cell types further away in lineage to the cell type from which the transcription factor binding sites are observed. In this study we also find that co-localized transcription factors within 1kb of a target gene's transcription start site provides more information on the gene's expression than distal transcription factors. Nevertheless, we further show that eQTLs can be used to map more distal regulatory regions to target genes. These mapped regulatory regions, in turn, provide an explanation for the variation observed in eQTL results from different cell types. We anticipate that our findings will enable quantitative analysis of cell type-specific regulatory regions, and provide a general framework for the development of combinatorial models for explaining gene expression.

879F

Stress monitoring in the omics era and the future of saliva. *P. De Boever[1,2], N. Saenen[2], D. Santucci[3], G. Vermeir[4], V. Brümmer[5], M. Viaene[6], S. Schneider[5], G. Schoeters[7].* 1) Environmental Risk and Health, VITO, Mol, Belgium; 2) Hasselt University, Centre for Environmental Sciences, Hasselt, Belgium; 3) Istitute Superiore di Sanità, Department of Cell Biology and Neurosciences, Rome, Italy; 4) Openbaar Psychiatrisch Zorgcentrum (OPZ), Geel, Belgium; 5) German Sport University Cologne, Institute of Movement and Neurosciences, Cologne, Germany; 6) Catholic University of Leuven, Department of Occupational and Environmental Medicine, Leuven, Belgium; 7) University of Antwerp, Department of Biomedical Sciences, Antwerp, Belgium.

Environmental and social cues can activate the stress response system and this will influence the balance between the hypothalamus-pituitary-adrenal axis, the sympathetic nervous system and the immune function. These biological systems will stimulate a series of adaptation processes called allostasis. An inefficiently managed adaptation is then referred to as allostatic overload and is associated with an increased risk for getting a disease. We propose the use of space analog environments (such as an Antarctic station, parabolic flight and short arm human centrifuge) as unique settings to study the impact of acute and chronic stress on human physiology, and more specifically mood and mental fitness. These environments, much like actual manned space flight, represent a unique challenge for biological systems and early identification of adverse health effects is of paramount and possibly crucial for mission success. We use a suite of measurements including gene expression analysis, multiplexed immunoassays for protein analysis, and cognitive evaluations to address this issue and to identify biologically relevant warning signals. Furthermore, we are considering countermeasures such as physical exercise and dietary intervention to deal with adverse effects. Many of the biological data are collected from blood samples, but we also explore saliva as a source of a biomolecules. In the context of our studies we have shown that it is possible to collect saliva samples under challenging conditions and to obtain high quality transcriptomics data. The applicability of saliva analysis is further investigated because such a non-invasive and easy sampling procedure would have many advantages over the invasive blood analysis. Our presentation will give an overview of the current status of stress monitoring with several examples relevant for space research. Particular attention will be paid to the use of saliva and the ongoing initiatives to use this matrix to discover stress-relevant signals using transcriptomics and proteomics approaches.

880F

Evoked endotoxemia induces tissue-specific RNA-DNA differences. *J.F. Ferguson[1], Y. Liu[2], B.J. Keating[1], Y. Guo[3], M.P. Reilly[1], M. Li[2].* 1) Dept. Medicine, University of Pennsylvania, Philadelphia, PA; 2) Center for Clinical Epidemiology and Biostatistics, University of Pennsylvania, Philadelphia PA; 3) BGI-Shenzhen, Shenzhen, China.

Inflammation is a key component in the pathophysiology of cardiometabolic disease. We utilize a model of evoked endotoxemia (LPS) to explore inflammatory response. RNA-DNA differences (RDD), or single base sequence differences between RNA and DNA from the same individual, have recently been described. We hypothesized that the occurrence of RDD may be tissue-specific, and may be modulated by acute inflammation. We applied RNA sequencing (RNASeq) to four RNA samples from two tissues (adipose and blood) from a single individual (Caucasian female), before and after evoked endotoxemia (LPS 1ng/kg), a model of inflammatory disease. On average, 10 million 75 bp paired-end reads were generated for each sample. To identify RDDs, we aligned the RNASeq reads to the Gencode mRNA reference sequence (hg18) using Bowtie. We extracted uniquely-mapped reads, requiring ⁄ 20 reads, with a per-base sequence quality score for each of the covered base ⁄ 25, and restricted analysis to known monomorphic sites only. In an initial screen of RDD, we detected 4501 events in adipose pre-LPS (A), 3157 in adipose post-LPS (B), 1733 in blood Pre-LPS (C) and 1168 in blood post-LPS (D). We detected all 12 possible types of base difference between DNA and RNA. After filtering for RDDs present in at least 50% of reads, there were 236 events in A, 254 in B, 117 in C, and 109 in D. We filtered out any RDDs that were found on the boundary between reads, and screened for tissue- and LPS-specific events. We found 8 genes with tissue-specific RDDs. Looking at differential RDDs before and after LPS, we found 16 genes in adipose, and 8 genes in blood. A number of these genes have previously been implicated in disease. We detected RDDs in *MT1E* and *SPTBN1* in adipose at baseline but not after LPS. *MT1E* has previously been implicated in Type 2 Diabetes, while *SPTBN1* has been implicated in cancer. In blood, we detected an RDD in *TYROBP* before LPS but not after; this gene has been shown to be important in immune response, and in macrophage recruitment, thus representing an important biological candidate gene for inflammatory response. Our results are consistent with previous findings of RDDs and may represent a novel mechanism for regulation of genes involved in inflammatory cardiometabolic disease.

881F

Expression changes of xenobiotic efflux genes are associated with ileal inflammation in the pelvic pouch of individuals with ulcerative colitis. *B. Kabakchiev[1,2], A.D. Tyler[1,2], M.S. Silverberg[1,2].* 1) SLRI, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) University of Toronto, Toronto, Ontario, Canada.

Background: As many as 50% of ulcerative colitis (UC) patients who have undergone ileal pouch anal anastomosis (IPAA) develop de-novo inflammation in the ileal pouch within 10 years following surgery. With the use of microarray technology, we sought to investigate what gene expression changes occur in the pelvic pouch after surgery for UC and how these changes vary by outcome. **Methods:** Biopsy specimens from the pouch and afferent limb of the ileum were collected at the time of recruitment and preserved in RNAlater from patients who had undergone IPAA and closure of ileostomy at least one year prior. Based on clinical and endoscopic data at time of enrolment, 40 individuals from this cohort were allocated into 4 outcome groups - no pouchitis (NP), pouchitis (P), Crohn's disease - like phenotype (CDL) and familial adenomatous polyposis controls (FAP). The miRNeasy Kit was used to extract total RNA from all samples. The eluted transcriptomes were analyzed on Affymetrix Human Gene 1.0 ST arrays and the data were background corrected and normalized in Affymetrix Gene Expression Console. An ANOVA model in the statistical package R was used to assess the significance of each gene. Raw p-values were corrected for multiple comparisons by the false discovery rate method. **Results:** The expression levels of 144 gene transcripts were significantly associated with outcome at a corrected p-value cut-off of <0.05. There was also evidence that 117 of these were differentially regulated in the pouch compared to the afferent limb. Approximately 20% of the genes associated with outcome have known xenobiotic activity related to metabolizing and removing various drugs, toxins and other compounds from the cytoplasm of cells. All of these genes exhibited virtually the same expression pattern of up to 4 fold reduction in relative pouch mRNA abundance in the P and CDL groups compared to the NP and FAP groups. A prominent example is the gene ABCB1 also known as multi-drug resistance 1 (MDR1). Previous reports have shown that single nucleotide polymorphisms which result in attenuated ABCB1 expression are associated with UC. **Conclusions:** Transcriptome analysis of UC patients following IPAA showed that P and CDL are associated with significantly repressed drug and toxin efflux activity in the affected tissue. These findings corroborate the hypothesis that impaired barrier function could lead to development of intestinal inflammation.

Expression Profiling of Genes Involved in Transendothelial Leukocyte Migration in HIV-1 Resistant Women in the Pumwani Sex Worker Cohort. *P. Lacap[1], M. Luo[1,2], J. Sainsbury[1], M. Songok[3], F. Plummer[1,2].* 1) Public Health Agency of Canada, Winnipeg, Manitoba, Canada; 2) Department of Medical Microbiology, University of Manitoba, Winnipeg, Manitoba, Canada; 3) Department of Medical Microbiology, University of Nairobi, Nairobi, Kenya.

Objective: A group of sex workers in the Pumwani Sex Worker Cohort, located in Nairobi, Kenya, remains HIV-1 uninfected, as determined by PCR and serology, despite heavy exposure to the virus through sex work. Successful HIV-1 infection is contingent on the virus' ability to infect susceptible leukocytes that migrate to the site of acute infection. Delayed migration of susceptible cells may slow the onset of systemic infection, potentially allowing innate and adaptive immune responses to clear the infection. The aim of this study is to identify genes involved in transendothelial leukocyte migration that are differentially expressed between HIV-1 resistant and susceptible women.

Design: The expression level of 90 genes involved in transendothelial migration were examined in 38 resistant and 37 susceptible women using a custom RT^2 Profiler™ PCR Array (SABiosciences). RNA was isolated from whole blood using the PAXgene Blood RNA Kit (Qiagen). The cDNA was synthesized and amplified using the TransPlex® Complete Whole Transcriptome Amplification Kit (Sigma-Aldrich). The level of gene expression was compared between HIV-1 resistant and susceptible women.

Results: We identified 23 genes, which were differentially expressed in HIV-1 resistant women compared to susceptible women. The following genes were significantly up-regulated in HIV-1 resistant women: RBL2 (p= 0.000498), ITGB1 (p=0.000668), CDK6 (p=0.000677), PIK3CA (p= 0.00249), RASA1 (p=0.00347), DPP4 (p=0.00357), MAPK7 (p=0.00869), MAP4K1 (p=0.0104), MAP3K4 (p=0.0106), MAP2K1 (p=0.0110), CTNNB1 (p=0.0134), SHC1 (p=0.0153), PTPN11 (p=0.0195), RPS6KB1 (p=0.0206), CLTC (p=0.0240), TICAM1 (p=0.0256), TIMP1 (p=0.0307), and VCAN (p= 0.0380). In contrast, the following genes were significantly down-regulated in the HIV-1 resistant group: LEP (p=0.0112), TSC2 (p=0.0135), NFKBIA (p=0.0209), MAPK3 (p=0.0215), and MMP13 (p=0.0478).

Conclusion: The results showed that the expression level of many key genes involved in leukocyte migration in HIV-1 resistant women are different from women who are susceptible to HIV-1 infection. They may represent novel targets for HIV-1 prevention.

Revised Guidelines for RNA Quality Assessment for Diverse Biological Sample Input. *B. Lam, M. Simkin, N. Rghei, Y. Haj-Ahmad.* Norgen Biotek Corp, Thorold, Ontario, Canada.

Determining RNA quality is important prior to performing any downstream expression analysis such as microarrays or RT-qPCR. In many cases, good RNA quality could guarantee the success of the experiment. An RNA sample of poor quality could either lead to a labor-intensive cleanup process or compromise the results of the study. Especially while working with hard-to-obtain samples, starting with high quality, intact RNA could eliminate the burden of subsequent inhibited downstream applications. Traditionally, RNA quality is based on rRNA integrity (28S/18S). With the advancement in technology, additional parameters have been used, including spectrophotometry (260/280 and 260/230 ratios) and RNA Integrity Number (RIN) determined by bioanalyzer. Many of the above parameters and their acceptable values are based on traditional systems such as pure cell lines or tissues from healthy, lab-raised subjects. As scientists begin to study RNA expression in more diverse samples, such traditional standards become hard to achieve due to the nature of the sample input. This is often the case in clinical samples, such as bodily fluid as well as environmental samples where RNA concentration is low. Similarly, it is difficult to isolate a high quality RNA from formalin-fixed and paraffin-embedded (FFPE) tissues, as the RNA is often fragmented and chemically altered. Given the increase in input diversity for RNA extraction, there is a need to re-evaluate the acceptable values for RNA quality for each unique sample type. This study aims to generate a guideline for RNA quality for various inputs, particularly difficult-to-isolate samples including clinical (plasma/serum, blood and FFPE) as well as environmental samples (water, soil or plants). Two common methods (phenol-based and silicon carbide column-based) were employed for extracting total RNA including small RNAs. The various RNA quality assessment parameters were recorded and correlated with downstream application performance including RT-qPCR and microarray. Interestingly, for samples such as plasma/serum and FFPE with no intact large rRNA, RNA samples with RIN values and OD ratios that were significantly lower than commonly accepted still performed well in microRNA RT-PCR or microarray applications. Moreover, by comparing to a serial dilution of a good clean RNA, it was shown that most “out-of-range” RNA quality of clinical or environmental samples was due in part to the sensitivity of the instrument used instead.

Heteroallelic expression and RNA editing using high-throughput RNA sequencing. *J. Li-Pook-Than, R. Chen, G. Mias, L. Jiang, H. Lam, H. Tang, M. Snyder.* Department of Genetics, School of Medicine, Stanford University, Palo Alto, CA.

We are establishing a novel fully comprehensive human genotype-to-phenotype approach of whole -omics profiling analysis (genome, transcriptome, proteome). For the first time, the plethora of information gained from high-throughput genomic sequencing was integrated with transcriptome sequencing (RNAseq -Illumina) of peripheral blood mononuclear cells (PBMCs) in an individual. This was also combined with respective mass spectral proteomic data. We obtained an average of 146 million mapped transcriptomic reads for over 15 time points (including 2 infection states) collected over a year. This abstract focuses on heteroallelic gene expression, alternative spliced forms, as well as the phenomena of RNA editing. To identify RNA variants, we developed the RIT(E)2-seq pipeline (RNA Identifier Tool for Expression and Editing) which compares RNA information with the respective individual's genome (~3.7 million called SNPs). It applies filtering methods to minimize high instances of false positives due to intrinsic platform errors and misalignment to duplicated regions and pseudogenes. This pipeline incorporates several algorithms including TopHat, BWA, SAMtools and Polyphen-2 (Langmead et al, 2009; Li and Durbin, 2009; Li et al, 2009; Adzhubei et al, 2010). Our preliminary data show that of the 22,446 exonic-located genomic SNPs, ~21,700 are expressed across multiple time-points (min. ~5 FPKM): 7,755 are homozygous (~830 missense changes), 13,934 are heterozygous (~1,670 missense changes), ~800 are not present in dbSNP and are candidates for private SNPs. RNA editing is a post-transcriptional event, usually resulting in a deamination process: cytidine to uridine (C-to-U) or adenosine to inosine (A-to-I) conversion. We identify over 2,100 RNA editing candidates (min. 3 time points), including unusual edits that suggest processes unique from deamination. Validation of our RNA data include Sanger sequencing and quantification methods such as digital droplet PCR. So far, 90 missense variants are confirmed with our respective proteomics study. Notable is the importance of such high-depth coverage (total 2.2 billion mapped RNA reads) for the characterization of rare events as editing and low-level heteroallelic expression. This whole -omics approach provides valuable information for correlating variants with phenotype, captures the health state and risk of an individual, as well as gives insights into human diversity studies.

Transcriptome changes following site-specific DNA breaks. *S. Linker, D. Hedges.* HIHG, University of Miami, Miami, FL.

The coordinated response of the genome to double strand break (DSB) DNA lesions is vital for maintaining healthy cellular function. Insufficient repair response can contribute to a number of pathological phenotypes, including cancer. Global expression patterns have been previously analyzed under high-dose DNA damaging conditions, such as ionizing radiation or etoposide exposure. Even though these systems have been useful in studying the response to DSBs, they exaggerate conditions under which natural DSBs occur. In this study, we sought to examine transcription changes in a more natural context by restricting induced double strand breaks to a single genomic location. Using a synthetic zinc finger nuclease (ZFN), we induced a DSB at a unique location in the human genome and examined resulting expression changes. Whole transcriptome data was collected 24 hours after exposure of HeLa cells to the ZFN, which was targeted to the Adeno-associated virus site 1 on chromosome 19. cDNA libraries formed from total RNA were multiplexed, with two transcriptomes (treated and untreated) run per HiSeq2000 lane. Analysis is currently underway, and preliminary Web-Gestalt KEGG pathway analysis of differentially expressed genes suggests significant expression enrichment of genes involved in Parkinson's disease, oxidative phosphorylation, Huntington's disease, and Alzheimer's disease. A majority of the altered genes fall within distinct subclasses of transcription factor targets.

The transcriptome of the Rotterdam Study. *M.J. Peters[1,2], M. Jhamai[1,2], H.J. Westra[3], M. Ganesh[1,2], B. van Ast - Copier[4], F. Rivadeneira[1,2,4], J.M. Vergeer - Drop[4], A. Hofman[4], L. Franke[3], A.G. Uitterlinden[1,2,4], J.B.J. van Meurs[1,2].* 1) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, the Netherlands; 2) The Netherlands Genomics Initiative - sponsored Netherlands Consortium for Healthy Aging (NGI-NCHA), Rotterdam / Leiden, the Netherlands; 3) University Medical Center Groningen, Department of Genetics, Groningen, the Netherlands; 4) Department of Epidemiology, Erasmus Medical Center, Rotterdam, the Netherlands.

Purpose: Gene expression levels might mediate the association between genetic variants and diseases. Yet, expression levels can also be associated with diseases, independently of genetic variation. Within the Rotterdam Study (RS), we examined the overall variability of genome-wide gene expression levels of whole blood samples of 935 unrelated individuals, and assessed its association with 598,821 genotyped SNPs. In addition, we examined which genes are differentially expressed during aging, a strong risk factor for many complex diseases (i.e. osteoporosis, osteoarthritis and cardiovascular disease). Materials & Methods: For 935 randomly selected RS-3 participants, whole blood cells were collected (PAXgene Tubes-Becton Dickinson) and RNA was isolated (PAXgene Blood RNA kit-Qiagen): 891 samples (95.3%) with good quality RNA (RNA Quality Score or RQS ⁄ 7.0), 109 technical duplicates, and 4 control RNAs were amplified, labelled (Ambion TotalPrep RNA), and hybridized to the Illumina Whole-Genome Expression Beadchips (HT-12v4). eQTLs were mapped with AssociationGG (www.genenetwork.nl/associationgg). For differential expression analysis, the genome-wide significance threshold was set at p=1.97x10-6, thereby correcting for the number of tests performed. Association between normalized expression levels and age was analyzed by a linear regression model, adjusted for gender and technical batch effects (plate layout, time between blood donation and RNA isolation, RQS). Summary of the Results: The study sample consisted of 408 men and 471 women, mean age of 59.8 (±8.1). Out of 44,877 probes on the chip, 25,439 probes corresponding to 18,212 genes were significantly expressed in >5% of the samples. Expression levels of the probes were highly reproducible among the technical replicates (average Pearson correlation = 0.98). In total, 6138 expression Quantitative Trait Loci (cis-eQTLs) were detected (FDR<0.05; 25% of the probes have a cis-eQTL-effect). For differential expression analysis, 516 probes corresponding to 471 genes were significantly associated with aging. 38 (8.1%) genes were also found significantly associated by Zeller et al. (2010), which is 3 times more than expected by chance, indicating that our 471 associated hits are enriched for genes previously associated with aging. Most significant genes are VAMP5, IL7R, BCL11A, IRF8, and GRAP, involved in cell cycle progression, recombination, and signalling. Replication of these findings is currently underway.

SNP calling and allele frequency estimation of targeted sequencing of pooled samples. *X. Chen[1], T. Paranjape[2], J. Weidhaas[2], F. Slack[3], H. Zhao[1,4,5].* 1) Program in Computational Biology and Bioinformatics, Yale School of Medicine, New Haven, CT; 2) Department of Therapeutic Radiology, Yale School of Medicine, New Haven, CT; 3) Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT; 4) Department of Epidemiology and Public Health, Yale University School of Medicine, New Haven, CT; 5) Department of Genetics, Yale University School of Medicine, New Haven, CT.

Next generation sequencing has been widely used to study complex hereditary diseases as a powerful alternative to SNP genotyping through its ability to identify both common and rare variants without prior information on SNPs. Pooled sequencing of interested target regions can lower the cost and increase the sample size, thus the power, for disease-associated variant detection. However, compared to individual genomic sequencing which is relatively easy to analyze, pooled target region sequencing is complicated by many additional factors due to target amplification and capturing, formation of pools, and others which all contribute to the variance of the observed data and result in difficulties in SNP calling, allele frequency estimation and association test. Here, we use real pooling data from targeted sequencing of pooled samples with RainDance capture as well as corresponding sequencing of individual samples with NimbleGen capture to motivate a statistical model that encompasses different factors affecting the observed sequencing data. This rigorous model enables us to estimate the variance of the pooling data as a function of sequencing coverage, number of samples in a pool, and minor allele frequency in the sampled population. Equipped with this model and a better understanding of pooling variance, we evaluate the accuracy of allele frequency estimation and the power of association testing. We further propose a model to gain more precise estimation of allele frequencies of SNP positions and more accurate variant detection by incorporating target-capturing and sequencing errors and biases. Our studies show the performance of the target sequencing of pooled samples in disease association tests and provide a method to control the errors and biases in the processes of capturing and sequencing.

888F

Screening individuals with rare variants in large populations: deep re-sequencing the CRP locus. *C. Chen, A. McDavid, O. Kahsai, A. Zebari, C. Carlson.* Fred Hutchingson Cancer Research Center, Seattle, WA.

Common single nucleotide polymorphisms identified in GWAS to date generally account for small effects, leading to the hypothesis that rare variants might also play a functional role in determining phenotypes. Even though technological advances have allowed scientists to sequence many genomes in parallel, identifying individuals carrying rare variants is not a trivial task. One of the challenges is discriminating between sequencing errors and true rare variants. To address this, we have developed an algorithm, which, in combination with a unique pooling strategy, is able to efficiently screen a candidate gene for idiosyncratic variants in large samples.We demonstrate this novel approach by re-sequencing the c-reactive protein locus (CRP) in a sample of 2300 individuals, using just two lanes on an Illumina sequencer. Plasma CRP level is a biomarker predicting future risk of cardiovascular disease. Common variants explain little of the variance in CRP levels among individuals. To investigate whether rare variants at this locus also influence CRP levels, we sequenced a 6kb region spanning CRP extensively in individuals from the CARDIA cohort in 24 separate pools of 96 samples each. Keeping bases with high quality scores in high quality reads, we obtained a coverage depth of 36,000 per position on average across the 24 pools. We calculated a statistic for each position based on the distribution of minor allele frequencies across pools and designated the position to be polymorphic when its value is bigger than the statistic generated from a noise model parameterized from our data. This metric is robust with respect to the number of total number of sequencing pools, the minor allele frequency of the variant, and the number of pools with the variants. In total, we identified 140 polymorphisms, with 46 of these already known in dbGaP. To confirm these variants, we genotyped 63 loci (minor allele frequencies ranging from 0.05% to 25%) in the same population. Treating the genotyping results as a reference, we obtained a 98% sensitivity rate. With this approach, we were able to rapidly and cost-effectively screen for both common and rare variants in a large population. The high sensitivity of this approach enables us to identify variants with a minor allele frequency as low as one copy in 2000 individuals. We believe this efficient algorithm will be useful in replicating rare variants identified in large-scale studies.

889F

Next generation sequencing of centenarian and control genomes. *E.T. Cirulli, M. Zhu, K.V. Shianna, D. Ge, D.B. Goldstein.* CHGV, Duke Univ, Durham, NC.

The factors contributing to exceptionally long life have long been a topic of intense interest. While few clear genetic contributions to exceptionally long life have been identified, whole genome sequencing provides a new opportunity for investigating longevity genetics. Here we report the analysis of 10 centenarian (collected under the Murdock study community registry and biorepository Pro00011196) genomes compared with 50 population controls, all sequenced to an average of 30-40x coverage using next generation sequencing. We focused our analysis on the possibility that centenarians live longer than average because they have fewer rare, damaging mutations than average. We identified different categories of damaging mutations--stop gain, stop loss, nonsynonymous (split by PolyPhen prediction category), splice site, and large deletion--and compared their distributions in cases and controls. We find that for some of these comparisons, there is a lower burden of rare damaging mutations in the centenarians, suggesting that an overall lower burden of damaging genetic variants is a contributor to long life in humans.

MedSavant: a platform for identifying causal variants from disease sequencing studies. *M. Fiume[1], N. Nursimulu1[1], J. Foong[3], M. Manker[3], M. Brudno[1,2,3].* 1) Department of Computer Science, University of Toronto, Toronto, ON., Canada; 2) Donnelly Centre and Banting and Best Department of Medical Research, University of Toronto, ON., Canada; 3) The Center for Applied Genomics, Toronto, ON., Canada.

High Throughput Sequencing (HTS) technologies are providing economical means for deep cataloguing of human variation. Large volumes of genetic variants are being obtained from disease sequencing studies that aim to discover etiology. However, many of the candidate variants found are either not real or have no functional relevance. One of the most challenging problems is in identifying those few genetic variants (among millions predicted per individual) that are actually causal in disease. For this purpose we introduce MedSavant: a software platform for accelerating the identification of disease-causing genetic variants found in population sequencing studies by enabling complex and dynamic querying of patient data. The platform is comprised of a graphical interface and a backend database. The database is designed to store basic patient data, phenotype data, and genotype data for all sequenced individuals. The user interface enables users to dynamically visualize global trends in the data, construct complex queries, and analyze the results. The framework allows one to design queries that return, for example, only variants found in male patients in a specific disease cohort who share a rare point mutation with high predicted confidence. MedSavant also supports filters generated from external datasources, such as whether or not the variation has been discovered before (using dbSNP), is predicted to be damaging (using SIFT), is found in genes having a pertinent function (using GO), or has been associated with a related disease (using OMIM). Furthermore, MedSavant can be integrated with the Savant Genome Browser, for manual inspection of read alignment data supporting the most likely causal variants found in the filtration process. MedSavant will be made available at genomesavant.com/med.

891F

The genetics of endurance: increased frequency of the ACTN3 577X variant in elite endurance Ironman athletes. *R. Grealy[1], C.L.E. Smith[1], T. Chen[1], L. Haseler[2], D. Hiller[3], L.R. Griffiths[1].* 1) Genomics Research Centre, Griffith Health Institute, Griffith University, Gold Coast, QLD, Australia; 2) Heart Foundation Research Centre, School of Physiotherapy and Exercise Science, Griffith University, Gold Coast, QLD, Australia; 3) North Hawaii Community Hospital, Kamuela, Hawaii, USA.

Although human athletic endurance is a complex phenotype influenced by both environmental and genetic factors, genetic factors significantly contribute to endurance performances (with high heritability estimates for a number of endurance traits such as VO2 max and lactic acid anaerobic threshold). In order to examine the genetic components of endurance phenotype, we collected saliva samples, questionnaires, and performance times for 196 elite endurance athletes who participated in the 2008 Kona Ironman championship triathlon. This race is considered one of the most gruelling Ironman competitions in the world, representing athletes with an extremely high level of fitness and endurance. DNA was extracted from saliva and genotyped for the ACTN3 R577X polymorphism using high-resolution melt (HRM) analysis. The ACTN3 gene, coding for the (-actinin-3 protein expressed in fast-twitching muscle fibres, has been investigated as one of the genetic factors that underlie individual endurance ability and several studies have found an association of 577X with endurance, though this is not supported in all populations. One-way ANOVA showed that performance time did not significantly differ between genotype groups, and stepwise linear regression modeling the effect of all variables on finishing time showed that age, sex, and continent of origin were significant predictors of finishing time (age and sex: $p<5E-7$; continent: $p=0.01$). Genotype and allele frequencies obtained (RR 26.5%, RX 50.0%, XX 23.5%, R 51.5%, X 48.5%) were compared with frequencies reported in previous studies, and were found to be not significantly different from Australian, Spanish, and Italian endurance athletes, but were significantly different from Kenyan, Ethiopian, and Finnish endurance athletes ($p<0.01$). As R577X frequencies vary considerably in different ethnic groups (with null allele frequencies ~10% in African populations and ~50% in Eurasian populations) our observed frequencies reflect the predominantly North American, European, and Australian origin (93.9%) of our Ironman athlete sample. Further, obtained genotype and allele frequencies show significantly different frequencies from those reported for Australian and Spanish sprint/power athletes ($p<0.01$), as well as a trend for higher frequencies of XX genotype and X allele in endurance athletes compared with reported general Australian and Spanish population controls, and support a role for the 577X variant in endurance performance.

892F

Inference of modules regulated by eQTLs. *A. Kreimer[1], O. Litvin[3], K. Hao[4], C. Molony[4], D. Pe'er[3], I. Pe'er[2].* 1) Department of Biomedical Informatics, Columbia University, New York 10032, New York; 2) Department of Computer Science, Columbia University, New York, New York 10027, USA; 3) Department of Biological Sciences, Columbia University, New York, New York 10027, USA; 4) Merck Research Labs, 33 Ave. Louis Pasteur, Boston, MA 02115, USA.

Cataloging the association of transcripts to genetic variants in recent years holds the promise for functional dissection of regulatory structure of human transcription. Here, we present a novel approach, which entails detection and analysis of modules of transcripts, each co-associated to a single genetic variant. First, we search pair-wise connections between transcripts whose levels are co-associated to the same SNP. Second, we combine these pairs into modules that share an associated main SNP. We then assign a confidence score to each module. Finally, we find secondary SNPs whose association to transcript levels in a module is conditioned on the main SNP. We applied our method to existing data on genetics of gene expression in the liver. We detect 129,130 pairs of transcripts that are associated to the same SNP in either cascaded or mutually independent manner. These make up 10,354 modules, 518 of which include 10 transcripts or more. The modules are significantly more, larger and denser than found in permuted data. We quantify the confidence in a module as a likelihood score, and prune a subset of 95 distinct modules with FDR<0.02. We show that mild cis effects, underpowered to be detected directly but exposed by our method explain some of the reported modules. We observe similar annotations of modules from two sources of information: the enrichment of a module in gene subsets and locus annotation of the genetic variants. This and further phenotypic analysis provide a validation for our methodology.

893F

A likelihood-based framework for *de novo* mutation detection in families for next-generation sequencing data. *B. Li[1,2], G. Abecasis[1].* 1) Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Multiple lines of evidence indicate that *de novo* mutation events contribute to disease susceptibility for a variety of human diseases, including neurological disorders such as autism and mental retardation. Next generation sequencing can be used to systematically scan the genome for *de novo* mutation events, potentially improving our ability to understand the molecular basis of these traits. The standard approach to the study of *de novo* mutations is to sequence a small number of related individuals and then identify genotypes which violate Mendelian inheritance. However, due to sequencing errors and allelic drop-out, this naïve approach can lead to very high false positive rates for analysis focused on discovery of *de novo* mutation events. Here, we develop and implement a likelihood-based framework to detect *de novo* mutations by jointly modeling sequence data across a pedigree. Our model explicitly allows for *de novo* mutations and allows us to calculate the posterior probability of a *de novo* event conditional on all available sequence data - making it easier prioritize and contrast evidence for multiple candidate *de novo* events. Our integrated framework for *de novo* mutation detection and variant calling can handle both nuclear families and extended pedigrees. Through simulations we show that, compared to the naïve approach, our framework can achieve markedly improved sensitivity and specificity and that performance further improves as additional individuals are sequenced in each family. In addition, we make recommendations in terms of sequencing depth and choice of different technologies for studies aiming to use next generation sequencing to detect *de novo* events. To illustrate our approach, we apply our method to the two parents-offspring trios sequenced to high coverage by the 1000 Genomes Project and observe high concordance with their findings. For example, using only Illumina data, 39 of 48 of germline mutations in the CEU trio were identified by our method and majority of missing mutations were filtered out based on likelihood ratio due to lower depths. We hope that our work will accelerate continuing efforts to find genetic factors associated with complex diseases.

Genotype Imputation of Metabochip SNPs Using a Study-Specific Reference Panel of 3,924 Haplotypes in African Americans from the Women's Health Initiative. *E.Y. Liu[1], S. Buyske[5,6], A.K. Aragaki[7], U. Peters[7], E. Boerwinkle[8], C. Carlson[7], C. Carty[7], D.C. Crawford[9], J. Haessler[7], L.A. Hindorff[10], L.L. Marchand[11], T.A. Manolio[10], T. Matise[6], W. Wang[1], C. Kooperberg[7], K.E. North[2], Y. Li[3,4].* 1) Department of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 5) Department of Statistics, Rutgers University, Piscataway, NJ; 6) Department of Genetics, Rutgers University, Piscataway, NJ; 7) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 8) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 9) Department of Molecular Physiology and Biophysics, Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 10) Office of Population Genomics, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 11) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI.

Genetic studies of complex traits require large sample sizes. One cost-effective method to increase sample size across multiple platforms is genotype imputation, a standard practice in contemporary genetic studies. Several important imputation-related issues have not been adequately addressed in the literature, including imputation quality for less common (minor allele frequency [MAF] 0.5-5%) and rare (MAF < 0.5%) variants, imputation performance in admixed populations, such as African Americans, and construction of large study-specific reference panels for imputation of SNPs found on region-centric chips with high SNP density but uneven distribution across the genome (e.g., the Metabochip assessing ~200,000 SNPs and including a number of trans-ethnic fine mapping regions). These issues recently became addressable with GWAS follow-up studies that use dense genotyping or sequencing in large samples of non-European individuals. Here, we constructed a study-specific reference panel of 3,924 haplotypes from 1,962 African Americans in the Women's Health Initiative (WHI) genotyped on both the Metabochip (for the Population Architecture using Genomics and Epidemiology [PAGE] study) and the Affymetrix 6.0 GWAS platform (for the SNP Health Association Resource [SHARe] study). Imputation into 6,459 remaining WHI SHARe participants with only Affymetrix 6.0 GWAS genotypes confirmed imputation quality metric Rsq (estimated r^2) as an effective post-imputation filter. We recommend different Rsq thresholds for different MAF categories such that the average Rsq is at least 80% to achieve true r^2 (r^2 between imputed and unobserved true genotypes) of 80% or above. After applying the thresholds, 20.5% (52.0%, 83.6%, 97.5%, 99.9%) of SNPs with MAF 0.1-0.5% (0.5-1%, 1-3%, 3-5%, and >5%) passed the post-imputation filter. The average true r^2 for SNPs passing the filter, by masking and comparing with experimental genotypes, is 79.7%, 83.1%, 89.0%, 92.1%, and 94.7% respectively. These results suggest that, imputation of Metabochip SNPs in an ancestrally diverse population, including less common SNPs with MAF 0.5-5%, is feasible and worthwhile with the availability of a sizable reference panel.

Genetic associations with glycated hemoglobin in glycemic and hematological pathways. *J. Ryu, Y. Kim, C. Lee.* Soongsil University, Seoul, Korea.

Recent genome-wide association studies have identified single nucleotide variants associated with glycosylated hemoglobin in Europeans and Americans. We examined genetic association of the previously identified sequence variants with glycosylated hemoglobin and with glycemic and hematological phenotypes in non-diabetic Koreans. Genetic associations of glycosylated hemoglobin were replicated with sequence variants ($P = 3.77\times10^{-11}$ ~ 3.28×10^{-2}) in GCK, MTNR1B, SLC30A8, ANK1, FN3K, SPTA1, and HFE genes. The sequence variants in GCK, MTNR1B, and SLC30A8 genes were also associated with glycemic traits such as fasting glucose, 1-h glucose after oral glucose tolerance test, and 2-h glucose after oral glucose tolerance test($P < 5.0\times10^{-2}$). On the other hand, the variant in HFE gene was associated only with hematological traits such as hematocrit, MCH, and MCV. This indicates that the sequence variants associated with level of glycosylated hemoglobin were characterized by mechanisms involved in glycemic and hematological phenotypes.

896F

Genetic association between age-related macular degeneration and CASP6-PLA2G12A-CFI locus. *E. Ryu[1], N. Tosakulwong[1], K. Bailey[1], A. Edwards[2].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Institute for Molecular Biology, University of Oregon, OR.

Backgrounds: Genetic variation near the 3' end of the gene encoding complement factor I (CFI) on chromosome 4q25 has been associated with the risk of advanced age-related macular degeneration (AMD). Due to lack of obvious functionality of CFI, we expanded this region for better localization of the genetic variation associated with AMD.

Methods: Twenty-two single nucleotide polymorphisms (SNPs) across CFI and three adjacent genes (CCDC109B, CASP6, and PLA2G12A) were genotyped on 2156 AMD cases and 1150 control subjects in a genome-wide association study. Using HapMap II reference panel, 161 imputed SNPs in this region were investigated for their disease association.

Results: Individual SNPs within four genes (CCDC109B, CASP6, PLA2G12A, and CFI) in the chromosome 4q25 locus were associated with AMD. The most significant single SNP association was rs2285714 in the PLA2G12A gene. Conditioning on rs2285714 did not leave any significant association for the remaining SNPs in CCDC109B, CASP6, PLA2G12A, and CFI. Haplotype analyses suggested the best localization between CASP6 and PLA2G12A genes. All AMD subtypes showed similar genetic association.

Conclusions: The genetic variation contributing to AMD in this region best localizes to the CASP6 and PLA2G12A genes and not the CFI gene. However, determination of their roles for AMD development requires further work.

Genome-wide association study of adolescent idiopathic scoliosis in southern China. *Y.Q. Song[1], Y.H. Fan[1], K.M.C. Cheung[2], D. Chan[1], W.Y. Cheung[2], K.S.E. Cheah[1], P. Sham[3], K.D.K. Luk[2].* 1) Dept Biochemistry, Univ Hong Kong, Hong Kong, China; 2) Department of Orthopaedics and Traumatology, Univ Hong Kong, Hong Kong, China; 3) Department of Psychiatry, Univ Hong Kong, Hong Kong, China.

The cause of adolescent idiopathic scoliosis (AIS) is still not known. Although several candidate gene studies and linkage analysis have been done, no causal relationship has yet been established. We report a case-control based genome-wide association study (GWAS) for this trait. The study was undertaken in a set of 196 server cases with a specific AIS phenotype (based on Lenke's classification) in southern China, and in 401 controls without radiological evidence of scoliosis. A Replication set was performed. Two single-nucleotide polymorphisms (SNPs) on one particular chromosome showed marginal significant association (snp1: p=1.32x10E-6, odds ratio=0.52; snp2: p=1.23x10E-5, odds ratio=0.55). Imputation results suggested that three more SNPs in this region showed significant association (snp3: p=2.47x10E-7, odds ratio=0.49; snp4 and snp5: p=1.68x10E-6, odds ratio=0.53). The first replication set confirmed the association and the second replication are being carried out. Despite the small number of cases and controls, the strength of this study is in the use of a specific phenotype and that all controls were mature individuals with radiological confirmation of straight spines. We believe that these factors have contributed to the success of the GWAS. Our findings offer the potential to explore the pathogenesis of AIS with GWAS.

Detection of variants in human cancer genomes using PacBio RS and HiSeq 2000. *K. Stangier, H. Hegele, T. Kurz, Y. Kumar.* GATC Biotech AG, Konstanz, Germany.

The new Pacific Biosciences PacBio RS uses novel technology that enables single molecule, real-time, or SMRT™, detection of biological processes. The ability to resolve single molecules in real time allows the system to observe structural and cell type variation not accessible with other technologies. The Illumina HiSeq 2000 provides the industry's highest sequencing output and quality at fastest data generation rate and can be optimally used to obtain best sequencing quality in re-sequencing projects. Through a combination of different sized insert libraries SNPs, InDels and structural variations can be identified in whole human genomes. In combination with the new Pacific Biosciences PacBio RS real time single molecule sequencer the identified structural variations can be further analyzed in depth. The long reads in the range of Sanger sequencing and so-called strobe reads are perfectly suitable to accurately resolve even large-scale rearrangements. This is especially important in cancer research where structural variations are supposed to play an causative role. We will present data on human cancer genomes showing the usability of the combination of these two technologies. All dataset are produced in our own laboratory. For all analyses, special bioinformatics tools are used. The pipelines are developed in our internal bioinformatics department. High quality results will be achieved when optimally combining several library preparations and Next Gen technologies with state-of-the-art bioinformatics.

899F

Cell Lines Commonly Used as Models for Inflammation Contain Genetic Variation in Toll-Like Receptor Genes. *S.A. Tokarz, J.A. DeValk, B. Pattnaik, D.M. Pillers.* Pediatrics, University of Wisconsin, Madison, WI.

Background: Human-derived cell lines are commonly used in studies to investigate inflammation pathways, including the up-regulation of interleukins and other inflammatory cytokines after exposure to pathogens. Toll-like receptors (TLRs) are a family of transmembrane receptor proteins present in many cell types and serve as the first point of defense in the innate immune system. TLRs are essential in initiating the inflammatory cascade in response to infectious microorganisms. Single nucleotide polymorphisms (SNPs) in genes for TLRs 1, 2 and 4 occur in up to 20% of the population. TLR4 D299G, TLR4 T399I, TLR2 P631H, TLR2 R753Q and TLR1 N248S SNPs have been shown to be associated with a decrease in the innate immune response. Objective: We sought to determine the presence of a subset of common TLR SNPs associated with inflammation in a cohort of cell lines that are used extensively for inflammation studies. Design/Methods: DNA was isolated from the following cell lines: Human Umbilical Vein Endothelial Cells (HUVEC), Human Embryonic Kidney (HEK293), A549 lung epithelial, Human Retinal Pigment Epithelium (HRPE), HeLa, Jurkat lymphocyte cells, MCF-7 human breast adenocarcinoma, A431 human epithelial carcinoma, Y79 human retinoblastoma. Cell line TLR genotype was established using ABI TaqMan SNP Genotyping Assays. The Step OnePlus™ software was used to analyze the intensity of each fluorescent probe assigned to either the wild-type (WT) or natural variant (NV) allele and to produce an amplification plot of the data along with the C_t value. Results: TLR4 D299G, TLR4 T399I and TLR2 P631H SNPs showed heterozygosity for the WT and NV alleles in HeLa cells while the other cell lines were homozygous for the WT alleles. HeLa and HEK293 lines were homozygous for the WT allele for the TLR1 N248S SNP and all other cells were homozygous for the NV allele. All cell lines were homozygous for the WT allele for TLR2 R753Q. Conclusions: HeLa cells are used as a cell model for many inflammation studies, which may not be appropriate considering the heterozygosity of the TLRs in this cell line. The presence of SNPs may impact the normal function of a pathway. With the increasing evidence of the involvement of SNPs in a variety of disease pathologies this study suggests that a new era in cell biology must emerge in which the genetics of the cellular model used in experiments must be scrutinized more thoroughly.

An Exome Variant Server for the NHLBI Exome Sequencing Project (ESP). *Q. Yi, P.D. Robertson, M.J. Rieder, D.A. Nickerson on behalf of the Population Genetics Project Team and the NHLBI ESP Project.* Department of Genome Sciences, University of Washington, Seatle, WA.

The goal of the NHLBI Exome Sequencing Project (ESP) is to discover novel genes and mechanisms contributing to heart, lung and blood disorders through application of next-generation exome sequencing to samples drawn from large cohort and population-based studies. To date, the ESP has produced more than 5,000 exomes from samples with linked phenotype data. From this total set, exome variant data have been summarized from an initial data freeze of 2,500 samples. All exomes were sequenced to high average coverage (>100x depth) and variant calls derived from simultaneous, multi-sample genotyping across all samples To facilitate the distribution of these data to the scientific community, we have developed a web-based data server (NHLBI Exome Variant Server [EVS], snp.gs.washington.edu/popgenSNP). The EVS provides both a full dataset (ESP2500) and filtered (ESP2500P), with the latter being used for the ESP population genetics analysis. The full dataset consists of 2,439 samples and 1,153,118 variant cals. The filtered dataset consists of 2,275 exomes (1351 European and 924 African-American) and 481,712 variant positions from 26 Mb of the exome target. The EVS provides an easy-to-use interface for querying exome variants and sequencing coverage based on specific genes or genomic locations. Using our internally developed analysis pipeline (SeattleSeqAnnotation server - snp.gs.washington.edu/SeattleSeqAnnotation131/), we provide full annotation for every cataloged variant including: dbSNP rs numbers for known variants, minor allele frequency (for both European- and African-American populations), functional context (i.e. missense, synonymous, splice) mapped to multiple gene mRNA accession numbers, related cDNA and protein information, conservation scores based on nucleotide (GERP) and amino acid (Phastcons, Grantham substitution, protein function predictions (e.g. Polyphen) and known clinical implications. This database provides one of the largest, high-coverage exome datasets available, and is extremely useful for estimation of allele frequencies of rare variation (e.g. 0.01-3%) and filtering strategies applied to Mendelian traits. Orthogonal genotyping validation of a sampling of singleton and rare frequency variants is currently in progress. These data are also available publically via dbSNP (build 134) and a large fraction of this genotype data and linked phenotype information are available in dbGaP.

Using induced pluripotent stem cells to uncover the role of DHDDS in retinitis pigmentosa. *D. Dykxhoorn[1, 2], B. DeRosa[1], S. Zuchner[1, 2], G. D'Urso[3], J. Dallman[5], B. Lam[4], J.M. Vance[1, 2], M.A. Pericak-Vance[1, 2].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) John T. Macdonald Foundation Department of Humans Genetics University of Miami, Miami, FL; 3) Department of Molecular and Cellular Pharmacology, University of Miami, Miami, FL; 4) Department of Ophthalmology and the Bascom Palmer Eye Institute, University of Miami, Miami, FL; 5) Department of Biology, University of Miami, Miami, FL.

Retinitis Pigmentosa (RP) is a group of progressive retinal degenerative disorders. These disorders result from the abnormalities of the photoreceptor cells (rods and cones) or the underlying retinal pigment epithelium (RPE). This genetically heterogeneous disease is characterized by a progressive loss of the patient's peripheral vision leading to tunnel vision. Mutations in over 50 genes have been show to be involved in RP etiology. Through whole-exome sequencing, we recently discovered a rare variant in dihydrdolichyl diphosphate synthetase (DHDDS) as being the cause of RP in three affected siblings of a one generation, nonsyndromic family of Ashkenazi Jewish origin. The loss of DHDDS expression in zebrafish resulted in a loss of reaction to light, but not to touch. Histopathological examination of the retina in these zebrafish demonstrated degeneration of the outer segments of photoreceptors, similar to that seen in the human disease. Yeast modeling for DHDDS suggests that the mutant protein has enzymatic activity, but is decreased. This fits with the hypothesis that the patients have enough activity to serve most needs for DHDDS, except the retina, where the metabolic needs for DHDDS are very high. To begin to understand the relationship between this specific mutation and retinal cell functionality in the human eye, induced pluripotent stem cells (iPSCs) were derived from skin fibroblasts derived from the unaffected parents, three affected siblings and the one unaffected sibling. We identified factors that differentiated these iPSCs into photoreceptor and RPE cells to examine the functionality of these cells. These studies will provide valuable insights into the underlying mechanisms responsible for the development of this disease and other RP disorders.

The transcriptional basis of inter-ethnic disparities in glucocorticoid response. *J. Maranville, S. Baxter, J. Torres, A. Di Rienzo.* Department of Human Genetics, University of Chicago, Chicago, IL.

Glucocorticoids (GCs) are steroid hormones that mediate physiological responses to the environment and are widely used as pharmaceutical interventions. Clinical response to GC treatment varies extensively. This poses a serious threat to public health, as a large fraction of patients (~30%), especially those of African descent, show a weak response to treatment. Although little is known about the molecular basis of this variation, transcriptional response is likely to play a key role as GC action is largely mediated by the regulation of gene expression. We previously showed that cis-regulatory polymorphisms contribute to variation within and between populations in GC transcriptional response at some genes. In an effort to characterize the transcriptional basis of variation in GC response, we measured in vitro lymphocyte GC sensitivity (LGS), which is strongly predictive of patient response, and transcriptome-wide response to GCs in peripheral blood mononuclear cells (PBMCs) from African-American and European-American healthy donors (9 donors from each population total, and 6 out of the 9 were profiled for transcriptional response at 8h and 24h post-treatment). We found that transcriptional response after 8hrs treatment at 38 genes was significantly associated with LGS in African-Americans (FDR<0.1), suggesting a transcriptional basis for variation in GC response. We replicated a previous finding of lower LGS in African-Americans (p=0.019). Providing the first glimpse at the molecular basis of this inter-ethnic disparity, we found population differences in the average log fold change in expression at 19 genes (FDR<0.1). A number of these genes have clear relevance for lymphocyte-mediated immune response, such as *GIMAP5*, a regulator of apoptosis in T cells, and linker for activation of T cells family, member 2 (*LAT2*). Interestingly, significant population differences were only seen after 8hrs of treatment and not after 24hrs, suggesting that events early in the GC transcriptional cascade contribute to inter-ethnic disparities. Consistent with clinical and in vitro observations, we also found that the absolute log fold change was generally lower in African-Americans, with 16 of the 19 differentially responding genes showing a weaker response in PBMCs from African-Americans. Collectively, this work suggests a prominent role for transcriptional regulation, and likely regulatory polymorphisms, in variation within and between human populations in GC response.

HLA-DRB1*1501 intensifies the impact of IL-6 promoter polymorphism on the susceptibility to multiple sclerosis in an Iranian population. *M. Shahbazi[1], A. Tahmasebifar[2], H. Ebadi[3], D. Fathi[3].* 1) Medical Cellular and Molecular Research Center,Golestan University Of Medical Science ,Gorgan, Iran.MS-PhD; 2) Medical Cellular and Molecular Research Center,-Golestan University Of Medical Science ,Gorgan, Iran.MD-PhD; 3) Medical Cellular and Molecular Research Center,Golestan University Of Medical Science ,Gorgan, Iran.Neurologist.

BACKGROUND: The multifunctional cytokine interleukin-6 (IL-6) is involved in inflammatory processes in the central nervous system. It is well documented that amount of IL-6 is increased in serum, cerebrospinal fluid and central nervous system lesions of patients with multiple sclerosis. A single nucleotide polymorphism at position -174 in the IL-6 gene promotor appears to influence IL-6 expression. OBJECTIVE: To investigate the possible influence of IL-6/-174 polymorphisms on susceptibility to multiple sclerosis and its integration with HLA-DRB1*1501. Genomic DNA was extracted from whole blood of 345 patients with multiple sclerosis and 426 control subjects. METHOD: The SSP-PCR method was used to determine genotypes and Fisher's exact test was applied to determine differences between groups. RESULTS: HLA-DRB1*1501 was observed more frequently among multiple sclerosis patients compared with healthy subjects (45% and 34%, respectively; OR = 1.6, 95% CI = 1.2-2.2, p = 0.0018). At the IL-6/-174 position, the G allele had higher frequency among multiple sclerosis patients compared with controls (77% and 70%, respectively; OR = 1.4, 95% CI = 1.1-1.8, p = 0.0038). This difference was more significant among HLA-DRB1*1501-positive patients and controls (81% and 67%, respectively; OR = 1.9, 95% CI = 1.5-2.5, p < 0.0001). CONCLUSIONS: Our results have shown that the G allele at the IL-6/-174 promoter polymorphism may be associated with development of multiple sclerosis in this population, and may be strengthened by HLA- DRB1*1501.We suggest more studies to confirm these results in other populations.

Stefansson[1].* 1) Dept Statistics, DeCode Genetics, Reykjavik, Iceland; 2) Division of Mental Health and Addiction, Oslo University Hospital & Institute of Clinical Medicine, Oslo, Norway; 3) Dept of Cardiothoracic Surgery, Rigshospitalet, University of Copenhagen, Copenhagen, Denmark; 4) Center for Sleep and Circardian Neurobiology, Division of Sleep Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 5) Dept of Epidemiology, Biostatistics & HTA, Radboud University Nijmegen Medical Centre, Nijmegen, the Netherlands; 6) Comprehensive Cancer Center IKO, 6501 BG Nijmegen, the Netherlands; 7) Department of Urology, Radboud University Nijmegen Medical Centre, 6500 HB Nijmegen, the Netherlands; 8) Landspitali, The National University Hospital of Iceland, Department of Medicine, Reykjavik, Iceland; 9) Icelandic Medical Center (Laeknastretid) Laboratory in Mjodd (RAM),Reykjavik, Iceland,; 10) Landspitali, The National University Hospital of Iceland, Department of Clinical Biochemistry, Reykjavik, Iceland,; 11) University of Iceland, Faculty of Medicine, Reykjavik, Iceland; 12) Landspitali, The National University Hospital of Iceland, Department of Immunology, Reykjavik, Iceland.

We performed a genome-wide association scan of 16 million SNPs, identified through whole genome sequencing of 457 Icelanders, to search for association with gout and serum uric acid level. Genotypes for these SNPs were imputed into 41,675 chip typed Icelanders and their relatives, for an effective sample size of 968 gout cases and 15,506 individuals with measurements of serum uric acid. A low frequency missense mutation (c.1580C>G) in ALDH16A1 associates with gout (OR=3.12, $P=1.5\times10^{-16}$) and uric acid level (effect=0.36 SD, $P=4.5\times10^{-21}$). This association was confirmed by genotyping of 6,017 Icelanders through Sanger sequencing. The association with gout is stronger among males than females and the variant correlates with an early age at diagnosis. A second low frequency variant associates with gout (OR=1.92, P=0.046) and uric acid level (effect=0.48 SD, $P=4.5\times10^{-16}$). This variant is located at the centromere of chromosome 1, in close proximity to a common variant reported to associate with uric acid level. All previously reported loci were confirmed in our dataset, but their effects are substantially smaller than those of the two novel variants. In addition to the individuals sequenced and used above for the gout project, we plan to whole genome sequenced over thousand subjects during the summer of 2011. We will present the follow up process that we are developping with the purpose of discovering rare and low frequency variants having large effects for common diseases.

905F

Effect of rapamycin treatment on HEK293 cells- a muti-omics approach. *N. Guha, Y. Reddy, S. Rajagopalan, S. Joseph, S. Lateef.* Agilent Technologies India Pvt. Ltd., "C" Block, RMZ Centennial, Plot No. 8A,8B,8C,8D, Doddanakundi Indl Area, ITPL Road, Mahadevapura Post, Bangalore-560037, Karnataka, India.

Biological processes can be examined by collective information available at the genome, transcriptome, proteome and the metabolome levels. Data integration at all levels of omics analysis is required to perform "Systems analysis" which increases the confidence of results obtained from any one methodology. In this study, we performed multi omics analysis using an in vitro model of rapamycin treatment of HEK293 cells. Rapamycin is an immunosuppressant drug that specifically inhibits mTOR activity and cellular hyper-proliferation resulting in G1 growth arrest. HEK293 was harvested 16hrs post treatment of rapamycin or vehicle alone and RNA, miRNA, proteins and metabolites were analyzed. The SurePrint G3 Gene Expression arrays were used to evaluate the expression of both mRNA and large intergenic non-coding RNAs (lincRNAs). miRNA microarray analysis was performed using Human miRNA 8X15K V2 microarray. The complete genomic status of the cell was also interrogated using CGH 1X1M array. Combined gene expression and miRNA analysis was performed using GeneSpring 11.5-MPP which provides comprehensive analytical and visualization tools for different data types. Approximately 10000 mRNAs and 18 miRNAs were differentially expressed between treated and control samples. The target entity list of these miRNAs revealed by target scan showed good overlap with differentially expressed gene list from the gene expression microarray. A number of lincRNAs were found to be differentially expressed upon rapamycin treatment. CGH analysis showed that HEK293 cells possess large amount of aberrations at the genome level. Proteins extracted from HEK293 cells were analyzed on a QTOF coupled to HPLC chip MS system. Statistically significant differential proteins were identified by targeted MS/MS analysis followed by SpectrumMill search. Metabolites were analyzed using 7890 GC coupled to 5975C inert MSD and 1290 Infinity LC system coupled to 6520 QTOF for GC-MS and LC-MS studies, respectively. 200 metabolites were differentially expressed upon rapamycin treatment. The results obtained from the various `omics' was integrated using the pathway analysis tool in GeneSpring 11.5-MPP software enabling visualization of multiple changes occurring in different biological pathways. Rapamycin was found to affect several biological processes including translation, protein folding and stress response. The study demonstrates a workflow solution for multi-omics study in response to drug treatment.

Functional Screening of Novel Drug Candidates by High-throughput Cellular Microarray Using System Biology Strategy. *J. Liu[1], D. Chen[1], D. Liu[1], X. Gao[2], L. Wang[1].* 1) School of Medicine, University of California, Irvine, Irvine, CA, USA; 2) Abbott Vascular Inc., Santa Clara, CA, USA.

Screening a library of small molecules is the first step in the pre-clinical phase of drug discovery process. Due to the tremendous complexity of biochemical circuitry, how a cell would respond to a given small molecule is often unpredictable. By determining which of the thousands of gene products a given small molecule is interacting with would predict biochemical effects. Our goal is to use system biology strategy and automation as means to efficiently screen small molecule library in a high throughput fashion. We therefore set up cellular microarrays as a tool for high-throughput screening of large set of test samples. A yeast deletion set contains over 5,000 individual yeast clones--each with a different gene deleted. Screening small molecules with yeast deletion set in a high throughput fashion is a significant engineer challenge. We have designed a 3 axis platform automation for screening. To test the feasibility of the setup, we use rapamycin which is well characterized. Rapaymycin exerts its action by binding and inhibiting FK binding protein (FKBP) and affects TOR pathway. Wild type yeast clone would not grow due to activation of TOR pathway. To test if we can actually isolate FKBP using this system, we first add rapamycin to a gelatinous solid growth support on a culture plate. All 5,000 yeast deletion clones are robotically "arrayed" onto the solid growth media. Growth size of individual yeast clones are analyzed digitally on day 1, 2 and 3. Several yeast clones are shown to grow preferrential in the presence of rapamycin. Clones which have the most differential growth variation will be candidates. The identities of these clones are checked against the database. The yeast clone with FKBP gene deletion was singled out. We have, therefore, confirmed the feasibility of system biology approach for drug screening using yeast deletion set. Furthermore, we have also isolated several genes from mTOR pathway which is downstream of FKBP as well as other genes with unknown functions associated with mTOR pathway. Thus, by growing numerous cultural clones in the presence of a given small molecule candidate and observe the variations of growth patterns would allow us to determine which genes and biochemical pathways the unknown molecule are interacting with. Miniaturization used in cellular microarrays also increases assay throughput and reduce reagent consumption and the number of cells used. This efficient system will be applicable for a broad range.

Genetics and epigenetics of human gene regulation. *R.M. Myers[1], J. Gertz[1], T.E. Reddy[1], K.E. Varley[1], K.M. Bowling[1], F. Pauli[1], S.L. Parker[1], K.M. Newberry[1], K.S. Kucera[2], H.F. Willard[2], G.K. Marinov[3], A. Mortazavi[3], B.A. Williams[3], B. Wold[3].* 1) 1HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Duke University, Institute for Genome Sciences and Policy, Durham, NC; 3) California Institute of Technology, Department of Biology, Pasadena, CA.

Genome-wide studies to identify genetic loci associated with complex diseases frequently implicate mutations in regions of the genome that do not code for proteins. The characterization of non-coding variants is a particularly challenging and increasingly important endeavor. To address this challenge, we have used sequence-based functional genomics measurements to identify alleles that associate with gene regulatory differences in cis. Through a combination of ChIP-seq, RNA-seq and Reduced Representation Bisulfite Sequencing (RRBS), we have discovered allelic biases in gene regulatory events across the genome of a lymphoblastoid cell line. By analyzing SNPs in the RNA-seq data, we were able to determine transcripts that were not equally expressed from each allele. We found significant differential allelic expression of 979 human genes, indicating that 8% of genes are preferentially expressed from a single chromosome. RRBS measurements in the same cells indicated that 7.9% of heterozygous SNPs are associated with differential methylation in cis. By combining allelic differences in expression and DNA methylation, we found that 25% of genes harboring allele-specific methylation near the transcription start site exhibited allele-specific gene expression, which is twice as many as expected by chance. Our results demonstrate that genomic sequence variation can significantly influence DNA methylation. We measured genome-wide differential allelic occupancy of 24 sequence-specific transcription factors in the lymphoblastoid cell line by using ChIP-seq. We identified more than 150,000 transcription factor binding sites, 8% of which overlap heterozygous genomic positions. Using this extensive dataset, we found that transcription factors preferentially bind a single allele at more than 1% of the TF binding sites identified. Differential allelic occupancy of sequence-specific transcription factors predict differential allelic expression, but more weakly than RNA polymerase 2 biases, emphasizing the multi-factor complexity of cis-regulation. Together, these results reveal thousands of functionally associated sequence variants in non-coding portions of the genome. Several of these sequence variants reside in disease implicated loci and provide insight into the mechanisms underlying existing disease related variation.

908F

Rapid sequence-level characterization of transgene insertions reveals significant complexity with ramifications for studies of transgenic animals. *J.C. Jacobsen[1], C. Ernst[1], C. Chiang[1], C. Hanscom[1], A. Heilbut[1], M. Sun[1], S.R. Rudiger[2], C.S. Bawden[2], S.J. Reid[3], R.L.M. Faull[3], R.G. Snell[3], M.E. MacDonald[1], J.F. Gusella[1], M.E. Talkowski[1].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA., USA; 2) Molecular Biology and Reproductive Technology Laboratories, Livestock and Farming Systems Division, South Australian Research and Development Institute, SA., Australia; 3) The Centre for Brain Research, Faculty of Medical and Health Sciences, The University of Auckland, Auckland, New Zealand.

Stable expression of transgenes in model organisms or cultured cells is a fundamental genetic tool widely used in biological research, yet for most transgenics, little is known concerning the mechanism of transgene integration, the structural integrity of the introduced transgene, the precise site of integration or the effect of the integration event on the host genome. Using three independent sequencing approaches, we characterized the transgenic sequence and integration site in seven Huntington's disease (HD) animal models: two well-established huntingtin N-terminal fragment mouse models (R6/1 and R6/2, 1.9 kb transgene) and five recently created full-transcript length HD transgenic sheep (11.6 kb transgene). Our analyses precisely characterized the transgene integration site junctions, revealing extensive structural rearrangement complexity that altered both the transgene itself, and the genomic DNA adjacent to the integration site, including duplication, deletion, excision/insertion, inversion and integration of foreign sequence (bacterial DNA). In one model (R6/2), the transgene inserted into a novel, evolutionarily conserved gene, Gm12695, which we find to be up-regulated in mouse brain. These analyses indicate that alterations to the structure and function of transgenes introduced by pronuclear injection occur routinely. They also show that the site of integration and possible resultant rearrangement of the host genome are all factors that can confound interpretation in transgenic model experiments. Our findings argue that it is both feasible and advisable to perform sequence-level characterization of transgene insertions prior to extensive investment in phenotypic characterization of transgenic model organisms.

909F

A genome-wide association study for renal transplant dysfunction. *I. Rebollo Mesa[1], C.S. Franklin[2], J.E. Mollon[1,3], M. Hernandez Fuentes[1], E. Perucha[1], N. Anyanwu[1], P.J. Conlon[4,5], S.H. Sacks[1], N. Soranzo[2], G.M. Lord[1], M.E. Weale[1,3], United Kingdom and Ireland Renal Transplant Consortium and Wellcome Trust Case-Control Consortium 3.* 1) MRC Centre for Transplantation, King's College London, London, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, UK; 3) Department of Medical and Molecular Genetics, King's College London, London, United Kingdom; 4) Beaumont Hospital, Dublin, Ireland; 5) Royal College of Surgeons in Ireland, Dublin, Ireland.

There is a medical imperative to make transplanted kidneys last longer than they currently do. Graft survival varies widely between individuals, and while some of this variation can be attributed to known clinical factors there is much variation left unexplained. We hypothesize that there may be genetic factors in donors, recipients, or interactions between the two which influence graft survival time, and have carried out a donor-recipient genome-wide association study (GWAS) to test this.

Through the large multicentre United Kingdom and Ireland Renal Transplant Consortium, coordinated by King's College London in partnership with the Wellcome Trust Case-Control Consortium 3 and the National Health Service Blood and Transplant database, we have sourced (1) DNA and transplant-related phenotypes from ~2500 (cadaveric) donor-recipient pairs; (2) pre-existing GWAS data from ~600 pairs collected at King's College London, UK; and (3) pre-existing GWAS data from ~340 recipients collected at Beaumont Hospital, Ireland. All samples have been genotyped on Illumina Quad670 or Quad610 chips. Our primary scan fits Cox proportional hazards models for graft survival to donor SNP main effects, recipient SNP main effects and donor * recipient SNP interactions.

Complex correlation structures in the data result from the use of a donor's two kidneys in different recipients, and from the use of repeated serial grafts in the same recipient. We discuss methodological approaches to address this problem, present simulations to show that power and Type I error are expected to be robust for our scans of interest, and discuss the impact of the issues on the results of our primary scans.

910F

Tissue-specific activation of transposons-derived sequences in normal and cancer cells. *G. Bourque[1,2], P.E. Jacques[3], J. Jeyakani[3], X.Y. Woo[3].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Center, Montreal, Quebec, Canada; 3) Genome Institute of Singapore, Singapore.

Next-generation sequencing (NGS) technologies (e.g. ChIP-Seq, RNA-Seq) are now supplanting array-based technologies because of their accuracy, comprehensiveness and cost. Notably, these technologies enable an unbiased look at the functional contributions of the genome including the contributions of repetitive regions. We present results from the analysis of DNaseI hypersensitivity and ChIP-Seq ENCODE datasets in normal, embryonic and cancer cell lines that show that in all cell types between 8% and 12% of the open chromatin regions have been contributed by transposable elements with a significant over-representation of endogenous retroviral (ERV) repeat families. We also show that the same repetitive regions are enriched for relevant transcription factor binding motifs and are observed to be bound in vivo by various regulatory proteins. Interestingly, we further demonstrate that hundreds of these transposons-derived sequences are activated in a cell-type specific manner. We are also able to confirm that genes near repeat instances containing hypersensitive sites in a particular cell type tend to be more differentially expressed. Although we find that most of this tissue-specific activity on transposon-derived sequences is detected in embryonic stem cells and cancer cell lines, a few repeat families are also open in distinct differentiated cell types. For instance, close to 30% of the instances of the LTR2B ERV subfamily are only open in lymphocyte-related and in renal epithelial cells. Given that various repeat families are highly polymorphic across individuals, characterizing their regulatory activity is likely to be critical to understand functional variation and susceptibility to disease. Finally, the activation of specific repeat families in cancer is of particular interest as we show that it is associated with the deregulation of oncogenic gene subnetworks.

Identifying Genome Wide SINE Retrotransposons Contributing to Dog Size Variation. *N. Sutter, M. Tomlinson, J. Homburger, J. Allen, I. Welsh, H. Moghadam.* Clinical Sciences, Cornell University, Ithaca, NY.

Body size variation was very rapidly acquired in dog evolution, perhaps within a few thousand years of domestication. However, it is not known what functional sequence variation enabled this rapid diversification of a complex trait. Gene disruption via retrotransposon integration causes disease in both man and dogs (e.g. narcolepsy, centronuclear myopathy and merle deafness in dogs). Loci segregating retrotransposon insertion and non-insertion are rare in the human genome (~1500 total). In contrast, in the dog genome SINEC_Cf is frequently segregating; Wang and Kirkness identified 10,000 such loci by comparing just the two reference genomes, Boxer and Poodle. SINEs can disrupt gene expression, splicing, chromatin environments and DNA methylation patterns. We hypothesize that gene disruption via SINE integration is frequently the causal mutation for disease susceptibility and traits under selection in the dog such as body size. We have developed a method to create libraries highly enriched for sequences flanking dog SINEs. Using the Illumina genome analyzer we have sequenced seven such libraries. We identified >10,000 new putatively segregating SINEs including hundreds within promoters, exons and splice sites. PCR sizing and capillary sequencing has experimentally validated 32 out of 40 (80%) such candidates for gene disruption. We have identified segregating SINEs associated with body size variation, including the IGF1 SINE we previously discovered ($p<10E-99$) and SINEs integrated in other genes ($p<10E-12$, $p<10E-8$ and $p<10E-5$). The genome-wide pattern of these SINE integrations is currently being investigated.

912F

Uniparental disomy detection in Prader Willi/Angelman syndrome cases utilizing microarray. *D.L. Pickering, B.J. Dave, J.M. Carstens, A. Papugani, A.H. Olney, W.G. Sanger.* Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

The consequences of uniparental disomy (UPD) are evidenced because of the epigenetic mechanism of genomic imprinting. Due to differential methylation process, certain genes are expressed in a parent-of-origin-specific manner resulting in monoallelic expression of a gene without changing the genetic sequence. Although the majority of Prader Willi syndrome (PW) and Angelman syndrome (AS) are caused by a deletion within chromosome 15q11-q13, UPD and imprinting center mutation are among other etiologies. Diagnostic testing for PW/AS includes chromosome 15 methylation studies in conjunction with or followed by fluorescence in situ hybridization (FISH) or microarray to determine a deletion of 15q11-q13. Because imprinting center mutations are associated with high recurrence risk, it is crucial to assess for the presence of UPD among the non-deletion cases for counseling and management issues. To detect UPD, typically PCR is performed using at least two informative polymorphic markers in both the patient and parents. More recently, whole genome single nucleotide polymorphism (SNP) arrays have been utilized to identify UPD. To examine the feasibility of this technology as a reflex to methylation analysis in PW/AS, we identified 67 (33-PW; 34-AS) methylation-positive cases that were studied in our laboratory in the past decade. Seventeen of these cases (14-PW; 3 AS) were negative for 15q deletion. This subset of patients was investigated utilizing a UPD array with a combination of SNP and oligonucleotide probes distributed throughout the genome. The detection of isodisomy by SNP array does not require parental studies; however heterodisomy studies need a comparative parental analysis. We detected paternal uniparental isodisomy in 66% (2/3) AS cases and maternal uniparental isodisomy was identified in 7% (1/14) PW cases. Seven of 13 (53%) PW studies exhibited segmental loss of heterozygosity (LOH) on chromosome 15 ranging in size from 16-34Mb. Because this was a retrospective study, parental samples were available only in two PW cases and the UPD array confirmed maternal uniparental heterodisomy. As expected, there was a higher incidence of isodisomy among AS cases compared to PW cases. The UPD array thus facilitates isodisomy detection but is best utilized when parental samples are available for identification of heterodisomy and better definition of segmental LOH.

Next Generation Sequencing: Guiding the translation from research to clinical applications. *A.S. Gargis[1], L.V. Kalman[1], M. Berry[2], D.P. Bick[3], D.P. Dimmock[3], T.M. Hambuch[4], F. Lu[2], E. Lyon[5], K.V. Voelkerding[5], B.A. Zehnbauer[1], I.M. Lubin[1].* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) SeqWright, Inc., Houston, TX; 3) Medical College of Wisconsin, Milwaukee, WI; 4) Illumina Clinical Services, San Diego, CA; 5) ARUP Laboratories, Salt Lake City, UT.

Next-generation sequencing (NGS) has expanded beyond research applications to deliver clinically actionable test results that can effectively inform medical decision making. This new area of clinical testing lacks uniform practices for quality assurance and quality control (QC) that are essential to ensure the analytic validity of test results. Similarly, there is no laboratory practice guidance that is specific for NGS technologies and provides for compliance with existing regulatory and professional standards. To address these shortcomings, a workgroup meeting was convened on April 14-15, 2011 that included 41 invited participants from clinical and research laboratories, clinical care settings, manufacturers, software developers, relevant government agencies, accreditation bodies, and professional organizations. Test validation, quality control, proficiency testing/alternate assessment, and reference materials were key discussion topics. For NGS test validation and QC, accuracy, precision, robustness, and sensitivity were considered in terms of sequence coverage, an attribute not relevant to Sanger sequencing. Orthologous techniques such as Sanger sequencing and analysis by SNP arrays are useful comparators for test validation and QC but have inherent limitations that require validation for the intended application. Analysis of a gene panel, exome, or whole genome requires different approaches for test validation and QC. Meeting participants proposed new strategies to develop biologic, synthetic, and electronic reference materials. Traditional models for proficiency testing and alternate assessment may be impractical for clinical laboratories and new paradigms were considered. Consensus was achieved in several areas to define metrics and processes not currently described that are needed to establish analytic validity and to meet regulatory and professional standards. Outcomes from this meeting included the recognition of technical differences between NGS and Sanger sequencing that affect quality assurance practices and the identification of challenges to implementing NGS as a clinical test with respect to meeting regulatory and professional standards. Metrics and processes needed to assess the analytic validity of NGS results were addressed and participants identified issues that require additional data collection. These findings are being used to develop laboratory practice guidance to ensure the quality of NGS for patient testing.

914F

MiSeq: A rapid low cost sbs sequencing platform. *K. Hall[1], G. Smith[1], J. Betley[1], W. Meuleman[1], J. Weir[1], J. Quick[1], A. Breton[1], M. Wang[2], P. Podlevsky[2], J. Moon[2], B. Crane[2], N. Scheidler[2], R. Yang[2], S. Hong[3], E. Vermaas[3], B. Rabkin[3], M. Siu[3], M. Reed[3].* 1) Illumina Cambridge Ltd., Saffron Walden, Essex, United Kingdom; 2) Illumina Inc. 9885 Towne Centre Drive, San Diego, CA 92121 USA; 3) Illumina Hayward, 25861 Industrial Blvd. Hayward, CA 94545 USA.

Next generation sequencing has revolutionised the ability to collect large amounts of data from genetic material both in terms of depth of coverage and breadth of samples that can be sequenced. As we learn about genetic systems and together with existing applications there is a tremendous demand for a system that exhibits a fast time to answer.

Illumina has designed and produced a new sequencing platform MiSeq that enables extremely rapid sequencing of genetic material. The MiSeq instrument produces up to 1.5Gb from a 2x150 cycle run utilising paired end technology in just over a day. The instrument takes Illumina TruSeq and Nextera libraries and after only 20 minutes of set up time a sequencing run can be initiated that needs no further human intervention. The cluster growth and paired end processes are built into the instrument further simplifying workflow. The primary and secondary analysis including alignment, structural variant calling is also performed on instrument, supporting de novo assemblies of bacterial genomes and producing contig and coverage data. The sequencing is achieved using fast cycle time reversible terminator chemistry derived from the proven robust massively parallel sequencing by synthesis (SBS) chemistry used on Illumina's HiSeq and GA platforms. Depending on application it is possible to achieve sequence data from a library of over 3.4 million tags in less than 4 hours.

This system will have a broad range of applications including clinical sequencing from FFPE samples, amplicons, targeted resequencing and more general application for RNA, bacterial genomes and library quantification.

Development of SureSelect Target Capture Methods for Sequencing on the PacBio *RS*. *S. Happe[1], M. Guadalupe[1], S. Ranade[3], L. Lee[3], J. Barboza[1], B. Novak[2], E. Lin[2], C. Pabon-Pena[2], J. Ong[1], S. Joshi[1], H. Ravi[1], M. Visitacion[2], M. Hamady[2], F. Useche[2], D. Roberts[2], A. Giuffre[1], E. Leproust[2].* 1) Agilent Technologies Inc, Cedar Creek, TX; 2) Agilent Technologies Inc, Santa Clara, CA; 3) Pacific Biosciences, Menlo Park, CA.

Pacific Biosciences' PacBio *RS* is a powerful new technology for single molecule, real-time sequencing, featuring long reads, fast turnaround times, and capabilities for both both *de novo* sequencing and resequencing applications. To determine the efficacy of the Agilent SureSelect™ Target Enrichment System for targeted resequencing on the PacBio *RS*, we developed methods to prepare genomic DNA libraries and analyzed sequencing performance. First, to take advantage of the long read capability, we tested different shearing conditions to create inserts of varying sizes. Second, we modified the Agilent SureSelect^{XT} kit such that unique short adapter sequences were ligated onto sheared DNA, thereby allowing manipulation of the library throughout the target enrichment process. Following hybrid capture with SureSelect biotinylated RNA libraries and appropriate blocking reagents, PacBio SMRTbell™ templates were constructed using the enriched DNA and subsequently sequenced on the PacBio RS. Sequencing results revealed high specificity for capturing targets of interest, excellent uniformity, and deep coverage across the targeted regions. High performance was achieved across different sample types captured with SureSelect libraries of varying size, complexity, and content. Data obtained was used to efficiently identify SNPs and indels, and showed high correlation with previously-determined genotypes. Long insert libraries retained the advantages of long reads while focusing data on regions of interest. These findings illustrate the utility of the SureSelect method for target enrichment on the PacBio *RS* , and provide a path forward for targeted variation discovery and profiling.

916F

Comparison of two new methods to increase the sensitivity of next-generation sequencing (NGS) of short DNA for non-invasive prenatal and cancer diagnostics as well as for ChIP-seq, methyl-seq and other sonicated DNA applications. *E. Kamberov[1], J. Langmore[1], T. Tesmer[1], M. Luo[2], M. Jeong[2], D. Sun[2], W. Lei[2], L. White[2], G. Darlington[2].* 1) Rubicon Genomics, Ann Arbor, MI; 2) Baylor College of Medicine, Houston, TX.

There is an increasing need to sequence picogram quantities of short DNA for diagnostics and research. For example, 1) maternal blood contains small amounts of fetal DNA useful for prenatal diagnostics; 2) cancer patient plasma contains small amounts of tumor DNA useful for cancer diagnostics; and 3) immunoprecipitated DNA and nucleoprotein is used to identify sites of protein-binding and DNA methylation. Unfortunately, conventional NGS preps require ng or µg amounts of DNA.

We tested 2 methods to prepare pg amounts of DNA for NGS, using ChIP and plasma DNA as model systems--the Sigma GenomePlex WGA4 kit and the Rubicon NovaPlex NGS prep kit. H3k4me3 Ab were used to precipitate chromatin fragments from mouse hematopoietic stem cells (HSC). A 2 ng ChIP control was prepared using the Illumina protocol from 300K HSC, and 100-200 pg ChIP experimental samples were prepared from 50K HSC. Multiple GenomePlex experimental samples were amplified using the Sigma WGA4 protocol, followed by NGS adaptation with the Rubicon RetroPlex kit. Multiple NovaPlex samples were directly prepared from experimental ChIP DNA. Multiple NovaPlex samples were prepared from 3 ng human plasma DNA.

The ChIP samples gave similar statistics, with 23M - 38M reads per lane and 71%, 51%, and 58% uniquely mapped reads (control, GenomePlex, NovaPlex). The control had 15,900 significant peaks (p<10e-8), GenomePlex 30,000 peaks, and NovaPlex 15,100 peaks. Although 92% of the NovaPlex peaks overlapped the control, only 41% of the GenomePlex peaks did. The “false positive” GenomePlex peaks were primarily in distal intergenic regions.

NovaPlex plasma NGS samples had 51 base read statistics similar to a 3 µg Illumina prep. The GAIIx gave 30M NovaPlex reads/lane (99% high-quality in read 1 and 89% in read 2, of which 97% mapped to hg19 with <0.2% mismatch with hg19. Paired-end distances were 170 +/- 50), with 2x10e-6 mapped inconsistently due to inversion and <1% due to distance. NovaPlex consistently covered 50% of the genome in a single lane.

NovaPlex enables high-quality sequencing of very small amounts of ChIP and plasma DNA in 2 steps in two hr. Based on these initial successes, stringent testing with smaller amounts of ChIP and patient plasma DNA is being performed in third-party laboratories in order to fully characterize its performance on research and clinical samples.

917F

Cost-effective, high-throughput DNA sequencing libraries appropriate for highly multiplexed target capture. *N. Rohland[1,2], D. Reich[1,2].* 1) Genetics, Harvard Medical School, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA.

Improvements in technology have reduced the cost of DNA sequencing to the point that the limiting factor for many experiments is the time and reagent cost of sample preparation. We present an approach in which 192 sequencing libraries can be produced in a single day of technician time, representing an order of magnitude increase in throughput and an order of magnitude decrease in reagent costs. These libraries are effective not only for whole genome sequencing, but also for simultaneously enriching them in pools of at least 95 individually barcoded samples for a subset of the genome using solution hybrid capture without substantial loss in molecular complexity and efficiency of target capture. We illustrate the power and effectiveness of this approach on more than 2,000 samples from a prostate cancer study.

918F

Comparative Analysis of CHO Cell Transcriptional Dynamics under Different Cell Culture Conditions using Next Generation RNA Sequencing Technology. *J.J. Schageman[1], M. Liu[2], S. Wang[2], C. Mueller[1], R.A. Setterquist[1].* 1) Ambion Bioinformatics, Life Technologies Corp., Austin, TX., U.S.A; 2) Bioproduction, Life Technologies Corp.,Frederick, MD, U.S.A.

Next Generation RNA-Sequencing (RNA-Seq) is a methodology for comprehensive measurements of cellular transcription at a scale, accuracy and precision never seen with previous technologies. We conducted a comparative RNA-Seq study of basic cell growth conditions to understand and improve high quality therapeutic protein production in CHO cells. In this study, we examined global changes in gene expression in CHO cells across differing cell subtype and media- specific parameters. Eight CHO RNA samples from different cultures were sequenced on two full slides of a SOLiD™ System resulting in approximately 760 million, 50 base pair sequence reads. These reads were mapped to multiple reference sequences including CHO ESTs, mRNAs and well as mouse chromosomes with annotated genes with cognate functional data. From this, we report estimates of transcript expression levels and use known annotation to infer functional differences that can be associated with changing basic bioproduction growth conditions. These findings may uncover novel genetic mechanisms that could be optimized for improved bioproduction. This analysis of this data set represents the characterization of the CHO transcriptome at an unprecedented depth.

919F

Novel Technologies for Ribosomal RNA (rRNA) Removal (Ribo-Zero™) and Directional RNA-SEQ Library Preparation (ScriptSeq™). *R. Sooknanan, J. Hitchen, A. Khanna, A. Radek.* Epicentre® (an Illumina® company), Madison, WI.

Deep, massively parallel sequencing of cDNA libraries generated from RNA ("RNA-Seq") is rapidly gaining momentum for transcript profiling, discovery of novel transcripts, and identification of alternative splicing events. Current methods for making sequencer-specific di-tagged DNA fragment libraries for RNA-Seq typically comprise preparing rRNA-depleted RNA and either (i) RNA fragmentation, 5' and 3' adaptor-ligation, size selection, cDNA synthesis, and multiple clean-up steps; or (ii) cDNA synthesis followed by cDNA fragmentation, end-polishing, 5' and 3' adaptor-ligation, gel-size selection and multiple clean-up steps. These methods are generally time-consuming and require significant hands-on time. Further, even after removal of rRNA from intact total RNA samples using commercially available kits, 50 % or more of the sequence reads can still be from rRNA, decreasing sequencing depth and coverage of the RNA-Seq libraries. Additionally, these kits are not recommended for fragmented (e.g., FFPE) RNA samples, which further limits RNA-Seq applications. Here, we present RNA-Seq results obtained using a novel "single-pass" rRNA removal technology ("Ribo-Zero™") and a novel and rapid (simple workflow) RNA-Seq library preparation process that utilizes a unique Terminal Tagging technology for preparing directional cDNA libraries ("ScriptSeq™ Technology") for NGS. Directional cDNA libraries with ~98% strandedness can be prepared in about 2.5 hours from either intact or fragmented (e.g., FFPE) rRNA-depleted RNA samples without the need for end-polishing, adaptor-ligation, cDNA fragmentation or gel-size selection. ScriptSeq libraries generated from Ribo-Zero™ treated intact or fragmented total RNA samples for rRNA removal contain <2 % of the sequence reads that map to rRNA sequences (28S, 18S, 5.8S and 5S) while maintaining both coding and non-coding transcripts independent of polyadenylation. This reduction in rRNA sequence reads improves sequence depth and coverage, and increases the percentage of uniquely mapped reads. Further, there is a high correlation (R2=0.9235) between differentially expressed transcripts found in the ScriptSeq™ RNA-Seq libraries and the MAQC qPCR panel of genes.

920F

Post Amplification Ligation Mediated (PALM) barcoding for multiplexed RNA deep sequencing. *F. Van Nieuwerburgh[1], K. Podshivalova[2], E. Ay-Lin Wang[2], L. Schaffer[3], T. Hart[2], D. Deforce[1], D. Salomon[2], S. Head[3], P. Ordoukhanian[3].* 1) Laboratory of Pharmaceutical Biotechnology, Ghent University, Harelbekestraat 72, 9000 Ghent, Belgium; 2) Department of Molecular and Experimental Medicine, The Scripps Research Institute, 10550 N. Torrey Pines Rd, La Jolla, CA, 92037, USA; 3) Next Generation Sequencing Core, The Scripps Research Institute, La Jolla, California, 92037, USA.

Taking advantage of the increasing throughput achieved by second generation sequencing technologies, multiplexing several samples in one analysis can increase experimental throughput while reducing time and cost. We demonstrate a new method for unbiased multiplexed sequencing of microRNA, mRNA and DNA libraries using a novel, efficient and simple barcoding strategy we called Post Amplification Ligation-Mediated (PALM) barcoding. Barcoding is performed as the very last step of a standard Illumina library preparation, eliminating barcode-induced bias caused by PCR amplification of samples with different barcode sequences. As a proof of concept, we sequenced PALM barcoded reference microRNA and mRNA samples and evaluated the quantitative bias in comparison to the same reference samples prepared using a pre-PCR barcoding strategy. For the microRNA samples, we also compared the bias to a barcoding strategy that introduces the barcodes during the PCR step. Results show virtually no bias for barcoded samples prepared by the PALM and the during-PCR barcoding strategy, while samples multiplexed using a pre-PCR barcoding strategy show significant bias. The total number of past-filter reads was comparable between the different barcoding strategies. The number of reads for each of the individually barcoded libraries in the PALM multiplex pool was uniform, showing that none of the PALM barcoded libraries generates more clusters on the flow cell than the other ones. We applied PALM barcoding to search for differentially expressed microRNAs in human T cells activated and/or treated with immunosuppressant drugs. High correlations were found for biological replicates indexed with different barcodes.

***In vivo* analysis of DNA-bound proteins in the UAS_{Gal} region using the novel GENECAPP technology.** *H. Guillen Ahlers[1], M. Zickus[1], A. Musante[2], S. Mirza[1], A. Ludwig-Kubinski[1], M. Zelembaba[1], S. Zhang[1], R. Cole[1], M. Chesnik[1], C-H. Wu[2], Y. Yuan[2], G. Kreitinger[2], M. Scalf[2], M. Levenstein[2], M. Shortreed[2], L. Cirillo[1], L.M. Smith[2], M. Olivier[1].* 1) Wisconsin CEGS, Medical College of Wisconsin, Milwaukee, WI, 53226; 2) Wisconsin CEGS, University of Wisconsin, Madison, WI, 53706.

Numerous proteins mediate DNA stability, control its activity, and regulate transcription of the encoded genetic information. Currently, no technologies exist to examine these protein-DNA interactions in a comprehensive global manner. To overcome this challenge, we developed **G**lobal **E**xo**N**uclease-based **E**nrichment of **C**hromatin-**A**ssociated **P**roteins for **P**roteomics (GENECAPP). While Chromatin Immunoprecipitation (ChIP) characterizes DNA interacting with individual known proteins, GENECAPP, developed at the Wisconsin Center for Excellence in Genomics Science, utilizes oligonucleotide capture to isolate targeted DNA regions in a sequence-specific manner and analyzes captured DNA-associated proteins using mass spectrometry. The Gal upstream activator sequence (UAS_{Gal}) in *S. cerevisiae* was studied using the GENECAPP technology. Streptavidin-coated magnetic beads were used as the solid surface with attached sequence-specific capture oligonucleotides. Cells were lysed and nuclear extracts cross-linked and captured by hybridization after exonuclease-mediated generation of exposed single-stranded overhangs. After trypsin digestion, peptides characteristic of bound proteins were identified by tandem mass spectrometry using an Orbitrap Velos instrument. The analysis identified the majority of the known proteins that bind to the UAS_{Gal} region under repressive conditions. Additional novel proteins were uncovered that have not been previously reported to bind to the DNA sequence. Overall, the GENECAPP technology is evolving into a new powerful tool to identify previously unknown proteins bound to specific DNA regions of interest.

922F

Rapid DNA extraction from human buccal cells for PCR amplification. *J.A. Timbuak[1], A.E. Justice[2], M.H. Crawford[2], P. Williams[3].* 1) Anatomy, Ahmadu Bello University, Zaria, , Kaduna, Nigeria; 2) Department of Anthropology, University of Kansas, Lawrence KS; 3) Evogen Inc., Kansas City, MO.

A variety of methods exist for extraction of human DNA and recent developments in column-based extraction methods have allowed for purified PCR ready DNA with less time at the bench. However, these methods often result in the loss of some DNA on the filter accompanied by laborious protocols. For samples commonly used for anthropological genetics and forensics, such as buccal swabs, the purification of samples using filters is often unnecessary and costly. Evogen One™ (Evogen, Inc.) is a rapid, commercial DNA extraction method that uses a proprietary salting method of extraction. This study examines Evogen One™ to assess the time to extraction of PCR ready samples, sample concentration, and total DNA yield. To further demonstrate the utility of this extraction method, these extractions were compared to QiaAmp® DNA Mini Kit (Qiagen®), a spin column based extraction method. To test the efficacy of Evogen One™ for human buccal cells, 265 samples were collected with a cotton swab from four Nigerian ethnic groups. Evogen One™ uses a proprietary salt, detergent, and heat to lyse the cells. Lysed samples are centrifuged to pellet cellular debris, leaving supernatant containing PCR-ready DNA. A total of 231 samples were extracted using Evogen One, while 34 samples were extracted using QiaAmp® following manufacturer's protocol. Sample concentrations were obtained using a NanoDrop™ 2000c and adjusted for volume to obtain total DNA yield. Total extraction time was less than 25 minutes per 24 samples for Evogen One™ and ranged from approximately 90-120 minutes for QiaAmp®, including lysis steps. Evogen One™ resulted in an average concentration of 271.03 ng/µL (s2= 176.29) and QiaAmp® 31.97 ng/µL (s2= 12.73). Average final volume for Evogen One™ was 61.81 µL (s2= 52.93) and QiaAmp® was 136.32 µL (s2= 23.28). Average total DNA yield of 16.48 µg (s2= 24.57) was obtained for Evogen One™ and 4.32 µg (s2= 1.84) for QiaAmp®. Evogen One™ is a very promising extraction method for human genetics. When compared to column-based methods of extraction, it is more time and cost-effective and reduces lab waste as the total protocol takes place in a single tube. While the final DNA yields are more variable for Evogen One™ than the consistent concentrations of QiaAmp®, Evogen One™ results in greater than 3 times the total DNA yield and offers the researcher more flexibility with regard to purification and dilution of DNA.

Effects of Sample Preparation on Transcriptome Sequencing. *P. Zumbo[1,2,3], CE. Mason[1,2].* 1) Department of Physiology and Biophysics, Weill Medical College, Cornell University, New York, NY 10065, USA; 2) HRH Prince Alwaleed Bin Talal Bin Abdulaziz Alsaud Institute for Computational Biomedicine, Weill Medical College, Cornell University, New York, NY 10065, USA; 3) Epigenomics Core Facility, Weill Medical College, Cornell University, New York, NY 10065, USA.

High-throughput transcriptome sequencing has been herald as a `revolutionary tool for transcriptomics'. But beyond the hype and promise of gene discovery and absolute transcript quantification lies significant library construction biases. Here, we analyzed the effects of sample preparation methodology on transcriptome sequencing, utilizing synthetic RNA spike-ins from the External RNA Control Consortium. We showed that downstream discoveries and determinations are, in part, a function of library construction method, across different modalities of measurement (exon and gene expression, isform detection, novel transcript identification, and variant calling). Specifically, we compared Epicentre ScriptSeq against Illumina TruSeq RNA-seq, amplification versus amplification-free libraries, and ribosomal reduction contra polyadenylate selection. We demonstrated the utility of synthetic RNA spike-ins to correct for some of the biases between different library constructions, enabling more concordant expression measurements. These results can inform future transcriptome studies on an individual basis, and highlight the importance of uniform library methods within a study for comparability, as well as the benefit of multiple methods for fuller characterization of a transcriptome.

924F

DNA binding of Novel Oligoheterocycles. *S.I. Al-Aqeel[1], J.M. Gardiner[2].* 1) Department of Chemistry, Faculty of Science, King Saud University, Riyadh, PO Box 22452, Riyadh 11495, Saudi Arabia; 2) School of Chemistry and Manchester Interdisciplinary Biocentre, The University of Manchester, Manchester M1 7DN,UK.

There has been interest in heteocyclic systems as sequence-selective DNA minor groove binding agents (and some as RNA binding agents), such as dimeric benzimidazoles related to Hoechst33258 (and trimeric equivalents), and oligopyrroles (and benzimidazole-imidazole chimeras). More recently, some examples of symmetrical dimers or linked dimers, have been reported with similar targets, and at least some evidence of structures with potential for targeting G-quadruplexes. Developing new methods to generate novel bis- and oligobenzimidazoles and evaluation as nucleic acid binding agents is thus of interest. This contribution will describe synthesis of several families of novel oligoheterocyclic systems, designed to provide a modular approach to provide a range of new ligands types, categorized based on heterocyclic orientation, separation and various functionality of linkers incorporated, for example including compounds of the generic types shown. Additionally, other series of dimers, trimers and tetramers will be described. Data on evaluation of binding for an array of structures in the above classes to a series of target DNA sequences (containing various length (AT)n sections) will be presented, leading to identification of novel DNA-binding ligands in several structural families with sub-micromolar affinities.

925F

Next generation sequencing applied to Alport syndrome diagnosis. *F. Ariani[1], R. Artuso[1], C. Fallerini[1], L. Dosa[1], F. Scionti[1], M. Clementi[2], G. Garosi[3], L. Massella[4], R. Mancini[1], F. Mari[1], I. Longo[1], M. Bruttini[1], A. Renieri[1].* 1) Medical Genetics, Department of Biotechnology, University of Siena, Italy; 2) Medical Genetics, Pediatrics, University of Padova, Italy; 3) Nephrology, Dialysis and Transplantation, AOU Siena, Italy; 4) Nephrology and Dialysis, Ospedale Pediatrico Bambin Gesù, Roma, Italy.

Alport syndrome is an inherited disorder of type IV collagen, the major collagenous constituent of the basement membrane. Clinically, it presents as a progressive inherited nephropathy characterized by the association of progressive hematuric nephritis with ultrastructural changes of the glomerular basement membrane, high-tone sensorineural hearing loss and ocular lesions. The disease is genetically heterogeneous, but the majority of cases show X-linked dominant inheritance and are caused by mutations in the COL4A5 gene (Xq22). Dominant and recessive autosomal forms have also been reported and are characterized by mutations in COL4A3 and COL4A4 genes (2q36-37). Considering the absence of mutational hot spots and the large size of the genes implicated in Alport syndrome, mutational analyses by standard techniques, such as DHPLC and/or direct Sanger sequencing, represent a very expensive and exhausting molecular testing. To overcome these limitations, we designed a next generation sequencing protocol enabling simultaneous detection of all possible variants in the three genes. We used a method coupling selective amplification to the 454 Roche DNA-sequencing platform (Genome Sequencer Junior System). The application of this technology allowed to identify the second mutation in two patients (p.Ser1147Phe in COL4A3 and p.Arg1682Trp in COL4A4) and to exclude the diagnosis of Alport syndrome in a third patient. In this pilot study, Sanger sequencing was used to evaluate the number of false positive changes and to determine indicative cut-off values (variations detected in <25% of reads) to use in a routine diagnostic setting. Although improvements in accuracy and ease of data analysis will be necessary, our study demonstrates that this system can be used to perform a fast, sensitive and relatively low-cost screening of variations in Alport syndrome genes.

926F

Investigation of High Resolution Melting analysis as a tool for mutation detection. *C.A. Fahey, M. Gill, A.P. Corvin, D.W. Morris.* Trinity College Dublin, Dublin, Ireland.

High Resolution Melting (HRM) analysis using dsDNA-binding dyes and real-time PCR instrumentation is a relatively new and attractive mutation detection technique due to its rapid, high-throughput and sensitive post-PCR analysis. This approach enables investigation of genetic variation including SNP genotyping, DNA methylation, heterozygosity screening and mutation scanning. HRM methodology is based on amplifying a region of interest using primer specific PCR, followed by gradual denaturing of the target region and generation of a melt curve, allowing successful detection of genetic variation in the sequence. In order to test the efficiency of HRM we applied it to exonic regions of the VIPR2 gene. Rare chromosomal duplications at the VIPR2 gene have been found to result in a significant increased risk of schizophrenia (Vacic et al. 2011; PMID: 21346763). Our two-stage approach to testing the HRM method was: (1) Analyse a proportion HapMap CEU samples of known mutation content based on online data including 1,000 Genomes data to optimize performance of the method. (2) Blindly screen remaining HapMap CEU samples for mutations and compare results with online data. Stage 1: Melt curve analysis successfully identified a high proportion of expected mutations in tested HapMap samples. Stage 2: We will report on the specificity and sensitivity of the method when blindly applied to remaining HapMap samples. If the method shows accurate performance, it can be applied to our large sample of schizophrenia cases and control samples. Along with subsequent capillary sequencing, it could potentially identify rare risk variants in patient samples.

927F

Validation of a Next Generation Sequencing Platform in a Clinical Setting. *T.A. Maher[1], M. Zhao[1], R.K. Basran[1,2], A. Milunsky[1,2,3], J.M. Milunsky[1,2,3].* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Next Generation sequencing has now become a reality in the clinical laboratory with the advent of low cost instrumentation and relatively condensed sample processing. Our laboratory sought to validate the Ion Torrent system in a clinical setting. The technology uses a massively parallel array of proprietary semiconductor sensors to perform direct real-time measurement of the hydrogen ions produced during DNA replication. A high-density array of wells on the ion semiconductor chips provides millions of individual reactors. The process of generating sequence is straight-forward and involves four steps as follows: construct a library, prepare the template, generate base calls, and finally data analysis. Data analysis was accomplished using the Softgenetics NextGENe software package. Our validation consisted of ten previously identified mutations through traditional capillary sequencing. The mutations were spread across seven different genes and consisted of point mutations, multiple basepair deletions, an insertion/deletion and multiple point mutations in the same amplicon. The library design consisted of amplicons to generate 100 basepairs of bi-directional sequence according to the Ion protocol. One of the amplicons produced a suboptimal result and was not used. All the amplicons from the different genes were processed and analyzed together. There was sufficient coverage across all the amplicons to identify the mutations. The data was analyzed with NextGENe and all the mutations detected with capillary sequencing were correctly identified. The assay including generating the amplicons through software analysis was accomplished in four days by one technician who was also able to complete additional work in the laboratory. This workflow will easily allow a clinical laboratory to use the technology in multiple ways. One could sequence a panel of disease related genes using the Ion platform or with the availability of bar-coding, sequence multiple patients for the same set of genes simultaneously.

928F

Integration of the REM e Device on the Biomek FX Laboratory Workstation for Efficient High Throughput NGS Bead Enrichment Process. *K.L. Marshall[1], Z. Smith[2], J. Colbourn[2], K. Mockaitis[2], A. Jackson[1].* 1) Automated solutions, Beckman Coulter, Indianapolis, IN., Select a Country; 2) The Center for Genomics and Bioinformatics Indiana University, Bloomington, IN.

Next Generation Sequencing (NGS) is a powerful tool for determining the genetic sequence for subsequent applications such as gene discovery, mutation detection and forensic analysis. Most NGS systems, such as the Roche 454 sequencer, rely on time consuming construction and preparation of genomic libraries, prior to sequencing. The Beckman NGS Suite of methods automates the construction, quantification, normalization, emulsion PCR setup and Bead enrichment portions of the Roche 454 library preparation. Specifically, the Bead Enrichment process, where only 5-15% of monoclonal emPCR beads will be selected, is especially time consuming and prone to error. Beckman Coulter has integrated the Roche REM e device on the Biomek FX, FXP, NX & NXP Workstation Platforms for the automation of the bead enrichment process. This poster provides data on the integration of a single REM e device on the Biomek FX Dual Arm System with Span-8 and Multi-Channel Pipettor. Automation of the Roche protocols reduced hands-on time from 6 hours to 15 minutes. Actual method run times range between 2 ¾ to 3 ¾ hours depending on which protocol is run. The complete walk away automation method for large volume processing (2 - 4 cups) is simple, fast and accurate. Our 2 cup REM e data of Diptera cDNA Library from Indiana University was acceptable using Roche standards, with a 9% post enrichment bead recovery rate and 455 bp median Reads Length. For Laboratory Use Only; not for use in dagnostic procedures Beckman Coulter, they stylized logo, and Biomek are trademarks of Beckman Coulter, Inc. and are registered in the USPTO.

Detection of BRAF v600e to 0.1% Using Unlabeled Probes and High Resolution Melting through Amplification Bias. *M. Poulson, C. Gundry, R. Crisp.* Idaho Technology, Inc., Salt Lake City, UT.

Introduction. High Resolution Melting (HRM) is a set of post-PCR genetic screening techniques to rapidly detect mutations while reducing sample manipulation and time to results. HRM techniques are non destructive, allowing confirmatory sequencing when desired. HRM is highly suited for known mutation screening or targeted genotyping. BRAF v600e is a proto-oncogene mutation linked to many cancers including colorectal, thyroid, and melanomas. Diagnosis is made by taking biopsies of suspected tissue. As biopsies obtain varying amounts of cancerous tissue, a highly sensitive and accurate assay for the v600e mutation is required. This study highlights the ability of allele biased HRM techniques to identify the BRAF v600e mutation in varying wild-type allele backgrounds. Methods. This study was performed using the LightScanner® and the LightScanner®32 (Idaho Technology, Inc.) systems. Unlabeled probe (LunaProbes™) assays use three oligonucleotides, two target-specific primers and a probe, and asymmetric PCR in which the forward and reverse primers are present in unequal concentrations. Genotype differences under the probe are identified as changes in the probe melting profile. The introduction of the probe element can in some cases differentially amplify the mutant allele and increase the mutant allele signal. LunaProbe assays can be carefully optimized to favor the amplification of the mutant allele. In this study, allele blocking techniques were employed to identify the BRAF v600e mutant genotype in a wild-type background. This was done by matching the probe to the wild-type allele and adjusting amplification conditions to preferentially amplify sample-derived DNA containing the BRAF v600e mutation. Varying allele fractions were tested in a wild-type genetic background to determine the lowest detected allele fraction. Results. The LunaProbe assay combined with mutation amplification enhancing techniques were used to achieve extremely high sensitivity detecting the BRAF v600e mutation in a homogenous assay requiring no post-PCR manipulations. The mutant allele amplification bias resulted in detection of BRAF v600e mutation at 0.1% allele fraction. Conclusions. This study shows that HRM in combination with robust assay optimization and precise temperature control can identify the BRAF v600e mutation as low as 0.1% mutant allele fraction. This technique can be applied to many genotyping applications as a means to increase mutation discovery.

930F

Very High Sensitivity Somatic Mutation Detection using Ice COLD-PCR and BLOCker Sequencing. *K. Richardson, P. Eastlake, B. Legendre, G. Wu, R. Lin, Y. Shi, S. Jansen, S. Peterson, K. Echtenkamp, E. Comtois, J. Sommer.* Transgenomic, Inc., Omaha, NE.

Transgenomic has developed very high sensitivity methods for detecting somatic mutations notably in the discipline of cancer therapy where key genetic changes are associated with EGFR antagonists' effectiveness, e.g. in the genes EGFR, K-RAS, PIK3CA, BRAF, p53 and NRAS. The novel techniques of Ice COLD-PCR and BLOCker Sequencing preferentially enrich mutant alleles compared to wild-type alleles. These are not allele-specific techniques; therefore all mutations, both known and unknown, are enriched and identified in a single reaction. Together these methods allow mutations at concentrations as low as 0.01-0.05% in background of wild-type to be confirmed by sequencing. Additionally Ice COLD-PCR and BLOCker Sequencing require no special equipment using only standard DNA thermocyclers and Sanger sequencing equipment. Data will be presented showing how these methods allow DNA sequencing confirmation of somatic mutations in samples such as low tumour-load biopsies, formalin-fixed paraffin-embedded slides, fine-needle aspirates, circulating tumour cells and circulating free tumour DNA in plasma and serum. These methods can also be used to confirm low signal Pyrosequencing and next-generation deep-sequencing results. Using these techniques routine, rapid, simple and inexpensive detection of somatic mutations in (1) cancer patients' plasma or serum or; (2) samples where very limited tumour tissue is available, offers a non-invasive option for cancer biomarker detection as well as monitoring remission, relapse and emergence of resistance mutations post-treatment. Finally Ice COLD-PCR and BLOCker Sequencing can be applied to analysis of mixed viral infections and mitochondrial heteroplasmies.

931F

Identifying diagnostic EGFR mutants by real-time PCR with new DDS probe systems. *D.A. Shafer[1,2], P. Hu[1], D. Xie[3], C.E. Hill[2], M. Rossi[2], M. Bouzyk[3].* 1) GeneTAG Technology, Inc., Atlanta, Georgia; 2) Emory University School of Medicine, Atlanta, Georgia; 3) AKESOgen, Inc., Atlanta, Georgia.

Recent studies have shown that many patients with non small cell lung cancer (NSCLC) are highly responsive to EGFR tyrosine kinase inhibitors (gefitinib and elotinib) and that those responsive patients can be identified by mutations in the EGFR tyrosine kinase domain. The dominant mutations of this type are a single base change in Exon 21 L858R T>G, and a small deletion of 9-24 bp in Exon 19 at codons 746-750. These two mutations account for about 90% of all EGFR mutations in lung cancer. Moreover, another single base mutation of EGFR in exon 20 (T790M) is associated with acquired resistance to gefitinib in patients who were initially responsive to gefitinib. These mutations thus offer a small set of targets that are valuable for cancer diagnostics and pharmacogenomics. The first author has invented new probe technologies for real time PCR that offer high specificity and sensitivity compared to conventional Taqman or TaqmanMGB probes, and these new qPCR technologies have been effectively applied to DNA copies of these cancer related targets. The primary probe system, an internal DDS (DNA Detection Switch) probe, comprises two labeled components - a probe and an antiprobe - that interact together and with the target sequence during real time PCR. The antiprobe provides a signaling function and it also serves as an error checking device to prevent binding and detection of non-matching targets that differ by a single base. This unique mechanism thus enables precise and reliable single base discrimination over a wide range of annealing temperatures (10-20 degrees). Therefore, multiple iDDS probes for different targets can be run together without loss of specificity. The current focus is on testing a set of iDDS probes that can discriminate the L858R mutation and on a related DDS probe set that can detect the Exon 19 deletion site. This collaboration with Emory and AKESOgen is engaged in applying these probe systems to clinical samples from lung cancer patients and controls to validate this methodology for cancer diagnostics. Current progress on this project will be reported.

932F

Single-Day, Highly Multiplexed Library Preparation for Amplicon Sequencing with MiSeq. *A. Tian, E. Guzman, M. Won, W. Chang, D. Pokholok, R. Haigis, A. Iyer, E. Upsall, I. Lewis, S. Norberg, M. Ronaghi, K. Gunderson, R. Shen, C. Lin.* Illumina, Inc. 9885 Towne Centre Dr, San Diego, CA 92121.

Targeted enrichment strategies enable cost-effective analysis of desired genomic regions with next-generation DNA sequencers. We introduce TruSeq™ Custom Amplicon, a new sample preparation method developed and optimized for high-throughput amplicon sequencing on MiSeq™, the personal sequencing system from Illumina. 48 to 384 of user-defined genomic regions can be enriched in a single tube with high specificity (>90% of reads on target) and high uniformity (>85% of targets represented at ⁄ 0.2X mean coverage) in <8 hr (from purified genomic DNA to sequencing-ready library). By comparison, only a dozen or so targets can be amplified in a single tube with multiplex PCR, and hybridization-capture enrichment approaches require 3 days or more from DNA to library. In addition, we have developed a robust and highly scalable sample indexing strategy supporting 96 libraries to be sequenced simultaneously with MiSeq. We also will demonstrate a new library quantitation and normalization approach, which allows 96 libraries to be adjusted to sequencing-ready concentrations in <1 hr without using expensive equipment such as a qPCR thermocycler or Bioanalyzer. These innovations streamline amplicon sequencing workflows, and provide unprecedented amplicon and sample multiplexing. Here we present data demonstrating high-accuracy detection of single-nucleotide polymorphisms (SNP; ⁄ 99.5% concordance with microarray and 1000 Genomes data) and structural variants, some of which are implicated in drug metabolism and cancer biology. Specifically, regions representing mutation hotspots in genes including *TP53*, *KRAS* and *BRAF* were sequenced and the mutations in control samples were accurately identified. Copy numbers of the *GSTM1* and *GSTT1* genes (implicated in the breakdown of drug and carcinogenic compounds) determined by this assay also exhibited excellent concordance with microarray data. Multiple types of genetic variation can now be studied comprehensively in a single rapid assay through this new targeted enrichment approach.

933F

Enhanced genome assembly using single molecule, nanochannel analysis. *J. Sibert, O. Hampton, R. Mohr, S. Billeru, H. Sadowski, J. Finklestein, M. Austin, M. Requa, D. Bozinov, H. Cao.* BioNanomatrix Inc., Philadelphia, PA.

Despite significant advances in short read sequencing technology, de novo genome assemblies using only short read data are generally incomplete due to the complexities found in large genomes. This complexity, which consists of large duplications and repetitive regions, complicates short read assemblies and subsequent comparative genomic analysis. We present a nanochannel array technology that can help resolve these difficulties by providing single molecule analysis of whole genomes at several hundred kilobase scale. The technology provides a visual map of the genome at scales that span repetitive elements and other complexities, allowing more complete short read scaffolding. The system consists of a high resolution imager, disposable nanochannel array chips and software for converting the raw image data into mapped results. The technology is demonstrated here though whole genome mapping of model organisms.

934F

Miniaturize Genotyping Reactions with the Echo® Liquid Handler. *T. Allison, C. Glazer, J. Barco, S. Datwani.* Labcyte, Sunnyvale, CA.

Advances in miniaturization of genotyping assays have tremendously improved reaction throughput, but not without challenges. Efforts to reduce reagent costs have led to higher risks for variability, cross-contamination and additional validation for new detection equipment. Tipless, touchless transfers with the Labcyte Echo® liquid handler eliminate the need for costly disposable tips, wash cycles and greatly simplifies assay development efforts. Precise and accurate drop placement eliminates cross-contamination, while offering the flexibility to transfer from any well of a source plate to any well of a destination plate. This work highlights the ability to transfer nanoliter quantities of PCR reagents for 384-well genotyping analysis utilizing the Roche LightCycler® 480 system. With zero cross-contamination as demonstrated by interleaving positive and negative controls, standard deviations less than 0.25, and CVs less than 1.25%, we demonstrate that the Echo platform ideally suited for miniaturized genotyping assays.

Taking Life Technologies' SOLiD™ Total RNA Seq Kit to the Next Level. *D.M. Batten, N. Hernandez, C. San Jose Hinahon, J. Gu, K. Lea, J. Brockman, J. Schageman, P. Whitley, S. Heater, K. Bramlett.* Life Technologies, Austin, TX.

As next generation sequencing (NGS) technologies continue to evolve and become more readily available to the every day consumer, the need for simple, fast and flexible workflows is a necessary requirement. NGS users are no longer limited to the scientists in the lab but now include an array of consumers and the library preparation methods must be amendable to their equipment and capabilities. Life Technologies' SOLiD™ Total RNA-Seq Kit produces the highest quality RNA-Seq libraries for the NGS market. However, the workflow contains technically challenging steps, is time consuming and is not designed for processing large numbers of samples in parallel. To address these difficulties we introduced beads for purification and size selection, shortened the ligation time and created stable mastermixes to ease the transition onto XYZ platforms. These changes in workflow resulted in over a 82% decrease in the total number of user steps to create a whole transcriptome RNA-Seq library and reduced total bench time from 1.5 days to just over 5 hours. The data is of the same quality and scope as the original SOLiD™ Total RNA-Seq kit. In addition, we have included guidelines with specific details on using lower input RNA into the workflow and new fragmentation methods to allow for more sample flexibility. These changes to the library workflow make it simpler and faster with increased flexibility for the NGS user and demonstrate the evolution of the SOLiD™ Total RNA-Seq kit to generate high quality libraries.

936F

Exome capture of cDNA increases ability to detect splice junctions and low level transcription. *L. Feuk, J. Halvardson, A. Zaghlool.* Dept of Immunology, Genetics & Pathology, Rudbeck Laboratory, Uppsala University, Uppsala, Sweden.

RNA sequencing has become a standard method to measure gene expression, identify alternative splicing and to characterize novel transcript. Compared to array based measures of expression, RNA-seq benefits from providing an unbiased view of the genome without the need to select probes representing putative exons. There is also less of a saturation effect in RNA-seq, and therefore a better linear increase from transcripts of low expression to transcripts exhibiting very high levels of expression. However, since there is a limited number of reads in a given sequencing experiment, highly expressed transcripts will use up a very large fraction of the reads, potentially at the expense of transcripts present at low levels. As an alternative way to measure transcription, we have converted RNA to cDNA and then used standard exome capture followed by sequencing. We find that this approach leads to detection of transcripts expressed at very low levels compared to RNA-seq of total RNA from the same samples. We also find that exome capture of cDNA leads to detection of a larger number of splice junctions, as more exons are represented in the sequencing results. Several novel human exons are also identified using this approach, primarily representing alternative splice variants or alternative 5' exons expressed at low levels. Replicate experiments of the same samples indicate that measures of expression are highly consistent between experiments, but that the relative expression between genes is a poorly correlated with total RNA-seq data from the same biological sample. By using data from exome capture of DNA, where we know that the copy number equals two, we find that we can partially normalize for probe hybridization efficiency and increase the correlation with total RNA-seq data. The results are also compared to quantitative PCR data as an independent measure of levels of expression. Our data indicates that sequence capture of cDNA is a useful method for specific applications and provides higher sensitivity than total RNA-seq for detection of low level transcription in human cells.

937F

Comparison of RNA fragmentation methods for RNA-Seq. *J. Gu, K. Lea, S. Heater, J. Schageman, K. Bramlett.* Life Technologies, Austin, TX.

RNA-Seq technology enables global transcript analysis in an unprecedented level of sensitivity, accuracy and complexity. Unfortunately, due to the limitation on the read lengths using current sequencing technologies, RNA/cDNA fragmentation step is indispensable in order to get uniformly distributed reads within the transcripts they represent. The assumptions underlying a number of RNA-Seq analysis approaches have been based on randomness and uniformity of RNA hydrolysis. However, recent data has revealed that both positional and sequence-specific biases exist in sequenced fragments. To evaluate the biases from different fragmentation methods, we constructed libraries from Hela polyA RNA using either enzymatic (RNase III) or chemical/physical fragmentation methods (Mg^{++}, Zn^{++}, heat or sonication) in combination with SOLiD™ Total RNA-Seq kit. Triplicate libraries from each method were sequenced on SOLiD™ V3.5 system with 25-35 million reads obtained from each library. Data analysis indicated similar mapping statistics across methods with the exception of sonication which gave the lowest percentage of mapped reads and detection sensitivity. Spearman correlations on RefSeq were overall high (>0.95) with the highest between heat and sonication methods (0.991). Enzymatic and chemical fragmentation (Mg^{++} and Zn^{++}) methods also showed very high correlation (0.986), which indicated comparable performance for transcript quantification. To evaluate complexity of libraries, percentages of unique genome positions were calculated. Results indicated that libraries from chemical fragmentation using Mg^{++} or Zn^{++} were the most complex ones with more than 60% unique genome positions, while libraries made by sonication were the least complex, with only about 40% unique positions. Further analysis on the nucleotide frequencies at RNA cleavage sites confirmed that chemical fragmentation generated the least bias. Our results indicated that even though the mechanisms of RNA fragmentation were very different for different methods, little impact has been observed on transcript quantification. However, chemical fragmentation using cation is more preferred for exon quantification as well as SNP detection since it provides relatively uniform coverage within the transcripts. To further reduce the biases, it requires not only improvements on fragmentation method, but also development of bioinformatic correction approaches.

Enabling RNA-seq on the Ion torrent PGM. *B. Sanderson, N. Hernandez, D. Batten, J. Cienfuegos, J. Gu, S. Heater, K. Lea, L. Qu, C. San Jose, M. Gonzales, K. Bramlett.* Transcriptome Analysis Group, Ambion, Austin, TX.

The Ion Torrent, Personal Genome Machine (PGM) is a Next Generation Sequencing instrument with immense potential for both research and clinical purposes. As various applications for this platform are introduced and the Ion One Touch automated sample preparation system comes online, RNA whole-transcriptome library construction kits will provide an important addition to the functionality of the instrument. We will report on development work currently being completed which will enable RNA-seq on the PGM. We will also introduce the External RNA Controls Consortium (ERCC) spike-in RNA controls. The ERCCs consist of a blend of 92 RNA transcripts of varying lengths and concentrations which can be deployed to measure experimental sensitivity and ensure RNA library quality control. These RNA library reagents and controls, in conjunction with the PGM instrument capabilities and continuous workflow improvements, will empower users to achieve quality sequencing data that is an accurate representation of RNA content and expression levels in experimental samples.

Detection of Genomic Components in a DNA Mixture using Allele-Specific Real-Time PCR Assays Targeting Insertion/Deletion Polymorphisms. *R. Fang, M. Schumaker, D. Merrill, SN. Liew, MR. Furtado.* Life Technologies 850 Lincoln Centre Drive Foster city CA 94044.

The need to discriminate between genomes of any two individuals is critical in post transplant chimeric research, forensic, and pharmacogenomic samples. The most commonly used methods, such as STR and FISH analysis, are labor intensive and involve multi-step workflows with sensitivity levels >1% (1 copy of allele A in 100 copies of allele B). We have developed a real-time quantitative PCR assay using TaqMan® for these applications. A panel of highly informative bi-allelic insertion/deletion (INDEL) markers were selected and used to design allele-specific real-time PCR assays. The resulting assays comprise an easy-to-use workflow that consistently reach a sensitivity level of <0.1%of minor genotypes. A panel of INDEL markers were chosen with a high minor allele frequency (0.2-0.5) across multiple populations. Allele-specific TaqMan® assays were developed using a propriety TaqMan® assay design algorithm and pipeline. Assays were screened for efficiency and specificity (deletion assay does not amplify DNA containing known insertion etc.) using ninety-one gDNA's consisting of African Americans and Caucasians. Assays meeting specific requirements were first tested on DNA mixtures which consisted of 14, 2-fold serial dilutions of “recipient” DNA in “donor” DNA and vice versa. Dilutions ranged from 1:0 to 1:8192 (250 ng to 15 pg). Twenty-nine INDEL assays were subsequently tested on three CEPH families. Our results show that these assays can sensitively detect a minor genotype in a mixture with high reliability. The maximum sensitivity attained for a single INDEL assay set was 0.006%; (15 pg of minor component in 250 ng of the major component). The polymorphisms selected are also highly genetically informative and comparable with the STR technology. When testing the CEPH samples, the average probability of identification between two individuals in a mixed sample was determined to be 4.0 x 10e-11. In addition, the INDEL assays we sued had genotype ratios conforming to Hardy-Weinberg expectations. In summary, the assay panel we developed can be used for rapid, sensitive, and accurate quantitative measurement of mixed genomic samples and can be effectively used in tissue or cell transplantation research.

940F

LifeScope software; easy analysis of high accuracy next-generation sequencing for the 5500 Genetic Analyzer using ECC chemistry. *F.C.L. Hyland, S. Utiramerur, H. Breu, Y. Lou, C. Yang, M. Sikora, S. Datta, X. Xu, E. Tsung, D. Brinza.* Biological Information Systems, Life Technologies, Foster City, CA 94404.

A substantial barrier to adoption of next-generation sequencing technologies is the challenge of data analysis. In addition to computational, algorithmic, and application needs, the rapidly growing throughput of next-generation sequencers necessitates sample management, reference management, and project management, as well batch analysis of many samples. These needs are addressed by the new LifeScope software. LifeScope™ software provides support for a number of common research workflows, including whole genome sequencing (mapping, SNP and InDel detection, and detection of structural variations, copy number variation and inversions, and annotation); targeted resequencing (mapping, enrichment reporting, SNP and indel detection and annotation); whole transcriptome analysis (customized mapping to genome and exon junctions: reporting of coverage, gene and exon counts, and detection and annotation of exon junctions and gene fusions); small RNA analysis (customized mapping, detection and annotation of known and novel microRNAs, including counts and coverage) ; and mapping for applications such as methylation, ChipSeq, and SAGE. LifeScope software is available via cloud computing, or on local hardware. Rich summary statistics and graphical reporting of results are available for QA and for a fast overview of an experiment.

Emerging high throughput next-generation sequencing technologies provide the ability to sequence genomes at high coverage and low cost. The extremely high accuracy available on the 5500 Genetic Analyzer, enabled by the new Exact Call Chemistry (ECC), and advanced decoding algorithms, makes possible research applications that rely on high accuracy, such as accurate calling of SNPs, insertions and deletions; low frequency variant detection, including discovery of somatic mutations in cancer cells; detection of exon junctions and gene fusions, and de novo assembly. LifeScope software embeds two algorithmic approaches to maximize accuracy with the ECC chemistry and to produce up to 99.99% accurate base sequence. (i) The first is enabled by the redundancy inherent in high coverage color-space data. (ii) The second is a BCJR decoding algorithm for ECC data, using multiple orthogonal readings of the same DNA fragment.

For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.

941F

Low-Cost, High-Throughput DNA Fingerprinting for DNA Quality Control in a Biobank Setting with Fluidigm SNPtype™ Assays. *S.N. Meyers[1], K. Ilic[1], X. Wang[1], G. Sun[1], W. Hwang[1], Y. Yi[1], J.A. Tischfield[2], A.I. Brooks[2], M.A. Unger[1], R.C. Jones[1], J. Wang[1].* 1) Fluidigm Corporation, South San Francisco, CA USA; 2) Rutgers University Cell and DNA Repository, Human Genetics Institute of New Jersey, Department of Genetics, Rutgers University, Piscataway, NJ USA.

Analytical and functional quality control and assurance are of paramount importance to all biorepositories and investigators using biobank samples for a variety of basic science and clinical applications. All archived and distributed samples must be of high quality, suitable for downstream applications and properly annotated. Analytical quality assessment of genomic DNA can quickly be performed by a variety of established methods. However, such methods cannot reveal potential sample contamination or mislabeling issues, nor can they assess sample performance for future PCR-based applications such as genotyping or next-generation sequencing. To this end, we have developed a rapid, reliable, low-cost and high-throughput DNA fingerprinting method for use in functional quality control. This solution pairs the ease and flexibility of Fluidigm Dynamic Array™ Integrated Fluidic Circuits (IFCs) with a new, low-cost genotyping panel of 96 Fluidigm SNPtype™ Assays for the determination of sample contamination, uniqueness, gender and ethnicity. New software features have also been implemented for data management and analysis. Here we describe the use of this product for assessing the quality of human gDNA samples in a biorepository setting and demonstrate data concordance with existing TaqMan® SNP Genotyping Assays. Call rates >99% as well as >99.75% accuracy have been achieved, qualifying this method as a standard quality control procedure for use by all biorepositories and investigators analyzing DNA.

942F

Using whole blood to create induced pluripotent stem cells (iPSCs) for the study of Autism spectrum disorders. *B. DeRosa[1], J.M. Vance[1,2], M.A. Pericak-Vance[1,2], D.M. Dykxhoorn[1,2].* 1) John P. Hussman Institute For Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) John T. Macdonald Foundation Department of Humans Genetics, University of Miami Miller School of Medicine, Miami, FL.

Autism spectrum disorder (ASD) refers to a group of neurodevelopmental disorders which are characterized by impaired reciprocal social interaction, repetitive movements, and difficulties in communication. The rapid development of high content genotyping and next generation sequencing platforms has made it possible to identify a variety of genetic variations that are correlated with ASD, including rare variants and copy number variants (CNVs). However, it is often unclear what role these variations are playing in the pathophysiology of autism. This difficulty in understanding the biological role that specific genetic variations are playing in the development of autism is compounded by the lack of appropriate model systems and tissue from patients. iPS technology, experimentally-derived stem cells produced from somatic cells by the enforced expression of a cocktail of transcription factors, could prove to be a powerful approach to uncover the impact that specific genetic variations have in development of key brain cell types . A collection of iPSC lines were developed from a diverse cohort of individuals with ASDs. To avoid the need for skin biopsies, we developed a protocol to derive iPSC lines from peripheral blood mononuclear cells. To investigate the impact that ASD may have on cellular functionality of these developing cells, these pluripotent lines were differentiated into GABAergic and glutamatergic neurons. These cells were investigated for mechanisms involving neurodevelopment, neuron morphology, and synaptic activity.

944F

Changing facial phenotype in Cohen syndrome: towards clues for earlier diagnosis. *S. EL CHEHADEH-DJEBBAR[1], E. BLAIR[2], M. HOLDER[3], A. MONCLA[4], A.M. FRANCES[5], M. RIO[6], F.G. DEBRAY[7], P. RUMP[8], A. MASUREL-PAULET[1], N. GIGOT[9], P. CALLIER[10], L. GUENEAU[11], L. DUPLOMB[11], B. ARAL[9], F. HUET[1], C. THAUVIN-ROBINET[1,11], L. FAIVRE[1,11].* 1) Centre de génétique, CHU de Dijon, Dijon, France; 2) Department of Clinical Genetics, Churchill Hospital, Headington, Oxford, United Kingdom; 3) Service de Génétique, Hôpital Jeanne de Flandres, Université de Lille, Lille, France; 4) Département de Génétique Médicale, Hôpital d'Enfants de la Timone, Marseille, France; 5) Service de Génétique, Hôpital Font-Pré, Toulon, France; 6) Département de Génétique, Hôpital Necker - Enfants Malades, APHP, Paris, France; 7) Service de génétique humaine, CHU Sart Tilman, Liège, Belgique; 8) Department of Genetics, University Medical Center, Groningen, The Netherlands; 9) Laboratoire de Génétique Moléculaire, Plateau Technique de Biologie, CHU Dijon, France; 10) Laboratoire de Cytogénétique, Plateau Technique de Biologie, CHU de Dijon, France; 11) Equipe GAD, Université de Bourgogne, Dijon, France.

Cohen syndrome (CS) is a rare autosomal recessive condition caused by mutations and/or large intragenic rearrangements in the VPS13B gene and characterized by mental retardation, typical facial dysmorphism, childhood hypotonia, post-natal microcephaly, truncal obesity, slender extremities, joint hyperextensibility, myopia, progressive chorioretinal dystrophy and intermittent neutropenia, which are the two hallmarks of this syndrome. Typical facial dysmorphism tends to evolve with age and comprises thick hair and eyebrows with low hairline, downward slanting and wave shaped palpebral fissures with long eyelashes, and a prominent and beak shaped nose with high nasal bridge. The philtrum is usually short and upturned leading to an open mouth expression and appearance of prominent central incisors with a grimacing smile. The diagnosis is generally raised during adolescence, when chorioretinal dystrophy is diagnosed, therefore excluding accurate genetic counselling and reproductive choices. The aim of this work is to analyse facial dysmorphism through ages, in order to try to find clues for earlier diagnosis. Photographs of 18 patients with molecularly proved CS were transmitted by the parents, from birth to school age, and when possible to adulthood. Comparing their facial phenotype at subsequent ages together with literature data, we confirmed that the typical facial characteristics of CS are usually not noticeable before 3 years of age. However infants with CS already share some common facial features that tend to change with advancing age. We also observed older patients presenting with an atypical facial phenotype, making the diagnosis difficult to suggest on clinical examination only. These observations emphasize the importance of neutrophils blood count and ophthalmologic tests, especially electroretinography, in the work-up for children in preschool age presenting with developmental delay, persistent hypotonia and the described facial features, for earlier diagnosis of CS.

945F

ZEB2 missense mutations leading to an unusual presentation of Mowat-Wilson syndrome with moderate intellectual disability. *J. Ghoumid[1,2], A. Briand-Suleau[1,2], L. Drevillon[1,2], L. Goodwin[3], A. Moncla[4], P. Raymond[1], N. Bondurand[2], A. Amiel[5], M. Goossens[1,2], S. Lyonnet[5], D. Mowat[6], I. Giurgea[1,2].* 1) Department of Genetics, Hôpital Henri Mondor, Créteil, France; 2) INSERM U955, IMRB équipe 11, Hôpital Henri Mondor, Créteil, France; 3) Department of Clinical Genetics, Nepean Hospital, Sydney, Australia; 4) Département de Génétique Médicale, Hôpital des enfants de la Timone, Marseille, France; 5) Département de Génétique et INSERM U781, Hôpital Necker Enfants-Malades, Paris, France; 6) 5Department of Clinical Genetics, Sydney Children's Hospital, Sydney, Australia.

Mowat-Wilson syndrome (MWS, MIM#235730) is an intellectual disability-multiple congenital anomalies syndrome characterized by severe intellectual disability, epilepsy, agenesis of the corpus callosum, distinctive facial dysmorphism, heart defects, urogenital malformations and Hirschsprung disease. ZEB2 truncating mutations or deletions are disease causing. SIP1 (Smad Interacting Protein 1), the encoded protein, is a two-handed zinc finger/homeodomain transcriptional factor. Two separate clusters of zinc fingers have been characterized (in N-terminus and in C-terminus), and both must bind for transcriptional regulation. SIP1 target genes are numerous, and the best characterized is E-cadherin. SIP1 is early expressed by several tissues during embryonic development, including the neural crest, neuroepithelium, limb buds. We report two patients with heterozygote missense ZEB2 mutations (c.3164A>G, p.Tyr1055Cys; c.3211T>C; p.Ser1071Pro) localized in the C-terminus zinc finger, and possibly resulting in ADN/protein interactions. We performed in vitro functional tests, using the luciferase reporter system. The p.Ser1071Pro mutation abolished transcriptional repression of SIP1 on the E-Cadherin promoter, whereas, the p.Tyr1055Cys mutation, decrease this repressive activity in one neuroblastoma cell line (SHSY-5Y) only. Functional results correlate with patients' phenotypes, as the patient with the p.Ser1071Pro mutation was more severely affected (more obvious facial dysmorphy and epilepsy) than the patient with p.Tyr1055Cys, which presented only moderate intellectual disability and mild dysmorphism. In conclusion, we report a less severe clinical presentation of MWS with moderate intellectual disability and no malformations ascribed to ZEB2 missense mutations.

946F

Long-term clinical follow-up of a boy with a *de novo* deletion 12p13.33-p13.32 and duplication 12p13.2-p11.1 characterized by microarray-CGH. *A. Iglesias.* Dept Pediatrics, Div Gen, Beth Israel Med Ctr, New York, NY.

Deletions/duplications of chromosome 12p are extremely rare. A patient is presented. A full term boy was born vaginally after an normal pregnancy. Birth weight was 2,880 gr., length 46.5 cm and head circumference (HC) 32 cm. Jaundice, thrombocytopenia, pulmonary hypertension and persistent ductus complicated the newborn period. Except for the neonatal thrombocytopenia, all complications resolved. No major dysmorphic features were noted except beaked nose and apparent hypertelorism. Family history was negative. At one month of age his weight, length and HC were in the 5th percentiles. Folded helices, beaked nose, hypertrichosis in his back and arms, and 7 café-au-lait (CAL)spots larger than 0.5 cm were noted. Development was appropriate. Chromosomes were 46, XY, add (12)(p13.3). Parents were normal. Microarray-CGH showed a *de novo* 2 Mb del 12p13.33-p13.22 and a 23.4 Mb dup 12p13.2-p11.1. Follow-up was done at 4 ½, 7 ½, 12, and 22 months. Progressive delay in milestones, growth retardation and microcephaly developed after the first 3-4 months of life. At 6 months, dysmorphic features included microbrachycephaly, narrow forehead, thin eyebrows, horizontal palpebral fissures, hypertelorism, depressed nasal root, beaked nasal bridge, bulbous nasal tip, anteverted nares, short philtrum, thin upper vermilion, folded helix, left supernumerary nipple, umbilical hernia, hypertrichosis, 7 CAL spots larger than 0.5 cm and muscle hypotonia. No other features of neurofibromatosis type 1 (NF1) were seen. Questionable small testicles were noted lately. Growth and development while on therapies and dietary supplements have being steady, but poor. Currently, he is a 22 month-old boy with growth retardation, microcephaly, developmental delay and dysmorphic features with a de novo complex chromosome 12 aberration. To our knowledge, this is the first reported patient combining a deletion/duplication in chromosome 12p encompassing bands 13.33-13.32 for the deletion and a larger duplication at 13.33-13.11.1. Although phenotypic features share findings previously found in both deletion and duplications 12p, his phenotype seems unique. Moreover, it has been evolving over time and it seems to be currently well established. The presence of the café-au-lait spots has not been reported in previous cases and is intriguing. Continuing his clinical follow-up and testing for NF1 will be done to better assess his phenotype and to better characterize this chromosome aberration.

947F

A Population Study of Prader-Willi Syndrome in Chinese. *S. Lam, H. Luk, T. Tong, K. Lai, I. Lo.* Department of Health, Clinical Genetic Service, Hong Kong, Hong Kong, Hong Kong.

Background: This is a retrospective study of all Chinese Prader-Willi Syndrome (PWS) patients diagnosed at Clinical Genetic Service (CGS), the only genetic referral centre in Hong Kong, from 1995 to 2010. PWS is a complex neurodevelopmental disorder with multisystem involvement. It is caused by haploinsufficiency of paternally expressed genes in the imprinted domain on chromosome 15q11-q13, as a result of mainly three different genetic mechanisms, namely paternal microdelection, maternal uniparental disomy (UPD) and imprinting centre defect. DNA-based methylation analysis of the SNRPN locus by methylation specific polymerase chain reaction (MS-PCR) is the mainstay of genetic test which is positive for over 99% of cases. Fluorescence in-situ hybridization (FISH) is used to confirm microdeletion. Microsatellite analysis is used to confirm maternal UPD. Imprinting centre defect is diagnosed by exclusion. Population studied: A total of 62 cases of PWS were confirmed by methylation study in CGS from 1995 to 2010, 55 of whom were Chinese. The total estimated Chinese births in Hong Kong during this period was 902,224, the incidence of Chinese PWS was hence 1 per 16,404 live births, which is comparable to other parts of the world. Genotype and phenotype analyses: In this cohort of Chinese PWS, 57% was caused by paternal microdeletion, 41% by maternal uniparental disomy and 2% by imprinting center defect. For their clinical features, 89% had severe hypotonia and 77% have significant feeding difficulty during the neonatal period. Early onset hyperphagia and obesity developed in 77% of cases. 51% had moderate- severe intellectual disability. For the 14 adults in this cohort, 14% developed type 2 diabetes mellitus that required therapy. Conclusion: This is the first population study of PWS in Chinese. The incidence, clinical features and pattern of underlying genetic defect is comparable with other western populations. Early accurate diagnosis and multidisciplinary management are important for caring PWS patients. With more understanding of underlying pathophysiology and the use of growth hormone among selected PWS patients, it is expected that their quality of life and life expectancy will be greatly improved.

948F

Deletion of the MBD5 gene is associated with a distinct phenotype. *G.J. Noh, J.M. Graham, Jr.* Medical Genetics Institute, Cedars-Sinai Medical Center, LA, CA.

Epilepsy is one of the most common and genetically intricate neurological disorders in children. Previous studies have shown that chromosomal abnormalities impart susceptibility to epilepsy. Since the introduction of the array CGH, several new deletion and duplication syndrome have been delineated, giving rise to clinically recognizable phenotypes. We report a 2 year old female who initially presented with seizures, developmental delay and dysmorphic features who was found to have a 0.3 Mb deletion at chromosome 2q23.1 encompassing the critical seizure gene, MBD5. Her distinct physical features include bifrontal narrowing with brachycephaly, low anterior hairline, hypotonic facial features with short upturned nose, flat nasal bridge, hypertelorism, tented upper lip with everted lower lip, downturned corners of her mouth, and relatively coarse facial features including thickened tongue. She also had a short neck, brachytelephalangy, clinodactlyly, and hypertrichosis. At 3 ½ years of age, she developed progressive ataxia; and at the age of 4, was able to stand only when holding onto objects when she had starting walking at the age of 2. She also lost vocabulary that she had previously acquired, placing her language skills at the 24 month level. Regression has been reported in one other case of MBD5 deletion. MBD5 is a member of the methyl binding gene family and appears to be responsible for regulating DNA methylation in the central nervous system. Our patient was entirely deleted for this single gene, which suggests that haploinsufficiency of MBD5 is responsible for the distinct phenotype observed. This supports the hypothesis that MBD5 is indeed the critical gene implicated for the findings seen in patients with deletions of chromosome 2q23.1. Further studies are necessary to delineate the role that the MBD5 gene plays in the development of the brain and physical characteristics.

Copy Number Variation Analysis in Cohesion/Condensin genes by a CGH in Cornelia de Lange Syndrome Patients. *D. Pehlivan[1], M. Hullings[2], C.M.B. Carvalho[1], C.G. Gonzaga-Jauregui[1], E. Loy[2], L.G. Jackson[3], I.D. Krantz[2,4], M.A. Deardorff[2,4], J.R. Lupski[1,5,6].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Human Genetics, The Children`s Hospital of Philadelphia, Philadelphia, Pennsylvania, USA; 3) Department of Obstetrics and Gynecology, Drexel University School of Medicine, Philadelphia, Pennsylvania, USA; 4) University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA; 5) Department of Pediatrics, Baylor College of Medicine, Houston, Texas, USA; 6) Texas Children`s Hospital, Houston, Texas, USA.

Cornelia de Lange syndrome (CdLS) is a multisystem malformation syndrome diagnosed primarily on the basis of characteristic facial dysmorphism, intellectual disability/developmental delay, extremity abnormalities and hirsutism. About 60-65% of the cases of CdLS are due to mutation in the NIPBL, SMC1A and SMC3 genes. Since it has been shown that NIPBL is a dosage sensitive gene, we proposed that large genomic rearrangements of cohesion/condensin complex subunit genes may play a role in the molecular etiology of CdLS. We designed an Agilent Custom 8x60K comparative genomic hybridization (CGH) array to analyze copy number variations (CNV) in all cohesion and condensin complex subunit genes; 46 genes and 50 kb up/down stream of those genes have been in our array. To date, array CGH was performed in 162 patients with CdLS, for whom mutations in known CdLS genes were previously negative by sequencing. In seven subjects deletions containing NIPBL exons, ranging in size from 4 kb to 750 kb, were detected (~5%). Breakpoint junctions were obtained in five out of seven patients; which implicated microhomology mediated replicative mechanisms (such as SRS and FoSTeS/MMBIR) as a predominant contributor to these CNVs. Genotype-phenotype correlations suggest patients with larger deletion tend to have more severe growth retardation than those smaller deletions. In two patients we found deletion in NCAPD3 of 3 kb and 6 Mb sizes. Breakpoint analyses showed a 3 kb deletion involving exons 8 to 11; apparently mediated by FoSTeS/MMBIR. Parental studies revealed that the mother carries the same deletion. Another patient was foundto have a 3.3 Mb deletion including the RAD21 gene, in twelve patients deletion and duplication CNVs of exon 2 of SMC4 were identified, and in one patient 10 kb in size deletion of 30 kb upstream of SMC6 and in one patient 3 kb in size deletion of 250 bp downstream of PTTG1 were detected. These findings suggest the identifcation of rare CNV by aCGH may be a cost-effective approach to discover additional CdLS genes. RAD21, NCAPD3, PTTG1, SMC6 and SMC4 are amongst potential candidate genes for the remaining cases. Furthermore, exonic deletion rearrangements of NIPBL are responsible for ~5% of cases. Thus, screening for CNVs may be clinically prudent in mutation negative CdLS cases. Replicative mechanisms, especially FoSTeS/MMBIR, appear to be a prominent underlying mechanism for NIPBL deletion CNVs. Larger deletions convey a more severe phenotype.

950F

Nail-Patella Syndrome (NPS): Of a New Case. *E.J. Ramirez-Lizardo[1,2], S.E. Totsuka Sutto[1], T.A. Garcia Cobian[1], L. Garcia Benavides[1], D. Roman Rojas[3], E.G. Cardona Muñoz[1].* 1) Unidad de Inv Cardiovascular, CUCS Univ de Guadalajara; 2) Instituto Jalisciense de Cirugia Reconstructiva, SSJ; 3) Doctorado Farmacologia CUCS.

Nail-Patella syndrome (NPS; OMIM #161200), also known as Hereditary Osteoonychodysplasia, Turner-Kieser syndrome, Fong disease, is a rare clinical entity autosomal dominant, is due to mutations in the LMX1B gene, is a pleiotropic condition with a classic clinical tetrad of dysplastic finger nails, absent or hypoplastic patellae, elbow dysplasia and iliac horns (bony protuberances of the iliac). In addition abnormalities such as renal dysplasia, muscle weakness, impaired hearing, wadding gate, scapular wining and short stature may be present. The incidence is estimated at 1 in 50,000 live births. We describe a 8-years old female, who was referred to plastic surgery by bilateral antecubital pterygia. She was born after a 40-week gestation, abdominal delivery was normal without complications, psychomotor development was normal. At physical examination showed normal weight and height, enamel abnormalities, dental caries, bilateral antecubital pterygia, fingers nails dysplastic, short Achilles tendon. Radiology evaluation showed hypoplasia patellae and iliac horn. The diagnosis of NPS is based on clinical finding. Molecular genetic testing of LMX1B, the only gene known to be association with NPS, is avaible on clinical basis. The present case show a patient with NPS supported on the clinical data of dysplastic finger nails, hypoplasia patellae, bilateral antecubital pterygia and iliac horn. The history family not reveled similar clinical finding in other relatives, the father was 33 and the mother was 32 years of age at the time of birth so the autosomal dominant inheritance or germline mosaicism cannot be discarded.

951F

Genetic testing of Ras/MAPK pathway syndromes at Tohoku University. *Y. Saito[1], Y. Aoki[1,2], T. Niihori[1], Y. Abe[1], S. Kure[1], H. Ohashi[2], K. Kurosawa[2], N. Okamoto[2], H. Kawame[2], S. Mizuno[2], T. Ogata[2], S. Kuriyama[2], Y. Matsubara[1,2].* 1) Dept Med Genet, Tohoku Univ Sch Med, Sendai, Japan; 2) The Costello/CFC/Noonan Study Group, Japan.

Growing attention to Ras/MAPK pathway syndromes (RASopathies; Costello syndrome, CFC syndrome, and Noonan syndrome) and discoveries of new disease-causing genes in recent years result in sharp increase of requests for genetic testing of these disorders. Molecular diagnosis of these syndromes is often challenging because of their overlapping clinical symptoms and numerous pathogenic genes (PTPN11, SOS1, SHOC2, HRAS, KRAS, BRAF, MEK1/2, NRAS, CBL). Although ultimate solution would be the application of next-generation sequencing, the cost is prohibitively high at the moment. We have been providing genetic testing of Ras/MAPK pathway syndromes since our discovery of HRAS mutations in Costello syndrome (2005) and KRAS/BRAF mutations in CFC syndrome (2006). The tests are offered for free of charge on a research basis, because the cost is not subsidized by the national health insurance service in Japan. To maximize the efficient use of limited resource, we use practical flow charts for the molecular diagnosis of these elusive disorders. At first, detailed clinical information and photographs of the patients are collected and carefully evaluated by a group of experienced clinical dysmorphologists to exclude other anomaly conditions and to select most appropriate set of candidate genes to be analyzed. The “Noonan set” includes selected exons of PTPN11, KRAS, SHOC2 and RAF1 genes. The “Costello/CFC set” includes selected exons of HRAS, BRAF and MEK1/2 genes. When no mutation is identified by either set, all coding exons in SOS1 are analyzed. Mutation-negative cases are re-evaluated by dysmorphologists, analyzed for other missing exons of relevant genes, and subsequently subjected to exome sequencing by next-generation sequencer to search for novel disease-causing genes. We found thorough clinical evaluation of the case is one of the most critical and important steps in efficient genetic testing.

952F

A case of hemiparesis, hemihypoplasia, and athetoid posture with unilateral vision loss - An example of a very rare disorder: familial porencephaly. *H. Ulucan[1], A. Koparir[1], M. Seven[1], E. Yosunkaya[1], G. Guven[1], M. Ozen[1], A. Yuksel[2].* 1) Dept of Medical Genetics, Cerrahpaşa Medical Faculty of Istanbul University, Fatih, Istanbul, Turkey; 2) Dept of Pediatrics, Medical Faculty of Bezm-i Alem University, Istanbul, Turkey.

We describe a 33-year-old female referred to us for unilateral vision loss, suggested to be Leber's optic atrophy by optalmologists.Her medical history and physical examination revealed that she suffered from unilateral hemiparesis, hemihypoplasia,and athetoid posture affecting the right side of her body since infantile period. Her mother described a single occurrence of non-febrile convulsion when she was 13 years old. Family history is remarkable with a maternal grand-mother with hemiplegia,multiple paternal relatives with migraine, a paternal female cousin with mental retardation, and a younger brother deceased from ischemic encephalopathy, and a living sister with mild unilateral hemihypoplasia. Magnetic resonance imaging of the current case showed a cranial cyst, and pulmonary stenosis appeared on echocardiography. Familial porencephaly is a very rare developmental abnormality of the brain, which is mainly characterized by cranial cysts, hydrocephaly, hemiplegia, seizures, and visual defects. We initially considered this disorder in differential diagnosis for the present case. Additionally, hereditary non-progressive athetoid hemiplegia (HHHH), which was reported once in 1977, is a very rare disorder,characterized by hemiparesis, hemihypoplasia, and unilateral atheoid posture. However, in succeeding case reports, HHHH was also interpreted as infantile hemiplegia with porencephaly. Conclusively, we are conducting molecular studies for Leber's optic atrophy and for collagen type IV, alpha-1 gene (COL4A1) mutations, reported to be responsible from familial porencephaly.

953F

Mandibulofacial dysostosis and bowed femora: a new syndrome. *K.N. Weaver[1,2], E.A. Sellars[1,2], P.L. Bender[1], C.B. Gordon[3,4], H.M. Saal[1,2,3].* 1) Div Human Genetics, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH; 2) Department of Pediatrics, Cincinnati Children's Hosp Med Ctr, Cincinnati, OH; 3) Division of Plastic Surgery, Cincinnati Children's Hosp Med Ctr, Cincinnati OH; 4) University of Cincinnati College of Medicine, Cincinnati, OH.

At least five mandibulofacial dysostoses have been described in the literature, with Treacher Collins Syndrome being the best-known of these disorders. Common features to all include variable degrees of maxillary and mandibular hypoplasia, defects of the orbits and eyelids, ear anomalies, and hearing loss. A related group of disorders are the acrofacial dysostoses, which have similar craniofacial anomalies in addition to distal limb defects. We report a patient with severe mandibulofacial dysostosis and bowed femora, which is a combination of features that has not previously been described. The patient was identified prenatally as having craniofacial anomalies including severe micrognathia necessitating delivery via EXIT procedure, with a tracheostomy performed prior to discontinuation of placental circulation. Initial physical examination showed bilateral lower eyelid colobomas, bilateral anotia, maxillary hypoplasia, micrognathia, complete clefting of the secondary palate, and short lower limbs with bowed femora. Colobomas were so severe that there was essentially no lower eyelid present. There were no radial or distal limb anomalies. Facial CT with 3D reconstruction revealed bilateral absence of the mandibular rami and zygomata. Genetic testing has included normal chromosomes, SNP microarray, and TCOF1 sequencing. The family history was negative for deafness, cleft lip, cleft palate, or other birth defects. This patient's features are not consistent with any of the previously described mandibulofacial or acrofacial dysostosis syndromes because of the severity of the craniofacial defects and the presence of femoral abnormalities without pre- or post-axial limb defects. To our knowledge, this is the first reported case of a patient with this constellation of anomalies and therefore it likely represents a new mandibulofacial dysostosis. It is our hope that further cases can be identified to help delineate etiology and natural history.

954F

Birth prevalence rates of osteochondrodysplasias (OCD) in South America (SA): an epidemiologic study in a large population. *C.O.B. Buck[1], I.M. Orioli[2], E.E. Castilla[3,5], J.S. Lopez-Camelo[4], M.G. Dutra[5], D.P. Cavalcanti[1].* 1) Depto. Genética Médica, FCM/Unicamp, Campinas, São Paulo, Brazil; 2) Dept de Genética - Laboratório de Epidemiologia de Malformações, UFRJ, Rio de Janeiro, Rio de Janeiro, Brazil; 3) Dirección de Investigación, CEMIC: Centro de Educación Médica e Investigaciones Clínicas, Buenos Aires, Buenos Aires, Argentina; 4) Dept Genética, IMBICE: Instituto Multidisciplinario de Biologia Celular, La Plata, La Plata, Argentina; 5) Laboratório de Epidemiologia de Malformações Congênitas, Instituto Oswaldo Cruz, Fundação Oswaldo Cruz, Rio de Janeiro, Rio de Janeiro, Brazil.

The osteochondrodysplasias (OCD) birth prevalence rate of 2.0/10,000 is underestimated. This study aimed to assess OCD epidemiology using a large population in SA with the ECLAMC (a case-control, collaborative hospital-based program for birth defects) data. All OCD cases from ECLAMC files born between 2000-2007 were revised and diagnosis ranked in five evidence levels, taking level 1 as gold-standard, having available X-rays or DNA test. EpiInfo™3.5.8 was used for statistical analysis, and significance was defined as p value < 0.05. For comparative analysis all controls born in the same period were used. Prevalence rates are shown by 10,000 births. After excluding 44 from 536 ascertained cases, the prevalence in 1,544,496 births was 3.2 (CI 2.9 - 3.5). Lethal cases were 50% (244/492 - 65 stillbirths plus 179 cases with early neonatal death). Prenatal diagnosis was made in 73% cases. Among the 211 cases from level 1, the main OCD groups according the ISDS were: G-25(OI) - 33% (59% OI-II); G-1(FGFR3) - 29.5% (56% Thanatophoric D); G-2(Collagen 2) - 6.7% (29% Achondrogenesis 2); G-18(Bent bones) - 8% (71% Campomelic D); G-9 (SRP) - 5.7%. The prevalence of the main OCD types were: OI - 0.72 (0.59 - 0.87); Thanatophoric D - 0.47 (0.36 - 0.59); and Achondroplasia - 0.45 (0.34 - 0.56). Paternal age (31.2 yo), parity (2.6) and consanguinity rate (5.4%) were all increased in cases ($p < 0.001$). Birth weight (2,498 g) was lower in cases, however differences were found just for gestational age over 31 weeks ($p < 0,001$). In conclusion, the OCD overall prevalence rate of 3.2 per 10,000 found seems to be more real than the usually cited value of 2.0. This study also indicates a high rate of prenatal OCD diagnosis in SA, confirmed the overall high infant morbimortality, and the association with paternal age. Finally, a high parity and rate of parental consanguinity was observed.

Molecular study of Iranian patients affected with Dystrophic Epidermolysis Bullosa. *M. Mahdavi, N. Hatamnejad, B. Sedaghati khayat, S. Abadpour, A. Yasari mazandarani, S. Matoo, A. Tavakoli tameh, A. Ebrahimi.* Parseh Medical Genetics Counselling Center, tehran iran, tehran, Iran.

Molecular study of Iranian patients affected with Dystrophic Epidermolysis Bullosa Mahdieh sadat Mahdavi; N.Hatamnejad; B.Sedaghati; Sh.Abadpour; A.Yassari; S.Matoo; A.Tavakoli; A.Ebrahimi Parseh Medical Genetics Counselling Center, Floor 7, No.75, Royan Alley,Keshavarz Bolv. Tehran, Iran Tel-Fax: +98 21 88966579,88996889 Coresponding Author:Dr. Ahmad Ebrahimi Molecular Genetics , PhD E-mail: ae35m@yahoo.com Epidermolysis bullosa is a severe skin disorder beginning at birth with several organs involvement. This is a life time onset disease that has a progressive pattern. Therefore molecular diagnosis, provide feasibility of differential diagnosis, help to controlling of the singes, suitable cure, , PND or PGD. The COL7A1 is the only responsible gene in which about 75% of mutations occur in 73-75 exons. Methods: Fifty affected patients recognized by clinical examination and antigen-antibody mapping were selected. Blood samples were collected based on genetic counseling and clinical signs then DNA was extracted. All selected coding regions of COL7A1 (73-75 exons) were amplified by intronic PCR primers and products analyzed by direct sequencing. Results: The results show that only 30% of patients have alterations in these regions of Col7A1. But direct sequencing of PCR products, showed some new sequence variations too. No large deletion was detected. This study revealed that according to heterogeneity of Iranian population the whole gene sequencing is needed. Key words: Epidermolysis, Dystrophic, COL7A1, PCR.

A *de novo* microduplication at 2q24.3 including *SCN2A* and *SCN3A* but not *SCN1A* in a patient with severe epilepsy and profound hypotonia. *M.N. Strecker[1], M. Chadehumbe[2], G. Parsons[3], P. Mark[3], S. Gunn[1], K. Hovanes[1].* 1) CombiMatrix Diagnostics, Irvine, CA; 2) Helen DeVos Children's Hospital, Grand Rapids, MI; 3) Spectrum Health Medical Group, Grand Rapids, MI.

We present a 29 month old female with severe epilepsy, global developmental delay, and profound hypotonia. **CLINICAL HISTORY** Seizures began at one month of age. EEG revealed a modified hypsarrhythmia pattern. Brain MRI demonstrated possible decreased peritrigonal white matter volume. The patient was diagnosed with infantile spasms and placed on levetiracetam and steroids, to which she had no response. She was subsequently switched to topiramate and experienced a 6 month seizure-free interval, at which point she was weaned off of topiramate. Seizures returned at 21 months of age and topiramate was restarted. Since then, she has had good seizure control. **LABORATORY STUDIES:** The patient has profound hypotonia. At 29 months of age, she continues to have significant head lag and is not able to sit unsupported. Previous testing included karyotyping, screening for inborn errors of metabolism and a muscle biopsy to look for evidence of a mitochondriopathy, all of which was normal. A 180K oligonucleotide chromosomal microarray was performed and revealed a 418 kb duplication: 2q24.3(165,602,448-166,020,886)x3, encompassing the sodium channel, voltage-gated, type II subunit alpha (*SCN2A*) and type III alpha (*SCN3A*) genes. Parental microarray studies were normal, indicating a de novo event in the child. **GENOTYPE/PHENOTYPE CORRELATIONS:** *SCN1A* and *SCN2A* have been implicated in a number of seizure disorders. The role of *SCN3A* in relation to seizure disorders is less clear. Functional studies of pathogenic *SCN2A* mutations (such as I1473M) demonstrate altered electrophysiologic channel properties leading to hyperpolarization of the neuron. Since *SCNA2* is highly expressed in the brain and skeletal muscle, we postulate that the duplication of *SCN2A* results in an increased number of sodium channels along the cell surface which leads to ultra-rapid cellular hyperpolarization. In the neuron, this manifests as neuronal hyperexcitability causing epileptiform discharges, and in the striated myocyte, leads to impaired contractile function. The patient's excellent response to topiramate (a sodium channel blocker) supports this hypothesis, however functional studies are needed to further characterize this duplication.

957F

Molecular analysis in hypotonic infants detects high incidence of Genetic diseases. *N. Najera[1], J. Perez[1], E. Barragan[2], N. Garibay[1], T. Martinez[1], L. Gonzalez[1], G. Queipo[1].* 1) Human Genetic, Hospital General de Mexico, Mexico City, Mexico; 2) Neurology, Hospital Infantil de Mexico Federico Gomez.

Neonatal central hypotonia is the lack of spontaneous movement, with or without muscular weakness, and generalized hypotonia during the neonatal period. This condition can be caused by a number of different pathological processes in the brain or defects to any structure in the motor unit. Central hypotonia affects the central nervous system, including the spine, and among its most frequent causes is systemic illness. As part of the central approach to the hypotonic baby, it is important to eliminate syndromic and genetic causes. Some reports have been proposed that 40% of the central hypotonic neonates had Prader Willi the most common genetic cause of obesity however, in children under 2 years of age the diagnosis is especially difficult. It is clear that early diagnosis of PWS o any other genetic entity is crucial to avoid complications and decrease morbidity and life expectancy. Nevertheless, other genetic syndromes have central hypotonia as main clinical manifestation during infancy. So, genetic approach is mandatory during the initial clinical intervention. We present the genetic approach in 30 consecutive pediatric patients with central hypotonia as a major symptom, referred by the neuro-pediatrician. According with the clinical genetic evaluation and presumptive clinical diagnosis, molecular analysis was performed detecting that 70% of the cases had a genetic disorder. We conclude that genetic evaluation is crucial in the central hypotonic clinical approach, proposing that all the central idiopatic hypotonic babies should be evaluated by a clinical genetic professional.

958F

Analysis of 11q22.2-q22.3 chromosomal region for genetic linkage in families with class III malocclusion from Brazil and Colombia. *J. Hartsfield[1], J. Turner[1], G. Falcao-Alencar[1], L. Otero[2], R. Cruz[3], L. Morford[1], D. Fardo[1], S. de Oliveira[4], T. Kluemper[1].* 1) Univ Kentucky, Lexington, KY; 2) Pontificia Universidad Javeriana, Bogotá, Colombia; 3) Private practice, Brasilia, Brazil; 4) Universidade De Brasilia, Brasilia, Brazil.

Objective: Class III malocclusion has an autosomal dominant inheritance with variable expressivity and incomplete penetrance. The purpose of this study was to investigate the potential genetic linkage of a section of chromosome 11 to Class III skeletal malocclusion within two populations from South America: Brazil and Colombia. Methods: Microsatellites DNA polymorphisms, microsatellites D11S1886 and D11S4204 in the 11q22.2-q22.3 chromosomal region, were previously implicated in linkage to Class III in Colombian families (LOD 2.0 and 1.8, respectively) by Frazier-Bowers et al. 2009. Our study focused on the 11q22.2-q22.3 chromosomal region and genotyped another type of DNA polymorphism, single nucleotide polymorphisms (SNPs), near D11S1886 and D11S4204 (SNPs: rs666723, rs578169, rs12416856 and rs1386719). A pedigree for each family was constructed. The affected status of family members was determined by dental charts, cephalometrics, facial and dental photos, and/or dental models. Biosamples were collected from affected and unaffected family members and genomic DNA was isolated for genotyping. SNP analysis was performed using TaqMan Genotyping Assay Kits in the Roche LightCycler480®. The program MENDEL was used to estimate genetic linkage. Results: LOD scores were obtained for all SNPs genotyped, ranging from -1.94 to -7.17. LOD scores for the Brazilian population alone ranged from 0.94 to -3.32, while LOD scores for the Colombian population alone ranged from -1.95 to -3.84. LOD scores with two large Colombia families removed these large families. Removal of the largest or two largest families from the Colombian dataset yielded LOD scores from -0.01 to -2.60 in both cases. Conclusion: Using these markers, in the families included in this study, we did not find any genetic linkage with Class III phenotype. While this does not support the earlier report of linkage in this area in another Colombian population sample, the small number and different type of markers used and the heterogeneity of Class III malocclusion does not preclude this area from further analyses in other samples or genotyping arrays. This study was supported in part by International Centre for Genetic Engineering and Biotechnology grant ICGEB CRP/COL04-03 (LMO), and the E. Preston Hicks Endowed Chair in Orthodontics and Oral Health Research at the University of Kentucky (JKH).

PRRX1 is mutated in an otocephalic newborn infant conceived by consanguineous parents. *D. Kamnasaran[2,3], P.O. Simsek[1].* 1) Clinical Genetics Unit, Department of Pediatrics, Hacettepe University, Ankara, Turkey; 2) Pediatric Research Unit, Centre de recherche du CHUL, Québec, Québec, Canada; 3) Department of Pediatrics, Laval University, Québec, Canada.

Background: Agnathia-otocephaly, is a rare, often sporadic and lethal malformation complex with an estimated incidence less than 1 in 70,000 births, and with etiologies linked to both genetic and teratogenic factors. We previously reported the *PRRX1* gene is mutated in a fetus having agnathia-otocephaly. PRRX1 is a transcription factor with pivotal roles during mandibulofacial development. In this study, we analyzed the *PRRX1* gene for mutations in a new case of a newborn infant with agnathia-otocephaly. **Methods and Results**: The proband was the third child of otherwise clinically normal and healthy parents from a consanguineous first cousin marriage. The family history was unremarkable. Autospy examinations identified the proband with synotia, an extreme hypoplastic oropharynx with a blind-ended and small stoma, hypoplastic and retropositioned tongue, hypoplastic and dysmorphic larynx and epiglottis, agenesis of the trachea-oropharynx connection, and a blind-ended proximal trachea. Furthermore, the external auditory canals were open and atretic, and there was evidence of tracheomalacia, bilateral pulmonary hypoplasia and a secundum type of atrial septal defect. Both the proband's and parents' karyotypes were normal. Molecular genetic testing was undertaken by sequencing all five exons of *PRRX1* using genomic DNA isolated from the peripheral blood lymphocytes. A homozygous G_1004_C recessive mutation was identified in the *PRRX1* transcript isoform 2 of the proband, and was bi-parentally inherited from each parent who were carriers of a heterozygous G_1004_C mutation. Only the homozygous mutation, which causes a A230P missense mutation in the OAR domain of the PRRX1 protein, results in a loss-of-function; a mutation which is unidentified in 100 normal control individuals examined, and human single nucleotide polymorphism databases. **Conclusion:** We identified a rare event which is the first homozygous loss-of-function recessive mutation in *PRRX1* in a newborn infant conceived by consanguineous parents. Findings from this study have important applications in prenatal diagnosis, and to better understand mandibulofacial development in this severe birth defect.

Fragile X Syndrome screening in Korean women of reproductive age. *M. Kim[1], D. Kim[1], J. Yang[1,2], H. Ryu[1,2], S. Park[1].* 1) Laboratory of Medical Genetics, Cheil Medical Research Institute, Cheil General Hospital & Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea; 2) Department of Obsterics and Gynecology, Cheil General Hospital & Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

Fragile X syndrome (FXS) is the most common inherited form of mental retardation after the Down syndrome. FXS is caused by expansion and methylation of a CGG repeat in the 5' untranslated region of FMR1 located Xq27.3. Although several population-based studies have established prevalence of FXS in Caucasians, only a few studies have reported prevalence of FXS in Asians. In Korea, there has been no report of population-based study on FXS except for some studies performed in selected population like mental retardation, autistic group. This study attempts to estimate the FMR1 allele distribution, the frequency of FXS permutation and full mutation in the general population. Screening tests were carried out in 5003 women of reproductive age between September 2003 and December 2010. Our study showed that 70.32% of the women were heterozygous alleles and remains were homozygous alleles for the CGG-repeat size. We found that 9,977 alleles were in the normal range (7-44 CGG repeats) and 19 alleles were in the gray zone (45-54 CGG repeats). Within the normal FMR1 alleles, the most prevalent allele was 27 (37.09%), followed by 28 (31.94%) and 34 (9.08%), respectively. Also 10 carriers were observed (a frequency of 1 in 500); 9 had a permutation and 1 had a full mutation. Prenatal diagnosis for FXS was performed in 11 pregnancies; 5 inherited the maternal normal allele, 5 had a premutation allele, and 1 had a full mutation allele. Two expansions observed when transmitted from mother to offspring. This is the first population-based study to assess the carrier frequency of the fragile X syndrome in the Korean population. Although there may be a founder effect, there is a little difference in our results compared to Caucasians. However, it is believed that these results might be valuable information to understand the fragile X syndrome in Koreans and other Asians.

Intragenic and interspecific alignment of fibrillin-1's calcium-binding EGF-like domains reveals clinically-relevant sequence constraints and improves Marfan syndrome mutation assessment. *B.A. Salisbury, T.E. Callis, L.R. Susswein, J.L. Carr, E.W. Johnson.* Transgenomic, New Haven, CT.

INTRODUCTION: Mutations in the gene *FBN1*, which encodes fibrillin-1, cause Marfan syndrome (MFS) and several other connective tissue disorders. Hundreds of causative mutations have been reported. These mutations can be grouped into various categories, some of which are included among the strong diagnostic indicators for MFS. One such category is disruption to the 47 EGF-like domains, in particular the 43 that are calcium-binding (cbEGF). We sought to identify those aspects of the domains that are most uniform and where mutations are accordingly most likely to be pathogenic. **METHODS:** We aligned the 43 cbEGF domains, which make up most of the fibrillin-1 protein sequence. After determining the most consistent features, we compared the locations of missense variants reported as case mutations at the UMD *FBN1* mutation database with those from 419 ethnically diverse, ostensibly healthy controls that we sequenced. Conservation across chimp, dog, cow, mouse, rat and chicken was also examined. **RESULTS:** The cbEGF motif that we determined for fibrillin-1 is Dx(D/N)ECmCmCx(D/N)xx(G/S)x(Y/F)xCxCmC, where m refers to a variable number of unspecified amino acids and x refers to exactly one. In the previously published motif, the first position is given as D/N and the fourth as E/Q, reflecting variation seen in cbEGF domains found in other proteins. The G/S position and fixed spacing requirements in the middle of the motif are also newly specified. These fixed elements are all almost perfectly conserved across the species. None of the 19 missense variants (18 novel; 1 previously reported as pathogenic) found in our controls altered any of the fixed aspects of these domains, whereas a large fraction of the 367 missense variants from cases in the UMD *FBN1* database did. Further, D>N mutations are found in position 1 in cases but not in position 3 reflecting the extra constraint evident for position 1 versus 3 in the cbEGF domains of fibrillin-1. **CONCLUSIONS:** The highly conserved nature of fibrillin-1 can be leveraged to improve variant classification in MFS genetic testing. By recognizing a larger set of constraints on its sequence, we will be able to ascribe pathogenicity to a larger fraction of otherwise un-characterized variants in clinical testing. Efforts like this are critical for improving the clinical utility of genetic tests that must deal with an appreciable background rate of benign genetic variants that could be confused with pathogenic ones.

962F

FCGR2A, JAK2 or HNF4A variants are associated with ulcerative colitis susceptibility in Koreans. *M. Hong, H. Kim, Y. Jung, S. Yang, K. Song.* University of Ulsan College of Medicine, Seoul, Korea.

Recent genome-wide association studies have identified over forty candidate genes contributing to ulcerative colitis susceptibility. The goal of this study was to test the reported ulcerative colitis susceptibility genes including FCGR2A, SLC26A3, JAK2, and HNF4A in Korean patients with ulcerative colitis and Crohn's disease. Five single nucleotide polymorphisms from 4 loci including FCGR2A, SLC26A3, JAK2, and HNF4A were genotyped in 661patients with ulcerative colitis, 642 patients with Crohn's disease, and 601 healthy controls Statistically significant associations with ulcerative colitis were found at FCGR2A (rs1801274, p = 2.3 x 10-4, OR = 0.70 (95% CI = 0.57-0.84) under the allelic model), the JAK2 locus (rs10975003, p = 6.7 x 10-4, OR = 1.43 (95% CI = 1.16-1.77) under the allelic model), and HNF4A (rs6017342, p = 0.002, OR = 0.66 (95% CI = 0.51-0.85) under the allelic model). The association of FCGR2A was much stronger in female patients with ulcerative colitis (p = 5.7 x 10-6) than in males (p = 0.50). Except rs10975003 from the JAK2 locus, none showed positive association with Crohn's disease. Our data suggest that FCGR2A, JAK2 or HNF4A variants play a role in the pathogenesis of ulcerative colitis in Koreans.

963F

Different Penetrance in cases of Dystrophin deletion. *C. Trujillo[1], M.K. Alwasiyah[2].* 1) Dept Gen, CES Inst, Jeddah, Saudi Arabia; 2) MOH, Jeddah, Saudi Arabia.

We report a family with a deletion of exons 45 to 49 of the dystrophin gene, detectted by MLPA test. The proband is at 18 years of age with complete motor impairment, and using a wheel chair since he was 18 years of age. His brother age 26 is almost completely asymptomatic despite of having the same deletion of exon 45 to 49 detected by MLPA, he relates some claudication when he tries to climb stairs. Muscle biopsy showed typical abnormalities associeted with Duchenne Muscular Dystrophy. We assume that there are some modifier genes related to the clinical phenotype in Muscular Dystrophy. This modifier genes are unkwon at the present.

964F

A novel mutation in the gene LEMD3 in a patient with sub-clinical Osteopoikilosis. *A.R. Couto[1,2], S. Meneses[1,2], M. Soares[1,2], J.P. Pinheiro[1,2], J. Bruges-Armas[1,2].* 1) SEEBMO, Hospital de Santo Espírito, Angra do Heroismo, Azores, Portugal; 2) Institute for Molecular and Cell Biology (IBMC), Universidade do Porto, Portugal.

Osteopoikilosis (OMIM 166700) is a rare autosomal dominant skeletal disorder characterised by the presence of multiple hyperostotic lesions in different parts of the skeleton. This disorder can occur in isolation or in association with other skin and bone dysplasias such as melorheostosis (OMIM 155950). The objective of this study was to identify putative mutations in the gene LEMD3 in affected individuals from a multiple affected Azorean family with sub-clinical osteopoikilosis - with scarce and negligible hyperostotic lesions. The investigated family is a two-generation family of Azorean origin. The proband, a 79 year old female, was identified from patients attending the Rheumatic Diseases Clinic - Hospital de Santo Espírito, Angra do Heroísmo. Three other individuals affected with sub-clinical osteopoikilosis were further identified in this family. All the individuals had a full skeletal radiographic survey. Genomic DNA from the above patients and 40 healthy controls was isolated from peripheral blood and amplified by PCR. The mutated LEMD3 exon and flanking splice sites was sequenced. We identified a novel heterozygous mutation in exon 13 of gene LEMD3. This non-synonymous mutation, a C to T substitute at position 2701bp (cDNA), changes amino acid at 901(1) from Arginine to a Tryptophan, and segregates with the phenotype of all the affected individuals in the Azorean family. None of the healthy controls has this mutation. We here describe a mutation located in the carboxyl-terminal nucleoplasmic region of LEMD3. This region (aminoacids 789-911) is predicted to be an RNA recognition motif-like (RRM-like) protein interaction domain named U2AF homology motif. Further studies will be necessary to investigate the consequence of the mutation in protein function. Our findings suggest that the novel LEMD3 mutation reported here is the cause of the sub-clinical osteopoikilosis.

965F

Absence of *NPY2R* in Saliva Predicts Successful Oral Feeding in Premature Neonates. *J.L. Maron[1, 2], J.A. Dietz[1], M.L. Chen[1], K.L. Johnson[1, 2], D.W. Bianchi[1, 2].* 1) Floating Hospital for Children at Tufts Medical Center, Department of Pediatrics, Boston, MA; 2) Mother Infant Research Institute at Tufts Medical Center, Boston, MA.

Background: Identifying key physiological regulatory genes in neonatal saliva holds great promise for improving our understanding of neonatal biology and advancing clinical care. Currently, only subjective assessment tools exist for determining an infant's readiness to orally feed, placing premature neonates at risk for choking, aspiration, and hypoxia. Previously, we identified a subset of genes, including neuropeptide Y2 receptor (*NPY2R*), through salivary gene expression analyses that were differentially expressed in neonates learning to orally feed. *NPY2R* has been shown by others to modulate feeding behavior, metabolism, and energy homeostasis in humans and mice. Hypothesis: Absence of *NPY2R* in neonatal saliva predicts successful oral feeding in premature neonates and regulates the physiological feeding pattern characteristic of normal postnatal exponential growth. Methods: Salivary samples were collected from 56 preterm and 14 term neonates at various gestational ages (25 4/7 to 41/4/7 weeks) and feeding milestones (no feeds, partial nasogastric feeds, full nasogastric feeds, partial oral feeds, full oral feeds). RNA was extracted from all samples (n=113) using the QIAGEN RNeasy Protect Saliva Mini Kit. Multiplex qRT-PCR was performed for *NPY2R* and three housekeeping genes: *GAPDH*, *YWHAZ*, and *HPRT1*. Presence or absence of *NPY2R* in saliva was determined if *NPY2R* did or did not amplify in the presence of ⁄2 amplified housekeeping genes, respectively. Chi-squared tests were performed between *NPY2R* and feeding status; correlation coefficient was determined for *NPY2R* expression and gestational age. Results: Absence of *NPY2R* expression significantly correlated with feeding status (chi-square p = 0.019). Expression of *NPY2R* was negatively correlated with gestational age (R2= 0.91). Conclusion: Our results support the hypothesis that *NPY2R* is a developmentally regulated gene. Decreased *NPY2R* expression significantly correlates with successful oral feeding in the preterm infant. The salivary transcriptome provides targeted, real-time, functional information about the developing preterm neonate. This work suggests that objective tests, based on gene expression, can be developed for application in newborn care.

966F

Mutations of Connexin Genes 26(GJB2) and 30(GJB6) in a Peruvian Deaf Population. *R.D. CHACON[1,2], R. BADILLO[3], M.R. CORNEJO[1], O. ORTEGA[1], V. MARCA[1], R.J. DESCAILLEAUX[4], J.A. RUBIO[5], P.E. MAZZETTI[1].* 1) Neurogenetics Division, Instituto Nacional de Ciencias Neurologicas, Lima, Lima, Perú; 2) Biology-Genetics School, Universidad Nacional Mayor de San Marcos, Lima, Lima, Perú; 3) Oto-neurosurgery Department, Instituto Nacional de Ciencias Neurologicas, Lima, Lima, Perú; 4) Celular Biology and Genetics, Universidad Nacional Mayor de San Marcos, Lima, Lima,Perú; 5) Otolaryngology, Hospital Nacional Guillermo Almenara Irigoyen, Lima, Lima, Perú.

Hearing loss has a prevalence of 1 per 1000 newborns. Mutations in genes GJB2 and GJB6 cause approximately 50% of the genetic cases. In Latin American populations, 35delG and S199F mutations varies from 17 to 40%, and Δ(GJB6-D13S1830) and Δ(GJB6-D13S1854) mutations varies from 2 to 9% of deaf population. The aim of this study was to estimate the frequencies of 35delG and S199F mutations at GJB2 gene and Δ(GJB6-D13S1830) and Δ(GJB6-D13S1854) mutations at GJB6 gene and, to establish a genotype-phenotype correlation. We evaluated 120 unrelated mestizo patients with non-syndromic sensorineural hearing loss (NSHL), 55 of them with family history and 5 without it. Molecular diagnosis was applied with PCR-RFLP and PCR-MULTIPLEX techniques previously described. In case of S199F mutation, a PCR-RFLP genetic test was developed using the primers F(TCGAGGAGATCAAAACCCAG) and R(GGGAAATGCTAGCGACTGAG) and the enzyme AlwNI (Cail). Pure-tone average (PTA: 05-3 kHz) was obtained after a pure tone audiometry. Positive mutation controls were used in all cases. The S199F, Δ(GJB6-D13S1830) and Δ(GJB6-D13S1854) mutations were not found in this population. The 35delG mutation was found in 12.5% (15/120) of the cases [2.5% homozygous and 10% heterozygous]. In familial cases, 35delG mutation was found in 6 patients (10.9%) while in sporadic cases it was found in 9 cases (13.85%). The allelic frecuency of 35delG mutation was 7.5% (18/240). In the homozygous cases (3), PTA was found under 90 dB (total average: 100.625), with a profound hearing loss phenotype. In the heterozygous cases (12), PTA varies from 72.5 db to 106.25 dB (total average: 87.5) corresponding to severe hearing loss phenotype (6 cases) and profound hearing loss phenotype (6 cases). This findings suggest the presence of other mutation(s) associated to the peruvian population, which receives an important contribution from natives amerindian populations. 35delG homozygous genotype is related to the most severe phenotype, while 35delG heterocygous genotype varies according to the other expected mutation in the same gene or in a different associated gene. We strengthen the importance of genetic diagnosis, specially for 35delG mutation, providing early treatment and genetic counselling of deaf patients and their families.

967F

Molecular analysis of Indian patients with Rett syndrome: Identification of mutations and genotype-phenotype correlation. *D.K. DAS[1], D.A. SANGHAVI[1], R.A. ADHIA[1], V. UDANI[2], A. MAITRA[1].* 1) GENETIC RESEARCH CENTRE, NATIONAL INSTITUTE FOR RES IN REPROD HEALTH, MUMBAI, MUMBAI, INDIA; 2) PD HINDUJA NATIONAL HOSPITAL AND MEDICAL RESEARCH CENTRE, SWATANTRYA VEER SAVARKAR MARG, MAHIM, MUMBAI, INDIA.

Rett syndrome (RTT) is an X-linked neurodevelopmental disorder, primarily affecting females and characterized by regression, epilepsy, stereotypical hand movements, and motor abnormalities. Its prevalence is about 1 in 10,000 female births. Rett Syndrome is caused by mutations within methyl CpG-binding protein 2 (MECP2) gene, Over 200 individual nucleotide changes which cause pathogenic mutations have been reported, however eight most commonly occurring missense and nonsense mutations account for almost 70% of all mutations. Small deletions associated with deletion hotspots in the C-terminal region of MECP2 protein account for an additional 9% of pathogenic mutations Rett Syndrome cases have been reported from India. The phenotype (classical and atypical inclusive) has many differentials. However a genetically based confirmed diagnosis would help in management and counselling. In this study we have analysed MECP2 mutations in 30 Indian sporadic patients diagnosed clinically as having RTT and 5 missense, 3 nonsense, 1 frameshift and 3 silent mutations in MECP2 have been detected. Five mutations (c.806Gdel, p.T158M, p.R255X, p.R168X, p.R270X) were the part of 8 hotspot mutations identified worldwide and are present in classical cases. Four mutations (p.R133C, p.R306C, p.T203M, p.P152R) were identified with atypical cases. We also identified 5 patients with small (7 bp deletion) to large deletion (409 bp deletion) in exon 4 of MECP2 gene. We have also analyzed cyclin dependent kinase like 5 (CDKL5) gene mutation in patients having without mutations and 4 different novel and known mutations in CDKL5 gene were identified. The clincical severity of this disorder also depends on the pattern of X chromosome inactivation (XCI). Therefore, the patterns of X chromosome inactivation were analyzed in all the patients for genotype-phenotype correlation. We found that the skewing pattern of inactivation was correlated with the clinical severity of this disorders. We have also performed multiple ligation dependent probe amplification (MLPA) for the mutation negative patients but no abnormalities have been detected. Our study would help in establishing the panel of mutations prevalent in Indian cases of Rett syndrome.

968F

A panel of genetic tests identifies causative mutation in around 40% of patients affected by bilateral syndromic and non-syndromic congenital limb malformations. *A. Jamsheer[1,2], A. Sowinska[1,2], A. Latos-Bielenska[1,2].* 1) Department of Medical Genetics, University of Medical Sciences in Poznan, Poznan, Poland; 2) Center for Medical Genetics GENESIS, Poznan, Poland.

In recent years, significant number of genes, loci and regulatory elements (RE) involved in human embryonic limb development has been identified. Mutations in those genes, loci and RE result in abnormal genetic programming and lead to various congenital limb malformations (CLMs). The aim of this study was to assess the relative frequencies of known genetic abnormalities in a cohort of Polish probands affected by bilateral CLMs. A 110 probands with bilateral isolated (non-syndromic) or syndromic CLMs were recruited for the study. The probands were clinically evaluated and qualified for genetic testing, based on the tentative diagnosis (karyotype, molecular screening by means of DNA sequencing and/or MLPA). Karyotyping and molecular screening of selected 17 genes and loci known to be involved in pathogenesis of human limb malformations allowed for identification causative mutation in 46 probands (41.8%). Patients diagnosed with the panel of tests comprised 2 probands with apparently balanced chromosomal translocations, 11 probands with preaxial polydactyly type 4 or Greig cephalopolisyndactyly carrying GLI3 mutations, 10 probands with split-hand-foot malformation (SHFM), with 6 out of them carrying TP63 mutation and 4 having 10q24.31-10q24.32 duplication (SHFM3 locus), 4 probands exhibiting synpolydactyly with HOXD13 mutations, 4 with ODDS/syndactyly type III and GJA1 mutations, and 4 with TAR syndrome carrying a deletion in the critical region of 1q21.1. In 2 probands with the diagnosis of Feingold syndrome, MYCN mutations were found; similarly, 2 probands with Bardet-Biedl syndrome had mutations in BBS10, and 2 cases with Townes-Brocks - mutations in SALL1. 4 probands were recognized as having isolated brachydactylies and were subsequently confirmed to carry causative alterations (2 probands manifesting BDB - ROR2 mutation, 1 case of BDC - GDF5 mutation, 1 case of BDE - HOXD13 mutation). In addition, 1 proband manifesting carpal-tarsal coalition syndrome accompanied with symphalangism carried a mutation in NOG. The study shows relative frequencies of specific molecular defects underlying bilateral CLMs and provides suggestions for tests that should be considered in the diagnostic process of patients presenting with bilateral CLMs.

UGT1A1 is a Major Locus Influencing Bilirubin Levels in African Americans. *G. Chen[1], E. Ramos[1], A. Adeyemo[1], D. Shriner[1], J. Zhou[1], A. Doumatey[1], H. Huang[1], N. Gerry[2], A. Herbert[3], A. Beneley[1], H. Xu[1], B. Charles[1], M. Christman[2], C. Rotimi[1].* 1) NHGRI, NIH, Bethersda, MD; 2) Coriell Institute for Medical Research, Camden, NJ 08103 USA; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, Massachusetts 02118 USA.

BACKGROUND: Total serum bilirubin, an important byproduct of heme metabolism, has been associated with several clinical outcomes, including cardiovascular disease, diabetes and drug metabolism. Previous genome-wide association studies (GWAS) of serum bilirubin performed in European and East Asian populations reported that variants in the UGT1A1 gene (2q37.1) significantly influence serum total bilirubin levels. These findings have not been replicated in African ancestry populations; thus, we conducted a GWAS in African Americans to attempt to replicate reported findings and to identify novel loci influencing serum total bilirubin levels. METHODS: A total of 619 healthy unrelated individuals who participated in the Howard University Family Study (HUFS) were included in this study. Using a dense panel of over two million genotyped and imputed SNPs, we conducted a GWAS in African Americans for serum total bilirubin level. We assumed an additive genetic model and all statistical models were adjusted for age, sex, and the significant principal component from the sample covariance matrix of genotypes. RESULTS: Heritability for serum total bilirubin was estimated to be 0.42. Thirty-nine SNPs spanning a 78 kb region within the UGT1A1 gene (2q37.1) displayed p-values lower than the pre-determined genome wide significance threshold of 5×10-8. The lowest p-value was 1.7×10-22 for SNP rs887829. Notably, none of the other 38 SNPs in the UGT1A1 gene remained statistically significant in conditional association analyses that adjusted for SNP rs887829. We showed that rs887829 is in tight LD (r2／0.74) with rs10929302 (-3156G > A, UGT1A1*91) located in the phenobarbital response enhancer module that is about 3kb upstream of the (TA)n variant reported to a better predictor of toxicity irinotecan - a cancer drug. We also replicated the reported association between variants in the SEMA3C and bilirubin in this cohort of African Americans. CONCLUSIONS: We observed that UGT1A1 is a major locus influencing total bilirubin levels in African Americans, adding to the evidence that this gene plays an important role in the determination of bilirubin level in human populations with different ancestral backgrounds. Our findings may also contribute to the understanding of the etiology of hyperbilirubinaemia and the pharmacogenomics role of UGT1A1 variants in drug (e.g., irinotecan) metabolism in African Ancestry populations.

A Genome-Wide Association Analysis for Pathological Myopia in Japanese. *I. Nakata[1,4], K. Yamashiro[1], H. Nakanishi[1,4], H. Hayashi[1,4], Y. Kurashige[1,4], M. Miyake[1,4], A. Tsujikawa[1], M. Moriyama[2], K. Ohno-Matsui[2], M. Mochizuki[2], Q. Fan[3], X. Zhou[3], J.L. Xuan[3], SM. Saw[3], T. Kawaguchi[4], R. Yamada[4], F. Matsuda[4], N. Yoshimura[1].* 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Department of Ophthalmology and Visual Science, Tokyo Medical and Dental University Graduate School of Medicine, Tokyo, Japan; 3) Department of Epidemiology and Public Health, Yong Loo Lin School of Medicine, National University of Singapore, Singapore; 4) Center for Genomic Medicine/Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Myopia is one of the most common ocular disorders worldwide, and is in much higher prevalence in Asians than in Caucasians. Pathological myopia, also called high myopia, comprises 1% to 5% of the general population and is one of the leading causes of legal blindness in developed countries. To identify genetic determinants associated with pathological myopia in Japanese, we conducted a genome-wide association study and follow-up replication studies in Chinese and Japanese. In the first stage, we genotyped 505 elderly cases with pathological myopia (axial lengths > 28.0 mm in both eyes) and 3498 general population controls using the Illumina HumanHap 550k and 660K arrays in a Japanese population. We found 767 SNPs which showed P-values smaller than 0.001, and tested them in the dataset of Singaporean Chinese individuals for 222 cases with high myopia, defined by spherical equivalent (SE) ≤ -6.0 diopters (D), and 448 controls (SE between -0.50 and +1.00 D). According to this replication study, 3 SNPs on 3 loci (rs4472734 at PTPN14, rs7634255 on 3q25, and rs6060750 at C20orf152) showed significant associations in high myopia in Chinese (P < 0.05). However, a further replication study in Japanese using additional 638 elderly cases with pathological myopia (axial lengths > 26.0 mm in both eyes) and 1194 general population controls using Taqman SNP assay revealed no significant association for all 3 SNPs (P > 0.05). In the present study, we could not find a susceptibility locus for pathological myopia. Further studies on genetic backgrounds of pathological myopia would lead to understanding pathogenesis of pathological myopia.

971F

Genetic modifiers of the 22q11 microdeletion syndrome: Preliminary results of a GWA study. *G.M. Repetto[1,2], S. McGhee[3], M.L. Guzman[1], N. McLennan[4], M. Palomares[5,6], M. Vasquez[1], G. Lay-Son[1,2,6], A. Ziegler[1].* 1) Dept Gen, Clin Alemana- Univ Desarrollo, Santiago, Chile; 2) Hospital Padre Hurtado, Santiago, Chile; 3) Stanford University, Stanford, CA; 4) UCLA, Los Angeles, CA; 5) Fundación Gantz, Santiago, Chile; 6) Hospital Calvo Mackenna, Santiago, Chile.

Chromosome 22q11 microdeletion syndrome (del22q11) has an estimated frequency of 1/4000 live births. Most patients share a common 3 Mb deletion but despite molecular similarity, the clinical phenotype shows marked variable expressivity. Approximately 50-70% of patients have congenital heart disease, predominantly conotruncal, and 70-80% have palatal abnormalities, including submucous cleft palate and velopharyngeal insufficiency. The cause of the incomplete penetrance of the individual features is unknown. We performed a genome wide association study (GWAS) to search for genetic modifiers of the cardiac and palatal phenotype in Chilean patients with del22q11. DNA samples from 124 patients with del22q11, 67 of them with cardiac anomalies and 87 with palatal anomalies were analyzed with Affymetrix ® v. 6.0 SNP array. Significant differences were found at SNPs in chromosomes 6 and 8, among others, when comparing patients with any cardiac defect to patients normal cardiac anatomy (p 5.8 x 10-7 and 6.1 x 10-7, respectively) and in the same SNPs (p 1.12 x 10-6 and 1.4 x 10-6, respectively) and one in chromosome 2 (p 4.3 x 10-7) when comparing patients with conotruncal heart defects (tetralogy of Fallot and IAA) with patients with normal heart structure. Comparison between patients with or without palatal abnormalities showed evidence of association between SNPs in chromosomes 4 (p 6.8 and 7 x 10-6 for 2 SNPs on this chromosome), 14 (7.6 x 10-6) and X (6.2 x 10-6). Our results suggest that common genetic variants outside of the 22q11 region modify the effects of the deletion, and that these modifiers may be different for the cardiac and the palatal phenotypes, implying that these malformations could involve independent pathways. Funded by Fondecyt-Chile Grant #1100131.

Pathogenic CNVs and causative genes detected by two-stage screening in 647 patients with mental retardation and multiple congenital anomalies of unknown etiology. *S. Hayashi[1], I. Imoto[2], Y. Makita[3], A. Hata[4], J. Inazawa[1].* 1) Dept Molec Cytogenetics, Tokyo Med & Dental Univ, Tokyo, Japan; 2) Dept. Human Genetics and Public Health Graduate School of Medical Science, the University of Tokushima, Japan; 3) Education Center, Asahikawa Medical College, Japan; 4) Department of Public Health, Chiba University Graduate School of Medicine, Japan.

Recently several types of microarrays are available to analyze cases with congenital disorders. We have investigated 647 cases with multiple congenital anomalies and mental retardation (MCA/MR) of unknown etiology for six years by using several types of microarray. First, we performed a two-stage screening by application of two types of in-house bacterial artificial chromosome (BAC)-based arrays in order to detect pathogenic copy number variants (pCNV). In the 1st screening we used `MCG Genome Disorder Array (GDA)' containing BACs covering loci associated with known 30 genomic disorders and subtelomeric regions of all chromosomes as a diagnostic tool, and detected pCNV in 69 of 647 cases (10.7%). In the 2nd screening we used `MCG Whole Genome Array-4500 (WGA)' harboring 4523 BACs throughout human genome and detected pCNV in 57 of 474 cases (12.0%). Based on the accumulation of genotype-phenotype information and bioresources through the screenings, we could show a relation between phenotypes and several pathogenic genes, e.g. BMP4 or UBE2A. Notably, we investigated genotype-phenotype correlation in detail about the CASK gene. We recruited more than ten female patients with MR, microcephaly, disproportionate pontine and cerebellar hypoplasia (MIC-PCH), and demonstrated that all the patients had variable genetic aberrations causing null mutation of CASK. Inspired by these results, we are searching a mutation of another candidate disease-associated gene(s) in a cohort of subjects with resembling phenotypes. Moreover, we are investigating etiologies of the remaining cases by multiple approaches. Currently we are analyzing 387 negative cases of the BAC array screenings by employing SNP array (illumina, HumanOmniExpress) as the 3rd screening in order to detect a small CNV and a partial uniparental disomy affecting phenotypes. We are also re-assessing pCNVs in 55 cases detected by the BAC arrays using high-resolution oligonucleotide array (Roche NimbleGen, Human CGH 2.1M Whole-Genome Tiling Arrays) in order to detect second CNV(s) potentially affecting phenotypes and/or causative genomic structure(s) of the CNV. Here we demonstrate our multiple genome-analyzing approaches to investigate etiology of MCA/MR.

973F

Study of SLC29A3 gene in Rosai-Dorfman histiocytosis associated with hearing impairment. *S. Marlin[1, 2, 3, 4], L. Jonard[5, 2, 3, 4], V. Couloigner[6], S. Pierrot[6], M. Louha[5, 2, 3, 4], B. Neven[7], S. Gherbi[1, 2], R. Couderc[5, 2, 3, 4], A. Fischer[7], E.N. Garabedian[8, 2, 3, 4], F. Denoyelle[8, 2, 3, 4].* 1) Clinical genetics department, Trousseau Hospital, Paris, France; 2) Centre de référence des surdités génétiques, Trousseau Hospital, Paris, France; 3) INSERM, UMRS_587, Institut Pasteur, Paris, France; 4) UMPC, Pierre et Marie Curie University, Paris 6, Paris, France; 5) APHP, Trousseau Hospital, Biochemistry and Molecular Biology department, Paris, France; 6) APHP, Necker Hospital, Pediatric Oto-Rhino-Laryngology department, Paris, France; 7) APHP, Necker Hospital, Immunology department, Paris, France; 8) APHP, Trousseau Hospital, Pediatric Oto-Rhino-Laryngology department, Paris, France.

SLC29A3 is implicated in a syndromic form of genodermatosis: H syndrome. The major features encounters in H syndrome are Hearing loss, Hyperglycaemia, Heart anomalies, Hypertrichosis, Hyperpigmentation, Hepatomegaly and Hypogonadism. More recently, SLC29A3 mutations have been described in families presenting syndromes associating generalised histiocytosis to systemic progressive features: severe camptodactyly, hearing loss, hypogonadism, hepatomegaly, heart defect and skin hyperpigmentation. We have identified a homozygous novel missense SLC29A3 mutation in a patient presenting with only a progressive sensorineural hearing impairment and a single cervical node. The same mutation was revealed in another patient with Rosai-Dorfman histiocytosis, profound hearing impairment, chronic inflammation with pericarditis and ophthalmological disorders. Both patients originated from North Africa and their mutation may be related to a common ancestor. Our results suggest that SLC29A3 should be studied in patients presenting with histiocytosis and hearing impairment.

Correlation between CFTR mutation and the CF phenotypes. *R. Sebro[1,2], H. Levy[3,4].* 1) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Department of Radiology and Biomedical Imaging, University of California, San Francisco, CA; 3) Division of Pulmonary and Sleep Medicine, Children's Hospital, Milwaukee, WI; 4) Clinical Research Institute of the Children's Hospital of Wisconsin and Medical College of Wisconsin, Milwaukee, WI.

Cystic fibrosis (CF) is a simple recessive disease with a complex phenotype that can affect the liver, pancreas, sweat glands, gastrointestinal system, vas deferens and lungs. CF is the most common genetic disorder in Caucasians. Morbidity and mortality associated with CF are related to progressive pulmonary function decline, and associated with frequent lung infections. Over 1600 mutations have been identified in the cystic fibrosis membrane transporter receptor (CFTR) gene, however there is difficulty correlating CFTR mutation with phenotype, primarily because all of the mutations except for the DF508 mutation have a prevalence of around 1%. Three mutation scoring schemes were evaluated. The biological classification score is based on the in vitro activity of the mutant CFTR membrane transporter. We hypothesize the in vitro function predicts the in vivo CF phenotype. The Grantham score is based on the degree of chemical dissimilarity between the native and the substituted amino acid. The Sorting Intolerant From Tolerant (SIFT) score uses sequence homology to predict whether an amino acid substitution will affect protein function and potentially be deleterious. SIFT and Grantham scores were calculated for non-synonymous missense mutations. We analyzed cross-sectional data from 108 DF508 compound heterozygotes (1 mutation is the DF508 allele, and the other is a known non-DF508 allele) from a cohort of CF patients at Children's Hospital Boston. Three aspects of the CF phenotype were considered: the pulmonary disease was assessed using the % predicted FEV1, the sweat chloride level, and pancreatic exocrine sufficiency. Linear and logistic regression models were used using age, sex and the mutation classification scores as covariates. Mutations with higher biological classification scores (milder mutations) are associated with more normal sweat chloride levels ($p<0.001$) and pancreatic sufficiency ($p<0.001$). Lower Grantham scores are associated with more normal sweat chloride levels ($p<0.001$) and pancreatic sufficiency ($p=0.01$). Higher SIFT scores are associated with more normal sweat chloride levels ($p<0.001$) and pancreatic sufficiency ($p=0.01$). No association was found between the % predicted FEV1 and either the biological classification ($p=0.08$), Grantham ($p=0.28$) or the SIFT scores ($p=0.62$). Our findings suggest the pulmonary disease may be influenced by modifier genes and environmental factors.

A patient with hemihoplasia, normal growth and *H19* hypomethlation. *L. Zhang[1,2], L. Cohen[1], L. Konczal[1,3].* 1) Dept Human Gen, Case Western Univ SOM, Cleveland, OH; 2) Dept Med, Case Western Univ SOM, Cleveland, OH; 3) Dept Ped, Case Western Univ SOM, Cleveland, OH.

Russell-silver syndrome (RSS) is characterized by severe intrauterine followed by postnatal growth retardation. A significant number of patient with clinically diagnosed RSS have been found to have hypomethylation of *H19* on chromosome 11p15.5. In contrast, the opposite end of the spectrum, Beckwith-Wiedemann syndrome, characterized by large for gestational age at birth and subsequent overgrowth, has been associated with hypermethylation of the *H19* locus, at least in some patients. Both pre- and post-natal growth retardation in RSS is thought to be the result of deficiency of *IGF2*, a paternally expressed growth factor important for fetal and placental growth in utero as well as postnatal growth. Hypomethylation of the 11p15.5 locus results in loss of expression of *IGF2* from the paternal allele and biallelic expression of *H19*. We describe a patient with congenital hemihypoplasia, normal growth both in utero and postnatally and hypomethylation of the *H19* locus on 11p15.5. Our patient is a 10-week-old girl with congenital hemihypoplasia. Her birth weight and height were both between 25-50th percentile. Her current weight (50th percentile), length (25th percentile) and head circumference (75th percentile) are all within normal limits. She has a small triangular face with a relatively broad forehead. Her face, body, upper and lower extremities all show apparent asymmetry with the right side significantly larger than the left. She does not have any other clinical manifestations that are frequently associated with RSS, including 5th finger clinodactyly, cafe-au-lait macules, genitourinary anomalies, feeding difficulty or hypoglycemia. Our case demonstrates that *H19* hypomethylation may be seen in patients with isolated body asymmetry without IUGR or postnatal growth retardation. Further study of the allelic expression pattern of *IGF2* is required to elucidate the mechanism. Close to normal level of methylation may allow appropriate fetal and postnatal growth. Also, more cases with *H19* hypomethylation and a wider spectrum of clinical manifestation may be identified if we expand the testing indication beyond RSS and BWS and include individuals with isolated body/facial asymmetry.

976F

Fetal hemoglobin production cannot be induced by) -thalassemia/ hemoglobin E disease caused by novel 1-bp insertion mutation at codon 35 of *HBB* gene. *O. Trachoo[1], P. Niparuck[2], S. Pingsuthiwong[1], K. Srichan[1], T. Sura[1], B. Phakdeekitcharoen[3].* 1) Division of Medical Genetics and Molecular Medicine, Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok 10400, Thailand; 2) Division of Hematology, Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok 10400, Thailand; 3) Division of Nephrology, Department of Medicine, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok 10400, Thailand.

) -thalassemia disease (MIM #141900) is one of the most common public health problems in Southeast Asian countries. The disease is caused by the mutations in *HBB* gene resulting in abnormal) -globin protein synthesis. Clinical manifestations include hemolytic anemia, jaundice, hepatosplenomegaly, failure to thrive, multiple endocrinopathies and hemochromatosis since early childhood. The mutations in *HBB* gene are heterogeneous and hemoglobin E (Hb E, Glu26Lys) is the most prevalent hemoglobinopathy in Thailand. Compound heterozygosity of Hb E and either) ^{0} or) $^+$ mutation gives rise to) -thalassemia/Hb E disease which has diverse clinical phenotypes, from mild to severe form. Mainly, the absence and dysfunction of) -globin trigger the production of . -globin protein comprising fetal hemoglobin (Hb F) which is not normally expressed in adult life. Here we report a middle-age Thai male patient who presented with clinical thalassemia disease, markedly elevated ferritin level and end-stage renal disease. Hb analysis showed the presence of more than 90% Hb E and very low level of Hb F misleading to homozygous Hb E which is a benign condition. Direct DNA sequencing of *HBB* gene revealed the heterozygous Hb E mutation and novel 1-bp G insertion at codon 35 was found. Based on protein prediction analysis, this particular insertion mutation results in frame shift and generating premature stop codon. Therefore, molecular diagnosis of) -thalassemia/ Hb E disease was confirmed. However, Hb F production cannot be induced by) -globin mutation as observed in other common) -thalassemia/Hb E diseases. These genetic and biochemical findings lead to the interest on how Hb F production is affected. Next step to move on includes the works on . -globin expression and . -globin gene sequencing which are hypothesized to modulate Hb F synthesis.

977F

A novel 5-bp deletion in clarin 1 in a family with Usher syndrome. *E. Akoury[1], E. Elie El-Zir[2], A. Mansour[3], A. Megarbané[4], J. Majewski[1,5], R. Slim[1].* 1) Human Genetics, McGill University Health Centre, Montreal , Quebec, Canada; 2) Department of Otorhinolaryngology, Hôpital Sacré-Coeur, Baabda, Lebanon; 3) Department of Ophthalmology, American University of Beirut, Lebanon; 4) Unité de génétique médicale, Faculté de médecine, Université Saint Joseph, Beirut, Lebanon; 5) McGill University and Genome Quebec Innovation Centre, Montreal, Canada.

Background and purpose: Usher syndrome (USH) is an autosomal recessive disorder combining sensorineural hearing loss and retinitis pigmentosa (RP). It is the leading cause of deaf-blindness in humans with a prevalence estimated to range from 2 to 6.2 per 100,000.Our aim was to identify the genetic defect in a Lebanese family with two sibs diagnosed with Usher Syndrome but could not be classified into types I or III because of the intra-familial variability and the absence of progressive deafness. **Materials and Methods:** Exome capture and sequencing was performed on DNA from one affected member using Agilent In Solution Bead Capture, followed by Illumina sequencing. **Results:** This analysis revealed the presence of a novel homozygous 5-bp deletion, in the exon 2 of the Clarin 1 (CLRN1), a known gene responsible for Usher syndrome type III. The deletion is inherited from both parents and segregates with the disease phenotype in the family. The 5-bp deletion, c.301_305delGTCAT, p.Val101SerfsX27 was found within a region of 10.3 Mb of homozygosity on chromosome 3 and is predicted to lead to a frameshift in the second transmembrane domain and result in protein truncation after 27 amino acids. Sequencing all the coding regions of the CLRN1 gene in the proband did not reveal any other mutation or variant sustaining therefore that this 5-bp deletion is responsible for the Usher phenotype in this family. **Conclusion:** Here we describe a novel deletion in CLRN1 in a Lebanese family with Usher syndrome. Our data support previously reported intra-familial variability in the clinical features of Usher syndrome type I and III and highlight the importance of next-generation sequencing in mutation analysis.

978F

Evidence of DLL1 as a Susceptibility Locus in Indian Visceral Leishmaniasis. *S. Mehrotra[1], M. Fakiola[2,3], A. Mishra[1], P. Tiwari[1], M. Sudarshan[1], S. Jamieson[3], D. Selvi Rani[4], S. Sundar[1], J. M Blackwell[2,3].* 1) Department of Medicine, Institute of Medical Sciences, Banaras Hindu University Varanasi, India; 2) Cambridge Institute for Medical Research and Department of Medicine, University of Cambridge School of Clinical Medicine, Cambridge, UK; 3) Telethon Institute for Child Health Research, Centre for Child Health Research, The University of Western Australia, Subiaco, Western Australia, Australia; 4) Centre for Cellular and Molecular Biology, Hyderabad, India.

Previous genome wide linkage studies in Sudanese and Brazilian populations identified chromosome 6q27 as a strong candidate region containing a gene(s) regulating susceptibility to visceral leishmaniasis (VL). The region contains genes involved in the host immune response, amongst which the most compelling candidate susceptibility gene for VL is DLL1 (Delta Like Protein 1), a member of the notch signalling pathway that directs naïve T helper differentiation towards Th1, Th2 or regulatory T cell lineages. This population-based study investigated the role of the 6q27 genes (PHF10, C6orf70, DLL1, FAM120B, PSMB1, TBP) in Indian VL by genotyping (Sequenom) twenty-one single nucleotide polymorphisms in 941 VL cases and 992 ethnically-matched controls. Logistic regression analyses using additive and genotypic models show significant associations with variants at DLL1 (rs1884190) and FAM120B (rs9366198, rs9460106, rs2103816). FAM120B_rs9460106 (intronic) was the most associated SNP (OR=1.22; 95%CI=1.07-1.39; P=0.0027), but the associated variants all fall within a strong linkage disequilibrium block. Quantitative gene expression was analysed in 19 paired pre- (Day 0), and post- (Day 30) treatment splenic aspirate samples from VL patients receiving antileishmanial drug therapy. DLL1 showed significantly (P value less than 0.0001) higher expression in Day 0 samples compared to Day 30. These genetic and functional studies in an endemic Indian population provide strong evidence for DLL1 acting as a susceptibility locus for VL in India.

979F

Mutations in the WNT10A gene are the most frequent cause of isolated hypodontia. *M.H. van den Boogaard[1], M. Créton[2], A.Y. Bronkhorst[1], A.H. van der Hout[3], M. Cune[4,5], J.K. Ploos van Amstel[1].* 1) Department of Medical Genetics, University Medical Center Utrecht, Utrecht, Utrecht, Netherlands; 2) Department of Oral and Maxillofacial Surgery, Prosthodontics and Special Dental Care, University Medical Centre Utrecht, The Netherlands; 3) Department of Genetics, University Medical Center Groningen, The Netherlands, Groningen; 4) Section of Oral Function, Academic Centre for Oral Health, University Medical Center Groningen, The Netherlands; 5) Department of Oral-Maxillofacial Surgery, Prosthodontics and Special Dental Care, St. Antonius Hospital Nieuwegein, The Netherlands.

Ectodermal Dysplasia (ED) is a clinically and genetically heterogeneous disorder. ED features involve the abnormal development of at least two of the ectodermal structures namely teeth, hair, nails and sweat glands. Genes that are associated with ED are e.g. EDA1, EDAR, EDARADD and WNT10A. Mutations in the WNT10A gene have been identified to be associated with several forms of ectodermal dysplasias including odonto-onycho-dermal dysplasia (OODD). Hypodontia is a common feature in these ectodermal dysplasia forms, which makes WNT10A a good candidate as a cause of isolated hypodontia. Recently, indeed a family with isolated hypodontia has been described that is caused by missense mutations in the WNT10A gene. Other genes that are known to cause isolated hypodontia are MSX1, PAX9, AXIN2 and IRF6. To get insight in the genetic heterogeneity of isolated hypodontia, we tested a panel of 36 probands that show variable severity of tooth agenesis. The probands all had agenesis of six or more teeth (excluding the third molars), with a range of 6 - 28 teeth. There was a positive family history for tooth agenesis in ~ 70% of the patients. The genes that have been analyzed were MSX1, PAX9, IRF6, AXIN2 and WNT10A. The gene tests involve the direct sequencing of the exons and their flanking sequences that were amplified by PCR. Twenty probands (56%) showed alterations in the WNT10A gene: 8 probands were homozygous, 3 probands were compound heterozygous and 9 probands were heterozygous for a single WNT10A mutation. Heterozygosity for a mutation in the PAX9 gene was identified in 3 patients. One patient showed a nonsense mutation in the AXIN2 gene. We also tested patients with hypodontia and an additional feature (hypodontia plus) e.g. 1 patient had clefting with tooth agenesis outside the cleft region. In these patients also WNT10A mutations could be identified. The WNT10A mutation p.Phe228Ile (48% of the alleles) was identified in 8 out of 352 control chromosomes (2.3%). The hypodontia status of the controls is not known. Strikingly, this WNT10A allele frequency fits with the incidence of tooth agenesis in the general population (~5%). We conclude that mutations in the WNT10A gene are by far the most frequent cause of isolated hypodontia. Thus, should be implemented in the DNA diagnostics of isolated hypodontia. Furthermore, there is an indication for a genotype-phenotype relationship for WNT10A mutation carriers depending on type of mutation and zygosity.

980F

Haplotypes of the 3'untranslated region of the HLA-G gene are associated with TD1. *R. de Albuquerque[1, 4], C. Leal[2], E. Castelli[3], N. Lucena-Silva[4], D. Rassi[2], C. Mendes-Junior[5], E. Donadi[2].* 1) Departamento de Genetica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo,Ribeirão Preto, São Paulo, Brazil; 2) Departamento de Clínica Médica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo,Ribeirão Preto, São Paulo, Brazil; 3) Departamento de Biologia Geral, Universidade Federal de Goiás,Goiás,Brazil; 4) Departamento de Imunologia, Centro de Pesquisa Aggeu Magalhães, Fundação Oswaldo Cruz, Recife, Pernambuco, Brazil; 5) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil.

The TD1 (Type 1 Diabetes) is a multifactorial disease in which the autoimmune destruction of pancreatic cells is mediated by humoral and cellular mechanisms. Various subpopulations of lymphocytes are involved in this process, however, the CD8 + T lymphocytes appear to be the cells responsible for early insulitis. Genetic susceptibility to TD1 has been primarily attributed to MHC genes: a recent study mapping the MHC region identified the HLA-G region as an independent susceptibility gene for the disease. A major function of HLA-G is the inhibition of Natural Killer cells (NK) and cytotoxic T cells (CTL), by interaction with inhibitory receptors found in these cells. The HLA-G gene presents a 3' untranslated region (3'UTR) that contains at least eight polymorphisms, three of them related with several posttranscriptional regulatory elements. Study the 3'UTR of the HLA-G gene in 110 patients with TD1 and 110 controls from the same geographical region of the patients. DNA was extracted from peripheral blood cells by the salting out procedure. The 3'UTR fragments were amplified using the polymerase chain reaction (PCR) and were directly sequenced in an ABI310 Genetic Analyzer (Applied Biosystems, Foster City, CA, USA). The presence of significant associations between the SNPs detected at the 3'UTR of the HLA-G gene was evaluated by means of a likelihood ratio test of linkage disequilibrium (LD), using the ARLEQUIN version 3.1 program. The PHASE method and expectation-maximization (EM) algorithm were used to infer 3'UTR haplotypes. For the eight polymorphic sites (14bp Del/Ins, +3003T/C, +3010C/G, +3027C/A, +3035C/T, +3142C/G, +3187A/G and +3196C/G), only the +3010 genotype CC was significantly associated with protection against the disease, being less frequent in patients compared with the control group ($p = 0.0461$; OR = 0.5139). In a recent study, our group has identified the +3010C/G site as a putative target for microRNAs, suggesting a possible posttranscriptional control of this site in HLA-G expression. Regarding 3'UTR haplotypes, we have observed a significant increase in the frequency of haplotype UTR-6 among patients, conferring susceptibility to TD1 ($p = 0.0034$, OR = 3.068), and a significant decrease of haplotype UTR-3, suggesting a protective role to TD1 ($p = 0.0082$, OR = 0.3547). In conclusion, the present study revealed significant associations between 3'UTR polymorphisms and haplotypes with Type 1 Diabetes susceptibility.

981F

SNPs located in regulatory regions of TPM1 and TPM2 affect gene expression and are associated with clubfoot. *K.S. Weymouth[1,2], S.H. Blanton[3], S. Richards[4], M.J. Bamshad[5], A.E. Beck[5], A. Savill[6], M.B. Dobbs[7,8], C.A. Gurnett[7,8], J.T. Hecht[1,2].* 1) Dept Pediatrics, Univ Texas Medical Sch, Houston, TX; 2) Graduate School of Biomedical Sciences, Houston, TX; 3) University of Miami Miller School of Medicine, Miami, FL; 4) Texas Scottish Rite Hospital, Dallas,TX; 5) University of Washington, Seattle,WA; 6) University of Cardiff, Wales, UK; 7) Washington University School of Medicine, Saint Louis, MO; 8) Saint Louis Shriners Hospital for Children, Saint Louis, MO.

Isolated, nonsyndromic clubfoot is a common birth defect affecting 135,000 newborns worldwide each year. Clubfoot is characterized by an inward posturing of the foot in a rigid, downward position. Calf muscles in the affected leg(s) are underdeveloped and remain small even after corrective treatment. Clubfoot is a complex birth defect and is posited to be caused by perturbation in multiple genes. However, the genetic variation contributing to this birth defect is largely unknown. To identify the genetic variation(s), we interrogated fifteen muscle contraction genes in our family-based discovery clubfoot dataset composed of multiplex and simplex families. Single SNP, haplotype and gene interaction analyses identified 3 associated SNPs (rs4075583, rs3809565 and rs3825973) in tropomyosin 1 (TPM1, fast-twitch muscles) and 2 (rs2025126 and rs2145925) in tropomyosin 2 (TPM2, slow-twitch muscles genes). All of these SNPs were located in potential regulatory regions. In silico analysis predicted that all the associated regulatory SNPs in TPM1 and TPM2 could alter DNA binding depending on whether the ancestral or alternate allele was present. EMSA (gel shift) and luciferase assays were performed in differentiated and undifferentiated muscle cell nuclear extracts and muscle cells, respectively. EMSA analysis showed that the alternate allele of rs4075583/TPM1 and rs2025126/TPM2 eliminate a DNA binding site, while two DNA binding sites are created when the alternate allele of rs2145925/TPM2 is present. No effect on DNA binding was seen for rs3809565/TPM1 and rs3825973/TPM1. Importantly, we find that the alternative allele of rs4075583 causes decreased gene expression. Studies to assess the effect of rs4075583/TPM1, rs2025126/TPM2 and rs2145925/TPM2 on gene expression are on-going. For clubfoot, we show that regulatory variants affect DNA binding sites and gene function in two different but related muscle-specific biologically relevant genes. These results support the multifactorial etiologic model for clubfoot and suggest dysregulation of gene expression as a mechanism underlying clubfoot. These exciting and novel findings provide important insight about a potential cause of clubfoot.

982F

Protein Biomarker Development in Niemann-Pick Disease, type C. *S.M. Cologna[1], X-S. Jiang[1], P.S. Backlund[2], N.M. Yanjanin[1], C.A. Wassif[1], A.L. Yergey[2], F.D. Porter[1].* 1) Program in Developmental Endocrinology and Genetics, NICHD, NIH, DHHS Bethesda, MD; 2) Biomedical Mass Spectrometry Facility NICHD, NIH, DHHS Bethesda, MD.

Niemann-Pick Disease, type C (NPC) is a genetic, neurodegenerative, lipid storage and transport disorder. As a result of lipid accumulation found in NPC, a cascade of pathological events occurs including oxidative stress, apoptosis and neuroinflammation. The phenotypic spectrum of NPC is broad, typical clinical presentations include ataxia, liver dysfunction and seizures among others. There is no FDA approved therapy for NPC therefore we sought to identify differentially expressed proteins in an attempt to (i)develop therapies to target the pathological cascade and (ii)identify protein markers that can be used as tools when testing therapeutic interventions. Protein lysates were obtained from female *Npc1*$^{+/+}$ and *Npc1*$^{-/-}$ mice cerebella ($n \checkmark 4$) at 1, 3 and 5 weeks post birth. Protein pools were subjected to 2D-gel electrophoresis in triplicate and silver stained. Differentially expressed spots were excised, digested with trypsin and analyzed using MALDI-TOF/TOF and/or LC-ESI-MS/MS. MS/MS data was submitted to Mascot and validated using Scaffold. Protein identifications at the 99% confidence level required two peptides (95% confidence level). In total, 109 spots were differentially expressed relative to controls ($R>1.5/<0.67$, $p<0.05$). One novel finding was the altered expression of fatty acid binding protein (FABP) family members in the cerebellum of mutant mice. FABPs are responsible for fatty acid transport and metabolism. We identified three differentially expressed FABPs: FABP3, FABP5 and FABP7 which were over-expressed in the mutant relative to control. Interestingly, increased cerebrospinal fluid (CSF) FABP3 expression has been observed in Alzheimer disease, a disorder with pathological overlap with NPC. FABP5 has been associated with inflammation while FABP7 has been proposed as a biomarker for brain injury. We used Western blot to validate the FABP3 expression. To translate our findings to the clinic, increased FABP3 expression levels were validated in CSF from NPC patients relative to controls using ELISA. The concomitant increase found in both studies suggests that FABP3 may be a candidate protein marker to study. Furthermore, NPC patients taking off-label miglustat, a glycosphingolipid inhibitor, show lower CSF FABP3 levels, relative to age-matched controls and FABP3 levels decreased significantly after initiation of the therapy. We are currently studying the function of these FABPs in NPC and exploring other differentially expressed proteins.

983F

Classification of severity of cleft lip and palate in patients attending the genetic consultation in Operation Smile. Colombia. *J. Martinez[1], A. Venegas[3], I. Briceno[2,3].* 1) Bioscience, Grupo de Genetica Humana, Universidad de La Sabana, Chia, Colombia; 2) Biocience, Grupo de Genetica Humana, Universidad de La Sabana, Chia, Colombia; 3) Grupo de genetica Humana, Universidad Javeriana, Bogota, Colombia.

The Cleft Lip-Palate (FLP) is one of the most common congenital malformations and is caused by an alteration in the fusion of the tissues that give rise to the upper lip and palate during embryonic development. According to etiology, the timing of embryonic development that occur and its epidemiological characteristics, the FLP are classified in Non sindromics and Sindromics, into four groups: pre-palatal clefts or primary palate, fissures of secondary palate (which can affect the hard palate and / or soft), mixed (with involvement of the lip and palate) and minor fissures of rare occurrence. The manifestation of these malformations is conditioned by genetic, environmental and nutritional factors. The global frequency of these malformations is 1 for every 1,200 live births. Colombia is a multiethnic country, with the population distributed in different regions, from dry deserts, mountains and rainforest. Currently there are no studies to determine precisely the extent of these malformations in Colombian population. This study was performed in 1100 patients who attended the genetic consultation under the program “Operation Smile Colombia”, in different regions of the country, which underwent a full genetic evaluation and classification of each of the presented malformations The results indicate that of the 1100 patients, 1019 are non-syndromic and 81 are syndromes, these syndromes have heart defects 19, 24 have Aarskog syndrome and the remaining 38 have other syndromes. , the results are the closest to the impact of this anomaly in the Colombian population.

MOMO syndrome is a rare mental retardation /multiple anomalies syndrome of unknown etiology, characterized by macrosomia, obesity, macrocephaly, and ocular abnormalities. We report a new case in an adult patient to describe the natural history of this entity.This patient is a 23 years old, brazilian boy, third child of healthy non-consanguineous parents. Gestation was uneventful and delivery was at term. Birth weight of 3550g and length 53cm.The boy had developmental delay and needed special education. Obesity was present since childhood, and recently he appeared to be hyperactive and aggressive. At 8 years he presented with delayed neuropsychomotor development, hyperactivity, and macrosomia. Height was 137cm(90th-97th), weight 47,3kg (>97th), and OFC 54,5cm(98th centile), internipple distance 20cm (>97th).Craniofacial features included coarse facies, macrocephaly, high forehead with plain supraorbital ridges, deep set eyes, strabismus, synophrys, hypertelorism, overfolded horizontal ear helix, large nose with broad nasal root, short philtrum, cupid bow mouth, irregular teeth, prognatism, and short neck. Limited supination and pronation of the forearm as well as limited flexion of the knees and elbows, and flat feet were present.Patient developed obstructive sleep apnea at 18 years old. At current physical exam he was 169,8cm (25th-50th) tall, weighted 113 kg (>97th), OFC 59cm (>98th) and kept the same dysmorphic features and mental retardation. Eye exam showed high myopia, retina and vitreous alterations. So far, he hasn't had increased intraocular pressure, nevertheless he is still at risk . Mild to moderate conductive hearing loss on the right ear was detected. Orthopaedic evaluation showed gait abnormalities, shoulder, hip and knees contractures. Macrocrania and advanced bone age were seen on X-rays. Echocardiography was normal. Brain MRI revealed ventricular, cortical sulci, cisterns and fissures dilatation, and craniofacial disproportion with increased extra-cranial soft tissues. Citogenetic analysis was normal. Southern Blotting analysis for methylation 15q11-13 showed biparental pattern. Microsatellites segregation analysis for 1p36 region excluded microdeletions. Molecular analysis for FRAXE and FRAXA (Xq27.3 q28) were normal. At this point, the patient is one of the eldest already reported having MOMO syndrome. Therefore we aimed to extend the clinical spectrum, and provide a possible natural history for this condition.

985F

Past and present investigations in a family with Christianson syndrome and SLC9A6 gene defect. *S.G.M. Frints[1,2], C.E. van Roozendaal[2,3], V.M. Kalscheuer[4], W.O. Renier[5], D. Tserpelis[2], E.E. Smeets[1,2], A.P. Stegmann[1,6], R. Blok[2,3], I.P. Krapels[1,2], C.T.R.M. Schrander-Stumpel[1,2], H.H. Ropers[4], C.E.M. de Die-Smulders[1,2].* 1) Department of Clinical Genetics, Maastricht University Medical Center+, azM, Maastricht, the Netherlands; 2) Research Institute for Oncology and Developmental Biology, GROW, Maastricht University, Maastricht, The Netherlands; 3) Clinical Genomics, Department of Clinical Genetics, Maastricht University Medical Center+, azM, Maastricht, the Netherlands; 4) Max Planck Institute for Molecular Genetics, Department Human Molecular Genetics, Ihnestrasse 73, D-14195 Berlin, Germany; 5) Department of Neurology, Canisius-Wilhelmina Hospital, Nijmegen, The Netherlands; 6) Cytogenetic Laboratory, Department of Clinical Genetics, Maastricht University Medical Center+, azM, Maastricht, the Netherlands.

Christianson syndrome (OMIM 300243) is a rare syndromic form of X-linked intellectual disability disorder (XLID) which resembles clinically Angelman syndrome at young age. Affected men have profound cognitive dysfunction without or with nearly no speech. They show spasticity, ataxia and facial grimacing. They are relatively microcephalic and have cerebellar a-/hypoplasia. In adulthood, they develop a lean body and present with constant drooling. One-third of the carrier women have learning disabilities, dyslexia with or without additional clinical features. The underlying SLC9A6 (OMIM 300231) gene defect has been reported in families with Christianson syndrome. We present a new family with Christianson syndrome with additional brain pathology and molecular investigations. Clinically, classical features of Christianson syndrome were present in affected men. Open brain biopsy, performed in the past, in an affected man showed distinct pathological second and poorly differentiated third and fourth cerebral cortical layer using the Golgi-Cox staining. Cerebrospinal fluid investigations were normal, as well as other metabolic and infection parameters in blood. Carrier women had mild learning problems and were relatively microcephalic. Through next generation sequencing, the X-exome was systematically screened in this family. A SLC9A6 c.1481delG, p.Gly526fsX non-recurrent truncating mutation was identified which segregated with the clinical phenotype. Missense mutations in other causal XLID genes included GDI1 c.154-3C>T and SHROOM2 c.3608A>G (p.Asn1203Ser). Both mutations could, but FTSJ1 c.-87-10 (without splice effect after in silico analysis) variance could not be excluded through segregation analysis in this family. FTSJ1 expression analysis to investigate eventual modifying effect on the clinical phenotype in this family might be needed. We conclude, that through past and present investigations, the clinical phenotype of Christianson syndrome has further been delineated and that possible modifying effects of other XLID genes might interfere with the clinical phenotype or might explain inter and intra familial variability.

986F

A patient with Allan-Herndon-Dudley syndrome due to a complete deletion of exon 1 of the *MCT8* (*SLC16A2*) gene. *B. García de Teresa[1], A. González del Angel[2], ML. Ruíz Reyes[3], R. Calzada Leon[3], B. Perez Enriquez[3], MA. Alcántara Ortigoza[1].* 1) Laboratorio Biología Molecular, Instituto Nacional de Pediatría, Mexico City, México; 2) Subdirección de Investigación Médica, Dirección de Investigación, Instituto Nacional de Pediatría, Mexico City, México; 3) Servicio de Endocrinología, Instituto Nacional de Pediatría, Mexico City, México.

In 1944, Allan, Herndon and Dudley described a severe form of X-linked mental retardation with a particular thyroid hormone profile that was later known as AHD syndrome. Years later, mutations in *MCT8* (*SLC16A2*), a gene that codes for a thyroid hormone transporter, were found to cause this syndrome. Since then, affected males from 47 families carrying an hemizygous mutation in *MCT8* have been described. Case report: 30 month old patient, second son of a non-consanguineous couple, delivered by cesarean section at 39 weeks due to a history of polyhidramnios. The patient's neonatal screening for hypothyroidism was reported normal. At 3 months of age, his mother noticed somnolence, a wide anterior fontanel and difficult feeding, which required a gastrostomy. A recent physical exam confirmed a wide anterior fontanel, and revealed facial dysmorphism (long lashes, depressed nasal bridge, telecantus, bulbous nose, anteverted nares, prominent upper lip) and central hypotonia. The patient's psychomotor development is severely affected, he has not achieved cephalic support and is unable to speak. Thyroid tests show a particular profile: high T3, T4 in the lower limit of normal range, and normal TSH. Despite appropriate thyroid hormone replacement for over 18 months, no improvement of the condition has been documented. Upon the suspicion of AHD syndrome, molecular study of *MCT8* was performed by amplifying each of its six exons, following the method described by Schwartz et al. 2005.

The genomic DNA sample of this patient only allowed the amplification of five exons of *MCT8*. Despite many attempts, the expected 773 pb product of exon 1 was never obtained. The carrier status of the mother is being tested in a gene dosage assay. Conclusion: The results are consistent with a deletion that completely spans exon 1 of *MCT8*. To our knowledge, this would be the 48th family in which a *MCT8* mutation has been identified. Of all mutations, 52% are point mutations, 31% small in/dels and the remaining 17% large deletions. The complete deletion of exon 1 has been found in 4 different families, the rest are private mutations. This recurrence of the complete exon 1 deletion could be indicative of a genomic region prone to deletions. The loss of exon 1 predicts a complete inactivation of the MCT8 transporter and is associated with a severe phenotype where independent walk or speech are never attained. Our patient presents this severe phenotype.

987F

MEHMO syndrome: report of a male patient. *D. Gul[1], S. Vurucu[2], R. Akin[2].* 1) Dept Medical Genetics, GATA Medical Faculty, Ankara, Ankara, Turkey; 2) Dept Pediatric Neurology, GATA Medical Faculty, Ankara, Turkey.

The MEHMO syndrome (MIM 300 148) is the acronymic designation for a complex of mental retardation, epileptic seizures, hypogonadism and hypogenitalism, microcephaly, and obesity. In 1998, Steinmuller et al described the syndrome in a live male of the five affected males. To date four reports have been published and all seem inherited in X-linked fashion. We here report a 6-month-old male with MEHMO syndrome. A male, the first child of non-consanguineous parents, was delivered vaginally at 34 weeks' gestataion. The prenatal history was unremarkable. Her birth weight, length and head circumference had been 2 080 g, 46 cm and 31 cm. The family history was negative. He was referred because of motor retardation, epilepsy, and obesity at the age of 6 months. On admission, his height was 61.3 cm (10th centile), weight 11.800 g (> 97th centile) and OFC 40 cm (<3rd centile). He had motor retardation and several epileptic seizures. Microcephaly and severe obesity were also noted. Facial anomalies were evident: narrow bifrontal diameter, short nose, full cheeks, wide philtrum, and downturned corners of the mouth. The testes were hypoplastic, whereas the penis appeared small in size. Fundoscobic examination revealed a pale optic disc. Serum cholesterol and LDL-cholesterol were both elevated. On the Denver Developmental Screening Test (DDST) he was assessed abnormal. Cranial CT shows cerebral hemisphere atrophy in the temporal, frontal and parietal areas. Electroencephalography showed fronto-central epileptic discharges. Cytogenetic study using high resolution banding technique revealed 46,XY karyotype. PWS was excluded on FISH. Cerebellar atropy and hypercholesterolemia are the unusual findings in this patient.

988F

A contiguous 6.6 Mb region of homozygosity on chromosome 10 spanning the bands p15.1-p14 is associated with unusual obesity, dysmorphic features, and mild intellectual disability. *P.P. Koty[1], J.N. Hellwege[2], T. Jewett[1], M. Mortenson[3], G.A. Hawkins[4], D.W. Bowden[5], N.D. Palmer[5].* 1) Department of Pediatrics, Section on Medical Genetics, Wake Forest Baptist Health, Winston-Salem, NC; 2) Wake Forest University School of Medicine, Molecular Genetics and Genomics Program, Winston-Salem, NC; 3) North Carolina Department of Health and Human Services, Division of Public Health, Raleigh, NC; 4) Center for Genomics and Personalized Medicine Research, Wake Forest Baptist Health, Winston-Salem, NC; 5) Department of Biochemistry, Wake Forest Baptist Health, Winston-Salem, NC.

Here we report a 12 year old female with central obesity, very prominent striae overlying the abdomen and medial upper arms, a “buffalo hump”, and acanthosis nigricans who is mildly intellectually disabled. In addition, she has macrocephaly (as does her mother) together with telecanthus, ocular hypertelorism, large ears, and slightly tight Achilles tendons. Chromosome analysis revealed a 46,XX karyotype. Cytogenomic microarray analysis, which included zygosity analysis, revealed no copy number variants of interest but did show a contiguous 6.6 Mb region of homozygosity on chromosome 10 spanning the bands p15.1-p14. This region contains 29 known genes including several potential candidate genes for the patient's clinical presentation. Following IRB approval and informed consent, subsequent whole exome sequencing of this region confirmed the homozygosity and revealed rare variants, as compared to known variants in the HapMap and dbSNP databases, within several of the candidate genes. The first rare variant results in a missense amino acid substitution in *AKR1C4. AKR1C4* is one of four soluble human 3 (-hydroxysteroid dehydrogenase (HSD) isoforms that are members of the aldo-keto reductase (AKR) superfamily. Two other isoforms, *AKR1C2* and *AKR1C3*, have been implicated in the regulation of androgen availability in adipose tissue and dysregulation may result in abdominal obesity. Thus, this homozygotic missense variant within *AKR1C4* may be causative of the unusual abdominal obesity identified in our patient. Two other genes within this region, *NET1* and *RBM17*, have rare splice-site variants. Variants within *NET1*, which encodes a noradrenaline transporter, have been associated with attention-deficit/hyperactivity disorder (ADHD) in females, while *RBM17* has been shown to promote neurotoxity. Either or both of these variations may explain our patient's mild intellectual disability. Finally, two rare variants causing missense mutations within *ITIH5*, a gene that encodes a member of a family of structurally related plasma serine protease inhibitors involved in extracellular matrix stabilization, were identified. Variants within this gene may be unrelated to our patient's clinical presentation or may be involved in her dysmorphic features. Our data suggest several candidate genes that, at least partially, may explain our patient's clinical presentation, but additional investigation is needed for further validation.

989F

Outcomes of clinical genetic evaluation of 186 patients referred for intellectual disability or global developmental delays of unknown cause. *J. Moeschler[1], M. McClain[2], L. Burke[3], M.B. Dinulos[1], R. Smith[4], W. Smith[4], P. Miller[5].* 1) Dept Pediatrics, Medical Genetics, Dartmouth-Hitchcock Med Ctr, Lebanon, NH; 2) New England Genetics Collaborative, IOD/UCED, University of New Hampshire, Durham NH; 3) Department of Pediatrics and the Vermont Regional Genetics Center, Burlington, VT; 4) Dept of Pediatrics, Genetics Division, Maine Medical Ctr, Portland ME; 5) University of New Hampshire, IHPP, NEGC, Durham, NH.

The New England Genetics Collaborative includes a regional effort to improve the medical genetic evaluation process and outcomes for patients referred for global developmental delays (GDD) or intellectual disability (ID). The purpose is to improve outcomes for such patients by optimizing the diagnostic process. Diagnostic testing protocol was not set but guided by the clinician decision and existing published protocols. This presentation reports on results of all 186 consecutive patients referred to participating centers from March 2009 through May 2011 referred for intellectual disability (ID) or global developmental delay (GDD). 75 (36%) were referred for that alone; the remained included ID/GDD plus one or more other indications, e.g., dysmorphic features, malformations, micro- or macrocephaly (from a list 13 other indications). Patients ranged in age from <1 year to 23 years; median age 5 years. Male-to-female ratio was 60:40 (112 males; 74 females). Disability was mild (IQ 50-57) in 62%; moderate (25-49) in 34%; and, severe (<25) in 5%. Diagnoses were established in 76 (41%) after evaluation, with the following categorization: chromosomal conditions in13 patients; cytogenomic or microarray abnormalities in 28; X-linked genetic disorders in 13; monogenic conditions (not X-linked) in 10; known syndromes (and not another category) in 7; and, multifactorial in 5. 20 patients had more than 1 visit; in 4 (25%) the diagnosis was established only after a second visit. Among patients referred with GDD/ID and autism (46), outcomes differed significantly compared to those without this co-occurring presentation: significantly fewer with known cytogenomic (microarray) disorders ($p<0.01$); multiple minor anomalies ($p<0.001$); dysmorphic features ($p<0.05$); significantly more males ($p<0.01$); and significantly fewer with known diagnosis ($p<0.0001$). Of the 46 with autism, 10 (22%) resulted in a specific diagnosis with no one category of test predicting the outcome. In 117 patients the diagnosis remained unknown following the evaluation. Of these 38 (32%) had co-occurring autism; 30 (26%) were those with dysmorphic features (“multiple minor anomalies”); 16 (14%) were “non-dysmorphic” with no major or minor anomalies and no neurologic signs or symptoms, i.e., non-syndromic GDD/ID; and 11 (9%) had micro- or macrocephaly. The medical decision-making was key in process and outcomes. Cytogenomic conditions comprised the largest proportion of known diagnoses.

990F

Extremely high prevalence of primary microcephaly in Bushehrian population (a southern province of Iran): novel STIL and ASPM mutations. *E. Papari, M. Bastami, M. Hoseini, SS. Abedini, I. Bahman, L. Nori_vahid, F. Behjati, K. Kahrizi, H. Najmabadi.* Genetics Research Center, University of Social Welfare and Rehabilitation Siences, Kodakyar Street, Daneshjo Ave, Tehran, Iran;.

Autosomal recessive primary microcephaly (MCPH) is a rare condition characterized by mild to severe Mental Retardation and head circumference equal or more than three SDs below the population mean based on sex and age without any further major neurological findings. Up to now, seven genes (Microcephalin, WDR62, CDK5RAP2, CEP152, ASPM, CENPJ and STIL) have been known to cause this disorder. In this study, we distinguished primary microcephaly in 14 families out of 55 Bushehrian families (25.45%) mostly with two or more mentally retarded individuals. Genotyping carried out using appropriate microsatellite marketers for 7 MCPH loci. Linkage was established in two families; one for MCPH5 and the other to MCPH7. The remaining 12 (85.71%) families did not showed linkage to any of the known MCPH loci. Further analysis by DNA sequencing in the two linked families revealed a homozygous (c.4849C>T) truncating mutation in the ASPM gene, and a homozygous missense mutation (c.2392T>G) in STIL gene, respectively . In present study we could only detect mutation in two out 14 families with MCPH (14.29%) by using linkage analysis and direct sequencing methods. The high prevalence of MCPH in Bushehr Province (southern Iran, with a long coastline onto the Persian Gulf) and the fact that we could only identify the causative mutation in a couple of families shows the need for more follow up in the rest of the families; therefore, homozygosity mapping, exon enrichment and next-generation sequencing (NGS) for the remaining families are currently under way to determine the responsible genes for the remaining families.

991F

Searching for copy number changes in nonsyndromic X-linked intellectual disability. *E.G. UTINE[1], P.O. KIPER[1], Y. ALANAY[1], G. HALILOGLU[2], D. AKTAS[3], K. BODUROGLU[1,3], E. TUNCBILEK[1,3], M. ALIKAŞIFOGLU[3].* 1) Hacettepe University, Department of Pediatrics, Genetics Unit, Hacettepe University, Ankara, Turkey; 2) Hacettepe University, Department of Pediatrics, Neurology Unit, Hacettepe University, Ankara, Turkey; 3) Hacettepe University, Department of Medical Genetics, Hacettepe University, Ankara, Turkey.

Intellectual disability (ID) has a prevalence of 2-3% with 0.3% of the population being severely retarded. Etiology is heterogeneous, owing to numerous genetic and environmental factors. Underlying etiology remains undetermined in 75-80% of mildly disabled patients and 20-50% of those severely disabled. Twelve% of all ID is thought to be X-linked (XLID). This study covers copy number analysis of some of the known XLID genes, using multiplex ligation-dependent probe amplification (MLPA) in 100 nonsyndromic patients. One of the patients was found to have duplication in all exons of MECP2 gene, and a pair of brothers had duplication in the fifth exon of TM4SF2/TSPAN7 gene. Affymetrix® 6.0 whole-genome SNP microarray confirmed the duplication in MECP2 and showed duplication of exons 2-7 in TM4SF2/TSPAN7, respectively. MECP2 duplication has recently been recognized as a syndromic cause of XLID in males, whereas duplications in TM4SF2/TSPAN7 are yet to be determined as a cause of XLID. Being an efficient, rapid, easy-to-perform, easy-to-interpret and cost-effective method of copy number analysis of specific DNA sequences, MLPA presents wide clinical utility and may be included in diagnostic work-up of ID, particularly when microarrays are unavailable as a first line approach.

992F

47 XX iso 18p Syndrome. *A. venegas, i. briceno.* Medicine, Universidad Javeriana, Bogota, Colombia.

CASE REPORT: Female patient (19 years old), with moderate mental retardation in the fine and coarse movements, language and coordination areas. She presented severe gastroesophageal reflux disease during her first year of age. Her mother suffered pre-eclampsia during her pregnancy. First signs of developmental delay became evident at three months of age because of floppiness, walked at 22 months and although her first words were at 12 months, her vocabulary is scarce and has difficulty in constructing sentences. No consanguinity or relevant family history. Physical examination showed height 1.53 cm., weight 57 kg hypoplasia of 4th and 5th toes from right leg, kyphoscoliosis and lumbar lordosis . Kariotype showed: 47XX + mar. Microarray analysis showed: 47XX iso (18p) (p11.21-pter). Brain nuclear magnetic resonance and tomography: Normal Echocardiogram: Normal.

993F

The first case of Sjögren-Larsson syndrome with a mutation in ALDH3A2 in Korea. *K.Y. Koo, J.Y Yang, C.H. Lee, J.S. Lee.* Department of Clinical Genetics, Yonsei University, College of Medicine, Seoul 120-752, Korea.

Sjögren-Larsson syndrome (SLS, OMIM #270200) is a rare autosomal recessive disorder characterized by ichthyosis, mental retardation, and spastic diplegia or tetraplegia. It is caused by mutations in the ALDH3A2 gene that encodes fatty aldehyde dehydrogenase (FALDH, OMIM *609523, EC 1.2.1.3), a microsomal enzyme that oxidizes fatty aldehyde to fatty acid. Secondary accumulation of abnormal lipid in the membrane of the skin and brain is thought to cause the pathogenesis of cutaneous and neurologic symptoms of SLS. The prevalence of SLS has been estimated as 0.4 per 100,000 or lower in Sweden, and over 200 cases have been reported worldwide since first reported by Sjögren. However, there is currently no report in the Korean population and we present the first cases of SLS in Korea. The patient manifested generalized ichthyosis predominantly on the posterior neck, both axillary areas, and hands since the age of one month and subsequent neurological delay since the age of 9 months with spastic diplegia. By this typical triad, we could diagnose SLS with mutation analysis of the ALDH3A2 gene.

994F

Genetic Heterogeneity of Mabry syndrome. *M.D. Thompson[1], T. Rosioli[2], M.N. Nezarati[3,8], E. Sweeney[4], P. Meinecke[5], D. Horn[6], P.M. Krawitz[7], R. Londono-Mendoza[3], H. van Bokhoven[2], D. Andrade[9], A. Munnich[10], H.B. Brunner[2], D.E. Cole[1].* 1) Laboratory Medicine & Pathobiology, Banting Inst, Univ Toronto, Toronto, ON, Canada; 2) 2Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 3) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 4) Royal Liverpool Children's Hospital, Liverpool, United Kingdom; 5) Medizinische Genetik, Altonaer Kinderkrankenhaus, Hamburg, Germany; 6) Institut für Medizinische Genetik, Charité Universitätsmedizin Berlin, Berlin, Germany; 7) Berlin-Brandenburg Center for Regenerative Therapies; 8) Department of Genetics, North York General Hospital, Toronto, ON, Canada; 9) L'Hopital NECKER, Paris, France; 10) Toronto Western Hospital, Toronto, ON, Canada.

Mabry syndrome (hyperphosphatasia with developmental disability) was first described by Mabry et al.(OMIM#239300) in 1970. At first considered rare, improved syndrome identification has led to recruitment of more than twenty families world-wide. Salient features of the disorder include: characteristic facial dysmorphology (hypertelorism, a broad nasal bridge and a tented mouth); variable shortening of middle and distal phalanges; and neural abnormalities on biopsy (plaques disrupting Schwann cells). Like many infantile metabolic storage disorders, seizures associated with Mabry syndrome have an onset in the first year of life. Persistently elevated serum alkaline phosphatase (ALP) levels are now known to be associated with abnormalities of the phosphatidylinositol glycan (PIG) anchor, which has been found disrupted in ten of these families. Lysosomal storage material detected in patients with Mabry syndrome has been putatively identified as glycolipid in nature - possibly resulting from the improper formation of the PIG anchor. Since mutations of the PIGV gene have not been identified in all patients with a clinical diagnosis of Mabry syndrome, we describe further molecular work on genetically heterogeneous cohort. Since there are more than 15 genes integral to PIG anchor synthesis, the disorder may result from disruptions to other genes in the PIG anchor biosynthesis pathway. This work will assist in elucidating the inborn errors of metabolism that underlie the spectrum of abnormalities found in Mabry syndrome.

995F

Effect of NSD1 Mutations on the DNA Methylome in Patients with Sotos Syndrome. *S. Choufani[1], J. Hailey[1], Y.A. Chen[1], D. Grafodatskaya[1], R. Mendoza[1], S. Bowdin[1], W. Reardon[2], C. Cytrynbaum[1], R. Weksberg[1].* 1) The Hospital for Sick Children, Toronto, On, Canada; 2) Our Lady's Hospital for Sick Children, Dublin, Ireland.

Sotos syndrome (OMIM 117550), is a genetic overgrowth and malformation disorder associated with a variety of neurodevelopmental problems including intellectual and behavioral issues. More than 75% of individuals with Sotos syndrome are haploinsufficient for NSD1 (nuclear receptor-binding SET domain protein 1), a histone lysine methyltransferase important for multiple aspects of normal development. Recently, NSD1 was shown to bind near various promoter elements and regulate multiple genes via interactions with H3K36 methylation and RNA polymerase II suggesting a potential role of NSD1 in regulating transcription initiation via epigenetic mechanisms such as DNA methylation. The goal of this project is to define the impact of loss of NSD1 function on the DNA methylome. The identification of such DNA methylation alterations will elucidate the molecular pathophysiology of Sotos syndrome and identify potential molecular targets for therapeutic intervention. Sotos syndrome patients were recruited at the Division of Clinical and Metabolic Genetics at the Hospital for Sick Children. Bisulfite modified blood DNA from 8 NSD1 mutation- positive cases were investigated by genome-wide profiling of DNA methylation using the Illumina Human Infinium 27K Microarray covering the promoter of over 14000 genes. Differential methylation analysis identified large scale significant differences between Sotos cases and age/sex/tissue -matched controls (n=12). We report for the first time a significant loss of methylation identified in 493 probes (mapping to the promoter of 443 genes).This group of genes was enriched in anatomical structural morphogenesis, ectoderm development, and carbohydrate transport processes. These epigenetic alterations are likely to explain the developmental features of Sotos syndrome such as malformations, developmental delay/mental retardation. These data demonstrate how crosstalk between deficiency of a histone methyltransferease results in alterations in promoter DNA methylation and how the molecular pathophysiology of a genetic syndrome can be defined by a specific epigenetic signature.

996F

46,XX male associated with a de novo duplication of the SOX3 gene. *R. Babul-Hirji[1], D. Wherrett[2], D. Bagli[3], D. Chitayat[1,4].* 1) Div of Clin and Metab Genetics, Hosp Sick Children, University of Toronto, Toronto, ON, Canada; 2) Division of Endocrinology, Hosp Sick Children, University of Toronto; 3) Division of Urology, Hosp Sick Children, University of Toronto; 4) The Prenatal Diagnosis and Medical Genetics Program, Dept of Obst and Gyne, Mount Sinai Hospital, University of Toronto, Toronto, ON.

Sex in mammals is determined genetically by the sex chromosome complement (XY males and XX females) and phenotypically by the development of gender-specific anatomy, physiology, and behavior. Complete or partial mismatch between the genetic and phenotypic sex result in disorders of sexual development (DSDs). The incidence of complete sex reversal (46,XY females and 46,XX males) is about 1 in 20,000 births. As not all cases of 46,XX male sex reversal involve the SRY gene, other gene(s) or mechanisms are thought to be involved in this disorder. One of the genes recently found to be involved in sex determination is the SOX3 gene. We report a newborn male with an undervirilized male phenotype including bifid scrotum, penoscrotal hypospadias and chordee with a normal phallic length, width and erectile tissue and testes palpable in the labioscrotal folds. His karyotype was 46,XX, FISH for SRY was negative and microarray analysis showed a de novo 0.494 Mb copy number gain in chromosome region Xq27.1. This region contains approximately 4 genes including the SOX3 gene. Sox3 gain-of-function in the developing gonad was found to induce testis development by functioning as a surrogate for SRY. Sutton et al., (2011) reported 3 patients with XX male sex reversal associated with a unique genomic rearrangement of the SOX3 regulatory region. Our case supports the theory that rearrangements of SOX3 cause XX male sex reversal in humans.

997F

XY disorder of sexual development (DSD) associated with microdeletion of chromosome 9p33.3 including the *NR5A1*(SF-1) gene. *L.M. Blanchard[1], K. Desai[1], S. Nimkarn[2], T. Brandt[1], L. Edelmann[1], L. Mehta[1].* 1) Dept. of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Dept. of Pediatrics, Weill Cornell Medical College, NY.

A 6 1/2 -year-old female with mild developmental delay and minor dysmorphisms presented for re-evaluation due to a new twin pregnancy in her mother. Karyotype at age 3, done for developmental delays, was reported to be 46,XY. Facial features included prominent forehead, long palpebral fissures, slightly cupped ears, malar flattening, full mouth, and 3-4 small café-au-lait macules over the trunk. She was phenotypically female with normal height (-0.064 SDS for females) and normal prepubertal female external genitalia. Pelvic sonogram did not identify a uterus or gonads. Adrenal hormone production after ACTH stimulation was normal. Gonadal testosterone showed poor response to hCG stimulation but normal T to DHT ratio. AntiMüllerian hormone, FSH, LH, inhibin B were appropriate for age. Sequencing of the *AR*, *SRD5A2*, *SRY*, *NR5A1* and *WT1* genes did not detect any pathogenic mutations. At age 6 1/2, she was receiving special education services for communication and articulation problems. Array CGH revealed a novel 1.54 Mb interstitial 9q33.3 deletion. FISH studies on the proband, her mother and cultured chorionic villi from the mother's ongoing twin pregnancy (both fetuses 46,XY) confirmed that the deletion had occurred de novo. The deleted region encompassed 11 genes including *NR5A1*, a transcription factor implicated in testicular and adrenal development. XY patients with heterozygous mutations in *NR5A1* have been reported with variable degrees of undervirilization (from micropenis, underdeveloped testes, genital ambiguity to complete female external genitalia), with presence or absence of Mullerian structures. Adrenal insufficiency was a less consistent finding. Women (XX) with *NR5A1* mutations are mostly ascertained through family studies, and do not have DSD; a single XX patient with adrenal insufficiency is reported. There are two reports of patients with deletions of *NR5A1*: one with genitopatellar syndrome due to a 3 Mb contiguous gene deletion, and another with 970 kb microdeletion and XY DSD. The exact role of *NR5A1* in sexual differentiation and adrenal function remains unclear. This patient further expands the literature, and illustrates the value of array CGH studies in patients presenting with unusual DSDs.

998F

Further Clinical Delineation of BPES associated with microdeletions encompassing *FOXL2*. *K. Enomoto[1,3], Y. Sugawara[2], N. Furuya[3], M. Adachi[4], S. Mizuno[5], Y. Yamanouchi[6], M. Masuno[6], T. Kondo[7], S. Doi[1], S. Mizutani[2], K. Kurosawa[3].* 1) Department of Pediatrics, Perinatal and Maternal Medicine, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 2) Department of Pediatrics and Developmental Biology, Tokyo Medical and Dental University Graduate School, Tokyo, Japan; 3) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Division of Endocrinology and Metabolism, Kanagawa Children's Medical Center, Yokohama, Japan; 5) Department of Pediatrics, Aichi Prefectural Colony Central Hospital, Kasugai, Aichi, Japan; 6) Kawasaki University of Medical Welfare, Kurashiki, Okayama, Japan; 7) Institute for The Handicapped, Mutsumi Home, Misakaeno-sono, Nagasaki, Japan.

Blepharophimosis Ptosis Epicanthus Inversus Syndrome (BPES; MIM# 110100) is a clinically well recognizable autosomal dominant disorder, characterized by the complex eyelid malformation consisting of the literal triad and telecanthus with or without ovarian dysfunction caused by FOXL2 mutations. Individuals with BPES and an intragenic disease-causing mutation, so-called classical BPES, generally have normal intelligence and few extraocular dysmorphic features. In contrast, patients with genomic rearrangements ranging from partial or total FOXL2 deletions to cytogenetically visible microdeletions encompassing neighboring genes frequently present mental retardation, growth failure, and evident extraocular dysmorphic features. In this study, to refine the genotype-phenotype correlations and to add novel insights to clinical diagnosis, we present three new BPES cases associated with microdeletions encompassing FOXL2. Genome-wide microarray-based copy number screening using Agilent SurePrint G3 arrays showed that the deletion intervals varied between 13.7 to 21.6 Mb. Patient 1 is a 10-year-old boy, who presents typical dysmorphic features of BPES, post-natal growth failure, intellectual disability, cerebellar hypoplasia and left hemidiaphragmatic eventration. As diaphragmatic eventration had been misdiagnosed as diaphragmatic hernia in prenatal period, he underwent some excess therapies and examinations in neonate. Patient 2 is a 1-year-old boy, who also presents typical facial features and left hemidiaphragmatic eventration apart from feeding difficulty and growth failure with mental retardation. It was necessary for him to have home oxygen therapy resulted by respiratory disorder with micrognathia complicated by laryngomalacia, and surgical canthoplasty to prevent deprivation amblyopia owing to severe periocular triad. Patient 3 is a 13-year-old girl, who has mild dysmorphic features consistent with BPES and mild eventration of the left diaphragm. She suffers from complex congenital heart disease consisting of truncus arteriosus with left pulmonary arterial defect and right pulmonary arterial malformation leading to significant pulmonary hypertension. She also presents pre-natal growth failure without post-natal catch-up and intellectual disability. Our observations indicate that the cytogenetic rearrangement involving FOXL2 is a recognizable syndrome associated with BPES and cardinal features in the skeletal and diaphragm.

999F

A novel de novo microduplication of 1q21.3-q22 in a patient with growth retardation and developmental delay. *S. Gunn[1], M.N. Strecker[1], P. Mark[2], K. Hovanes[1].* 1) CombiMatrix Diagnostics, Irvine, CA; 2) Spectrum Health Medical Group, Grand Rapids, MI.

We present a 3 year 2 month old male with poor growth and developmental delay. He was the product of a triplet conception which resulted in an *in utero* demise of a female fetus and survival of the two males, born at 29 weeks. Medical history is significant for severe gastroesophageal reflux disease, nystagmus and sleep apnea. Height, weight and head circumference are all <3rd centile. He walked at 24 months and spoke his first word at 30 months. He is generally non-dysmorphic. The twin brother of our patient has been diagnosed with autism spectrum disorder, tachycardia and asthma. A 105K oligonucleotide microarray revealed a duplication of approximately 2.49 Mb: 1q21.3q22(151,137,486-153,630,210)x3, encompassing 93 genes. Confirmation was performed by BAC array. Parental testing was normal, indicating that this is a *de novo* event in the child. To our knowledge, this particular duplication has not been reported previously. A female with a microdeletion of 1.4 Mb overlapping the duplicated region in our patient has been reported as having moderate mental retardation, poor appetite and growth, a high arched palate, and persistent fetal pads. Two patients with larger duplications (10.9Mb and 11.4Mb) overlapping this region have been reported in DECIPHER. This duplicated region overlaps with many genes implicated in OMIM disorders as well as genes expressed in neurons. Autosomal dominant disease genes include: *LOR* (Vohwinkel syndrome and ichthyosis), *CHRNB2* (nocturnal frontal lobe epilepsy), *TPM3* (infantile nemaline myopathy), *ADAR* (dyschromatosis symmetrica hereditaria). Autosomal recessive disease genes include: *PKLR* (hereditary hemolytic anemia due to pyruvate kinase deficiency), *GBA* (Gaucher disease types I), *DPM3* (congenital disorder of glycosylation type I) and *HAX1* (severe congenital neutropenia). Neuronally expressed genes include: *EFNA1*, *EFNA3* and *EFNA4* (members of ephrin gene family which is involved in mediating developmental events, especially in the nervous system) and *KCNN3* which encodes an integral membrane protein that forms a voltage-independent calcium-activated channel involved in regulation of neuronal excitability. It is difficult to know how much the patient's prematurity affects the phenotype, however, follow-up of this patient and classification of other patients with similar and/or overlapping duplications may further elucidate genotype-phenotype correlations and identify the dosage-sensitive genes in the region.

1000F

Copy number alterations in VACTERL association detected by chromosomal microarray analysis. *SY. Shin[1, 2], EJ. Seo[1, 2], JO. Lee[2], M. Hong[2], KJ. Kim[2], AR.E. Kim[3], HW. Yoo[2,3], JK. Ko[2,3], YH. Kim[2,3], IS. Park[2,3].* 1) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan medical Center, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 3) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

VACTERL association is a non-random clustering of congenital anomalies: vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies and limb malformations. Although it is relatively common, the underlying genetic mechanisms are not well known yet. In the present study, we performed high resolution 244K or 180K oligonucleotide microarray to find genetic copy number alterations. Fourteen cases (M:F ratio, 1:1) presenting three or more diagnostic signs for VACTERL association were subjected. All the cases had various cardiac defects. Anal atresia was observed in 13 cases (92.9%), renal anomalies in 10 cases (71.4%), vertebral anomaly in 8 cases (57.1%), limb anomaly in 7 cases (50.0%) and tracheo-esophageal fistula in 4 cases (28.6%). Four cases showed single umbilical artery (28.6%). Probably pathogenic copy number alterations were found in three cases (21.4%): deletions at 6q25.3-q27 (10.7 Mb) and 18q12.1 (42 Kb) in two cases, respectively, and gain at 8q24.22-q24.3 (12.0 Mb) with deletion at 7q36.1-q36.3 (9.7 Mb) in another case. The deletion region at 6q25.3-q27 contains genes related to the anatomical structure morphogenesis (MAS1, T, KIF25), and cell proliferation or apoptosis (RPS6KA2, FGFR1OP, PDCD2). The small deleted region at 18q12.1 contains DSC2 which has been reported in familial arrhythmogenic right ventricular dysplasia and cardiomyopathy (OMIM #610476). The case who had gain at 8q24.22-q24.3 and deletion at 7q36.1-q36.3 by der(7)t(7;8)(q36.1;q24.22)-mat presented bilateral colobomas and Currarino's triad overlapping to VACTERL association. Intriguingly, MNX1 reported in a family with Currarino's triad and SHH related to holosencephaly, polydactyly, cleft lip/palate and colobomatous microphthalmia, are located in 7q36. Two cases with large-scale copy number alterations had other multiple malformations besides four signs of VACTERL association, which seems to be caused by contiguous gene syndrome. Case with small deletion at 18q12.1 revealed five signs including limb anomaly of left thumb hypoplasia, suggesting that a further validation is needed for the role of the deleted gene in VACTERL association. The remaining cases without evidence of copy number alterations could be applied to whole-genome or exome sequencing to identify clinically relevant variants.

1001F

Intragenic *De Novo* Deletion of *COL11A1* in a Patient with Stickler/ Marshall Syndrome. *M.L. Wiggins, B.J. Dave, D.L. Pickering, J.M. Stevens, D.M. Golden, J.M. Carstens, D.L. Bishay, E.T. Rush, R. Lutz, W.G. Sanger.* Dept Human Genetics, Univ Nebraska Medical Ctr, Omaha, NE.

Current customized high resolution microarray platforms allow for the detection of novel intragenic copy number alterations that are not detectable and hence cannot be confirmed by FISH, typically the `gold standard' for microarray verification studies. The detection of these very small deletion/ duplications often times present a challenge for the laboratory to establish the clinical relevance and phenotypic correlation is essential for the interpretation. We present a 21-month-old female patient referred for microarray analysis after an evaluation with a clinical geneticist who noted strabismus, cataracts, “ear issues,” a flattened nasal bridge, a small upturned nose and a modestly hypoplastic midface. She was previously examined at birth for chromosome analysis and FISH due to dysmorphic features and multiple congenital anomalies. The laboratory results had revealed a normal 46,XX karyotype and normal aneuploidy FISH results at that time. The current microarray analysis, using a customized oligonucleotide (180K) array that targets genes and exons therein, revealed a 5Kb interstitial deletion within the *COL11A1* target gene region at 1p21.1 implicated in Stickler and Marshall Syndromes. These syndromes exhibit considerable phenotypic overlap and are speculated to represent one phenotypic spectrum. Due to its small size, FISH confirmation was not possible, however, the deletion was confirmed by quantitative PCR (qPCR) utilizing pre-designed copy number assays both within and outside the minimum deletion interval. Parental microarray studies showed the deletion to be a *de novo* event in this patient. Genotype-Phenotype correlations helped in categorizing the microarray result as abnormal. Development of microarray with exon coverage has enabled the detection of intragenic deletions and duplications throughout the human genome. The present study exemplifies that genotype-phenotype correlations along with parental studies are essential for the interpretation of small intragenic copy number changes observed by high-resolution gene arrays. Additionally, confirmatory methods other than FISH are necessary to verify some results detected by high resolution microarray studies.

1002F

Analysis of clinical phenotype and inheritance in 50 nuclear pedigrees carrying mitochondrial DNA m. 3243A>G mutation. *Y. MA[1], F. FAN[2], Y. CAO[3], Y. YANG[3], J. WANG[3], L. ZOU[4], Y. ZHANG[1], S. WANG[1], S. ZHU[5], Y. QI[1].* 1) Central Laboratory Dept, Peking University First Hospital, Beijing, China; 2) Neurology Dept, Beijing Children's Hospital, Beijing, China; 3) Pediatrics Dept, Peking University First Hospital, Beijing, China; 4) Pediatrics Dept, General Hospital of People's Liberation Army, Beijing, China; 5) Statistics Dept, Peking University First Hospital, Beijing, China.

m.3243A>G mutation in mitochondrial DNA (mtDNA) is the most frequent heteroplasmic mtDNA mutation. Individuals carrying m.3243A>G mutation may manifest either as syndromic or nonsyndromic mitochondrial disorders, while others may be asymptomatic. The mechanism underlying the diversity of its clinical presentations is not fully understood. To understand the factors that affect the inheritance of mutant mitochondria from mothers to their descendents, we analyzed clinical presentations and history, characteristics of inheritance, and mitochondria related complications in 50 Chinese families. We recruited 50 patients carrying m.3243A>G mutation of Chinese Han ethnicity and treated in our hospitals, as well as their 50 mothers and fathers during the period from 2005 through 2007. Informed consent was obtained from the patients or patient guardians and their related family members. The study protocols were approved by the Medical Ethics Committee of Peking University First Hospital. The symptoms, disease history, inheritance, mitochondria related complications and m.3243A>G mutation load of 50 probands and their parents were analyzed. In the probands, myopathy, seizures, hirsutism, headache, cognitive impairment, weight loss and short stature were the most common clinical features, and which occur at the same time; and the lactic acid, pyruvate and MRI were abnormal in the most probands. Normal phenotype was found in most mothers, and myopathy, weight loss and short stature were their most common clinical features. m.3243A>G mutation was detected in 50 probands and 45 mothers. In the probands, the mutation ratio in blood was threefold higher and the ratio in urine was twofold higher than those of their mothers. m.3243A>G mutation load in mothers' blood correlated positively with that in offspring's blood, the correlation coefficient r=0.438, P<0.01. In conclusion, the phenotype of patients carrying m.3243A>G mutatiom is variant, the symptoms and results of laboratory in probands were more severity than that in mothers, which might due to the higher m.3243A>G mutation ratio in their tissues. m.3243A>G mutation load in mothers' blood may have a positive correlation with the mutation load in blood a in their children.

1003F

Relatively high frequency of patients with Aarskogg syndrome in a group of patients with cleft lip and palate from Operation Smile Foundation. Colombia. *I. Briceno[1 y 3], A. Venegas[3], J. Martinez[2].* 1) Bioscience, U Niversidad de La Sabana, Chia, Colombia; 2) Grupo de genetica humana, universidad de La Sabana, chia. Colombia; 3) Grupo de Genetica Humana, Universidad Javeriana, Bogotá. Colombia.

Description: Aarskogg syndrome is a very rare congenital disorder characterized by structural abnormalities, growth retardation, wide facial features, short hands and feet, genital abnormalities and mental retardation. Only about 100 cases have been reported with this syndrome in the literature. The most common features are: hypertelorism, ptosis, short hands with short fingers, wide ears, small and very flexible joints, flat feet with wide bulbous toes, abnormal scrotum with extension around the base of the penis, inguinal hernia, and criptorchidea. A rare feature is Cleft lip and palate. The gene responsible is in the short arm of chromosome X (Xp11.21) Case Report: During the medical missions of Operation Smile, Colombia, the Human Genetics group from University of La Sabana, examined 500 patients with cleft lip and palate, syndromic and nonsyndromic, including 6 cases also showing Aarskog syndrome features. The high frequency observed, considering that is a very rare syndrome, suggests a founder effect in Colombian population-.

1004F

Genome-Wide Association Study Identifies Three Loci Associated with Pyloric Stenosis. *B. Feenstra[1], F. Geller[1], C. Krogh[1], M.V. Hollegaard[2], S. Gørtz[1], H.A. Boyd[1], J.C. Murray[3], D.M. Hougaard[2], M. Melbye[1].* 1) Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Section of Neonatal Screening and Hormones, Statens Serum Institut, Copenhagen, Denmark; 3) Pediatrics, University of Iowa, Iowa City, Iowa.

Pyloric stenosis (PS) is a severe condition of infancy in which hypertrophy of the pyloric sphincter smooth muscle leads to obstruction of the gastric-outlet. Symptoms, including projectile vomiting, weight loss and dehydration, typically appear between 2 and 8 weeks after birth. Family and cohort studies have established that PS is highly heritable, but the genetic basis of the condition is poorly understood. To identify sequence variants associated with PS, we carried out the first genome-wide association study of the condition on 1,001 surgery-confirmed cases and 2,401 controls with samples drawn from the Danish National Biobank. The 6 most strongly associated SNPs were tested in a replication set of 796 cases and 876 controls, and three SNPs reached genome-wide significance (OR=1.61, P=1.5 x 10^{-17}; OR=1.42, P=1.5 x 10^{-15}; and OR=1.41, P=4.3 x 10^{-12}). Two SNPs represent independent signals (r^2<0.0001) close to the muscleblind-like 1 gene (*MBNL1*), which plays a central role in the regulation of splicing transitions occurring shortly after birth. The third variant is located near the cardiac transcription factor gene *NKX2-5*, which is known for its role in development of cardiac muscle tissue, but also is important for embryonic gut development. In addition to the genetic association signal near *NKX2-5*, we found epidemiological evidence suggesting commonalities in the etiology of PS and congenital heart defect (CHD). Using a cohort of all persons born in Denmark in 1977-2008, the incidence rate ratio of PS given a CHD diagnosis was 2.61 (95% confidence interval 2.05-3.27).

1005F

A novel PAX9 mutation caused oligodontia in a Japanese family. *M. KIDA[1], T. KIKUIRI[2], T. ARIGA[1].* 1) Department of Pediatrics,, Hokkaido University Graduate School of Medicine, Sappro, Japan; 2) Department of Pediatric dentistry, Hokkaido University Graduate School of Dental Medicine.

<Introduction> Agenesis of permanent teeth is defined by two terms; hypodontia (an absence of fewer than six teeth) and oligodontia (an absence of six or more teeth). Agenesis of permanent teeth occurs in 7.1~7.8% of the Danish schoolchildren, whereas the prevalence of oligodontia is very rare at only 0.16%. We had an opportunity to study a Japanese family with nonsyndoromic oligodontia including molecular genetic defects. We performed mutation analysis of the *PAX9* responsible for nonsyndoromic oligodontia in the family, and found a novel mutation.

<Method> Genomic DNA isolated from PBMCs from all the family members in the table below, as well as that from control individuals (n=50), were analyzed. We performed the mutation analysis in the *PAX9* gene. PCR amplified spanning the entire coding region of the *PAX9* using the originally designed primers. For the mutation screening in the patients, PCR products were analyzed by a single-strand conformation polymorphism (SSCP) method. Coding exons of the *PAX9*, together with their flanking introns, were PCR-amplified and then directly sequenced.

Number of missinng teeth

Proband : 16	Proband's brother : 19	Proband's mother : 16	Proband's father : 0

<Result> The number of missing teeth was described in the table above. Proband had fusion teeth consisting of the left lower central incisor and lateral incisor; the mother and brother had peg-shaped upper lateral incisors. Mutation analysis revealed a novel heterozygous single deletion (c.591delC, S197fsX211) within exon 2 of the *PAX9* gene. The mutation was detected only in the patients in the family, not detected in the other family members or control individuals.

<Conclusion> We have identified the novel mutation (c.591delC, S197fsX211) of the *PAX9* in a Japanese family with nonsyndoromic oligodontia. Interestingly, the number of missing teeth was varied among the affected family members, however, the patterns of missing teeth in maxilla was symmetrical in all affected family members.

Cafe Variome: a novel platform for the routine exchange of genetic variation data. *O. Lancaster[1], R.K. Hastings[1], R. Dalgleish[1], D. Atlan[2], G.A. Thorisson[1], R.C. Free[1], A. Webb[1], J. Muilu[3], M. Byrne[3], A. Blavier[4], F. Wolinski[4], P.E.M. Taschner[5], A.J. Brookes[1].* 1) Department of Genetics, University of Leicester, Leicester, LE1 7RH, United Kingdom; 2) Phenosystems SA, Belgium; 3) Institute for Molecular Medicine, Finland; 4) Interactive Biosoftware, France; 5) Leiden University Medical Center, Netherlands.

Diagnostics laboratories assess DNA samples from many patients with various inherited disorders, and so produce a great wealth of data on the genetic basis of disease. Unfortunately, those data are not usually shared with others. To address this gross deficiency, a novel system has been constructed that aims to facilitate the automated transfer of diagnostic laboratory data to the wider community, via the internet-based Cafe Variome. Diagnostic laboratories are not reluctant to release their data. Instead, the obstacles are merely practical: First, diagnostic laboratory personnel do not have time nor funding to manually submit data to internet depositories such as Locus Specific databases (LSDBs). Second, diagnostic laboratories would receive no recognition or reward for releasing their data, giving them little incentive to even try. The Cafe Variome approach takes account of the real-world obstacles and the needs of diverse LSDBs and aims to minimize the effort required to publish variant data by: a) Endowing data analysis tools used by diagnostic laboratories with a `data submission' function that automatically pushes processed data onto the internet b) Offering manual support to laboratories to move their variant datasets into Cafe Variome (legacy data and new data in batches or in real time) c) Producing a single internet depot (café) to receive these data and make them available for download by diverse third parties. Cafe Variome is not a database, but a depot that mediates data flows between data uploaders and data downloaders and subsequently allows any interested parties to announce and discover a comprehensive listing of observed neutral and disease-causing variants in patients and unaffected individuals. The development of Cafe Variome (based at the University of Leicester) involves the cooperation of diagnostic software companies PhenoSystems (Gensearch) and Interactive Biosoftware (Alamut) as well as academic partners in the Bioinformatics Support Group at Leiden University Medical Centre (LUMC) whose Mutalyzer data-validation tool will allow us to feedback data-inconsistencies to submitters, at the Institute for Molecular Medicine Finland whose development of a standardized variant exchange format (VarioML) allows the system to use just one format for exchange and at the NGRL Manchester who have extensive expertise in diagnostic databases through their development of DMuDB. http://www.cafevariome.org.

***MLL2* mutation spectrum and clinical phenotype in patients with Kabuki syndrome.** *N.J. Lench, A.N. Barrett, C. Gerveshi, N. Trump, R. Palmer, L. Jenkins, R.H. Scott.* NE Thames Regional Genetics Service, Great Ormond Street Hospital for Children, London, WC1N 3BH, United Kingdom.

Background: Kabuki syndrome (KS) is a rare disorder characterised by a recognisable facial dysmorphism, mild to moderate mental retardation, growth retardation, skeletal and cardiac anomalies and immunological defects. Mono-allelic loss of function mutations have been identified in the *MLL2* gene, a member of the SET domain family of histone methyltransferases that account for approximately 66% of Kabuki syndrome cases. Here we describe the *MLL2* mutation spectrum and clinical profile of 60 patients ascertained from the UK with a clinical diagnosis of Kabuki syndrome. **Methods:** A total of 83 DNA amplicons encompassing the 54 coding exons and intron-exon boundaries of *MLL2* were analysed by bidirectional Sanger sequencing in 60 probands. Where available, parental DNA samples were obtained and sequenced to determine if putative mutations had arisen *de novo* or were stably inherited. In order to screen for large intragenic insertions and deletions in mutation negative patients, we designed a Nimblegen 135k custom microarray encompassing the entire genomic region of the *MLL2* gene. Standardised clinical information was collected on all patients and, where available, facial photographs were also obtained for central review. **Results:** DNA sequence analysis identified *MLL2* mutations in 40 patients (~66%). The mutations were distributed across the entire gene and included frameshift, non-sense, mis-sense and splice site changes. 2 mutations have been reported previously, the remainder are novel. Targeted chromosomal microarray analysis did not identify any obvious copy number changes. Phenotypic features associated with *MLL2* mutations included the characteristic facial features of Kabuki syndrome and growth retardation. **Conclusions:** Our data support other published studies confirming that *MLL2* point mutations are the major cause of Kabuki syndrome, accounting for approximately 66% of cases. However, we were unable to detect mutations in the remaining 33% of patients suggesting that there are other, as yet unidentified causative genes. These findings highlight the importance of *MLL2* mutation screening in patients with Kabuki syndrome and this is now part of the diagnostic portfolio of the NE Thames Regional Genetics Service.

1008F

Multiple or high flow cerebral arteriovenous shunts in children: prospective angiographic and genetic analysis of 26 consecutive cases. *A. Ozanne[1], M. Eyries[2], J.P. Pelage[3], T. Chinet[3], J.H. Blondel[3], F. Coulet[2], J. Roume[3], L. Gouya[3], I. Bourgault-Villada[3], S. Blivet[3], D. Corbazan[3], C. Fagnou[3], G. Lesur[3], M.C. Waill[2], P. Lasjaunias[1], G. Saliou[1], D. Ducreux[3], B. Raffestin[3], P. Lacombe[3].* 1) Neuroradiology, CHU Kremlin-Bicetre, Le Kremlin-Bicêtre, France; 2) Oncogenetics and Angiogenetics laboratory, Pitié-Salpétrière Hospital, AP-HP, Paris, France; 3) HHT pluridisciplinary clinics, Hôpital Ambroise Pare, AP-HP, Boulogne, France.

Hereditary hemorrhagic telangiectasia (HHT) is a heterogeneous vascular disease that can present with a variety of clinical manifestations. The neurovascular complications of this disease, especially in children, may be potentially devastating. The clinical diagnosis of HHT is determined by using the following Curaçao diagnosis criteria : -Epistaxes -Telangiectasias : multiple, at characteristic sites (lips, oral cavity, fingers and nose) - Visceral vascular lesions: gastrointestinal telangiectasias (with or without bleeding) and arterio-venous malformations (pulmonary, hepatic, cerebral and spinal arteriovenous fistula) - Family history : a first-degree relative with HHT. However, Curaçao criteria may not be all present in the pediatric population, and genetic analysis is recommended in case of central nervous system (CNS) high flow arteriovenous fistula (single or multiple). Mutations of the Endoglin (ENG) and Activin A receptor type II-like kinase-1 (ACVRL1) genes are known to be the major genetic factors of HHT. Recently, RASA1 mutations were described in CM-AVM (capillary malformation-arteriovenous malformation) and an association between RASA1 mutations and spinal arteriovenous anomalies was reported. We selected 26 consecutive cases of high flow cerebral arteriovenous fistula (CAVF) presenting at the pediatric age among patients refered for endovascular treatment of CNS arteriovenous shunt in Bicêtre. We excluded single nidus or micro arteriovenous malformation (AVM), and spinal arteriovenous shunt. Angiogramms were analysed, and the possible multiplicity of AV shunts was carefully sought. Genetic variation of HHT1 (Endoglin), HHT2 (ACVRL1) and RASA1 genes was assayed by PCR and sequencing of the entire coding sequence and intronic junctions of the 3 genes. Multiplex ligation-dependent probe amplification (MLPA) was used to screen for large rearrangements of the ACVRL1 and Endoglin genes. Mutations in Endoglin, ACVRL1, and RASA1 genes were found both in single and multiple CAVF. The rate of single versus multiple CAVF seems predominantly associated to RASA1 mutations than HHT1 or HHT2 mutations. The rate of positive genetic analysis in this cohort of pediatric arteriovenous high-flow fistula is 57%. This study emphasizes the importance of the RASA1 gene in pediatric CAVF.

One extra expanded allele in Huntington patient do not affect the phenotype. *S. Dadgar[1], M. Dehghan[1], O. Aryani[1], M. Houshmand[1, 2].* 1) Genetic Department of Special Medical Center, , No.10, Ostad Nejat allahi Ave, Enghelab St., Tehran, Iran; 2) National Institute of Genetic Engineering & Biotechnology, Pazhohesh Blv. 17th Km Tehran-Karaj Highway, Tehran, Iran.

Huntington disease (HD) is a progressive disorder of motor, cognitive, and psychiatric disturbances. The mean age of onset is 35 to 44 years and the median survival time is 15 to 18 years after onset. Huntingtin gene is the only gene associated with Huntington disease. A trinucleotide CAG repeat expansion is the only cause of the disease. HD is inherited in an autosomal dominant manner. The range of normal alleles are 26 or fewer CAG repeats whereas the range of intermediate alleles and HD-causing alleles are 27-39 and 39-121 CAG repeats, respectively. Anticipation increases disease severity or decreases age of onset observed in successive generations which is known to occur in HD. In the current study, 86 patients were investigated for HD gene by PCR-based method. The results were including 29 patients with one expanding allele (39-53 repeats), five patients with an intermediate allele, one patient with two expanding alleles (40-50 repeats) and one patient with both intermediate and expanding alleles (36 and 42 repeats, respectively). Although we expected that the patients who had two expanding alleles to represent more severe phenotype compared to those with one expanding allele, they both showed the same phenotype. Other overlapping diseases which are most Huntington-Like disease, must be investigated for the rest 50 negative cases.

1010F

A male infant of Leigh syndrome complicated with Fukuyama congenital muscular dystrophy. *H. Kondo[1], C. Tabata[1], A. Yamada[1], K. Hayashi[1], M. Kotani[1], K. Tanda[1], M. Kihara[1], Z. Kizaki[1], K. Murayama[2], A. Otake[3].* 1) Pediatrics, Kyoto First Red Cross Hospital, Kyoto, Japan; 2) Metabolism,Chiba Children's Hospital,Chiba,Japan; 3) Pediatrics,Saitama Medical University Hospital,Saitama,Japan.

Introduction: Fukuyama congenital muscular dystrophy (FCMD) is an autosomal recessive disorder, characterized by hypotonia, symmetric generalized muscle weakness, and CNS migration disturbances that result in changes consistent with cobblestone lissencephaly with cerebral and cerebellar cortical dysplasia. Leigh syndrome (LS) is a progressive neurodegenerative disorder with motor and intellectual developmental delay, signs and symptoms of brain stem and/or basal ganglia involvement, and raised lactate levels in blood and/or cerebrospinal fluid. The disease is caused by either mitochondrial or nuclear gene mutations. We report the first case of LS complicated with FCMD. Case report: A 15 month-old Japanese boy as the third child of the non-consanguineous healthy parents. The older brother died of sudden cardiac dysfunction at 4 months of age. This case was born without any complications, but the serum concentration of creatine kinase was extremely high at the 1st day of age. He suffered from lactic acidosis, hyperglycemia and acute heart failure at 17th day of age. Subsequently he presented with consciousness disturbance, muscle weakness, respiratory failure, hypertrophic cardiomyopathy and hydrocephalus. MRI images showed pachygyria in the frontal region and bilateral symmetrical lesions in the brainstem. A homozygous mutation of the FCMD gene was detected by PCR analysis. The activity levels of mitochondrial respiratory chain complex I+II were decreased in his skin fibroblasts. We diagnosed the case as LS and FCMD by clinical findings, neuroimaging, laboratory data and molecular genetic testing. Conclusion: The comorbidity of LS and FCMD has not been previously reported. We suspected that he had both LS and FCMD not by a contiguous gene syndrome but by chance.

1011F

Molecular analysis and Genetic counseling in Tuberous Sclerosis. *P. Balakrishnan, R.D. Puri, U. Kotecha, S. Kohli, R. Saxena, S. Bijarnia, I.C. Verma.* Center of Medical Genetics, Sir Gangaram Hospital, New Delhi, Delhi, India 11 0060.

We report our experience of molecular diagnosis and counseling in patients of Tuberous Sclerosis attending the genetic clinic. There were twenty three subjects for whom deletion / duplication analysis by MLPA and sequencing of TSC 1 and TSC2 genes was performed between February 2010 and May 2011. The indications for molecular testing in these patients were evaluation during pregnancy for prenatal diagnosis in 6 families and preconception counseling in 9. Mutations have been identified in 13/23 (15 families), of which 04 had deletions identified by MLPA and 09 mutations identified by sequencing of TSC2 gene. There were 09 deletions and 04 point mutations in TSC2 gene. No mutations were identified in TSC1 gene. One novel mutation was present. Of the twenty three subjects, no mutations were identified in 10 probands. Prenatal diagnosis was performed in 06 families. In one family where the mother and two children were symptomatic, prenatal diagnosis was performed by linkage analysis and the fetus was not affected. In the rest of the cases, the mutation identified in the family was evaluated in the fetus. Four pregnancies were not affected. In this cohort, three probands had a positive family history, but in two of them, diagnosis in the parent was established after the current clinical and molecular evaluation. One family decided to continue pregnancy of an affected fetus. This was in view of mild manifestations in the husband and first daughter. However after birth the child developed seizures and has significant neuro-developmental delay. Based on our experience we have formulated a protocol for evaluation of families with tuberous sclerosis. In view of the costs involved in diagnosis, we first perform deletion / duplication of TSC1 and TSC2 by MLPA, followed by sequencing of TSC2 gene. If no mutations are identified so far, we carry out the sequencing analysis of TSC1 gene. Ensuring cost effectiveness of genetic testing is of critical importance in developing economies like India as they are not covered by State or insurance.

Whole-exome sequencing combined with linkage analysis identifies BSCL2 mutations in two Korean Charcot-Marie-Tooth families. *S.K. Koo[1], M.H. Park[1], H.M. Woo[1], B.O. Choi[2], K.W. Chung[3].* 1) Division of Cardiovascular and Rare Diseases, Center for Biomedical Sciences, National Institute of Health, Cheongwon-Gun, Korea; 2) Department of Neurology, Ewha Womans University School of Medicine, Seoul, Korea; 3) Department of Biological Science and Research Center for Biotechnology, Kongju National University, Gongju, Chungnam, Korea.

Charcot-Marie-Tooth (CMT) is a clinically and genetically heterogeneous disorder of the peripheral neuropathy. To identify the causative mutations in two Korean CMT families (FC51 and FC305) with autosomal dominant transmission, we conducted genome-wide linkage analysis using Axiom Genome-Wide Human Array and whole-exome sequencing with two individuals in each family. In the whole exome analysis, two patients of FC305 were used for the identification of the sharing variants, while one patient with a normal relative of FC51 was applied for the exclusion. We found that evidences of linkage in each family mapped to a region on chromosome 11p11-11q13.3 with LOD scores of 2.7 (FC51) and 3.3 (FC305), respectively. In this linkage region, we identified 147 variants (FC51) and 287 and 266 variants (FC305) after filtering the non-functional changes (intronic or synonymous varitnats). Integrating the results from the two individuals within the family, we identified the causative mutations of BSCL2 in each family, which were previously shown to be associated with distal hereditary motor neuropathy (silver syndrome). Our study shows that the power of exome sequencing with linkage analysis could be efficiently applied to the diagnosis in a dominant-trait disease.

Differences in fractures and activity in children with NF1. *E.K. Schorry[1], J.K. George-Abraham[1], M.B. Rieley[3], D.A. Stevenson[2], D.H. Viskochil[2], L.J. Martin[1], H.J. Kalkwarf[1], R.J. Hopkin[1], A.M. Stevens[2], S. Allen[2].* 1) Div Human Gen, Cincinnati Childrens Hosp, Cincinnati, OH; 2) University of Utah, Salt Lake City, UT; 3) Bangor, ME.

Neurofibromatosis 1 (NF1) is an autosomal dominant genetic disorder which can affect multiple different organ systems. Osseous abnormalities occur in at least 30% of patients with NF1, and there is growing evidence of a generalized bone dysplasia associated with NF1. Mild osteopenia has been well documented in both adults and children with NF1, although the significance of this in terms of fracture risk has not yet been determined. We undertook a retrospective study to determine incidence, types, and location of fractures in children with NF1, ages 5-20 years, using a standardized questionnaire. We surveyed 256 individuals with NF1 from two multidisciplinary clinics, and compared to 178 controls of similar ages and gender. Data collected included numbers and location of fractures, dietary calcium intake, and physical activity levels. There were no significant differences in age, gender, or dietary calcium intake between the two groups. Interestingly, we found no significant difference in rate of ever having a fracture in the NF1 group (24.1%) versus the control group (23.7%). However, there were significant differences in location of bone fractured. Control patients were most likely to have fractures of the wrist and arm (54%), which are the most commonly fractured bones in the pediatric population; and rarely had fractures of the leg and ankle (5.3%). In contrast, NF1 patients (excluding those with known long bone dysplasia) were less likely to fracture wrist and arm (32%), and more likely to have fractures of the leg and ankle (15.5%). One NF1 patient with known osteoporosis had vertebral compression fractures, a fracture type not seen in any control patients. Physical activity scores, measured as MET/week, were significantly lower in the NF1 group compared to controls ($p<.001$). Based on these data, we speculate that NF1 patients, even those lacking a known dysplastic bone or tibial bowing, may have an inherent weakness in bones of the lower extremities, leading to increased fracture rate in those locations. Although overall rate of ever fracturing was not different between the 2 groups, the much lower physical activity level in the NF1 group may have prevented them from having a higher fracture rate. This study may lead to better understanding of the osseous dysplasia underlying NF1.

1014F

Interstitial duplication 15q11-q13 syndrome: language impairment, autism, abnormal EEG patterns and mild facial anomalies. *N. Urraca[1], J. Cleary[2], E. Pivnick[3], K. McVicar[3], V. Brewer[3], R. Thibert[4], LT. Reiter[1,3].* 1) Department of Neurology, UTHSC, Memphis, TN; 2) Department of Speech and Language Pathology, University of Memphis, Memphis, TN; 3) Department of Pediatrics, UTHSC, Memphis, TN; 4) Department of Neurology, Mass General Hospital, Boston, MA.

Chromosome 15 has a number of low copy repeats that predispose regions to deletion/duplication events mediated by non-allelic homologous recombination. The 15q11-q13 region also has a cluster of genes preferentially expressed from one parental allele. It is estimated that ~3-5% of all autism cases may be the result of this 15q copy number variant (CNV). Most cases are de novo and maternal in origin. There are two major types of interstitial duplications on 15q: class I with breakpoints at BP1 (proximal) to BP3 (distal) and class II with breakpoints from BP2 (proximal) to BP3. In this study we performed an in depth phenotype analysis of individuals with interstitial 15q duplications and determined if maternal duplication is required for the diagnosis of autism spectrum disorder (ASD). A Clinical Geneticist and a Pediatric Neurologist blind to parental origin and breakpoints evaluated the subjects. We used neuropsychological, language and ASD diagnostic tools for phenotypic analysis. Methylation Sensitive High Resolution Melting (MS-HRM) analysis of the maternally methylated SNRPN locus was used to determine the parent of origin of the duplication. Fifteen subjects have been recruited: 11 maternal and 4 paternal cases. Twelve are de novo and 3 familial cases with one pair of siblings. Four of 11 maternal cases were Class I and 4 of 11 Class II while the paternal cases 2/4 Class I vs. II. Most subjects had mild nasal labial fold asymmetry and a rounded short nasal tip. EEG report: 9/15 had excessive 18-22 Hz beta activities throughout the waking record. This EEG pattern appears to be specific to the duplication and not the parent of origin or presence of ASD. Nine maternal and 2 paternal subjects scored as ASD using ADOS/ADI-R analysis. Most subjects had a low-moderate adaptive functioning score on the Vineland II test with no differences among groups. All subjects performed below age corrected average for receptive language but we found a significant difference ($pval<0.03$) between maternal class I and maternal class II subjects. In conclusion, the majority of int dup(15) cases ascertained were maternal in origin, most likely due to the coincidence of ASD with maternal duplication. The size of the duplication did not correlate with the severity of the phenotype. Subjects had mild facial anomalies. Receptive language impairment was evident, but will require more subjects to be accurately described.

1015F

Exome sequencing identifies a DYNC1H1 mutation in a large pedigree with dominant axonal Charcot-Marie-Tooth disease. *M.N. Weedon[1], R. Caswell[1], R. Hastings[2], W. Xie[1], K. Paszkiewicz[3], T. Antoniadi[4], M. Williams[4], C. King[2], L. Greenhalgh[2], R. Newbury-Ecob[2], S. Ellard[1].* 1) Peninsula Medical Sch, Exeter, United Kingdom; 2) Clinical Genetics Department, University Hospitals Bristol NHS Foundation Trust, St Michaels Hospital, Bristol, United Kingdom; 3) Exeter Sequencing Service, Biosciences, College of Life & Environmental Sciences, University of Exeter, Exeter, United Kingdom; 4) Bristol Genetics Laboratory, Pathology Sciences, Southmead Hospital, North Bristol NHS Trust, Bristol, United Kingdom.

Charcot-Marie-Tooth disease is characterised by length-dependent axonal degeneration with distal sensory loss and weakness, deep tendon reflex abnormalities and skeletal deformities. It is caused by mutations in over 40 genes. We investigated a four generation family with 23 members affected with the axonal form (type 2) where the common causes had been excluded by Sanger sequencing.Exonic sequences from 3 affected individuals separated by 8 meioses were enriched using Agilent's SureSelect kit and sequencing performed on an Illumina GAII. Variants were filtered to exclude variants in the dbSNP131, 1000 genomes and our in-house exome databases.

We identified 177, 192 and 199 novel heterozygous variants in the three individuals. Only one variant was shared by all three and testing of 6 additional affected family members showed co-segregation with a maximum LOD score of 3.6. The shared DYNC1H1 gene variant is a missense substitution, p.His306Arg, at a highly conserved residue within the homodimerisation domain of cytoplasmic dynein heavy chain 1. Three mouse models with different mutations within this domain have previously been reported with age-related progressive loss of muscle bulk and locomotor ability.

This is the first report in humans of a dynein gene mutation linked to neuropathy. Cytoplasmic dynein is a large multi-subunit motor protein complex with a key role in retrograde axonal transport in neurons. Our results demonstrate the power of exome sequencing for genetic diagnosis and highlight the importance of dynein and retrograde axonal transport in neuronal function in humans.

1016F

Tay Syndrome: a rare syndrome diagnosed in two brothers. *F.T. de Lima[1], T.E. Sfakianakis[1], E. Perrone[1], M.F.F. Soares[2], V.F.A. Meloni[1].* 1) Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Department of Imaging Diagnosis, Universidade Federal de São Paulo, São Paulo, SP, Brazil.

Trichothiodystrophy (TTD) is a distinct group of autosomal recessive disorders with a wide range of phenotypic expression, unified by the presence of sulfur-deficient brittle hair. Patients with TTD have abnormal production of transcription factor IIH (TFIIH), active in basal transcription and nucleotide excision repair, due to mutations in genes encoding 3 subunits of TFIIH—ERCC2(XPD), ERCC3(XPB), and GTF2H5(TTDA). Associated findings may include short stature, intellectual disability, photosensitivity, ichthyosis, nail dystrophy, cataracts and immunodeficiency. Generalized dysmyelination is the most common neuroimaging abnormality in TTD. Some other nonspecific abnormalities may include hipomyelination, cortical heterotopias, partial agenesis of the corpus callosum, perimedullary fibrosis of the spinal cord, and intracranial calcifications. It has also radiological evidence of progressive central osteosclerosis. The association of TTD with uncommon features is far rarer and it is known by different names, such as Tay syndrome or PIBIDS (OMIM #601675), an acronym standing for Photosensitivity, Ichthyosis, Brittle hair, Intellectual impairment, Decreased fertility, and Short stature. We describe two brothers showing ichthyosis, nail dystrophy, short stature, and intellectual disability. Other clinical features presented in these patients were low birth weight, growth deficiency, microcephaly, low-set and posterior rotated ears, dental abnormalities and cataracts. The clinical picture prompted the diagnosis of TTD and, for the presence of additional symptoms, within the broader spectrum of Tay syndrome. They also had radiographic evidence of progressive central osteosclerosis, distal osteoporosis, and marked increase in density of several bones. There were MR imaging findings of dysmyelination and intracranial calcifications too. Similar cases with this combination of signs and symptoms have been described in literature, but little is known about the natural history of this disease. These further cases described here provide clear evidence that TTD should be included among the wide range of differential diagnosis of the affected pediatric population, as long as they carry this group of specific signs and symptoms, which are the presence of diffuse dysmyelination in conjunction with documented hair and skin abnormalities and the presence of central osteosclerosis. Key Words: Tay Syndrome - Trichothiodystrophy - Dysmyelination - Central Osteosclerosis.

1017F

Trajectories of Cognitive-Behavioral Development in Children with Wolf-Hirschhorn Syndrome. *GS. Fisch[1], JC. Carey[2], A. Battaglia[3], R. Falk[4], R. Simensen[5].* 1) NYU College of Dentistry Dept. Epidemiology & Health Promotion New York, NY; 2) University of Utah Dept. of Pediatrics Salt Lake City, UT; 3) Dept. Child Neuropsychiatry Postgraduate Medical School University of Pisa, Pisa, Italy; 4) Dept. of Pediatrics Cedar Sinai Medical Center Los Angeles, CA; 5) Greenwood Genetics Center Greenwood, SC.

Norms for neurocognitive and neurobehavioral development established early in the 20th century were used to detect infants with developmental delays. However, after a child is identified as delayed, it is important to establish trajectories of development in those youngsters, and for several reasons. First, trajectories aid clinicians and caregivers what to expect as individuals in this cohort ages. Second, they facilitate research examining brain-behavior relationships. Third, if specific genetic disorders are involved, to determine genotype-brain-phenotype relationships. Previously, we and others have examined trajectories of development in children with the fragile X mutation (FMR-1), Williams-Beuren syndrome (WBS), and NF1. In our researches, we found different trajectories for each of these disorders. The purpose of our current research is to examine trajectories in children with subtelomeric deletions. Specifically, in this report, we tested 20 children with deletion 4p16, Wolf-Hirschhorn syndrome (WHS), and retested 15 two years later. Their ages at initial testing ranged 4-20 years. They were tested at 9 sites in the US and Europe, using a comprehensive neuro-psychological battery. Our assessment battery consisted of 5 standardized measures: cognitive ability (Stanford-Binet 4th Ed: SBFE), adaptive behavior (Vineland Adaptive Behavior Scale: VABS), emotionality and temperament (Child Behavior Checklist: CBCL), attentiveness/ hyperactivity (Conners Parent Rating Scale: CPRS), and autism (Child Autism Rating Scale: CARS). Most of our participants tested at or near the floor value of the SBFE and VABS. Therefore, we chose to examine this cohort using raw scores from these 2 tests, and to compare them with raw score trajectories of age-matched children diagnosed with FMR-1 or WBS. Results show that children WHS are able to complete fewer items on the SBFE, have fewer Daily Living Skills as measured by the VABS, have a flatter trajectory than children with either FMR-1 or WHS; but, socialization levels and trajectories are comparable among the 3 genetic disorders.

Variability of phenotype in monozygotic twins with Charcot Marie Tooth type 4C (CMT4C). *P. Laššuthová[1], D. Šišková[2], P. Seeman[1].* 1) Dept of Child Neurology, The Motol University Hospital 2nd Medical School, Prague, Czech Republic; 2) Dept of Child Neurology, Thomayer University Hospital, Prague, Czech Republic.

Charcot-Marie-Tooth (CMT) type 4C neuropathy (CMT4C) is characterized by autosomal recessive (AR) inheritance, demyelinating neuropathy and early onset spine deformities. CMT4C is caused by mutations in the SH3TC2 gene. Prevalent mutation in Czech population and also in several other populations is a nonsense mutation p.Arg954Stop. CMT4C seems to be the most frequent type of AR CMT and one of the most frequent of all CMT types among Czech patients. Scoliosis is a typical presenting symptom in most of the CMT4C patients. We report a striking variability in the phenotype of two monozygotic twins - brothers - who are both affected by CMT4C and both carry the same mutation p.Arg954Stop in the SH3TC2 gene in homozygous state. Despite this, each of them has had a different course of the disease. Neither parents nor other family members are affected. Mother and father are heterozygous carriers of the p.Arg954Stop. One of the boys has scoliosis since the age of 4, which is in contrast to the other brother who has no scoliosis at the age of 11 years. The last time we have examined them was when they were 11 years old. Patient 1 plays football and rides a bicycle. However, his ability to run is worsened. He has foot deformities. Muscular atrophy was only very mild. No scoliosis was visible. In patient 2, first symptoms were evident at the age of 4 with scoliosis. From this time on the disease has been slowly progressive. At the age of 11 the patient has prominent foot deformities and pronounced scoliosis. Whether exogenic factors, epigenetics or even modifier genes have contributed to phenotypic differences remains to be explained. Supported by IGA MZ CR NT 1521-4.

1019F

Molecular testing enhances characterization of EVC phenotypes. *L. Mehta[1], H.Q. Rana[1], M. Galdzicka[2], E. Ginns[2].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Molecular Diagnostics Laboratory, UMass Medical School, UMass Memorial Medical Center, Worcester, MA.

Weyers Acrofacial Dystosis (WAD) and Ellis van Creveld syndrome (EVC) are allelic conditions caused by mutations in the EVC and EVC2 genes. Historically, the WAD phenotype is described as a milder condition than EVC, with short stature, postaxial polydactyly and nail and dental anomalies segregating in an autosomal dominant pattern, while classic EVC is autosomal recessive, with congenital heart defects in 60% of patients. However, a wide range of severity is known for EVC. We describe a patient who appeared clinically to have a WAD phenotype, but on molecular testing was found to have compound heterozygous mutations in EVC2. The 40 year old man reported a history of bony postaxial polydactyly of his hands for which surgery was performed at 1.5 years of age. He has had dental problems with peg teeth. Height was 160 cm (3rd centile, SDS -2.67). Limbs were short with normal trunk. He had hypoplastic nails on both hands and feet. Echocardiogram was normal. Family history was negative for similar problems, with parents being of normal heights. Sequencing of the EVC and EVC2 genes revealed two mutations in the EVC2 gene, Q755X and IVS21+2T>C. Each parent was heterozygous for one of the mutations. These mutations have been reported in patients with EVC in association with a second mutation. Neither mutation has been reported to cause WAD phenotype. Mutation Q755X results in a premature stop codon in exon 14 (c.2263C>T) and produces a truncated protein. The intron 21 change has previously been described in two cases of EVC and is predicted to cause a splicing error. While the initial consideration in our patient was for WAD, the molecular testing supports a diagnosis of mild EVC. This case highlights the phenotypic continuum of EVC and WAD, both disorders caused by mutations in EVC and EVC2. Since mild EVC and WAD cannot be distinguished on a clinical basis, in a “simplex” case with negative family history and no consanguinity, molecular testing is critical for accurate genetic counseling.

Genetic Effects on the Craniofacial Morphology of Unaffected Parents of Children with Oral Clefts. *L.M. Moreno[1], S. Miller[1], D. Defay[1], S. Weinberg[2], M.L. Marazita[2], J.C. Murray[3], G.L. Wehby[4].* 1) Dows Inst Dental Research, Univ Iowa, Iowa City, IA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Department of Pediatrics, University of Iowa, IA; 4) College of Public Health, University of Iowa, IA.

Purpose: Nonsyndromic cleft lip and palate (NSCL/P) is a common birth defect caused by genetic and environmental factors and their interactions. Besides overt clefts of the lip and palate, other subphenotypic characteristics such as distinct craniofacial morphology can be present in NSCL/P individuals and their close relatives. Most of the genetic effects that account for this diversity of NSCL/P phenotypes are yet to be identified. The purpose of this study was to identify features of distinct craniofacial morphology in unaffected parents of children with NSCL/P and control parents of unaffected children and to investigate whether candidate genes for NSCL/P and left-right asymmetry exert effects on these features using a multivariate regression model. Methods: Facial 3D images of 123 unaffected parents (39 males and 84 females) and 57 control parents (23 males and 34 females) were analyzed with 24 common anthropometric landmarks. 3D coordinates were used to derive nine linear distances and were scaled for size using Procrustes methods. Procrustes residuals were analyzed using principal component analyses. All analyses were performed for males and females separately. DNA samples were genotyped for 13 SNPs on 4 clefting candidate genes/loci (IRF6, FOXE1, 8q24, 20q12) and 4 left-right asymmetry genes (LEFTY1, LEFTY2, SNAI1, ISL1). Results: Preliminary results indicate that male cases have significantly (uncorrected $p<0.05$) narrower and more protrusive faces than controls. Female cases have significantly (uncorrected $p<0.05$) larger philtrum widths, lower face height, lower face protrusion and smaller facial sizes than controls. In males, SNP rs1443434 near FOXE1 explains about 24% of the difference in facial width and lower face protrusion ($p=0.02$) between case and control parents. In females, rs37585249 near FOXE1 explains about 7% of the difference in lower face height ($p= 0.04$) and SNP rs360059 near LEFTY1 explains about 7% of the difference in lower face protrusion between case and control parents ($p=0.03$). Conclusions: Identifying genotype-phenotype correlations between distinct craniofacial morphology features and genes involved in craniofacial development is essential for understanding the genetic etiology of NSCL/P. Support:DE016148, CDC5R01DD000295, AAOF 2008 OFDFA.

1021F

Association of CFH and HTRA1/ARMS2 Polymorphisms with Early-Age related Maculopathy. *H. Chen[1], J.H. Chen[1], Y. Yang[1], P.O.S. Tam[2], M. Zhang[1], C.P. Pang[2].* 1) Joint Shantou International Eye Center, Shantou, Guangdong, China; 2) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong Special Administration Region, China.

Purpose: The polymorphisms of complement factor H (CFH) and HtrA serine peptidase 1 (HTRA1)/Age-related maculopathy susceptibility protein 2 (ARMS2) have been reported to be associated with age-related macular degeneration (AMD). However, the genetics of early age-related maculopathy (ARM) less investigated and remains unclear. In the current study we investigated the association of CFH and HTRA1/ARMS2 polymorphisms with early ARM in a Chinese Han cohort. Methods: The current study cohort contained 157 early ARM patients and 161 controls recruited in Nan'ao, an island in southern China. CFH single nucleotide polymorphisms (SNP) rs1061170 and rs800292 and HTRA1/ARMS2 SNPs rs10490924 and rs11200638 were genotyped using Taqman genotyping assays. Logistic regression implemented by the R statistical language was used for association analysis. Results: None of the 4 SNPs deviated from Hardy Weinberg Equilibrium ($P > 0.05$). For association with early ARM, none of the SNPs showed any statistical significance in single SNP association analysis, with allele odds ratio ranging from 1.03 to 1.15 ($P > 0.05$). Neither haplotypes of CFH or HTRA1/ARMS2 were significantly associated with early ARM ($P > 0.05$). Conclusions The association of HTRA1/ARMS2 and CFH polymorphisms in early ARM was not detected in our cohort. The odds ratios close to 1 might indicate the effects of AMD-associated gene in early ARM could be much lower compared to those in AMD. These preliminary findings thus warrant further studies.

Clinical genetics resources at NCBI: ClinVar and ISCA support evidence-based interpretation of human variation. *J. Paschall, D.R. Maglott, J. Lee, L. Phan, D.M. Church, G. Riley, M. Ward, D. Shao, R. Maiti, R. Tully, S. Chitipiralla, J. Garner, S. Stefanov, M. Feolo, S.T. Sherry, J.M. Ostell.* NCBI, NIH/NCBI/NLM, Bethesda, MD.

The interpretation of genetic variants observed during clinical genetic testing is increasingly a limiting factor in translating genomic technology advances into medical practice. Current practice is often insular, because records of variation, supporting clinical and experimental evidence, and current interpretations are not captured in a structured format or available from a shared public resource. Patient safety as well as practicality and efficiency demand a community effort of integrating data so evidence based methods of interpreting clinical variation can be facilitated. We are working with members of the testing community to establish such a shared framework. **The ClinVar database (http://www.ncbi.nlm.nih.gov/clinvar)** was established to provide structured, archived, versioned records of asserted relationships among observed variations, phenotype, and supporting evidence. ClinVar is part of the infrastructure of NIH's Genetic Testing Registry (GTR, http://www.ncbi.nlm.nih.gov/gtr), but also has a wider scope. Review of analytical validity is supported by capturing methods of identifying the variation. Types of evidence include observations in affected or unaffected individuals, animal models, in vitro assays, and in silico predictions. We are actively working to ensure that submitted data can be exchanged with other groups seeking an integrated and cross-validated clinical-grade global knowledgebase. Some of the data in ClinVar are provided from another project hosted at NCBI, the International Standard Cytogenetic Arrays consortium (ISCA), which is focused on accumulating observations and applying evidence-based standards in the area of cytogenetic clinical testing. The ISCA effort incorporates tools to identify regions of conflicting interpretation to direct expert review, as well as establishing evidence-based guidelines where the current weight of evidence is judged by experts to support such conclusions. Data in ClinVar are integrated with other resources such as OMIM ®, PubMed, Gene, dbSNP, dbVar, and RefSeq. In addition to the web site, ClinVar can be accessed via ftp and standard NCBI tools such as E-utilities API, RSS feeds, and queries registered in MyNCBI. We expect to provide reports that can be incorporated into existing clinical interpretation analysis workflows. We strong encourage feedback and participation from the clinical genetics community, please contact us at (clinvar@ncbi.nlm.nih.gov).

Telegenetics Clinics in the United States: Successes, Challenges, and Future Directions. *S. Au[1], H. Andersson[2], L. Creel[3], S. Kubendran[4].* 1) Genetics Program, Hawaii Department of Health, 741 Sunset Avenue, Honolulu, HI 96816; 2) Hayward Genetics Center SL-31, Tulane University Medical Center, New Orleans, LA 70112; 3) Mountain States Genetics Regional Collaborative Center, 8501 North MoPac, Suite 300, Austin, Texas 78759; 4) KU School of Medicine-Wichita, 1010 N. Kansas, Wichita, KS 67214.

In much of the U.S., there is a shortage of genetic specialists, and rural and isolated populations are often underserved. Telemedicine offers a cost-effective solution to this problem by increasing access to genetic services for families living far from genetic centers. It is being increasingly used by many specialties as an innovative way of delivering clinical services and decreasing travel time for both the patient and the provider. However, the utilization of telemedicine in clinical genetic services has been limited, and there is a general lack of knowledge of telemedicine as a successful service delivery model among genetics professionals. With health care reform working to incorporate telemedicine into routine care including appropriate reimbursement, the genetics community must proactively take advantage of the benefits and promise of telemedicine. Funded through the Health Resources and Services Administration, the seven Genetics and Newborn Screening Service Collaboratives (RCs) are in various stages of using telegenetics to increase access to genetic evaluation, counseling, and management, particularly in rural and underserved communities. This session will include discussions of programs in the Heartland, Southeast, Mountain, and Western States RCs. The Heartland RC holds regularly scheduled telegenetics clinics located in AR, KS, and MO that provide services within these states and across state lines. The Southeast RC provides clinical telegenetics services from the genetic specialists directly to an in-patient hospital floor and also to a community pediatric clinic. The Southeast RC also hosts monthly telegenetics regional grand rounds for continuing genetic specialist education. The Mountain States RC provides genetic counseling services for oncology and pediatric hearing loss patients through telegenetics. The Western States has telegenetics activities within states (OR and WA), between states (OR to ID), and across the waters of the Pacific (Honolulu and Hawaii neighbor islands). The panel discussion will: 1) illustrate the successes and challenges faced by a small medical specialty in adapting to telehealth, 2) address gaps in knowledge and performance by providing concrete steps on how to establish and maintain a telegenetics program, and 3) demonstrate telegenetics as an innovative service delivery model that could be emulated in other underserved regions in country.

1024F

A rare DNA variant in a cis-overlapping motif in an IRF6 enhancer element is associated with Van der Woude Syndrome. *W. Fakhouri[1], F. Rahimov[2], H. Zhou[3], T. Du[1], E. Kouwenhoven[3], H. van Bokhoven[3 and 4], J. Murray[2], B. Schutte[1 and 5].* 1) Microbiology and Molecular Gen, Michigan State University, Lansing, MI; 2) Department of Pediatrics, University of Iowa, Iowa City, Iowa; 3) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences; 4) Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition, and Behavior, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) Department of Human Development, Michigan State University, Lansing, MI.

Cleft lip and palate (CLP) is one of the most common birth defects in humans with an incidence rate of 1/700 live births. DNA variation in Interferon Regulatory Factor 6 (IRF6) causes Van der Woude syndrome (VWS), an autosomal dominant form of CLP, and contributes risk for orofacial clefting, including a common DNA variant rs642961. Rs642961 is located in a multi-species conserved sequence (MSC) that is 9.7 kb upstream from the IRF6 transcriptional start site. The MCS9.7 element was shown to possess enhancer activity that mimicked the expression of endogenous Irf6 in oral epithelium and periderm, but not in medial edge epithelium of the palatal shelves. In order to identify possible etiologic DNA variants, we sequenced MCS9.7 in DNA samples obtained from individuals with VWS. We screened 48 DNA samples for which no disease-causing mutation was detected in IRF6 exons. We observed one new DNA variant. The DNA variant is an A insertion that is predicted to disrupt the DNA binding for both p63 and for bHLH transcription factors. Interestingly, the predicted binding sites for these two families of trans factors overlap completely. For the large family of bHLH trans factors, we focused on four members whose expression pattern appeared to overlap with Irf6. Using a DNA binding assay, we observed that this DNA variant abrogated binding by p63 and reduced the binding affinity for the bHLH trans factors. In a transient transactivation assay, we observed strong enhancer activity by the MCS9.7 element. This activation was highly dependent on p63, and the activation was abrogated by the A insertion mutation. In conclusion, these data are consistent with the hypothesis that the rare DNA variant at the cis-overlapping site in MCS9.7 is etiologic for VWS, and supports the rationale for additional mutation screening of the MCS9.7 enhancer element in patients with cleft lip and palate.

Histopathologic changes associated with development of retrosternal CDH in *Frem1*-deficient mice. *T.F. Beck[1], M.J. Wat[1], B.J. Kim[1], H. Zaveri[1], O. Shchelochkov[2], M. Justice[1], B. Lee[1], D.A. Scott[1].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Pediatrics, University of Iowa, Iowa City, IA.

Congenital diaphragmatic hernia (CDH) is a life-threatening sporadic birth defect that affects approximately 1 in 4000 newborns. Terminal deletions of chromosome 9p have been identified in several patients with CDH. However, the gene(s) that contribute to the development of CDH in these patients have yet to be identified. In a recessive ENU mutagenesis screen we identified a mouse strain that was homozygous for a truncating mutation (L826X) in *Frem1*—a basement membrane protein encoding gene located on chromosome 9p22.3. A portion of *Frem1*-deficient mice develop retrosternal CDH. Penetrance of this phenotype is highly dependent on strain background, providing evidence for the existence of one or more genetic modifiers. Several other genes have been implicated in the development of retrosternal CDH in mice including *Slit3*—which encodes another extracellular matrix protein—and *Gata4*—which encodes a transcription factor that has also been implicated in the development of CDH associated with 8p23.1 deletions in humans. We have shown that both of these genes interact genetically with *Frem1* in other developmental processes. Analyses of *Slit3* and *Gata4* mouse models of CDH suggest that a number of histopathalogic changes in the anterior diaphragm may contribute to an increased risk of developing CDH. These changes include decreased cell proliferation, increased cell death, decreased diaphragm thickness and disorganized collagen fibrils in the central tendon. We are presently working to determine if similar changes are present in Frem1-deficient mice. Preliminary results of phospho-histone H3 immunostaining revealed a trend towards decreased cell proliferation in the anterior and central diaphragm of *Frem1*$^{L826X/L826X}$ mice compared to littermate controls. A similar pattern has been reported in *Slit3* mice, suggesting that the extracellular matrix plays an important role in regulating cell proliferation in the developing diaphragm. We are also working to determine the expression pattern of Frem1 and associated genes in the developing diaphragm. These studies will help us understand the mechanisms by which *Frem1* deficiency causes retrosternal CDH in mice and may provide insight into the causes of similar hernias in humans.

1026F

Infantile systemic hyalinosis presenting as multiple joint pain. *B. Chung[1], E. Lausch[2], A. Superti-Furga[3], T.Y. Tan[1,4].* 1) Pediatrics & Adol Med, University of Hong Kong, Hong Kong, ON, China; 2) Centre for Pediatrics and Adolescent Medicine, University Hospital Mathildenstr., Freiburg, Germany; 3) Centre Hospitalier Universitaire Vaudois, University of Lausanne, Switzerland; 4) Genetic Health Services Victoria, Murdoch Children's Research Institute, Department of Paediatrics, University of Melbourne, Australia.

Background: Infantile systemic hyalinosis (ISH) is a rare autosomal recessive disorder characterized by abnormal hyaline deposits in the papillary dermis and other tissues. It presents in early infancy with severe pain with movement, progressive joint contractures, thickened skin and hyperpigmented macules over bony prominence. Gingival hypertrophy, skin nodules, perianal masses are common but late findings. We report a female infant with ISH and subsequently confirmed to have known pathogenic mutations in the ANTXR2 gene. Clinical information: The proband was the 3rd child of a Pakistani couple who were first cousins. Her elder sister passed away at 8 months with unknown cause. She was born full term by NSD with normal growth parameters and Apgar scores. Newborn examination was normal. She presented with decreased limb movement at 3 months. Clinical assessment showed that limb movement was limited by severe pain; her ears were simple but prominent and there were hyperpigmentation over the finger knuckles and ankles. Skeletal survey showed metaphyseal/submetaphyseal widening. Bone marrow examination excluded myeloproliferative disorders. The absence of fever and skin rash, normal ophthalmologic examination and normal levels of serum inflammatory markers made the diagnosis of Chronic infantile neurolological, cutaneous and articular (CINCA) syndrome unlikely. As limb pain and the skin findings could be the only findings in the early stage of ISH, genetic testing was offered to the parents with genetic counseling. A known pathogenic homozygous mutation, c.[652T>C] was found in the ANTXR2 gene causing an amino acid substitution in codon 218, p.C218R, confirming the diagnosis of ISH. The parents were carriers of the same mutation. Conclusion: ISH is more commonly reported in ethnic groups with consanguineous marriage. This patient developed protein-losing enteropathy at 5 months, perianal masses at 6months and mild gingival hypertrophy at 8 months. The prognosis of patients with ISH was poor and they usually die at infancy with recurrent infections and malnutrition.

1027F

A patient with Van den Ende-Gupta syndrome: Molecular analysis and comparison of clinical features with previously reported patients. *G.C. Gowans, K.C. Platky, K.E. Jackson, P.L. Brock, J.J. Wetherbee-Landis, J.H. Hersh, K.M. Goodin, A. Asamoah.* Genetics Unit, WCEC, Pediatrics, University of Louisville, Louisville, KY.

Mutations in the SCARF2 gene (MIM 613619) have recently been identified (AJHG, 87:553-559.) in some patients with the rarely reported Van den Ende-Gupta syndrome (MIM 600920). Van den Ende-Gupta syndrome is characterized by distinctive craniofacial and skeletal manifestations including blepharophimosis, malar and maxillary hypoplasia, a convex nasal ridge, an everted lower lip, arachnodactyly, and camptodactyly with mild bowing of the long bones. The physical growth and cognitive development is normal in the approximately 25 previously described patients. We describe the craniofacial and skeletal features of a now 5 year and 3 month old Laotian female child and compare these features to the previously reported patients. We also describe the analysis of our patient's SCARF2 genes.

1028F

Increased bone density, short stature and bowed lower limbs in an inbred kindred: a probable new genetic skeletal disorder. *G.F. Leal[1], R. Lyra[2], E.O. Silva[1].* 1) Medical Genetics Service, Instituto de Medicina Integral Fernando Figueira, Recife, Pernambuco, Brazil; 2) Endocrinology Service, Universidade de Pernambuco, Recife, Pernambuco, Brazil.

The 2010 Revision of the Nosology and Classification of Genetic Skeletal Disorders includes 456 entities placed in 40 groups defined by clinical and radiographic features and molecular pathogenesis. Two groups are characterized by increased bone density, and together they comprise forty recognized diagnostic conditions. We have ascertained a consanguineous family presenting a clinical picture that do not completely fit with any of these conditions. The genealogical data from seven generations show 13 affected persons (eight females and five males) distributed in eight sibships, and born to consanguineous parents. The ages and heights of the living affected individuals (four females and one male) varied, respectively, between 17-45 years and 128-149 cm. In addition to the short stature, all the patients presented bowing of the lower extremities involving femora, tibiae, and fibulae. There was no evidence of hearing loss, visual impairment or any other neurological problems, and no history of bone fractures. Head circumference and intelligence were normal in all patients. The radiological studies of the complete skeleton performed in two of them showed generalized cortical hyperostosis affecting all bones. The thickening and sclerosis were particularly marked in skull, clavicles, pelvis, and long bones. Bowing of femora, tibiae, and fibulae, and coxa vara were also observed. Biochemical exams were performed in two patients: serum levels for alkaline phosphatase, phosphorus and calcium were respectively elevated, decreased and normal. Serum parathyroid and thyroid hormones were normal in the only patient investigated. The radiographic features of van Buchem disease and sclerosteosis overlap to some extent to those seen in our patients, however short stature and bowing of lower limbs are not seen in these disorders. Individuals with van Buchem disease or sclerosteosis are of normal or tall stature, have a large mandible, and may present facial paralysis, deafness and optic atrophy due to progressive cranial nerve palsies. Osseous or skin syndactyly, and absent or hypoplastic phalanges have also been found in sclerosteosis. Considering that our patients present only short stature and bowing of lower limbs in addition to the increased bone density, we suggest that their phenotype constitute a new genetic skeletal disorder.

1029F

Oculodentodigital dysplasia in a family with multiple malformations of hands and feet. *G.L. Yamamoto[1], M.C. Moreira[1], I. Gomy[1], A.C. Pereira[2], C.A. Kim[1], D.R. Bertola[1].* 1) Genetica Medica ICR-FMUSP, Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) Laboratório de Biologia e Cardiologia Molecular, InCor, Faculdade de Medicina da Universidade de São Paulo, São Paulo, São Paulo, Brazil.

Malformations of hands and feet, such as polydactyly and syndactyly, are easily identified, but commonly ignored in clinical practice. These findings are mainly autosomal dominant traits with variable penetrance. However, some forms of presentation may be suggestive of specific diseases such as the fourth and fifth fingers syndactyly, that must address to the possibility of oculodentodigital dysplasia (ODDD). ODDD is an autosomal dominant disease associated to the gap junction protein alfa 1 (GJA1) gene, with high penetrance and pleiotropic phenotype that includes typical facial appearance with epicantic folds, prominent columella, hypoplastic alae nasi and oculodentodigital anomalies (microphtalmia, microcornea, hypoplastic or carious teeth and complete syndactyly of fourth and fifth fingers). Sparse curly hair, progressive spastic paraparesis and palmoplantar keratoderma are also described. We report a two-month-old female infant, born of unrelated healthy parents, with unremarkable pre-natal and neonatal history. At initial evaluation, large anterior fontanel, short palpebral fissures, hypoplastic alae nasi, inverted nipples, bilateral complete syndactyly of fourth and fifth fingers and partial syndactyly of third and fourth toes were noted. Her parents had normal hands and feet and her sister had post-axial polydactyly in left hand. In the paternal family history, there were cases of fingers and toes syndactyly, whereas multiple maternal relatives presented post-axial polydactyly in hands. There were no abnormalities upon cardiac, abdominal and ophthalmological evaluations. X-ray showed left hand synostosis of the distal phalanges of fourth and fifth fingers and agenesis of middle phalanges of toes. Parents' X-ray was normal. GJA1 gene sequencing of the proband revealed the pathogenic p.R202H heterozygous mutation, confirming the hypothesis of ODDD. Although there were no hand abnormalities in the proband's parents, the family history is suggestive of autosomal dominant ODDD and polydactyly with incomplete penetrance. Therefore, the ongoing molecular analysis of the parents and affected relatives is important to confirm the diagnosis and for an accurate genetic counseling.

1030F

Two sibs with mulibrey nanism reported from Japan. *H. Yoshihashi[1], S. Oomori[2], S. Satoh[2], C. Torii[3], K. Kosaki[3].* 1) Div Med Gen, Tokyo Metropolitan Children's Med Cente, Tokyo, Japan; 2) Div of Pediatr, Saitama City Hospital, Saitama, Japan; 3) Dep of Pediatr, Keio University, School of Medicine, Tokyo, Japan.

Mulibrey (MUscle-LIver-BRain-EYe) nanism (MUL ; MIM #253250) is a rare autosomal recessive disorder caused by *TRIM37* (located on 17q22-q23), encoding cytoskeletal adaptor protein. To date, at least 130 patients are known worldwide, most of them from Finland, including sporadic cases reported from different ethnic groups. MUL is characterized by prenatal onset growth failure, distinctive face, fibrous dysplasia of long bones, hepatomegaly, pericardial constriction, and no psychomotor delay. Some of them are compatible with Silver-Russel syndrome (SRS; MIM #180860) phenotype. Here, we present the first affected two sibs from Japan, whose parents are not consanguineous. Subject1: 3y8m-male. At 39 weeks of gestation, he was delivered without any critical problems during the perinatal period, but including IUGR (1662g,-3.3SD), atrial septal defect (ASD), hypospadias, and undescended testis. At the age of 21 months, the poorly-distensible cardiac membrane made it impossible to correct ASD with surgery. At 3 years old, he had no developmental delay and needed to be treated with GH therapy. However, he died as a result of fungous pneumonia at the age of 44 months. Subject2: 1y6m-female. In pregnancy, the fetal screening echo showed short limbs and IUGR. At 40 weeks of gestation, she was born by induced delivery due to growth arrest. Birth weight was 2244g (-2.5SD), length45.5m (-2.2SD), and head circumference 32.0cm (-1.0SD). There were no severe perinatal involvements, except for TTN. At the age of 18 months, she presented with failure to thrive and short stature(68.5cm, -3.3SD), including distinctive face (relative macrocephaly, broad forehead, low depressed nasal bridge), rhizomelia, and gracility of long bones. The features led to the clinical diagnosis of MUL. The direct DNA sequencing of *TRIM37* gene revealed novel compound heterozygous mutations in the exon 11 (c.874_877delAGAG p.Arg292Gln fsX18) and the exon 12 (c.1016C>G p.Ser339Cys). Conclusion: MUL is not well clinically-recognized syndrome in Japan. The evaluations of the bone X-P survey and echocardiographic study will help in distinguishing MUL from SRS and three M syndrome type1(3M1; MIM #273750). The genetic counseling may fall into a “pitfall” about estimating the recurrence risk for patients diagnosed with SRS, especially not caused by aberrant methylation status.

1031F

Novel mutations in *ADAMTSL4* in non consanguineous isolated ectopia lentis. *A. Chandra[1, 2], JA. Aragon-Martin[1], DG. Charteris[2], A. Saggar[3], AH. Child[1], G. Arno[1].* 1) Cardiac & Vascular Sciences, St George's University of London, London, United Kingdom; 2) Vitreoretinal Research Unit, Moorfields Eye Hospital, City Road, London, United Kingdom; 3) Clinical Genetics Unit, St George's University of London, London, United Kingdom.

Introduction: Mutations in *ADAMTSL4* are associated with the ophthalmic clinical condition of autosomal recessive isolated ectopia lentis. We have previously described six distinct mutations, with one recurrent mutation (c.767_786del20) identified in exon 6 being found most prevalently by different research groups throughout Europe. Herein we describe further probands with *ADAMTSL4* mutations. Methods: Known syndromes associated with ectopia lentis, particularly Marfan Syndrome, were excluded in affected probands. DNA underwent PCR and Sanger sequencing using optimised conditions and primers previously described. Results: Three probands were analysed. All patients had bilateral ectopia lentis. Family histories suggested possible recessive inheritance. There was no history of consanguinity in any of the families. Two probands, both white Caucasian were found to be homozygous for c.767_786del20 mutation on exon 6. The third proband was found to be compound heterozygous for two mutations. This included the c.767_786del20 (p.Gln256ProfsX38), leading to a frameshift resulting in a premature termination codon in exon 6. The proband also had a novel heterozygous deletion c.237delC (p.Pro80ArgfsX53) in exon 5 leading to a frameshift resulting in a premature termination codon in exon 5. Discussions: We confirm the importance of the c767_786del20 mutation in autosomal recessive ectopia lentis. Its prevalence in other reports may suggest it originates from within Europe. This supposition is further supported by the racial origin of our probands. Our novel mutation results in a premature termination codon. The majority of the mutations detected in *ADAMTSL4* seem to result in protein truncation, if the resulting protein survives nonsense-mediated decay (NMD). If, as we suspect, the truncation mutations result in mRNA that undergoes NMD, this would suggest that a null phenotype is associated with disease and the role of ADAMTS-like 4 is critical to ciliary zonule function.

1032F

Small size Xq28 duplication with unusual Filamin A (FLNA) gene amplification associated with mental retardation, severe behavioural inhibition, and high intensity signals of periventricular white matter. *F. BILAN[1], N. BAHI-BUISSON[2], B. MANIERE[1], P. DUMAINE[1], A. KITZIS[1], B. GILBERT-DUSSARDIER[1].* 1) Medical Genetics, CHU , Poitiers, France; 2) Neuropediatrie, CHU Necker-Enfants Malades Paris, France.

A 14-years old boy had development anomalies, behaviour disorders and epilepsy. At birth, after an uneventful pregnancy, he had some signs of overgrowth (birth weight: 4170g, birth height: 53cm and head circumference: 37cm). Then, growth was in the mean range but he kept up a macrocephaly at +3SD. He had normal motor development with walking at age of 14 months. His mental development was marked by language delay and moderate mental disability leading to specialized education. The main feature of his behaviour was an unusually severe shyness and inhibition making him very uncomfortable in his social life. He had some dysmorphic features: slight hypertelorism, straight eyebrows, bulbous nose tip, slight microretrognathia, brachymetatarsia of both 5th toes. Generalized epilepsy was also reported. Cerebral MRI showed mild subcortical atrophy with cerebellar hypoplasia, and T2/FLAIR hypersignal in periventricular white matter. His mother had also been in a specialized educative course and a maternal aunt was said to have a mild mental retardation. Index patient DNA was subjected to array-CGH analysis using 105K microarray (Agilent technologies). We highlighted a previously reported 250 kbp Xq28 duplication (Vandewalle et al., 2009) involving 17 genes in which 6 were reported as causing disease genes in the OMIM database. This chromosomal anomaly was then confirmed by several MP/LC (Multiplex PCR/ Liquid Chromatography) in the patient. In a second step it was also studied in his large kindred for genetic counselling purpose. We show that Xq28 duplication was inherited from his mildly affected mother in whom the chromosomal rearrangement occurred de novo. Surprisingly, we show that FLNA encoding filamin A was de novo duplicated within the large Xq28 duplication in the index patient. This result differs from Vandewalle et al. and shows that GDI gene alone is not sufficient to explain mental retardation observed in such duplication. Moreover, the maternal grand-mother who does not harbour this 250 kbp duplication, presented a non expected increase of the copy number of IKBKG gene and pseudogene as compared to healthy subjects and five of her six children. This anomaly was transmitted to the mildly affected aunt of the index patient. Taken together, these data strengthen that Xq28 region is prone to recombine and that IKBKG gene and pseudogene located within Xq28 region might play a crucial role in this chromosomal rearrangement.

1033F

A novel Xq28 duplication syndrome distal to *MECP2* accounts for 10% of male patients with combined callosal and cerebellar anomalies. *S.L. Christian[1], S. Sajan[2], C.T. Sullivan[1], L. Fernandez[3], S. Esmeeli[3], E. Rider[3], P.G. Wheeler[4], K. Silver[5], D. Mei[6], E. Parrini[6], R. Guerrini[6], J.T. Glessner[7], H. Hakonarson[7], E.H. Sherr[3], W.B. Dobyns[1].* 1) Center for Integrative Brain Research, Seattle Children's Research Institute, Seattle, WA; 2) Division of Medical Genetics and Department of Genome Sciences, University of Washington, Seattle, WA; 3) Department of Neurology, University of California, San Francisco, CA; 4) Division of Genetics, Nemours Children's Clinic, Orlando, FL; 5) Division of Pediatric Neurology, University of Chicago, Chicago, IL; 6) Pediatric Hospital A. Meyer, University of Firenze, Firenze, ITALY; 7) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Although duplications of Xq28 that contain *MECP2* have been documented in more than 50 patients, only a few have been reported with duplications of the more distal ~300 kb region (Vandewalle et al., 2009), and even fewer with details of brain imaging. We genotyped a total of 340 patients with agenesis of the corpus callosum (ACC) or cerebellar hypoplasia (CBLH), including 67 with both, on the Illumina HumanHap 610 Quad SNP arrays. Our initial copy number variation (CNV) bioinformatics analysis discovered small overlapping duplications of Xq28 distal to *MECP2* in 2 males with combined ACC and CBLH. We next manually curated all the CNV in these subjects and found 2 additional males with the same duplication. All duplications were present in only male patients consistent with an X-linked disorder. We thus detected this duplication in 2% (4/214) of all male subjects with ACC or CBLH, and in 10% (4/42) of male subjects with combined ACC and CBLH. We also obtained breakpoint data for one previously reported boy with a small visible dup Xq28 (Dobyns et al., 1997). The phenotype in all 5 males plus 2 affected male siblings consists of severe intellectual disability and seizures with brain imaging findings of ACC, CBLH and brainstem hypoplasia. In addition 3/7 had periventricular nodular heterotopia. The arrays and fine mapping by qPCR showed that the SRO extends from *FLNA* through *CTAG2* (chrX:153,576,900-153,816,423 hg19), a region containing 19 RefSeq genes but not *MECP2*. Mutations of *FLNA* have been associated with X linked periventricular nodular heterotopia and oto-palato-digital syndrome, while mutations of *GDI1* have been associated with XLMR. Quantitative PCR was performed to determine the copy number and detected internal triplications in 3 of 4 males tested. The phenotype did not differ in the two boys with larger duplications that included *MECP2*. However, the brothers with the largest internal triplication had a more severe phenotype than the others. Finally, the CNV were often inherited, as 3 mothers and 1 grandmother also carried extra copies of Xq28. In summary, we have defined a novel CNV syndrome that may account for up to 10% of male children with combined ACC and CBLH.

1034F

Long Term Survival in TARP Syndrome and Confirmation of *RBM10* as the Disease Causing Gene. *K.W. Gripp[1], E. Hopkins[1], J.J. Johnston[2], C. Krause[2], W.B. Dobyns[3], L.G. Biesecker[2].* 1) Division of Medical Genetics, A. I. duPont Hospital for Children, Wilmington, DE; 2) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 3) Seattle Children's Research Institute, Seattle, WA.

TARP syndrome (talipes, ASD, Robin sequence, and persistence of left superior vena cava LSVC), is X-linked with pre- or postnatal lethality in males. Exon resequencing in 2 families identified *RBM10* as disease causing gene. Clinical report: Pt. 1 was born preterm with U-shaped cleft palate, ASD and persistent LSVC, facial dysmorphia and cryptorchidism. He had severe respiratory distress and at age 3 ½ years remains ventilator-dependent at night and tube-fed. Brain anomalies include partial ACC, dysplastic caudate, and megacisterna magna. He has hypotonia, sensorineural deafness, optic atrophy and cortical visual impairment. Atrial flutter required ablation. Results: A novel *RBM10* frameshift variant was found in Pt. 1 and his mother was heterozygous. Table 1: Pt. 1's findings, compared to previously diagnosed TARP syndrome individuals

	Talipes	ASD	Cleft	Persist. LSVC	Infant Death	Cryptorchidism	Low-set ears
Pt. 1	-	+	+	+	-	+	+
Gorlin 1970	6/7	3/7	4/6	4/7	7/7	+	+
Johnston 2010	2/3	1/1	3/3	0/0	3/3	+	+
Combined N=11	8/11 (73%)	5/9 (100%)	8/10 (80%)	5/8 (63%)	10/11 (91%)	3/3 (100%)	(100%)

Discussion: We confirm *RBM10* as pathogenic for TARP. This first TARP patient with long term survival expands the phenotype to include brain anomalies; hypotonia and developmental delay; deafness and optic atrophy; arrhythmia and characteristic facial features. Maternal heterozygosity underscores the importance of accurate diagnosis and counseling.

1035F

Functional analysis of novel missense alleles in Arylsulfatase E and identification of potential phenocopies in patients with X-linked recessive brachytelephalangic chondrodysplasia punctata (CDPX1). *C. Matos-Miranda[1], G. Nimmo[1], S. Bale[2], B. Williams[2], N. Braverman[1].* 1) Montreal Children's Hospital Research Institute, Dept. of Human Genetics, McGill University, Montreal, QC Canada; 2) GeneDx, Gaithersburg, Maryland, USA.

Inherited deficiency of Arylsulfatase E (ARSE) causes CDPX1, which features chondrodysplasia punctata, nasomaxillary hypoplasia and brachytelephalangy. There is a spectrum of clinical severity in affected males. Diagnosis requires molecular analysis due to the absence of a biochemical assay for endogenous ARSE. Yet, a significant number of patients with CDPX1 phenotypes do not have identifiable ARSE mutations and are thought to represent phenocopies due to fetal vitamin K deficiency inhibiting a normal ARSE enzyme. From 2008-2010, assisted by referring physicians and the Collaboration Education and Test Translation program (CETT) for CDPX1, ARSE mutation analysis was performed in 41 male probands with CDPX1 phenotype and clinical data was collected to determine genotype-phenotype correlations and to identify maternal effects in mutation negative patients. 20 novel ARSE alleles were studied for activity using a transient COS1 expression system and the fluorogenic artificial substrate, 4-MU sulfate. Initial studies showed absence of ARSE activity for most alleles, but potential residual activity for alleles located towards the C-terminus. Here we optimized the ARSE assay to include enzymatic time courses and report negligible activity for these C-terminal alleles. We also found that the product 4-MU was relatively unstable over time at neutral ph, which is required for this assay. In conclusion, our results showed that (1) frequency of all ARSE mutations identified in male probands with CDPX1 phenotype is ~ 56% (17/30), using prospective data from CETT), (2) all studied missense alleles had negligible ARSE activity suggesting they are pathological, (3) since the mutations are located throughout the protein and similar phenotypes are observed whether a gene deletion or missense alleles is present, genotype-phenotype correlations are unlikely, (4) maternal effects in mutation negative patients could not be established because the clinical data collections were incomplete, and also suggest the possibility of undetected ARSE mutations or genetic heterogeneity, and (5) the fluorescent product (4MU) at neutral pH adds variability to the ARSE assay results. Future focus on further evaluation of mutation negative patients, as well as development of an endogenous ARSE assay is warranted.

1036F

Ehlers-Danlos syndrome and bilateral periventricular heterotopia due to the novel mutation of p.G132V in the CHD1 in FLNA: An infantile case presented with respiratory distress due to tracheomalacia. *Y. Watanabe[1], J. Okada[1], K. Kimura[1], Y. Okamatsu[1], T. Oya[1], M. Yoshino[1], H. Yagi[2], M. Sato[2].* 1) Dept Pediatrics, Kurume Univ, Kurume, Japan; 2) Dept Morphological and Physiological Sciences, University of Fukui, Fukui, Japan.

Background: Bilateral periventricular heterotopia is known to be caused by mutations in FLNA. Other disease phenotypes with FLNA mutations include Frontometaphyseal dysplasia (FMD), Otopalatodigital syndrome (OPD type 1 and 2), Melnick-Needles syndrome (MNS), Cardiac valvular dystrophy, Ehlers-Danlos syndrome and bilateral periventricular heterotopia (BPNH-EDS). Three cases of BPNH-EDS was first reported in 2005 and approximately 10 cases of this rare genetic condition have been reported. Mutations in the one of the two calponin homology domains, CHD1, have been identified in the majority of the cases. Since many of the patients were diagnosed in their adulthood, clinical features seen in infantile cases have not been well documented. The case presented in this report describes clinical features of an infant with BPNH-EDS due to the novel mutation in FLNA. **Case Report:** The patient was a full term 3028 g baby girl, born by NSVD to a 28 year-old G2P1-2Ab0 Japanese woman who is in good health. Prenatal care was reportedly unremarkable. Apgar scores were 91 and 105. Parents noted her as a newborn baby to be floppy compared to her elder brother. At age 4 Mo, she had seizures and developed RS virus pneumonia requiring assisted ventilation for 28 days. BPNH was diagnosed by MRI. At 6 Mo, she was readmitted to a hospital for persistent wheezing and failure to thrive. After 7 Mo, she has been in chronic use of an assisted ventilator due to frequent episodes of respiratory distress. Tracheomalacia as well as generalized increased skin elasticity were noted. FLNA mutation analysis revealed the novel heterozygous mutation of p.G132Vconfirming the diagnosis of BPNH-EDS. The patient had a lung volume reduction surgery (LVRS) for chronic pneumonia at age 1 years and is stable and growing well. Physical Examination at age months was remarkable for generalized loose elastic skin, hypertelorism, frontal bossing, tracheomalasia, hyperextensible major and minor joints. No digital/toe anomalies noted. Hearing was normal. **Discussion:** FLNA mutations consist of two types: loss of function mutations and gain of function mutations. Periventricular heterotopia is believed to be due to the former mechanism. OPD, FMD, and MNS are thought to be due to the latter mechanism. The presented case showed clinical features of both mechanisms. Tracheomalacia is rare in patients with FLNA mutations although two sibling cases with OPD have been reported.

1037F

Phenotype and Genotype in 22 Slovene Patients with Incontinentia Pigmenti. *K. Writzl, N. Teran, B. Peterlin.* Institute of Medical Genetics, Ljubljana, Slovenia.

Incontinentia pigmenti (IP) (OMIM 308300) is a rare genodermatosis that segregates as an X-linked dominant disorder and is almost always lethal prenatally in male. The disorder demonstrates high penetrance, but its phenotypic expression is highly variable. In affected females it causes abnormalities of the skin, nails, teeth, hair, eyes and central nervous system. In 2000 the mutations in IKBKG gene were found to be causative of IP. Here we report the phenotype and genotype of 22 female IP patients from 16 different families from Slovenian approximately two million population. In 9 families (11 patients) an IKBKG mutation was found. Mutations included a common deletion of exons 4-10 (in 7 families; 8 patients) and two frameshift mutations (in 2 families; 3 patients). No genotype-phenotype correlation could be found. All patients with confirmed mutation but only 55% of patients without mutations were reported to have stage I skin abnormalities. Neurologic findings including cognitive delay and seizures were present in two patients only; both had IKBKG mutation. Lower limb asymmetry was found in four patients; two with and two without mutation. One family had three members with characteristic skin lesions, hypodontia and dystrophic nails. No mutation was found using target mutation analysis for common deletion and sequence analysis of IKBKG, but linkage analysis confirmed co-segregation of Xq28 region markers with the disease phenotype. We conclude that IKBKG mutations were found in about 70% of IP patients with documented stage I skin lesions. The low mutation detection rate is probably partly due to the lack of strict diagnostic criteria for IP but also to the fact that not all IKBKG mutations can be detected using analysis for common deletion and sequence analysis of IKBKG.

1038F

Amplicon Resequencing of the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Gene. *L. Joe[3], R. Achmann[1], F. Stellmer[1], S. Zhan[1], L. Argyrioul[1], R. Greither[2], R. Dixon[2], A. Rico[2], A. Sartori[2], N. Fong[3], R. Padilla[3], R. Fish[3], N. Patel[3], J. Berena[3], T. Burcham[3], B. Auber[1].* 1) MVZ genteQ GmbH, Lornsenstr. 4, 22767 Hamburg, Germany;; 2) Life Technologies GmbH, Frankfurter Str. 129B, 64293 Darmstadt, Germany;; 3) Life Technologies, 850 Lincoln Centre Drive, Foster City, CA. 94404 USA.

Cystic Fibrosis (CF) is a common autosomal recessive disorder caused by mutations in the Cystic fibrosis transmembrane conductance regulator (CFTR) gene. Depending on ethnical and phenotypic background there can be great mutational heterogeneity. More than 1800 CFTR mutations are known. Commercial screening kits consider only a subset of relatively frequent mutations covering around 80% of mutations causing classic CF. However, only about 50 to 60% of mutant alleles in the CFTR genes of individuals with atypical forms of CF like congenital aplasia of the vas deferens (CBAVD) are interrogated. Resequencing of the entire coding sequence of the gene would increase the sensitivity of mutation detection, but Sanger sequencing is still costly. Alternatively, Next-Generation Sequencing can be cost effective, especially when samples are multiplexed. We describe a pilot study comprising 20 samples (17 with known and 3 control samples from healthy individuals with unknown CFTR gene mutational status), using a Multiplicom multiplexing assay for the CFTR gene, sample barcoding and subsequent Next-Generation Sequencing (NGS) with both the SOLiD™ 4 and 5500xl Genetic Analyzer Systems. We also executed a custom protocol for Ion Torrent's semiconductor-based Personal Genome Machine (PGMTM) System that enabled the sequencing of established (larger) amplicons. Finally, we performed Sanger sequencing and compared the data from all four systems.

1039F

Whole genome sequencing in a patient with aortic aneurysm: when gene panels are not sufficient. *C. Skrzynia[1], C. Schmitt[2], J. Berg[1].* 1) Genetics Department The University of North Carolina at Chapel Hill Chapel Hill, NC; 2) The Renaissance Computing Institute Chapel Hill, NC.

As the cost of whole genome sequencing (WGS) decreases, its ability to detect variation in all genes as well as genomic rearrangements, will make it highly attractive as a potential universal diagnostic test. The advantages of WGS are particularly evident in conditions with genetic heterogeneity, in which the cost of comprehensive genetic testing exceeds the cost of WGS. Furthermore, clinically available testing may not include all genes known to cause a given disorder. We identified a proband with aortic root aneurysm at age 33. Her sister died at age 41 due to dissection of a 7.1cm aortic root aneurysm. Several family members had features consistent with connective tissue disorders but no specific diagnosis had been established. Our proband did not have physical findings of Marfan syndrome but had joint hypermobility. In order to determine a specific diagnosis, we obtained extensive testing of genes known to cause familial thoracic aortic aneurysm and dissection (FBN1, ACTA2, TGFBR1, TGFBR2, and MYH11) and genes associated with forms of Ehlers-Danlos syndrome (COL3A1, COL5A1 and COL5A2). This testing was negative. We investigated the possibility of WGS in order to identify mutations in genes not yet available for clinical testing (for example, MYLK) or genomic rearrangements. During extensive pre-test counseling, we reviewed possible outcomes of the diagnostic evaluation and the potential for discovery of incidental findings. We organized the consent using a system of “bins” that categorize incidental findings according to clinical actionability. WGS was obtained through Illumina's clinical sequencing program, and the patient's insurance provider reimbursed the cost of the WGS testing in full. To our knowledge, this is one of the first cases of insurance coverage for WGS. WGS data is in the process of being analyzed. The diagnostic analysis will evaluate all genes associated with aortic root or thoracic aortic aneurysms, and results will be divulged in a formal genetic counseling session. Clinically actionable incidental findings, if any, will be revealed at that time. Other non-actionable incidental findings will be categorized according to the binning scheme we have developed, and the patient will be given the ability to select the categories of information she wishes to receive. We will present aspects of the medical and genetic counseling ramifications of WGS in this typical patient seen in our Adult Genetics Clinic.

Pre-test genetic counseling for whole genome sequencing: Development of a protocol and evaluation of participant experience. *K. Trzupek[1], A. Trivedi[1], K. Ormond[2], R. Sutphen[1,3].* 1) Informed Medical Decisions, Inc, St Petersburg, FL; 2) Dept of Genetics, Stanford University School of Medicine, Stanford, CA; 3) University of South Florida College of Medicine, Tampa, FL.

Background The broad spectrum and quantity of data yielded by whole genome sequencing (WGS) presents distinct challenges for the delivery of genetic counseling (GC). We developed a pre-test GC protocol for WGS that is currently being utilized as part of a research study providing WGS to faculty members at Stanford University. Methods “Genetically educated” faculty were offered the opportunity to participate in a WGS study with the option of clinical annotation; pre- and post-WGS GC are required for participation. Potential participants attend information sessions about the study, and schedule a pre-test GC appointment if interested. Following GC, participants can elect to pursue WGS; those who elect clinical annotation receive results via post-test GC. Participants are also invited to take part in ongoing behavioral surveys. Results The pre-test GC session is divided into three sections: 1) personal/family history review and risk assessment, 2) WGS technical capabilities and limitations for detecting a wide variety of genetic conditions, and 3) psychosocial benefits and risks. The counseling protocol evolved following feedback from the initial participants. At their request, additional information was included regarding the technical aspects and limitations of the sequencing methodology. Virtually all of the participants categorize themselves as “information seekers,” interested in receiving all available health information, and did not anticipate significant personal emotional risks. However, most participants recognize the sensitive nature of predictive genetic information for others, and engaged in discussing the psychosocial impact of WGS as it may relate to their family members. These familial implications became a focal point of the psychosocial counseling. Conclusion There is very limited experience to date with GC for WGS, particularly among asymptomatic individuals who are expected to comprise the majority of tested individuals in the future. Although targeted to a scientifically knowledgeable group, this pre-test GC protocol has implications for broader populations. Our protocol is evolving as an iterative process incorporating lessons learned in order to balance general information about the scope of findings from WGS with comprehensive personalized risk information to enhance client understanding, ensure true informed consent and optimize client preparedness for receiving and sharing WGS results.

Screening of LRTOMT gene (DFNB63 locus) in Iranian patients with autosomal recessive nonsyndromic hearing loss. *N. yazdanpanahi[2], S. Ashoori[1], E. Farrokhi[1], H. taghizade[1], R. heshmatifar[1], SH. Shahbazi[1], M. Hashemzade[1].* 1) Cellular and molecular research center, Shahrekord Univ of Med. Sci. Iran, shahrekord, Islamic Republic of Iran; 2) Islamic Azad University , Falavarjan branch . Iran,isfahan, Islamic Republic of Iran, Ph.D student.

Background: Prelingual hearing loss occurs in 1 in 1000 newborns and is inherited in more than 60 percent cases. Approximately more than 80 percent cases are nonsyndromic. Nonsyndromic hearing loss is so heterogene and more than 100 loci are known to be related to it. Objectives: To determine LRTOMT gene mutation profile in Iranian patients. Methods: 200 patients with nonsyndromic hearing loss from different provinces of Iran were recruited for this study. DNA was extracted using Phenol-Chloroform method. PCR reactions were done, then DNA sequencing of coding region was done. It's supposed to study all 10 exons of this gene. Three exons (1,3 , 5 and 9) have been studied up to now. Our work is in progress. Results: These four sequenced exons (1,3 , 5 and 9) were studied using Chromas software and no mutation was detected in these three exons. Conclusions: It seems that this gene has no critical role in hearing loss in these studied populations. But for a more accurate result, all of the exons must be studied.

1042F

Association of ADAM33 gene polymorphisms and their haplotypes with asthma in an Indian population. *P. TRIPATHI[1], S. AWASTHI[2], R. PRASAD[3], N. HUSAIN[4], S. GANESH[5].* 1) Pediatrics, Chhtrapati Shahuji Maharaj Medical University, Lucknow, UP., India; 2) Chhtrapati Shahuji Maharaj Medical University, Lucknow, UP., India; 3) Pulmonary Medicine, Chhtrapati Shahuji Maharaj Medical University, Lucknow, UP., India; 4) Pathology, Chhtrapati Shahuji Maharaj Medical University, Lucknow, UP., India; 5) Biological Sciences and Bioengineering, IIT, Kanpur, India.

Abstract: Background and purpose: A disintegrin and metalloprotease 33 (ADAM33), was the first identified asthma-susceptible gene by positional cloning. Presently, there is a need to study the association of all most common SNPs of ADAM33 with asthma and its severity. Therefore aims of present study were; (1) To assess association of ADAM33 gene polymorphisms(V2 C/T, T2 A/G, T1 A/G, Q-1 A/G, BC+1 A/G and S1 A/G) with asthma and its severity in all subjects as well as in children and adults separately . (2) To assess the distribution of ADAM33 gene polymorphisms haplotypes and association with risk of asthma. Methods: This was a case-control study, conducted after approval of institutional ethics committee and patients enrolled after obtaining informed consent of participants/ Guardians. Included were those aged between 1 to 50 years, in two groups; 1) children (age less than or equal to 19 years) and 2) adults (age greater than 19 years). Diagnosis and severity of asthma were made according to the Global Initiative for Asthma criteria (GINA) guidelines. Controls were age and sex matched non-relatives of cases without any respiratory disease. Genotyping was done by PCR-RFLP method. Results: From august 2007 to September 2009, total of 390 non- asthmatic controls (mean age 22.9years±14.5, 76.2% females) and 386 cases (mean age18.7years±15.9, 68.4% females) of asthma were recruited , of which 95 (24.6%) had mild intermittent, 235 (60.9%) had mild persistent and 56 (14.5%) had moderate persistent asthma. In all subjects as well as in children and adults separately, we found statistically significant association of SNPs T1, T2 and S1 with asthma (p value less than 0.05). Additionally association of SNP V2 was observed with asthma in only adults. SNPs T2, T1 and S1 showed statistically significant association with severity subgroups of asthma as compared with controls. However after analyzing children and adults separately, only T2 SNP was associated with severity subgroups of asthma in adults and T1 and S1 were associated with severity subgroups of asthma in children. The GTGGGG haplotype was found to be associated with asthma [OR=4.40; 95%CI=2.93-6.65; P value less than 0.0001]. Conclusion: There is an association of ADAM33 SNPs (T1, S1, T2 and V2) with asthma in Indian population.

1043F

Consensus: A novel framework for evaluation of uncertain gene variants in laboratory test reporting. *D.K. Crockett[1], P.G. Ridge[1], A.R. Wilson[1], E. Lyon[1], M.S. Williams[3], S.P. Narus[2], J.C. Facelli[2], J.A. Mitchell[2].* 1) University of Utah School of Medicine, Pathology, ARUP Laboratories, Salt Lake City, UT; 2) University of Utah School of Medicine, Biomedical Informatics, Salt Lake City, UT; 3) Intermountain Healthcare Clinical Genetics Institute, Salt Lake City, UT.

Purpose: As electronic medical records incorporate genetic sequence information, gene variant classification is critical to inform clinicians on the most appropriate course of treatment. Proposed guidelines have recommended classification terminology and definitions for improving laboratory gene variant reporting. A standardized framework however, does not yet exist for quantitative evaluation of disease association for uncertain gene variants in an objective manner.

Methods: Gene-specific prediction (PSAAP) was trained using clinically curated gene-disease data from the RET proto-oncogene. This predictor output was implemented into a Consensus framework, including a weighted metric of complementary prediction algorithms (SIFT, PolyPhen, PMUT and MutPred). Consensus score “reference intervals” were also calculated from known disease outcomes (benign, n=46; pathogenic, n=51). Prediction metrics for RET gene variants of uncertain significance (n=45) were then evaluated in this novel framework.

Results: Where authoritative collections of disease association-gene variants exist, the Consensus model yields highly accurate evaluation of uncertain or novel gene variants against the backdrop of calculated reference intervals from known benign and pathogenic gene variants. Algorithm limitations may include lack of representative variant in a training data set or nucleotide level splice variation. Where confirming evidence for a gene variant is lacking, visualization of the Consensus output is also proposed for augmenting diagnostic decisions.

Conclusions: Accurate interpretation of gene testing is a key component in customizing patient therapy. A reliable and objective phenotype classification framework with a quantitative metric for evaluation of novel or uncertain gene variants may supplement limited clinical information and assist in improving prediction algorithms as gene variant knowledge increases.

1044F

Association of Human Leukocyte Antigen Polymorphisms and Chronic Hepatitis B Infection Outcome. *A. Fejzullahu[1], L. Doganay[2], I. Tuncer[2], F. Enc[2], O. Ozturk[2], Y. Colak[2], G. Dinler[1,3].* 1) Molecular Biology & Genetics and Biotechnology Graduate Program, Institute of Science and Technology, Istanbul Technical University, Istanbul, Turkey; 2) Ministry of Health, Department of Gastroenterology, Goztepe Teaching and Research Hospital, Istanbul, Turkey; 3) Department of Molecular Biology and Genetics, Faculty of Science and Letters, Istanbul Technical University, Istanbul, Turkey.

Chronic hepatitis B virus (HBV) infection is a global health problem with an estimated 350 million people chronically infected worldwide. Considerable evidence suggests that the progression of hepatitis B virus infection is influenced not only by the viral genotype and the level of viremia but also host genetic factors play a significant role in the pathogenesis and clinical outcome of chronic HBV infection in several ethnic groups. It is mentioned that both cellular and humoral responses are required for viral clearance. Hence, the aim of this study is to investigate the association between the polymorphisms of HLA-DRB1 alleles and viral hepatitis B in Turkish population. In this study 324 patients were included; 63.4% male, 36.4% female and, where 23.5% of patients being HBe antigen positive, 23.8% having cirrhosis. The median age was 44.4 years, median follow up time was 86.5 months. HLA-DRB1 alleles in 324 patients with chronic hepatitis B were analyzed using the polymerase chain reaction/sequence specific primer (PCR/SSP) technique. In our group of patients, DRB1 alleles were not related to active or inactive disease, or interferon treatment response or virologic breakthroughs observed during nucleoside analog treatments. On the other hand our data showed that, patients who had DRB1*07 allele had lower probability to have cirrhosis (likelihood ratio chi square:4.17, p:0.04). In this case, DRB1*07 allele may be one of the host factors, which influences immune response to HBV, by self-limiting cirrhosis, one of the main complications of chronic HBV. Additional study is needed to validate these findings and to further explore the genetic pathogenesis of HBV infection.

Role of Population Counseling and Screening for Thalassemia Prevantion in India. *A. Nair, L. Sharma, J. Hatti, G. Mulgund, S. Aneeb, Q. Hassan.* Kamineni Hospital, Hyderabad, India.

Thalassemia which originated in the Mediterranean region is an inherited autosomal recessive blood disorder with an incidence of 10,000 to 12,000 thalassemic children born in India per year. Globally, 4.5% of the population has thalassemia minor and in India 1 out of every 25 individuals is a carrier. Despite the fact that India is a culturally diverse nation, arranged marriages between fixed endogenous populations are the norm. In the South Indian region this is compounded by the fact that consanguineous marriages are quite common. These facts increase the prevalence of recessive disorders like Thalasemia. There is no comprehensive governmental program for thalassemia prevention in India and several NGO's especially the Thalassemia and Sickle Cell Society of India are struggling to provide blood transfusion and chelating therapy at affordable costs to patients. However, they are not equipped for appropriate counseling. The present study highlights the role of genetic counselors in population screening and counseling to prevent thalassemia in our population. Andhra Pradesh(AP), is a state in South India, with 23 districts having a population of approximately 8 million, where consanguinity is seen in 48% of families. A study was carried out among 100 thalassemic families of AP to assess if consanguinity plays a major role in the high incidence of this pathology . 54% of the children were observed to be born out of consanguineous marriages. This shows that a high number of thalassemic children are born to non consanguineous couples. This can be attributed to the fact that most of the marriagesin the state are arranged within same communities. Therefore, just focusing on discouraging consanguineous marriages may not be the appropriate method of thalassemia prevention. But, since most of the marriages are still arranged in India, premarital testing of target group, consisting of females eligible for marriage (age range 16-30 years) and males (age18-35 years) by hemogram and followed by HPLC/Hb Electrophoresis would be useful. This program will help in identifying carriers, who would require a focused counseling regarding planning a suitable marriage and subsequent healthy offsprings.

1046F

Importance of Appropriate Genetic Counseling in Families to Prevent Thalassemia in India. *L. Sharma.* Kamineni Hospital, Hyderabad, India.

With over 35 million carriers of the abnormal gene for thalassemia and approximately 10,000 to 12,000 thalassemic children born every year, beta thalassemia is a genetic disorder of major concern in India. One hundred families registered with the Thalassemia and Sickle Cell Society, Hyderabad, India, were interviewed to evaluate information received during counselling and their understanding of the disease. 32% of the patients were <5 years, 34% between 5-10 years and 34% >10 years of age. 32% families had multiple affected members. The mean age of diagnosis was ± 6 months. 78% families were counselled by a general paediatrician. Most of them received information about the disorder from other families at the clinic, this was regarding recurrence risk, costs of the tests, treatment and measures for prevention, which was often incorrect. Social and religious beliefs also influenced their understanding. 69% of the families had misconceptions regarding various aspects: (i) 9% patients were aware of recurrence risks, (ii) 30% about prenatal testing, and (iii) 17% about extended family testing, 65% of these did not get the testing done because of social stigmatisation of carriers. Our study highlights the need for genetic counselling services by trained counsellors in the various centres which provide services to families of thalassemic patients. Due to the lack of trained genetic counsellors in India, patients do not receive the required counseling. To address this deficit adequately, there is an urgent need to develop training programs in genetic counselling. Continuing medical education in genetics for paediatricians is also sorely needed in India, to ensure that they understand the role of genetics in prevention of the disorder and the importance of referring patients for genetic counselling. Apart from this to increase public awareness about thalassemia various forms of media (audio, TV and print), educational print material for patient and genetic counselling are essential for making the thalassemia prevention program a success in India.

Next Generation Sequencing Panel for the Evaluation of Syndromal Autism. *C.D. Collins[1], E. Chin[1], S. Bhide[1], S. McGee[2], A. Tanner[1], D. Rhodenizer[1], J. Jones[2], M. Basehore[2], M. Friez[2], M. Hegde[1].* 1) Emory Genetics Laboratory, Department of Human Genetics, Emory University, Atlanta, GA; 2) Greenwood Genetic Center, Molecular Diagnostic Laboratory, Greenwood, SC.

Autism spectrum disorders (ASD) are a clinically heterogeneous group of neurodevelopmental disorders defined by a complex behavioral phenotype. Currently, identified genetic causes of ASD can be classified into cytogenetically visible chromosome abnormalities (~5%), copy number variants (10 - 20%), and single gene disorders (~5%). Individually, single gene causes of autism, which are frequently tested for on a gene-by-gene basis, typically make up <1% of the total etiology of autism. The implementation of Next Generation Sequencing (NGS) technology in the clinical laboratory has allowed for large-scale panel testing of many genes simultaneously at a reduced cost and turn-around time. As an initial effort to address autism using this technology, we have developed a NGS panel that is designed to target genes associated with genetic syndromes that include autism as a significant clinical feature. This panel also includes additional genes that have been previously associated with autism, along with a smaller number of well-characterized genes associated with conditions involved in the differential diagnosis of Rett syndrome and/or Angelman syndrome. In total, 62 genes have been incorporated into this panel which is intended to ultimately serve as a diagnostic tool for the evaluation of syndromal autism. Initial validation of the testing platform included 24 blinded positive control samples that were independently analyzed by bioinformatic personnel at both Emory Genetics Laboratory and the Greenwood Genetic Center. This preliminary evaluation detected 98% of the previously known mutations. Assay improvements are currently in progress to improve detection and overall sequence coverage. Additional probands from an undiagnosed autism cohort have also been studied and lessons learned will be presented. In conclusion, the use of NGS technology will add another dimension to the clinical evaluation of syndromal autism at a fraction of the cost and turn-around time of traditional Sanger sequencing.

1048F

Adaptive functioning and health-related quality of life of patients with Mucopolysaccharidosis type II (Hunter syndrome). *W. Packman[1,2], M.C. Needham[1], S. Packman[2].* 1) Palo Alto University, Palo Alto, CA; 2) University of California, San Francisco, San Francisco, CA.

We investigated the adaptive functioning and health-related quality of life (HRQOL) of patients with Mucopolysaccharidosis type II (MPS II; Hunter syndrome) through interviews with parents/caregivers of 73 patients. To investigate adaptive functioning, the Vineland Adaptive Behavior Scales (2nd Ed.) Parent/Caregiver Rating Scale (Vineland-II) was administered and the results were compared to the normative sample. On the Vineland-II, the parents/caregivers of MPS II patients reported scores significantly lower than the normative sample in the domains of communication, daily living skills, socialization, and motor skills, as well as for each subdomain of the measure. To examine health-related quality of life, the PedsQL Quality of Life, Parent Proxy Report was administered to 65 parents/caregivers of patients with MPS II; the results were compared to a healthy sample and an oncology sample. On the PedsQL, the reported HRQOL of the MPS II patients was significantly lower than the reported HRQOL of healthy children for the following scales: physical health, psychosocial health (including emotional functioning, social functioning, and school functioning), and the total score. Furthermore, statistically significant differences were found on all aforementioned PedsQL scales when comparing the scores reported by parents/caregivers of MPS II patients to the scores reported by parents of oncology patients. These findings demonstrate that individuals with MPS II have significant limitations in their adaptive functioning, as well as poorer HRQOL than healthy individuals and oncology patients in terms of physical, emotional, social, and school functioning. Professionals and caregivers involved in the lives of MPS II patients should be aware of, and attentive to, the limitations for MPS II patients within the realms of adaptive behavior and HRQOL. Additionally, it is important for those involved in the patients' lives to seek opportunities to improve the HRQOL of these patients.

Results and experiences involving microarray-based comparative genomic hybridization (aCGH) in an inner-city setting. *E. Pereira[1], A. Singh[2], J. Samanich[1], P. Levy[1], R. Marion[1], B. Morrow[3], K.H. Ramesh[2], L. Cannizzaro[2], Q. Pan[2], R. Naeem[2].* 1) Division of Genetics, Department of Pediatrics, Children's Hospital at Montefiore, Bronx, NY; 2) Department of Pathology, Montefiore Medical Center, Bronx, NY; 3) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY.

Microarray-based comparative genomic hybridization (aCGH) allows for a high-resolution evaluation of DNA copy number alterations. In 2010, the International Standard Cytogenomic Arrays (ISCA) Consortium and American College of Medical Genetics (ACMG) recommended using aCGH as the first tier genetic test for patients with developmental disabilities including autism spectrum disorders (DD ± ASD) and multiple congenital anomalies (MCAs). Using an Agilent custom design 44k array, we describe our aCGH testing experience from October 2007 to December 2010 on 623 consecutive patients at Montefiore Medical Center, which serves a large, underserved, inner-city population in the Bronx, NY. Testing indications were mainly for DD ± ASD (35%), MCAs (22%), neurological issues (13%), and suspected known genetic syndromes (10%). The majority of our patients were of Caribbean Hispanic (Dominican/Puerto Rican), Caucasian, and multiracial background, with higher rates of Caribbean Hispanic (29%) and multiracial (15%) patients than included in previous studies. A total of 160 patients (25.7%) had aCGH testing with reportable copy number variations (CNVs). Patients tested because of DDs ± ASD had a higher percentage of abnormal aCGH results than previously reported in previous studies (25% vs 17% respectively). We had similar rates of CNVs as reported in the literature for congenital anomalies (26%) and neurological abnormalities (24%). A limitation in interpreting abnormal results is the lack CNV data for the Caribbean Hispanic community. This is a significant short-coming in currently available published data and needs to be studied in more individuals before any generalizations can be made. Another limitation in interpreting abnormal aCGHs in our community stems from unavailable parental samples. Of the 132 abnormal aCGH results in which parental blood samples were requested, 47 (36%) had parental testing; only 15 patients (11%) had both parents sampled. In the Bronx where nearly one-third of households are single parent (maternal) homes, paternal sampling poses a challenge. From our experience, we recommend that pretest counseling emphasize the possible need of parental testing for abnormal results.

1050F

An Iranian cohort suspected to MELASE-MERRF with a known muatation (A5814) in tRNA Cys gene. *H. Aryan[1], O. Aryani[1], N. Farzan[1], M. Houshmand[1,2].* 1) Special Medical Center, Tehran, Iran; 2) National institute for genetic engineering and biotechnology, Tehran, Iran.

Background: The mitochondrial encephalomyopathies are a heterogeneous group of disorders associated with structural, biochemical, or genetic abnormalities of mitochondria. The most severely affected organs are those with high oxidative metabolism, such as brain, skeletal and cardiac muscle, and kidney. Another pathogenic mutation is the 5814T_C mutation reported independently by three groups to be associated with MELAS syndrome and with progressive external ophthalmoplegia in the first two cases. Materials and Methods: The proband was a 6-year-old boy, born at term by normal delivery. In the eighth months of life, the mother noted that he had muscular weakness. She controlled his head size at 2 years of age; he did not show any growth in his head, sat without support at 4, but could never stand without support or walk. He had multiple brief seizures, characterized by loss of consciousness and followed by generalized jerks. Genomic DNA was extracted from fresh blood samples of all patients using QIAGEN DNA Kit. All 22tRNA of mitochondrial DNA were amplified by PCR using specific pairs of primers which were designed in this laboratory and sequenced. Result: Sequence analysis of both proband's blood mt-DNA and his mother including all 22tRNA confirmed the presence of the homoplasmic T5814C mutation. Conclusion: PCR- sequencing of the 22tRNA genes showed the T5814C mutation in tRNA Cys previously described in association with a MELAS-like phenotype. However, our results showed that this substitution found not only in the patient but also in his mother both as homoplasmic change. This case suggests more consideration on this reported mutation.

1051F

Automatic annotation of mitochondrial variants from high throughput next generation sequencing in a clinical molecular diagnostic laboratory. *D.CY. Chen, V.W. Zhang, J. Wang, LJ. Wong.* Molecular and Human Genetic, Baylor College of Medicine, Houston, TX.

Mitochondrial diseases are clinically and genetically heterogeneous, with variable penetrance, expressivity, and different age of onset. The spectrum of mitochondrial DNA (mtDNA) mutations can range from point mutations, small insertion/deletion to large insertion/deletions. Point mutations are the major type of mutations responsible for mitochondrial diseases. With the introduction of next-generation sequencing (NGS) technology for molecular analysis of the mtDNA and the enormous amount of sequence data output, there is an urgent need to streamline the analysis workflow for efficient results output and patient's report with a clear molecular diagnosis.

Publically available mtDNA SNP databases; Mitomap and mtDB, were used in conjunction with our own database (MitoLink) of >4000 SNPs with family and clinical information collected through the past 5 years from more than 5,000 families. Due to the incompleteness and occasional disagreement among the public mtDNA SNP databases, the incorporation of clinical and genetic information from our MitoLink database is essential in making more accurate diagnosis.

The development of a bioinformatic software pipeline that encompasses publically available databases mitomap and mtDB; Sift and Polyphen2 for amino acid prediction; and the in-house built MitoLink database, facilitates the annotation of huge amount of sequence results from NGS quickly, efficiently, and accurately. MitoLink is a superb database which contains >4000 mtDNA variants with genetic and clinical information for the interpretation of the clinical significance in the complex mitochondrial disorders. In conclusion, the integration of MitoLink database into the analytical pipeline, allows accurate and comprehensive interpretation of the sequencing results, user friendly output of the complicate NGS results, and efficient clinical reporting.

1052F

Comprehensive molecular analyses of mitochondrial genome by next-generation sequencing. *H. Cui, V.W. Zhang, L.J. Wang.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Recent statistics suggest that 1 in 200 individuals develop mitochondrial diseases that are clinically and genetically heterogeneous, with variable penetrance, expressivity, and different age of onset. Disease causing mutations, such as point mutations and large deletions, in the mitochondrial genome often exist in a heteroplasmic state. Current molecular analyses require multiple different and complementary methods, including Sanger sequencing, quantitative PCR (qPCR), Southern blot or array CGH for the detection and quantification of point mutations, larger mtDNAs, and mtDNA depletion analysis. These procedures are labor intensive, time consuming, and costly.

We have developed and validated a clinically applicable “deep” sequencing technique by the application of next generation sequencing (NGS) to the clinical diagnosis (1). Our results demonstrated uniform coverage of each of the 16,569 bases of the mitochondrial genome at over 20,000 folds. Among the 36 samples that we have validated, all of them show 100% specificity and 99.9% sensitivity with quantitative base calls when compared to results from Sanger sequencing. We are also able to detect low levels of heteroplasmy, which were below the limit of detection by Sanger sequencing, in several family studies. Moreover, this approach allows detection of small and large deletions with exact breakpoints and deletion mutant heteroplasmy. We have successfully captured several large deletions including one 8 kb deletion at 90% heteroplasmy level. Proper qualitative and quantitative controls were analyzed along with each sample for quality assurance in a clinical setting. Our results demonstrated the superior sensitivity and specificity of base calling when compared to the gold standard Sanger sequencing, the importance of developing a mathematical formula for performance evaluation, and the incorporation of internal controls for quality assurance. In conclusion, the one-step “deep” sequencing approach offers a comprehensive qualitative and quantitative molecular analysis of mitochondrial diseases in a timely, accurate, and cost-effective manner.

Identification of three Novel Mutations within the FVIII Gene in Hemophilia A. *N.J. Faridi[1], N. Husain[1], I. Siddiqi[2].* 1) *Pathology, Ram Manohar Lohia Institute of Medical Sciences Lu, Luvknow, U.P., Uttar Pradesh, India; 2) # Molecular and Structural Biology Division, Central Drug Research Institute, Lucknow, India.

Background: Hemophilia A is a bleeding disorder caused by heterogeneous mutations of the FVIII gene. Direct mutation detection approach allows definitive diagnosis and allows carrier detection in sporadic cases as well as incomplete families. The current study is being done to detect small, novel mutations and Intron 1 inversion in the Hemophilia A gene in Indian cases with hemophilia and to predict structural and functional alterations in the gene using modeling Design: All 26 exonic regions including exon 14 were amplified by PCR in 23 cases with mild and moderate hemophilia A and screened with single stranded conformational polymorphism (SSCP) for mutations in FVIII gene. We have also screened 150 severe cases for intron 1 inversion mutations. DNA Sequencing was done in cases showing shift using ABI-XL3130 Genetic Analyzer (Applied Biosystem, USA) and sequences analyzed with Set-Scape Software. Structural change in F8 gene was predicted using modeling with Sybyl 7.1(Tripos) and GROMACS 4.0.5. Result: A total eight different Disease causing mutations were found in Cases with hemophilia A, three of which were described for the first time. We found intron 1 inversion in four cases with hemophilia A. Protein modeling to elicit the structural changes in FVIII protein due to these mutations was also done. Conclusion: We report three novel mutations not previously reported at the Hemophilia mutation database (HAMSTeRS). Small mutation detection can be achieved using SSCP-sequencing protocols and DNA modeling helps predict the structural and functional changes in the protein structure. The outcome of this study would enable us to give an accurate diagnosis in affected cases with hemophilia a by direct mutation analysis.

Optimizing genetic counseling services for prenatal patients in a subspecialty Neurogenetics clinic: Four years of experience with this patient population. *C.L. Goldsmith, M. Cloutier, K.M. Boycott.* Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Prenatal patients in Canada have traditionally been cared for in the context of a Prenatal Program servicing a wide-spectrum of genetic issues. A survey of Neurogenetics clinics in Canada did not reveal any clinic that provides prenatal genetic counseling in the context of a Neurogenetics clinic. We established a Neurogenetics specialty clinic in 2007 which serves pediatric and adult patients with neurological disorders or individuals with a family history of a neurological disease. One neurogeneticist and two genetic counselors saw all the patients in the clinic, allowing this small group of providers to develop expertise with the particular needs of this patient population. Since its inception four years ago, the prenatal aspect of our service has provided care to 56 patients. Our prenatal cohort includes pregnant patients who had a personal or family history of a neurological disease, as well as those with a non-aneuploidy-associated fetal brain abnormality. The majority of patients were referred for a family history of a pediatric onset neurogenetic condition (30/56). These included spinal muscular atrophy, Duchenne or Becker or other muscular dystrophies, (congenital) myotonic dystrophy, and hereditary seizure disorders. The next largest group was women referred because of a current, previous or family history of a non-aneuploidy-associated fetal brain abnormality (14/56). These included prenatal ultrasound detection of lissencephaly, Dandy Walker malformation, and cerebellar vermis hypoplasia. Follow-up of these complex patients often included fetal MRI, chromosomal microarray analysis, and post-delivery examination and investigation. Other patients in this group were referred for a family history of a fetal brain abnormality, such as a family history of Joubert syndrome or aqueductal stenosis. Referrals because of a personal or family history of an adult onset neurological disorder (6/56) included four for Huntington disease. Three of these were for women whose fetuses at 50% risk and all proceeded with prenatal diagnosis for HD. A consult with our bioethicist was required for one of these cases, highlighting the complex issues that can arise when discussing prenatal diagnosis for adult-onset neurogenetic diseases. The clinic model has been highly successful; uniquely providing optimal prenatal services for this group of patients with a focus on continuity of care in the context of a specialized Neurogenetics clinical setting.

Mitochondrial dysfunction in Mexican patients with Parkinson's disease. *E. Martinez[1], G. Dorazco[2], E. Lara[1], Y. Serrano[1].* 1) Univ de Guadalajara, Guadalajara, Mexico; 2) Hospital General de Zona No. 7. IMSS.

BACKGROUND: Parkinson's disease (PD) is the second most common neurodegenerative disorder after Alzheimer's disease, affecting approximately 1% of population aged over 60 years. Thus far, the molecular mechanisms underlying the pathogenesis of PD still remain unknown. But the majority of patients with PD sporadic show the presence of reactive oxygen species, and free radical stress play important roles in the pathogenesis of PD. On the other hand, have been found the presence of a defect of complex I activity in platelets, complex IV in brain and lymphocytes in PD patients. Also, has been found mutations in some complex I and IV of the mitochondrial respiratory chain. OBJECTIVES: Determine the frequency of T8993G mutation of mitochondrial ATPase6 gene, and their correlation with ATP synthase enzymatic activity, in PD patients and a control group. MATERIAL AND METHODS: In order to explore if mutation T8993G and the hydrolytic activity of the ATPase correlate with the PD, were studied 14 patients and the same amount of controls, matched-aged and gender. The mtDNA extraction was according to the Miller method and the activity enzymatic to the Summer method. RESULTS: The obtained data revealed that the hydrolytic activity of ATP synthase was significantly increased in patients with AD (14.3 ± 1.4 nmol PO4 min-1(mg protein)-1, n = 14) in comparison with the control group (10.0 ± 0.6 nmol PO4 min-1 (mg protein)-1, n = 14). The mutation T8993G was observed in 57.14% (8/14) of the PD patients, whereas in the control group it was not identified. CONCLUSION: These results probably suggest that a weak activity functional of the enzyme can be explained because of the T8993G mutation in ATPase6 gene affect the proton channel for enzymatic activity.

1056F

Study of Charcot-Marie-Tooth in Iran: Novel types? *E. Mohammadi Pargoo[1], O. Aryani[2], H. Tonekaboni[3], P. Yaghmaei[1], M. Houshmand[2,4].* 1) Science & research branch of I, Science & research branch of Islamic Azad Universi, tehran, Iran; 2) Medical Genetics Department, Special Medical Center, Tehran, Iran; 3) Mofid Hospital, Shahid Beheshti University of Medical Sciences, Tehran, Islamic Republic of Iran; 4) National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran, Iran.

Charcot-Marie-Tooth (CMT) disease is the commonest neurogenetic disorder with phenotypic and genotyping heterogeneity. Both the phenotypic features and disease severity can either be consistent or vary widely both within and among families. The affected individual typically has distal muscle weakness and atrophy often associated with mild to moderate sensory loss, diminished or absent deep tendon reflexes, high-arched feet and skeletal deformities such as pes cavus .The CMT hereditary neuropathies are categorized by mode inheritance and causative gene or chromosomal locus. We usually classified autosomal-dominant inherited CMT patients with demyelinating form, severely reduced nerve conduction velocities (NCVs) in type 1 (CMT1) and axonal form in type 2 (CMT2). X-linked inheritance pattern classified in CMTX and autosomal recessive classified in CMT4 type. All the patients (167), according to electro-clinical, neurologic Ex. and pedigree were investigated for: PMP22, GDAP1, GJB32, EGR2, MPZ and MFN2 genes by PCR-Sequencing method for all the exons and exon-intron boundaries. In order to show that these found novel mutations are pathogenetic 50 normal controls were sequenced for all of these genes for whom no such mutations were found. We are going to discuss about clinical and molecular finding in our patients. Key Note: The problem of genetic diagnosis of CMT is: a) Many genes involving for same phenotype b) Many phenotypes caused by same gene. So batteries of genetic diagnosis need to clarify the cause of CMT by investigation of other associated genes with the disease.

1057F

A revised diagnostic algorithm for analysis of Zellweger spectrum disorders peroxisome assembly defects. *G.S. Charames[1,2], B.A. Karczeski[1,2], G.R. Cutting[1,2,3], S.J. Steinberg[1,4,5].* 1) DNA Diagnostic Lab, Johns Hopkins University, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD; 5) Department of Neurology, Johns Hopkins University School of Medicine, Baltimore, MD.

Zellweger spectrum disorder (ZSD), comprising Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease, are autosomal recessive multi-system developmental disorders impairing brain, skeletal, hepatic and renal development. ZSD in humans are caused by defects in proteins encoded by 12 PEX genes. Complementation studies performed at Kennedy Krieger suggested that *PEX1* defects accounted for about 70% of ZSDs. However our pilot analysis of 91 patients indicated that only about 58% of patients had *PEX1* gene defects (Steinberg *et al* 2004; Yik *et al* 2009) and this was recently confirmed by a much larger study in 600 ZSD patients (Ebberink *et al* 2010). We developed an algorithm for PEX gene sequencing -The PEX Gene Screen- to identify the putative genetic defect (Steinberg *et al* 2004) based on sequencing the exons of the six PEX genes -*PEX1, PEX2, PEX6, PEX10, PEX12,* & *PEX26*- where mutations were most commonly reported in ZSD patients previously documented in the literature. The high proportion of *PEX1* cases is due to several common mutations found amongst exons 13, 15 and 18. In contrast, the second most common defective ZSD gene, *PEX6*, accounts for 10-16% of patients (Steinberg *et al* 2004; Yik *et al* 2009; Ebberink *et al* 2010), but does not have common, recurrent mutations across large populations. To help in the optimization of our PEX Gene Screen algorithm, we sequenced the entire coding region of *PEX1, PEX2, PEX6, PEX10, PEX12* and *PEX26* in 11 patients who were negative for the common PEX1 mutations in exons 13, 15 and 18. We identified two clearly pathogenic mutations in 9 patients: 4 *PEX6* defects, 2 *PEX1* defects, 2 *PEX2* defects, and 1 *PEX12* defect. In two patients we identified a single *PEX1* or *PEX6* mutation and further studies are underway in these cases. Although the number of patients included in this follow up study is small, it supports modifying our PEX Gene Screen algorithm to sequence the entirety of *PEX6* prior to looking for mutations in the other five most common gene defects in ZSD in those negative for the common *PEX1* mutations.

IL28B SNP rs12979860 genotyping: Allele frequencies in a diagnostic testing population. *M. Mikula, A. Buller Burckle, W. Sun, C. Strom.* Dept Molecular Genetics, Quest Diagnostics Nichols Inst, SanJuanCapistrano, CA.

Introduction: Knowledge of the genotype of patients infected with HCV aids in the clinical decision to initiate treatment with pegylated interferon-(/ribavirin (PegIFN/RBV). The importance of this prediction is that the treatment has limited efficacy and is poorly tolerated in certain patients, and the course of treatment is long (48 weeks). Genotyping of the SNP IL28B rs12979860 helps predict therapeutic response.The CC genotype in this SNP is associated with as much as a two-fold greater sustained virological response (SVR) to this treatment in European, African-American, and Hispanic populations compared to CT or TT genotypes. The purpose of this study was to determine the frequency of the genotypes in a mixed ethnic population. Methods: We detected “C” and `T” alleles at SNP rs12979860 in 608 de-identified samples on a real-time PCR platform using an allelic discrimination method. Results: We observed 159 C/C homozygotes (26%), 321 C/T heterozygotes (53%), and 128 T/T homozygotes (21%). The observed frequency of the “C” allele in our diagnostic testing population was 0.53. Our results show good fit with Hardy-Weinberg analysis (chi squared 1.931, P = 0.38) even though our sample population contains a mix of ethnicities known to have different allele frequencies. Conclusion: Nearly half of the individuals tested by this assay are predicted to have a clinically significant result with 26% of the individuals (C/C) predicted to have a SVR and 21% (TT) predicted to have only half as much response to PegIFN/RBV.

FAMILY MEMBERS OF PATIENTS WITH HEREDITARY HEMORRHAGIC TELANGIECTASIA: HHT CENTER PARIS EXPERIENCE IN 343 RELATIVES FROM 116 FAMILIES WITH GENOTYPING. *J. ROUME - BAUDRIER[1], M. EYRIS[3], I. BOURGAULT - VILLADA[1], J.H. BLONDEL[1], S. BLIVET[1], D. COBARZAN[1], J.P. PELAGE[1], A. OZANNE[2], C. FAGNOU[1], G. LESUR[1], L. CRIVAT[1], F. COULET[3], P. LASJAUNIAS[2], B. RAFFESTIN[1], L. GOUYA[1], T. CHINET[1], P. LACOMBE[1], F. SOUBRIER[3].* 1) Haemorragic Hereditary Telangiectasia Center PARIS PARIS V University CHU Ambroise Pare, AP-HP, Boulogne ,92100 France; 2) Neuroradiology National Rare Diseases Center: Neurovascular Malformations in Children. CHU Bicêtre Hospital- Paris Sud University AP-HP 78 rue du Général Leclerc Le Kremlin-Bicêtre 94275 cedex France; 3) Oncogenetic and angiogenetic Molecular Laboratory Groupe Hopitalier Pitié-Salpétrière Paris VI University AP-HP 47/83 bd de l'hôpital 75651 PARIS Cedex 13 France.

Hereditary Hemorrhagic Telangiectasia (HHT) is a heterogeneous vascular disease that can present with a variety of clinical manifestations. The visceral vascular lesions of this disease may be potentially devastating. The clinical diagnosis of HHT is determined by using the four following Curaçao diagnosis criteria: Epistaxes(1),Telangiectasias multiple(2)at characteristic sites,Visceral vascular lesions(3): gastrointestinal telangiectasias and arterio-venous malformations (pulmonary, hepatic, cerebral and spinal arterio-venous fistula)and family history(4). Mutations of the Endoglin (ENG) and Activin A receptor type II-like kinase-1 (ACVRL1) genes are known to be the major genetic factors of HHT. **OBJECTIVE**: To assess the clinical and genetic characteristics of family members of patients with hereditary hemorrhagic telangiectasia (HHT).**SETTING**: HHT Center in Paris. **PARTICIPANTS**: 343 members family of 116 genotyping HHT patients screened from January 2004, through December 2010. **INTERVENTIONS**: volunteers previously well informed directly by means of the educational course of the proband about the intrafamilial variability of symptoms and potential severe visceral complications; screened during one half a day by mean of a stepped multidisciplinary clinical screening protocol based upon Curaçao criteria and genetic screening systematically proposed. **MAIN OUTCOME MEASURES**: Age, sex, prevalence of cutaneo mucous telangiectases, visceral ArterioVenous Malformations(AVMs), genetic characteristics and proposed therapeutics. **RESULTS**: 182 relatives were found with manifestations of HHT. Below twenty years old:34%, between twenty and forty:31%, over forty: 35%. Sex Ratio:0.75. All four Curaçao criteria were present for 123 cases, three criteria for 30 cases, two criteria for 18 cases and 11 cases (6%) were asymptomatic with only the familial criteria and found by mean of the genetic focused screening. 108 were relatives of the 66 HHT1 probands. 41 of them were referred for embolization of large pulmonary arterio venous malformations (PAVMs); 74 were of the 50 HHT2 probands, one of them, proposed for cerebral AVMs embolization. Antibioprophylaxy was proposed for 123 patients with small PAVMs. **CONCLUSIONS**: 68% of HHT family members present visceral AVMs which can lead to life-threatening events. They should be encouraged to engage in a screening program, from earliest age, since the prevalence of potentially serious localizations is higher than previously thought.

Predictive testing for adult-onset neuromuscular diseases. *Y. Sato, Y. Ikegami, N. Minami, N. Okamoto, M. Mori, M. Murata, Y. Goto.* National Center of Neurology and Psychiatry, Kodaira, Japan.

Molecular genetics research has led to the identification of an increasing number of disease-associated genes. Genetic testing is now available to confirm the diagnosis for symptomatic individuals and to assess whether their families at risk have the gene mutation. Their lives may be affected or controlled by test results. Predictive genetic testing for adult-onset neuromuscular diseases is presently offered in a few medical centers in Japan. National guidelines suggest that these testing should be performed carefully under specific conditions after genetic counseling. We developed an original protocol for predictive testing program in 2009. Our staff includes board-certified medical geneticist, genetic counselor, neurologist, psychiatrist and molecular geneticist. Medical geneticist and genetic counselor assess the client's knowledge of disease, obtain the family history, consider the suitability for genetic analysis, explore the motivations for testing and determine the consequences of testing. Guidance for client's families is suggested as needed. Neurologist and psychiatrist provide specialized screening. Our program comprises at least four pre-test sessions. Genetic testing is performed in our laboratory under jurisdiction of the institutional review board. After the disclosure of test results, several post-test sessions are scheduled. During the period from April 2002 to March 2011, a total of 268 clients visited our genetic counseling unit, approximately sixteen percent of them concerned about predictive testing. We provided genetic counseling on predictive testing for eleven clients in the past year. Seven of them entered testing program, and three had the genetic testing. While two got negative results, one tested positive for Huntington's disease. We continually keep in contact with them. Our predictive testing program seems to provide appropriate care for clients up to now. The ease in access to the testing will likely increase the demand for services related to predictive testing. Every testing requires a case-by-case consideration. We may need to modify the program to comply with client's situation and medical infrastructure peculiar to Japan. A substantial number of appropriate genetic centers for predictive testing are required in Japan.

The combination of (((anti 3.7 triplication and) -thalassemia in an Iranian family. *f. moosavi, z. kaini moghaddam, a. Valaei, s. Zeinali, m. Karimipoor.* Molecular Medicine Dept., Biotechnology Research Center, Pasteur Institute of Iran.

Introduction: The pathophysiology and clinical severity of) -thalassemia are associated with the degree of (/non(-chain imbalance. A triplicated (-globin gene locus can exacerbate the effects of (-chain excess caused by a defective) -globin gene, although this combination in different individuals results in variable phenotypes. In the present study we report the molecular analysis of an Iranian subject with a thalassemia intermedia phenotype, heterozygous for) -thalassemia. Methods: Complete blood counts were measured with a Sysmex KX-21 cell counter. DNA extraction from peripheral blood leukocytes was performed by salting out method. Mutation analysis of the) -globin gene was detected by ARMS-PCR and multiplex-PCR was used to detect alpha triplication (((anti3.7). Multiplex ligation-dependent probe amplification (MLPA) technique was performed for confirmation the results of multiplex PCR. Results: The mother of index case was a carrier of) -thalassemia with IVSII-I mutation in heterozygous form and her husband was hematologically normal with no mutation in) -globin gene. The propositus, a 2.5 years old child presented a transfusion dependent thalassemia intermedia phenotype. Multiplex PCR detected the presence of extra (-globin gene in the patient and her mother but her father was normal. MLPA results indicated that there is a large triplication from probe 1 (upstream HS-40) to probe 26 (3.7 Kb downstream HbA) in their (-globin gene cluster. Conclusion: The clinical and hematological picture of) -thalassemia heterozygotes with a triplicated (-globin gene arrangement is variable, ranging from an asymptomatic presentation to a mild to moderate thalassemia intermedia phenotype and it depends on the size of the additional part within the (-globin gene cluster. This finding has important implications for genetic counseling and prenatal diagnosis programs. This family may be at risk for another child with severe thalassemia intermedia. The genetic and phenotypic characteristics of the patients described here indicate the need to consider the possibility of a triplicated (-gene allele in patients with heterozygosis for) -thalassemia who show an unexpected severe phenotype.

1062F

"THE MERRY-GO-ROUND OF DISCOVERY": DIAGNOSIS OF FRAGILE X SYNDROME AND DUCHENNE MUSCULAR DYSTROHPY. *A.D. Archibald[1], B.J. McClaren[1,2], S.H. Wong[1,2], M.N. Cotter[1], A. Kornberg[1,2,3], A.M. Jaques[1], S. Wake[2,4], J. Cohen[5,6], S.A. Melcalfe[1,2].* 1) Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 2) Department of Paediatrics, The University of Melbourne, Melbourne, Victoria, Australia; 3) The Royal Childrens Hospital, Melbourne, Victoria, Australia; 4) Genetic Health Services Victoria, Melbourne, Victoria, Australia; 5) Fragile X Alliance Inc, Melbourne, Victoria, Australia; 6) Centre for Developmental Disability Health Victoria, Monash University, Melbourne, Victoria, Australia.

Genetic conditions presenting as developmental delay early in childhood can often be difficult to diagnose due to non-specific symptoms and lack of awareness of these conditions amongst the community and health professionals. Fragile X syndrome (FXS) and Duchenne muscular dystrophy (DMD) are both X-linked conditions with variable initial presentations and ages of diagnosis. We investigated the experience of obtaining diagnoses of FXS and DMD in Victoria and Tasmania, Australia using a mixed methods approach to: 1) identify the age at which diagnoses of FXS and DMD occur and, 2) to explore the experiences of parents of children with these conditions regarding the diagnosis.An audit of laboratory and clinical records for all DNA tests ordered in Victoria and Tasmania for FXS (2000-2009) and DMD (2005-2010) was undertaken. Semi-structured interviews were conducted with relatives of individuals with FXS and parents of boys with DMD. Analysis of records revealed that the median age at testing for individuals with a FMR1 full mutation was 15 years (n=133 of 16,845 records) and was 4.6 years for boys with DMD(n=77 of 448 records); this age has not changed substantially over the time period investigated. Clinical indications for testing and referring health practitioner influenced age at testing with paediatricians being the predominant healthcare practitioners ordering the tests. Forty four interviews were conducted (FXS = 29; DMD = 15). In the vast majority of families, there was a delay between when initial concerns about the child's development were noticed by parents and when the diagnosis was received; all found this to be a very difficult time. For the parents of boys with DMD, this delay ranged from 6 months to almost 5 years. Families described taking a proactive and persistent approach to searching for a cause for their child's developmental delay and consulting multiple healthcare providers before genetic testing was undertaken. Initial emotional reactions following the diagnosis were shock and grief which, over time, gave way to relief at having an explanation for the child's difficulties.These results provide a valuable insight into diagnoses of FXS and DMD and indicate the process of diagnosing these conditions could be improved; new strategies for diagnosis should be considered. Based on these data we are currently developing a model of offering population screening for genetic causes of developmental delay, when the child is about 1 year of age.

1063F

The Role of Social Comparisons in Quality of Life following a Prostate Cancer Diagnosis. *S.S. Kalia[1], A.C. Madeo[2], D. Roter[3], L.A.H. Erby[3], T.O. Blank[4].* 1) Boston University School of Medicine, Boston, MA; 2) National Human Genome Research Institute, NIH, Bethesda, MD; 3) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) Human Development and Family Studies, University of Connecticut, Storrs, CT.

Introduction: Many prostate cancer patients grapple with uncertainty regarding the best treatment option. Comparing oneself with others is one way of coping with uncertainty. Limited research has shown that such social comparisons help prostate cancer patients to regulate their emotions. The objective of this study was to investigate relationships between social comparisons and quality of life among men who had been diagnosed with localized prostate cancer and participated in support groups. Hypothesis: The theoretical model for this study was based on Social Comparison Theory and the Transactional Model of Stress and Coping. We hypothesized that positive social comparisons would be positively associated with quality of life. Methods: Participants (186) were recruited from prostate cancer support organizations and provided responses through online and paper surveys. Quality of life was assessed with the Quality of Life Index-Cancer version. The Identification/Contrast measure was used to assess social comparisons on Likert scales with total scores between 3-15. Results: Participants reported comparing themselves to support group members, relatives, friends, and colleagues. Overall, participants reported making more positive (mean=10.9, SD=2.4) than negative (mean=6.2, SD=2.5) social comparisons ($p<0.0001$). Open-ended responses included positive comparisons such as, "I have been able to reorient and control my life, better than I think they will" and negative comparisons such as, "[I am] frustrated about how they got where they are... I'm at the end of the bell curve." Positive comparisons were positively correlated with quality of life ($r=0.351$, $p<0.001$). After controlling for covariates, the use of positive comparisons was a predictor of better quality of life () =0.170, p=0.002), and the use of negative comparisons was a predictor of poorer quality of life () =-0.259, $p<0.001$). Conclusions: The data indicated that men in the study population compare themselves to others and that their comparisons tend to reflect positively on their own situation. One's interpretation of social comparisons as positive or negative may be a determinant of one's quality of life. These findings are relevant to clinicians who help patients in making treatment decisions and adapting to a cancer diagnosis. Future research could investigate the impact on quality of life of interventions that help individuals to modify their social comparisons toward more positive interpretations.

1064F

Development of preventive strategy for healthy adults with family history of type 2 diabetes: Challenges in Japan. *M. Nishigaki[1], A. Ota[1,3], K. Kobayashi[1], T. Shibayama[1], E. Sato[1], Y. Tokunaga[1], S. Kosaka[1], N. Seki[2], M. Yokoyama[2], T. Yokomura[2], Y. Fujikawa[4], T. Shimomura[4], T. Ota[4], C. Matsuzaki[4], S. Taguchi[4], J. Nishida[5], K. Kazuma[1].* 1) Adult Nursing, University of Tokyo, Japan; 2) Social Insurance Funabashi Central Hospital, Chiba, Japan; 3) Fukuyama Transporting Shibuya Longevity Health Foundation; 4) Brain Attack Center Ota Momorial Hospital, Hiroshima, Japan; 5) Social Insurance Chuo General Hospital, Tokyo, Japan.

Drastic progression in genome analysis enables genome wide search for candidate genes for type 2 diabetes. However, the recent studies have shown that genotype would add slightly more information to predictive models which consists of common risk factors, including family history. Thus, family history is still an important tool for identification of high-risk populations in this post genomic era.

We have performed continuous work for developing preventive strategy based on family history of type 2 diabetes since 2004. Step1: collecting expert opinion; Step2: investigating subject's health belief and genetic risk perception; Step3,4: development and feasibility assessment of lifestyle intervention, and genetic counseling tool for type 2 diabetes; and Step5: Randomized controlled trial at medical check-up institution to investigate the effect of lifestyle intervention and genetic counseling on diabetes prevention.

Step1 study had showed that diabetes specialist thought that preventive intervention for relatives of type2 diabetes patients might be effective but there were several barriers to practice: lack of time and human resource, hard to contact the subjects, and less motivation to preventive behavior in relatives. Step2 study had revealed that half of relatives already took action for prevention while they had less knowledge about concrete method for prevention. This study also revealed that they tended to underestimate the effect of environmental risk factors while overestimate the effect of genetic risk factors. Then Step3 study developed genetic counseling tool(six-page booklet). This tool was aimed to facilitate adequate understanding about genetic-environmental interaction in diabetes onset. Simultaneously, Step4 established feasible preventive intervention via mail focused on education about concrete preventive method. These studies had revealed their possible effect and efficiency. On the other hands, these feasibility studies had also revealed difficulty of recruiting subjects into prevention program via patients. Based on these studies, now we have been running Step5 study at medical check-up institution in order to make face-to-face contact with relatives who have family history of type2 diabetes.

1065F

Characterizing the Role and Skills of the Research Genetic Counselor Over Time. *A. Rupchock[1], H. Zierhut[2], E. Heise[3], E. Burkett[4], A. Dressen[1], S. Hahn[1].* 1) Hussman Institute for Human Genomics, Miami, FL; 2) University of Minnesota Medical Center, Hugo, MN; 3) Duke University, Durham, NC; 4) Legacy Center for Maternal Fetal Medicine, Emanuel Hospital, Portland, OR.

According to the 1994 Professional Status Survey conducted by the NSGC only 2% of genetic counselors (GCs) reported a primary role in research (> 0.5FTE). By 2000, this increased to 31% and remains steady. Despite its prevalence, this role has not been well characterized over time. One objective of this study was to delineate the characteristics and roles of research counselors. A web-based survey was administered in 2003 and repeated in 2010. Participants were recruited via e-mail through the NSGC listserv and relevant special interest groups. The survey was taken by 110 and 129 GCs, respectively, with a current or past primary role in research. Most demographics were largely unchanged. Those with >10 years of experience increased from 7% to 19%, and average age increased from 34 to 36 years. The most common types of studies remain unchanged, but fewer have been involved in gene/mutation identification studies (79% vs. 66%) and more have been involved in translational/genomic medicine (23% vs. 30%). While the majority have still been a study coordinator and/or provided genetic counseling to study participants, the characteristics and roles appear to be evolving. Those who served as principal investigator or co-investigator increased, from 34% to 47%, with 18% of 2010 respondents having been a PI. Those pursuing or holding an advanced degree increased from 5% to 11%. Those who submitted their own grant also increased, with funding of at least one grant increasing from 60% to 73%. Those involved in focus groups increased from 15% to 22% with higher level skills also increasing. Designing the focus group guide increased from 53% to 89% and analyzing the data increased from 53% to 79%. For those involved in qualitative interview studies, study design increased from 50% to 74% and creating the guide increased from 56% to 76%. From the 2010 data, PIs/Co-Is are more likely to have submitted a grant, have more experience with statistical methods, and are more likely to be involved in focus group research, qualitative interviewing, and scale based research than those who have not been a PI or Co-I ($p<0.05$). These remain significant when adjusted for years of experience. Elucidating the characteristics of the research GC will expand the definition and roles of a GC, contribute to the identification of new and emerging opportunities for the profession, and may guide curriculum development among GC training programs.

Lack of lung function prediction value for genetically determined ancestry in French Canadian population. *J. Berube[1], M. Lamontagne[1], M. Laviolette[1], Y. Bossé[1,2], The Merck-Laval-UBC-Groningen Lung eQTL consortium.* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

A recent report suggests that genetically determined ancestry improves predicted lung function measurements in African Americans. In this study, we test whether genetic ancestry derived from genome-wide genotyping data is useful to predict lung function in a French Canadian population. A total of 426 subjects of French Canadian origin were genotyped for nearly 1.2 million SNPs using the Illumina Human1M BeadChip. 420 of them passed genotyping quality control filters. All these subjects underwent lung cancer surgery. Patients with concomitant bronchiectasis, infection, lymphoma, lymphangioma, mesothelioma, and organizing pneumonia were excluded. The genotypes of the 403 remaining subjects were filtered to eliminate SNPs in linkage disequilibrium ($r^2 \nearrow 0.1$) using the LD-based SNP pruning option in PLINK. We used genotypes from unrelated HapMap CEU and YRI populations as reference sets for European and African ancestry, respectively. This resulted in a final set of 66,749 autosomal SNPs in linkage equilibrium and shared across the different populations. This set of SNPs was used to calculate genetic ancestry using the ADMIXTURE program and fixing two ancestral populations (K = 2). Low variability in genetically determined European ancestry was observed in this French Canadian population (European ancestry range = 93.8 to 99.6%). We used linear regression, stratified by gender, to evaluate the association between lung function and European ancestry. None of the lung function measurements were significantly associated with the percentage of European ancestry. Two models were compared to assess whether genetic ancestry influences pulmonary function predictions. The first, labeled as the standard model, included age, age squared and height squared. The second one included all the same variables but also the individuals' percentage of European ancestry. Mean absolute differences of 6 ± 5 ml and 14 ± 13 ml were observed between the two models for men and women, respectively. These results suggest that genetically determined ancestry do not change the predicted lung function measurements in this French Canadian population. Further studies using different source of European populations and wider admixed populations will be required to evaluate the clinical potential of ancestry-based lung function prediction models.

Gene-gene and gene-environment interactions in risk prediction. *H. Aschard[1], J. Chen[2], P. Kraft[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Biostatistics, University of Pennsylvania, Philadelphia, PA.

Background. Genome-wide association scans have identified scores of common genetic variants associated with the risk of multifactorial diseases in the past few years. However their impact in discrimination and risk prediction beyond traditional risk factors has been shown to be limited. Therefore it has been suggested that the identification of gene-gene (GxG) and gene-environment (GxE) interactions would allow more accurate predictions of disease and facilitate prevention compared to risk-assessment models that include only the marginal effects of the known risk factors.

Method. In this study we conducted a simulation study to explore the potential improvement of discrimination if GxG and GxE interactions exist and we know them. The disease status of three common complex diseases, Breast Cancer (BRCA), Type 2 Diabetes (T2D) and Rheumatoid Arthritis (RA), were generated across a broad range of hypothetical GxG and GxE interaction effects. The interaction effects were defined such that the final marginal effects of known genetic risk variants and known clinical and environmental risk factors were equal to their previously reported estimated effects.

Results. The addition of the simulated GxG and GxE interaction effects in risk models shows overall very modest improvement in the discrimination ability as measured by the C-statistic (<5%). Moreover this improvement was dramatically decreasing with the increase discrimination ability of the marginal models (when no interaction was simulated): the average C-statistics of the models including only the marginal effects of the genetic and non-genetic risk factors were 0.62, 0.71 and 0.79 for BRCA, RA and T2D respectively; when adding ten low to large interactions the corresponding increases in C-statistic were 3.9%, 2.1% and 1.5% on average. Our simulations also show that few strong interactions are more likely to improve discrimination than a large number of small interactions.

Conclusion. The inclusion of GxG and GxE interaction effects in risk prediction models as usually described in the literature, is unlikely to improve significantly the discrimination ability of these models. If such interactions exist, other strategies should be explored to leverage this information.

1068F

X-Linked retinitis pigmentosa in a three-generation family of females and a female-sporadic case accounted for by single heterozygosity for RPGR mutations. *J. KAPLAN[1,2], N. DELPHIN[2], S. GOBIN[2], J.-P. BONNEFONT[1,2], J.-L. DUFIER[3], O. ROCHE[3], A. MUNNICH[1,2], J.-M. ROZET[1,2].* 1) Genetics and epigenetics of metabolic, sensorineural diseases and birth defetcs, INSERM U781-Paris Descartes University & Institute of genetic diseases IMAGINE, Necker - Enfants Malades University Hospital, Paris, France; 2) Genetics Department, Necker - Enfants Malades University Hospital, Paris, France; 3) Ophthalmology Department-Paris Descartes University, Necker - Enfants Malades University Hospital, Paris, France.

Purpose: To confirm unexpected X-linked dominance of RPGR mutations in a three-generation family of females and a female-sporadic case. The X-linked inheritance was suspected on a basis of a variable disease expression through the three generations along with existence of a unilateral high myopia in the oldest patient as well as in the female sporadic case. Patients and Methods: In Family 1, a 46 year-old woman was seen for a progressive decrease in visual acuity. Upon ophthalmological examination her fundus displayed diffuse “tiger-stripe” striations resulting from a diffuse retinal pigment epithelium atrophy revealing the underlying choroïdal vessels. Her sister and two brothers as well as her 5 nephews and 4 nieces had no known visual deficiency. Conversely, her 68 year-old mother presented since infancy with unilateral amblyopia and her fundus presented the same “tiger-stripe” striations. Finally, while her 24 year-old son had no visual problem, her 21 year-old daughter presented a moderate and well corrected myopia but her fundus was similar to that of her mother and grand-mother. In Family 2, a 39 year-old woman came to the consultation for history of night blindness since her 20s and progressive constriction of her visual field leading to an unambiguous diagnosis of RP. She displayed high asymmetric myopia and low visual acuity. Her parents, her three sibs and her three young children were healthy. The RPGR gene, including the ORF15 exon, was screened for mutation using direct sequencing in the two families. Results: The genetic screening of the RPGR gene evidenced truncating mutations in the ORF15 exon: a 4 bp deletion (c.3007-3010delGGAG; p.ORF15+Gly418fsX85) segregating with the disease in Family 1 and a 1 bp deletion (c.478delA, p.ORF15Glu249fsX503) in Family 2. In Family 1, the youngest patient asked for prenatal diagnosis in case of pregnancy of a male fetus. In Family 2, the proband had three healthy young children (7 year-old girl, 5 and 3 year-old boys). The girl and the youngest boy were found to carry the mutation. Conclusion: The existence of unusual retinal manifestations in women with no related affected males does not rule out X-linked transmission especially when highly asymmetric or even unilateral myopia and variable expressivity or incomplete penetrance are noted. In addition, the identification of RPGR mutations in females, including sporadic cases, suggests that the X-linked inheritance of RP is likely underestimated.

1069F

Stargardt disease: clinical utility and sensitivity of a next-generation sequencing panel. *S.M. Sperber[1], B.J. Williams[1], D. Blain[2,3], K. Goetz[3], V. Ndifor[3,4], M. Reeves[3,4], S. Vitez[3,4], X. Wang[3], S.J. Tumminia[5], N. Smaoui[1].* 1) GeneDx, Gaithersburg, MD; 2) MedStar Research Institute, Hyattsville, MD, USA; 3) 3Ophthalmic Genetics and Visual Function Branch, National Eye Institute/NIH, Bethesda, MD, USA; 4) 4BioSearch/Team Placement Service Incorporated, Rockville, MD, USA; 5) OD, National Eye Institute/NIH, Bethesda, MD, USA.

Background: Stargardt disease (SD) is the most common form of macular dystrophy found in patients under the age of 20, exhibiting a frequency of 1/10,000. Exemplified by decreased central vision and a bronzing of the macula with yellow flecks, SD progresses to blindness with some preservation of the peripheral vision. SD is inherited in an autosomal recessive manner and is caused by mutations in the ATP-binding cassette transporter (*ABCA4*) gene. Other types of macular dystrophy are inherited in an autosomal dominant form and include the *RDS*/*PERIPHERIN2* and *ELOVL4* genes. Here we present data assessing the clinical utility and sensitivity of genetic testing using a Stargardt next-generation sequencing panel.

Methodology: In our CLIA certified diagnostic laboratory, consecutive samples of 45 patients with clinically identified Stargardt disease were analyzed using the Illumina HiSeq platform to perform massively-parallel sequencing of an *ABCA4*, *RDS* and *ELOVL4* gene panel totaling 57 amplicons. PCR followed by conventional dideoxy capillary sequencing was used to confirm all mutations and variants of unknown significance.

Results: Seventy-six percent of patient samples harbored mutations or novel sequence variants of potential pathogenicity. The majority of patients carried mutations in ABCA4 (32/34). Mutations in the *RDS* gene were identified in two patients, and none were found in the *ELOVL4* gene. Of the total variants analyzed, 28% were novel (14/50). Thirty percent of the patients with identified *ABCA4* mutations had only a single heterozygous mutation or variant of unknown significance.

Conclusion: Our results suggest that diagnostic testing for suspected Stargardt disease with a sequencing panel for the *ABCA4* and *RDS* genes is sensitive and efficient. Five percent of the patients harbored mutations in the RDS gene, suggesting inclusion of the gene in genetic counseling sessions of this disorder. No mutation was found in a quarter of the samples, indicating that an expansion of the number of genes within the panel would increase its sensitivity.

1070F

Exome sequencing in phenotypic facioscapulohumeral muscular dystrophy (FSHD2). *A. Leidenroth[1], H.S. Sorte[3], P. Lunt[2], R. Lyle[3], J.E. Hewitt[1].* 1) The University of Nottingham, Nottingham, United Kingdom; 2) University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom; 3) The Norwegian High-Throughput Sequencing Centre, Dept. of Medical Genetics, Ullevål, Oslo University Hospital, Norway.

Most cases of facioscapulohumeral muscular dystrophy (FSHD1) are caused by the contraction of the 3.3kb macrosatellite repeat array D4Z4 on the chromosome 4 subtelomere. The current model of the underlying molecular disease mechanism is that the dystrophic defect results from contraction-dependent epigenetic changes at D4Z4. In turn, these allow aberrant transcription of the DUX4 retrogene, which is located within each repeat unit. DUX4 transcripts have recently been shown to be stabilized by a polymorphic polyadenylation signal at the distal end of D4Z4. This poly-A site is in linkage disequilibrium with markers proximal to the array, variants of which segregate with disease status. Between 5% and 10% of patients are diagnosed with the FSHD phenotype but do not have a contracted D4Z4 array (phenotypic FSHD or FSHD2). However, they do show the same epigenetic changes of histones and DNA methylation at D4Z4 as FSHD1 patients. Specifically, this includes the loss of histone 3 lysine 9 tri-methylation and hypomethylation at certain restriction enzyme sites (FseI, BsaAI and CpoI). The defect that triggers these epigenetic changes and the muscle phenotype in these patients is still unknown, and we intend to use exome sequencing to identify it. We have characterized the methylation status of a panel of FSHD2 patients by methylation-sensitive restriction digest assays combined with non-radioactive Southern blotting. For this, we developed a modification of the published protocol for D4Z4 methylation analysis for use with digoxigenin labeled probes. This analysis showed the proximal D4Z4 repeat to be hypomethylated in FSHD2 patients, confirming previous studies. For the exome sequencing we are using Agilent SureSelect 50Mb human exome capture combined with high-throughput analysis on the Illumina HiSeq2000. What makes phenotypic FSHD interesting is the fact that the molecular disease mechanisms of FSHD1 are still only poorly understood. While the case for a DUX4 involvement is convincing, we still do not understand how it affects downstream targets to cause a muscle phenotype. If we can identify the genetic mutation in FSHD2, pathway analysis could help explain the molecular link between these two related but distinct disorders. A better understanding of FSHD2 will help us develop therapeutic strategies for the majority of FSHD cases. We would like to thank The Muscular Dystrophy Campaign UK for funding.

Candidate gene and whole exome sequencing to identify novel muscular dystrophy mutations. *K.K. McDonald[1,2], E.E. Davis[3,4], J. Stajich[1], J. Rimmler[1], B. Rusnak[1], K. Crooks[1], N. Katsanis[3,5], A.E. Ashley-Koch[1,2], M.A. Hauser[1,2].* 1) Center for Human Genetics, Duke University, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC; 3) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 4) Department of Pediatrics, Duke University Medical Center, Durham, NC; 5) Department of Cell Biology, Duke University Medical Center, Durham, NC.

Muscular dystrophies are devastating diseases affecting 1 in 3,000 individuals worldwide, and there are no cures for affected individuals and no preventative therapies for individuals who are known to be at risk. There has been great progress in the identification of genetic mutations that cause some forms of muscular dystrophy; however, genetic heterogeneity is the rule rather than the exception. Consequently, many orphan dystrophies remain to be characterized and are a considerable burden to those affected individuals and their families. Several strategies can be utilized to identify new mutations and to confirm that they impair muscle function. Our group has identified a novel mutation in an orphan dystrophy family as a result of candidate gene sequencing of linkage peaks, and we have begun the analysis of second generation sequencing data to identify a causative mutation in another family. Linkage analysis for a family segregating a scapuloperoneal muscular dystrophy (SPMD) phenotype produced a peak on chromosome 14. Sequencing revealed a novel deletion of a lysine residue at amino acid position 1786 in MYH7 that segregated with affection status in the family and was not present in 382 control chromosomes. The deletion is consistent with observed skeletal muscle and cardiovascular phenotypes. We have also performed whole exome sequencing to identify variants causing disease in an autosomal dominant limb-girdle muscular dystrophy (LGMD) family. Preliminary analysis of these data has not revealed a previously identified muscular dystrophy mutation in these individuals. However, 98 novel, non-synonymous coding SNPs have been identified which are not present in two control individuals and are heterozygous in 3 cases. Seven splice site mutations were identified which met the same criteria. Segregation analysis in the full family is underway. Possible disease-causing SNPs will be sequenced in at least 500 control chromosomes. To show causality of any suspected muscular dystrophy mutations identified through sequencing, testing in a zebrafish model will be performed. As a proof of principle for this assay, zebrafish embryos were injected with mRNA containing the myotilin T57I mutation. These injections resulted in myofiber defects consistent with both the T57I mouse model and also LGMD patients harboring this mutation, demonstrating the utility of a developmental vertebrate model to assay late-onset muscular dystrophy alleles.

Genetic causes of primary lymphedema. *A. Mendola[1], A. Ghalamkarpour[1], C. Debauche[2], N. Van Regemorter[3], Y. Sznajer[4], D. Thomas[5], N. Revencu[1,4], Y. Gillerot[4], K. Devriendt[6], E. Legius[6], G. Pierquin[7], R. Hennekam[8], G.A. Diaz[9], J.B. Mulliken[10], L.M. Boon[1,11], M. Vikkula[1], The Lymphedema Research Group.* 1) Human Molecular Genetics, de Duve Institute Université catholique de Louvain, Brussels, Belgium; 2) Department of Neonatology, Cliniques Universitaires Saint-Luc, Brussels, Belgium; 3) Centre de Génétique ULB, Hôpital Erasme, Brussels, Belgium; 4) Center for Human Genetics, Cliniques Universitaires St Luc, Brussels, Belgium; 5) Unité diagnostic anténatal, Hôpitaux Iris Sud, Brussels, Belgium; 6) Center for Human Genetics, University Hospitals Leuven, Leuven, Belgium; 7) Center for Human Genetics, University Hospital Center-CHU Sart-Tilman, University of Liège, Liège, Belgium; 8) Department of Paediatrics, AMC, Amsterdam, The Netherlands and Clinical and Molecular Genetics Unit, The Netherlands; 9) Departments of Genetics & Genomic Sciences, Mount Sinai School of Medicine, New York, USA; 10) Vascular Anomalies Center, Plastic Surgery, Children's Hospital, Harvard Medical School, NY, USA; 11) Centre for Vascular Anomalies, Cliniques Universitaires St Luc, Brussels, Belgium.

Lymphedema is caused by a dysfunction of the lymphatic vessels, leading to disabling swelling occurring mostly on the extremities. There exist two major categories: primary (idiopathic) and secondary (acquired) lymphedema. Familial lymphedema usually segregates in an autosomal dominant or recessive manner. It can also occur in association with other clinical problems. In our lab, the screening of 237 primary lymphedema samples led to the discovery of different mutations in the five genes associated with lymphedema. VEGFR3, a class III receptor tyrosine kinase, is predominantly expressed in lymphatic endothelial cells in adults. Mutations in the gene cause primary congenital lymphedema or Nonne-Milroy disease. We found 10 mutations, 7 unpublished and 3 known, in 11 patients. Mutations in the transcription factor genes FOXC2 and SOX18 have been reported in lymphedema-distichiasis syndrome and hypotrichosis-lymphedema-telangiectasia syndrome, respectively. In our series, 9 patients had a mutation in one of these genes. We also screened two more recently identified genes: CCBE1 and PTPN14. CCBE1 (collagen and calcium binding EGF domain 1) was screened in 158 lymphedema cases. Mutations were identified only in patients with Hennekam syndrome. The PTPN14 gene, encoding a non-receptor tyrosine phosphatase, was reported to encompass an exon 7 deletion in one consanguineous family, in which affected individuals also present choanal atresia. We screened 188 samples for mutations by high resolution melting and sequencing. Only one mutation was found. In addition, intronic changes were identified, the disease-causing nature of which is unknown. We conclude that mutations in these genes are rare causes of primary lymphedema, limited to specific (syndromic) forms. The identification of the genetic causes of primary lymphedema nevertheless allows for more precise diagnoses, follow-up, and treatment, and enables the generation of disease models for future development of novel therapeutic approaches. Moreover, patients without a mutation in the known genes represent a valuable resource in the search for other genes causing primary lymphedema.

1073F

Mutations in Gene X cause enchondroma formation in Ollier disease and Maffucci syndrome. *T. Pansuriya[1], J. van Oosterwijk[1], R. van Eijk[1], M. van Ruler[1], S. Verbeke[1], D. Meijer[1], K.H. Nord[2], S. Daugaard[3], L. Sangiorgi[4], B. Toker[5], B. Liegl-Atzwanger[6], M. San-Julian[7], R. Sciot[8], L.G. Kindblom[9], K. Szuhai[1], J.V.M.G. Bovee[1].* 1) Pathology, Leiden University Medical Center, Leiden, Zuid-Holland, Netherlands; 2) Lund University Hospital, Lund, Sweden; 3) University Hospital of Copenhagen, Denmark; 4) Rizzoli Orthopedic Institute, Bologna, Italy; 5) Istanbul University Medical School, Turkey; 6) Medical University of Graz, Austria; 7) University Clinic of Navarra, Spain; 8) University of Leuven, Leuven, Belgium; 9) Royal Orthopaedic Hospital, Birmingham, United Kingdom.

In Ollier disease and Maffucci syndrome, patients have multiple enchondromas in their skeleton without (Ollier) or with (Maffucci) haemangiomas. Enchondromas are benign cartilage forming tumours. Malignant transformation of enchondromas into chondrosarcoma occurs in more than 30% of the cases. Point mutations in *PTH1R* have been reported in about 8% of Ollier patients whereas they are absent in Maffucci syndrome. In our series all four reported point mutations in *PTH1R* were absent. Genome-wide analysis and expression arrays were performed previously and no large genomic aberrations were found. In this study, we have selected three candidate genes, for which sequencing was performed using 56 tumours of 40 patients. We found somatic heterozygous mutations at a single codon position in one of the three candidate genes. Mutations were found in 95% of the enchondromas related to Ollier disease and Maffucci syndrome. Using immunohistochemistry for the mutant protein, we observed a mixture of cells expressing mutated and non mutated proteins within the tumour, suggesting presence of mosaicism in the enchondromas like in other type of benign bone tumours. In addition, in normal cells (normal bone) surrounding the tumour we also observed a very low frequency of mutated cells suggesting germ line mosaicism in these patients. The frequency of mutations decreases with increasing histological grade in chondrosarcomas. This result confirms that this mutation is an early event in enchondromagenesis while another hit is needed for progression towards chondrosarcomas. We speculate that this hit not necessarily occurs in the mutated cells but can also occur in the wild type cells of the benign enchondroma precursor. In conclusion, we studied the largest series of patients with these two rare and non hereditary skeletal disorders and found a causative mutation in gene X present in 95% of enchondromas and our results suggest germ line mosaicism in patients with non hereditary Ollier disease and Maffucci syndrome.

1074F

The Molecular Genetic Basis of Pentosuria: Solving Garrod's Fourth Inborn Error of Metabolism. *S.B. Pierce[1,2], C.H. Spurrell[2], J.B. Mandell[1], M.C. King[1,2], A.G. Motulsky[1,2].* 1) Medicine (Medical Genetics), University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

In 1908, Archibald Garrod introduced the concept of “inborn errors of metabolism,” citing albinism, alkaptonuria, cystinuria and pentosuria, each of which he postulated to be caused by recessive inheritance of a single mutation leading to deficiency of a specific enzyme. His concept supported the link between Mendelian factors, which had been rediscovered not long before, and enzyme chemistry, also then in its infancy. Of the four traits described by Garrod, the mutations responsible for the first three conditions have long since been solved. In contrast, the molecular genetic basis of pentosuria has remained a mystery. Pentosuria is characterized by high concentrations in urine of the pentose sugar xylulose and is associated with deficiency of the enzyme L-xylulose reductase. The trait is completely benign, but in the early and mid-20th century was important because it was confused with diabetes. Persons with pentosuria were often inappropriately treated with insulin, leading to severe reactions. As more specific diagnostic methods for diabetes were developed, persons with pentosuria were no longer at risk of being inappropriately diagnosed and treated as diabetic. Pentosuria is found almost exclusively among persons of Ashkenazi Jewish (AJ) ancestry. Families with pentosuria were studied for more than 30 years by Margaret Lasker, who demonstrated that inheritance was autosomal recessive and that the phenotype had no impact on longevity. In the 1960s, Mrs. Lasker bequeathed her records and data to AGM. This year, in the course of exome sequencing DNA from a control of AJ ancestry, we discovered by serendipity a frameshift (c.598delC) in *DCXR*, which encodes L-xylulose reductase. From the records of the families, we searched for surviving probands and adult children, finding informative members of 15 families, all of whom agreed to participate. In the families, we confirmed *DCXR c.598delC* and discovered a second mutation, *DCXR c.55(+1)G>A*, which leads to aberrant splicing and an unstable protein. All probands are homozygous or compound heterozygous for one or both of the mutations. Consistent with this, high levels of xylulose were detected in probands' serum. In 1240 AJ controls, the allele frequency of *DCXR c.598delC* was 0.0121 and of *DCXR c.55(+1)G>A* was 0.0040. Proband genotypes are as expected under Hardy-Weinberg equilibrium. Archibald Garrod and Margaret Lasker were entirely correct.

1075F

Exome sequencing in a consanguineous family segregating familiar juvenile polyarthritis. *R. Rabionet[1], J.I. Aróstegui[2], R. Medino[3], C. Tornador[1], D. Comas[4], E. González[2], S. Ossowski[1], J. Yagüe[2], X. Estivill[1].* 1) Genes and Disease, Center for Genomic Regulation and UPF, Barcelona, Spain; 2) Inflammatory Disease Unit, Immunology Service, Hospital Clínic i Provincial de Barcelona, Barcelona, Spain; 3) Pediatric Rheumatology Service, Hospital La Paz, Madrid, Spain; 4) Institut de Biologia Evolutiva (CSIC-UPF), Barcelona, Spain.

In the last year, exome sequencing has given a new spin to the genetics of rare Mendelian disorders. This new technology allows the analysis of diseases that were very difficult to tackle with traditional linkage and homozygosity mapping, especially those rare disorders with a small number of affected cases. We have applied exome sequencing to the analysis of a consanguineous family from Morocco carrying a rare recessive articular disorder. This pedigree consists of a consanguineous couple (first cousins) with three affected and two unaffected siblings, affected of a juvenile form of arthritis, with an onset at 2-4 y.o. Patients presented an erosive and symmetric polyarthtitis, and were seronegative for AntiNuclearAntibodies (ANA), Rheumatoid Factor (RF) and HLA-B27. Patients developed severe dysplasia and loss of walking ability before adulthood. The three affected siblings and one unaffected brother were genotyped with the Illumina 370K duo array, in search of regions of homozygosity. This produced four genomic regions, located in Chr3:4552500 - 10646218, Chr6:4707143 - 6584424, Chr6:106443904 - 123266646 and Chr13: 42419227 - 70194040. WISP3, a gene related to progressive pseudorheumatoid dysplasia, was located within the candidate regions. Sanger sequencing analysis did not identify variants in this gene. It was then decided to perform exome sequencing of two affected and one unaffected samples. Sequencing data was analyzed through our in-house developed pipeline for variant discovery. This lead to the identification of one novel (not in dbSNP, nor in 1000 genomes) nonsynonymous variant in each of the four homozygosity regions. These variants were then genotyped in 300 control samples from the Moroccan population, and all but one were absent in the control dataset. Additional characterization is ongoing in order to determine which of the remaining three variants leads to this damaging phenotype.

1076F

Discovery of defects in two central checkpoints of protein glycosylation associated with a broad spectrum of disorders. *S. Rust[1], L.C. Tegtmeyer[2], S. Moormann[2], E. Schrapers[2], A. Witten[1], J. Reunert[2], T. Marquardt[2].* 1) Leibniz-Inst f Arteriosclerosis Res, Albert-Schweitzer-Campus 1, Building Domagkstrasse 3, Münster, Germany; 2) Klinik für Kinder- und Jugendmedizin, Universitätsklinikum, Albert-Schweitzer-Campus 1, Building A13, 48149 Münster, Germany.

A large amount of proteins is N-glycosylated during synthesis at the endoplasmatic reticulum (ER). A preformed complex sugar moiety is transferred just when the respective Asn-residue of the growing peptide chain enters the ER-lumen. The sugar is then modified to produce the final glycoprotein. Protein glycosylation has many biological functions including basic functions in protein folding, protein interactions, stabilization, and regulated degradation of proteins. Genetic defects that disturb the glycosylation process are known as congential disorders of glycosylation (CDG), and defects typically are visible as reduced glycosylation of serum transferrin even in children. A large number of enzymes and transmembrane-transporters is involved in glycosylation. Typically CDG-defects are inherited as recessive traits. The aim of this study was to elucidate the genetic defects in two new CDG-families. In both families the parents were first cousins. Thus, we obtained candidate gene lists by homozygosity mapping (Illumina 660W SNP chips) and identified the defects by sequencing (incl. whole exome Illumina next generation sequencing). Interestingly in both cases the defective genes were previously not considered as CDG candidates and surprisingly turned out to be central checkpoints in protein glycosylation. One is involved in a gatekeeper position at the translocation pore through which the ribosome delivers the growing peptide chains of all new N-glycoproteins and the defect was lifethreatening. Our functional data show that the defective protein is essential to allow N-glycosylation of proteins, showing some site preferences. The other gene is a central player of sugar metabolism. It affects efficiency of glycogen usage and glycolysis, as well as synthesis of sugar-precursors for N-glycosylation. Defects in the same gene were discovered in a number of additional CDG-families. Hence, there is a broad range of traits associated with defects in this gene, including dilatative cardiomyopathy and liver fibrosis and affecting glycogen usage in muscles. As the metabolic intermediates are easily detected by small modifications of existing neonatal screening programs, this condition is suitable for predictive testing. Furthermore, since different affected metabolic intermediates may be restricted or substituted via diet we believe that already safety tested preventive treatment options are available.

1077F

Mutations in NOTCH2 cause Hajdu Cheney syndrome and serpentine fibula polycystic kidney disease. *M.A. Simpson[1], M.D. Irving[1,2], M.J. Gray[3], E. Asilmaz[1], D. Dafou[1], F.V. Elmslie[4], S. Mansour[4], S.E. Holder[5], C.E. Brain[6], B.K. Burton[7], K.H. Kim[7], R.M. Pauli[8], S. Aftimos[9], H. Stewart[10], C.A. Kim[11], M. Holder-Espinasse[12], W.M. Drake[13], S.P. Robertson[3], R.C. Hajdu-Cheney syndrome (HCS; OMIM 102500) is characterised by progressive focal bone destruction including acro-osteolysis and generalised osteoporosis together leading to characteristic radiographic abnormalities. To search for disease alleles in HCS we undertook whole exome sequencing of three unrelated affected individuals of European origin. Comparison of the exome variant profiles were undertaken using a model of a rare autosomal dominant disorder, requiring at least one previously unobserved heterozygous nonsynonymous or splice site substitution or a coding insertion or deletion in the same gene in all three individuals, a process that highlighted NOTCH2 as the only candidate gene matching these criteria. The three NOTCH2 variants are all located in exon 34, the terminal exon, of the 11.4kb transcript of this gene. We subsequently identified a series of novel heterozygous NOTCH2 genetic variants in 11 additional HCS kindreds with Sanger sequencing. All identified mutant alleles are predicted to lead to premature termination of the protein product before the complete translation of the PEST domain. We demonstrate that the level of expression of HCS alleles was comparable to that of wild-type alleles and total abundance of NOTCH2 transcript was equivalent to wild-type controls, suggesting the mutant transcripts evade the nonsense mediated decay pathway. Indeed, we were able to detect a protein of the size of the predicted truncated NOTCH2 intracellular domain in primary skin fibroblasts form an affected individual. These findings suggest that HCS alleles generate a mature NOTCH2 protein product which contains a disrupted or absent proteolytic PEST sequence the absence of which has previously been shown to increase Notch signalling. There is significant phenotypic overlap between HCS and serpentine fibula polycystic kidney disease (SFPCKD; MIM600330) a rare skeletal dysplasia with pronounced bowing of the long bones, polycystic kidneys and characteristic dysmorphic facies. One HCS subject in whom we had identified mutations had previously been reported as a SFPCKD case. We have now identified a NOTCH2 mutation in a second individual with SFPCKD suggesting that this disease forms part of the phenotypic spectrum of HCS and should no longer be classified as a distinct disease entity.

1078F

Chondrodysplasia, joint dislocations, brachydactyly and cleft palate caused by recessive mutations in *IMPAD1*, the gene coding for the Golgi-resident nucleotide phosphatase, gPAPP: a novel distinct phenotype associated with a proteoglycan sulfation defect. *A. Superti-Furga[1], E. Lausch[2], S. Unger[3], C. Gilissen[4], A. Rossi[5], U. Knoll[6], S. Nampoothiri[7], M. Nair[8], M. Del Rosario[4], H. Venselaar[9], J. Spranger[2], B. Campos-Xavier[1], H.G. Brunner[4], L. Bonafé[1], J.A. Veltman[4], B. Zabel[2], L. Vissers[4].* 1) Dept Pediatrics, University of Lausanne, 1011 Lausanne, Switzerland; 2) Div Pediatric Genetics, Centre for Pediatrics and Adolescent Medicine, Univ Hospital Freiburg, 79106 Freiburg, Germany; 3) Medical Genetics Service, University of Lausanne, 1011 Lausanne, Switzerland; 4) Dept Human Genetics, Nijmegen Ctr for Molecular Life Sciences and Inst Genetic and Metabolic Disorders, Radboud University Nijmegen Medical Ctr, 6500 HB Nijmegen, The Netherlands; 5) Department of Biochemistry, University of Pavia, 27100 Pavia, Italy; 6) Ctr for Prenatal Diagnosis, 10719 Berlin, Germany; 7) Amrita Institute of Med Sciences and Res Ctr, Cochin, Kerala, India; 8) Dept of Pediatrics, Medical College, Calicut, Kerala, India; 9) Ctr for Molecular and Biomolecular Informatics, Nijmegen Ctr for Molecular Life Sciences, Radboud University Nijmegen Medical Ctr, 6500 HB Nijmegen, The Netherlands.

We studied three individuals from two consanguineous families with a distinct condition characterized by short stature, chondrodysplasia with brachydactyly, congenital joint dislocations, cleft palate and facial dysmorphism. The differential diagnosis had included diastrophic dysplasia, Desbuquois dysplasia and recessive Larsen syndrome, but no mutation had been identified in *DTDST*, *CANT1* or *CHST3*. Whole exome sequencing revealed a single gene, *IMPAD1*, in which the three affected individuals had homozygous missense mutations. *IMPAD1* had been originally believed to code for an inositol phosphatase (hence the name) but was subsequently shown by Frederick et al (PNAS 105:11605-11612, 2008) to code for gPAPP, a Golgi-resident nucleotide phosphatase that hydrolyzes phosphoadenosine-phosphate (PAP), the byproduct of sulfotransferase reactions, to AMP. The mutations in our patients affected residues in or adjacent to the phosphatase active site and are predicted to impair enzyme activity. We then found homozygosity for a premature termination codon in *IMPAD1* in a fourth, unrelated newborn with the same phenotype. *Impad1* inactivation in mice has previously been shown to produce chondrodysplasia with abnormal joint formation and impaired proteoglycan sulfation (Frederick et al, 2008). The human chondrodysplasia associated with gPAPP deficiency joins a growing number of skeleto-articular conditions associated with defective synthesis of sulfated proteoglycans, highlighting the importance of proteoglycans in the development of skeletal elements and joints.

1079F

Exome sequencing a single proband reveals that mutations in the *MTHFD1* gene are responsible for a novel inborn error of folate metabolism. *D. Watkins[1], J. Ganesh[2], J.A. Schwartzentruber[3], L. Dempsey Nunez[1], J. Orange[4], J. Majewski[1,3], D.S. Rosenblatt[1].* 1) Dept Human Genetics, McGill University, Montreal, QC, Canada; 2) Section of Metabolic Disease, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 3) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada; 4) Division of Immunology, Children's Hospital of Philadelphia, Philadelphia, PA ,USA.

A 3-month-old infant presented with failure to thrive, megaloblastic anemia, severe neutropenia and thrombocytopenia, and increased plasma levels of homocysteine and methylmalonic acid. Studies in cultured fibroblasts showed a selective decreased ability to synthesize methylcobalamin from exogenous cyanocobalamin. Exome capture was performed on patient DNA using the Agilent SureSelect 50 Mb exome capture kit and sequencing with the Illumina Hiseq sequencer. Two sequence changes in the *MTHFD1* gene, which encodes a trifunctional folate metabolic enzyme containing methylenetetrahydrofolate (methyleneTHF) dehydrogenase, methenylTHF cyclohydrolase and formylTHF synthetase activities, were identified: c.727+1G>A, affecting the splice acceptor site of intron 8; and c.517C>T (p.Arg173Cys), which affects a conserved residue in the NADP-binding site of the methyleneTHF dehydrogenase domain of the trifunctional enzyme. Previous site-directed mutagenesis experiments have demonstrated that mutations affecting arginine 173 have a deleterious effect on enzyme function. Analysis of DNA from family members showed that the father was heterozygous for the c.727+1G>A mutation while the mother was heterozygous for c.517C>T; an unaffected sibling carried neither mutation. MTHFD1 catalyzes the reaction of formate, generated in the mitochondria, with THF to form formylTHF (required for purine biosynthesis) and its conversion to methyleneTHF (required for thymidylate synthesis, and the source of methylTHF required for homocysteine remethylation). This patient represents the first identified case of MTHFD1 deficiency. Our study demonstrates the capacity of exome capture and sequencing to identify novel causative genes even in cases where only a single patient is available for study.

1080F

Compound heterozygous mutations in the ERCC6 gene cause a severe form of Cockayne syndrome in an Amish isolate. *B. Xin, H. Wang.* DDC Clinic for Special Needs Children, Middlefield, OH.

Cockayne syndrome (CS) is a rare autosomal recessive multisystem disorder characterized by growth failure, mental retardation, progressive neurological dysfunction, premature aging, and photosensitivity. The clinical spectrum of CS encompasses a wide range of severity from severe prenatal forms to mild and late-onset presentations. The underlying cause of the disease is a defect in transcription-coupled DNA repair, specifically the nucleotide excision repair pathway. To date, most CS patients reported have been associated primarily with mutations in two genes, ERCC6 and ERCC8. Here, we report two patients with a severe form of CS from an Amish pedigree and the identification of causative mutations in ERCC6 gene. The patients presented with severe phenotype that includes failure to thrive, severe developmental delay, characteristic facial features, and congenital cataracts. DNA analysis revealed compound heterozygosity for 2 novel mutations in the ERCC6 gene in both patients: a 28-bp deletion in exon 5 (c.1293_1320del) and a splice-donor site mutation in intron 14 (c.2709+1G>T). The c.1293_1320del mutation leads to a frameshift and creation of a premature termination (p.Glu432LysfsX24) in translation; the splice site mutation c.2709+1G>T results in aberrantly spliced ERCC6 mRNA which leads to frameshift and production of truncated protein. Further targeted mutation analysis in the family showed that the 28-bp deletion was inherited by the paternal parent while the splice site mutation was maternally inherited. None of the unaffected siblings carried both mutations. Our findings indicate that loss of function of ERCC6 is responsible for this severe form of Cockayne syndrome and the possibility of compound heterozygosity in Amish which is extremely uncommon for a rare condition at an isolated founder population.

1081F

Molecular characterization of the disease genes in patients with Cornelia de Lange syndrome. *J.Y. Yang[1], J.Y. Wang[1], K.Y. Koo[1], C.H. Lee[1], S.J. Kim[2], J.E. Lee[2], J.S. Lee[1].* 1) Department of Clinical Genetics, Yonsei University, College of Medicine, Seoul 120-752, Korea; 2) DNA link, Seoul, Korea.

Cornelia de Lange syndrome (CdLS; OMIM #122470) is an autosomal dominant disorder that is classically characterized by typical facial features, severe growth and mental retardation, limb defects, hirsutism and other visceral system involvement. Currently, Heterozygous mutations in the cohesin regulator, NIPBL, or the cohesin structural components SMC1A (formerly SMC1L1) and SMC3 have been identified as causes of CdLS. The mutations in NIPBL and SMC1A genes correspond to 20% to 50 % or 5% of CdLS patients, respectively. This finding suggests genetic heterogeneity and other disease causing genes in CdLS. In this study, mutations in NIPBL and SMC1A genes were screened in 11 Korean patients with CdLS by PCR direct sequencing. Three patients showed mutations in NIPBL gene (27%) and one patient in SMC1A gene (9%), and overall detection rate of mutation was 36%. Array-based comparative genomic hybridization (array-CGH) was performed in seven patients who did not show mutation in NIPBL or SMC1A gene for whole genomic copy number variation screening with the resolution of 4X180K. Two patients showed DNA copy number alterations including a deletion on chromosome 5q12.1 and duplication on chromosome 16p11.2. This study suggests that genetic backgrounds of Korean patients with CdLS are heterogeneous, too. Moreover, whole exome sequencing among this group is going on in order to identify disease gene(s) for CdLS.

1082F

Exome sequencing identifies a *PLCG2* mutation in a dominantly inherited systemic inflammatory disease. *Q. Zhou[1], G. Lee[1], J. Brady[1], A. Sheikh[1], J. Khan[2], D. Kastner[1], I. Aksentijevich[1].* 1) National Human Genome Research Institute, Bethesda, MD, USA; 2) National Cancer Institute, Gaithersburg, MD, USA.

We have identified a family presenting with a chronic inflammatory disease characterized by recurrent blistering skin lesions, arthralgia, inflammatory eye and bowel disease. The affected father and daughter also have a history of recurrent sinopulmonary infections, and a mild immunodeficiency with a paucity of circulating antibodies (IgG or IgA). We performed exome sequencing using Agilent SureSelect Human All Exon 50 Mb Kit on three samples including the affected father and daughter, and the unaffected mother. A total of 15 Gb of mapped sequence was generated from paired-end 76 bp reads on the SOLiD™ System platform. The average coverage of each base in the targeted regions was 80 fold, and 80%; of these bases were covered sufficiently deeply for variant calling (>10x coverage). About 50,000 variants and 5,700 indels were called per sample with a quality score q>20. Exonic variants (non-synonymous and splice-site variants and coding indels) were filtered to exclude common variants identified in the dbSNP130 or 1000 Genomes databases along with benign variants as predicted based on the evolutionary conservation (GERP score). A total of 33 transcripts were identified as possible candidate genes. We focused our attention to six genes known to have a role in inflammation including the *PLCG2* gene that encodes phospholipase C. 2 (PLC. 2), an enzyme responsible for ligand-mediated signaling in B, NK, and mast cells and with a critical regulatory role in various inflammatory pathways. Recent work from our lab identified *PLCG2* exon skipping mutations in patients presenting with a distinct inflammatory disease manifesting with cold urticaria and immune dysregulation. The candidate missense variant, S707Y, is a de novo mutation in the father and was passed only to his affected daughter but not to an unaffected son. Furthermore, the S707Y mutation was not detected in 376 Ashkenazi Jewish healthy controls, 368 North American rheumatoid arthritis controls and 450 exome sequencing controls. The S707Y mutation affects a highly conserved residue in an autoinhibitory SH2 domain and is predicted to be probably damaging, however the effect of this mutation on the PLC. 2 activity is unknown. Preliminary study evaluating the effect of the S707Y variant in an overexpression system showed an increase in IP3 production relative to wild type protein suggesting a gain-of function mutation in the PLC. 2-mediated signal pathway.

1083F

Epistatic interaction of mutations in DOCK8 and CLEC7A as a cause of intractable diarrhea, eczema and immunodeficiency in four brothers. *D.L. Dinwiddie[1], S.F. Kingsmore[1], S. Caracciolo[2], F. Colombo[2], A. Prandini[2], G. Tabellini[4], M. Giacomelli[2], M.E. Cantarini[3], A. Pession[3], C.J. Bell[5], N.A. Miller[1], S.L. Hateley[5], C.J. Saunders[1], L. Zhang[6], G.P. Schroth[6], S. Parolini[4], R. Badolato[2].* 1) Children's Mercy Hospital, Center for Pediatric Genomic Medicine, Kansas City, MO 64108; 2) Clinica Pediatrica dell'Università di Brescia, Brescia 25123, Italy; 3) Divisione di Onco-ematologia Pediatrica e Terapia Cellulare, Università di Bologna, Bologna 40138, Italy; 4) Dipartimento di Scienze Biomediche e Biotecnologie,Università di Brescia, Brescia 25123, Italy; 5) National Center for Genome Resources, Santa Fe, New Mexico 87505; 6) Illumina Inc., Hayward, California 94545.

We report four brothers from a consanguineous Italian family with an immunodeficiency syndrome characterized by severe eczema, milk and egg allergies, recurrent infections, intractable diarrhea, failure to thrive and, in two of the four, lymphoma. One died at age 12 months of cardiovascular failure due to intractable diarrhea and another of T cell lymphoma. The three siblings surviving infancy were studied. All had severe T cell lymphopenia (from 160 to 1140 cells/μl), but normal levels of B lymphocytes and NK cells. An immunodeficiency syndrome, IPEX (Immunedysregulation, Polyendocrinopathy and Enteropathy, X-linked; OMIM #304790) was suspected but ruled out with negative FOXP3 mutation analysis and normal protein expression in CD25+ and CD127+ lymphocytes. 37.7 million nucleotides of all the exons in the genome were enriched 44-fold from genomic DNA of the proband. Next generation sequencing of the enriched exons yielded 171 million sequences, each 130 nucleotides long. ~95% of sequences aligned to the reference human genome uniquely, covering each exonic nucleotide ~135 times. A bioinformatic decision tree was used to identify and genotype nucleotide variants in the aligned sequences. Two homozygous variants were detected in the patient: The first was a nonsense mutation in the C-type lectin receptor gene (CLEC7A, p.Tyr238X, rs16910526), a pattern recognition receptor that signals via CARD9. This mutation has been reported to cause familial chronic mucocutaneous candidiasis (CANDF4, OMIM#613108). The second variant was a novel homozygous frameshift in exon 27 of the DOCK8 gene, c.3193delA. DOCK8 mutations cause hyper-IgE recurrent infection syndrome (OMIM# 243700), characterized by T lymphopenia, eosinophilia, elevated IgE, eczema, recurrent infections and severe food allergies. Sanger sequencing confirmed homozygosity for the DOCK8 and CLEC7A mutations in the three siblings and heterozygosity in their parents. The DOCK8 mutation is predicted to result in a premature stop codon 17 residues downstream of the deletion (Ser1065AlafsX17). The phenotypic severity and enteropathy despite a hypomorphic DOCK8 mutation appeared to reflect bridging defects (one null, the other hypomorphic) in two genes acting in parallel pathways. Previously reported cases of DOCK8 mutations were often characterized by viral cutaneous infections and not associated with enteropathy. Interestingly, this unusual phenotype resembles IPEX syndrome, despite normal FOXP3 sequence.

1084F

THE SPECTRUM OF MEFV MUTATIONS IN AN ARABIC COHORT. *A.A. Kohilan[1], R.Z. Taha[1], D.F. Ahram[1], S. Ayesh[2], J. Alami[1], H.I. El-Shanti[1].* 1) Shafallah Medical Genetics Center, Doha, Qatar; 2) Makassed Hostpital, Jerusalem.

Autoinflammatory diseases are a group of disorders characterized by seemingly unprovoked inflammation in the absence of high-titer autoantibodies or antigen-specific T cells. Familial Mediterranean fever (FMF) is an autosomal recessive disorder and is the archetypal autoinflammatory disease. It is characterized by recurrent self-limiting episodes of fever and painful polyserositis. FMF is prevalent in specific ethnic groups—namely, non-Ashkenazi Jews, Armenians, Turks, and Arabs. The gene responsible for FMF—MEFV—has been identified in 1997. There seems to be a distinctive clinical picture in Arab patients with FMF, and the range and distribution of MEFV mutations is different from that noted in other commonly affected ethnic groups. The aim of this study is to delineate the spectrum and distribution of MEFV mutations amongst an Arabic FMF patient cohort and to assist the genotype-phenotype correlation in these patients. We have collected DNA samples from 188 FMF patients (from Qatar, Jordan and Palestine) who have been clinically diagnosed with FMF, according to international and validated diagnostic criteria. We have designed primers to cover the entire genomic region of MEFV. As a first tier, mutation detection is done by resequencing the entire coding sequence and splice sites; as a second tier the rest of the genomic region including the promoter are resequenced. In the first tier, we have identified 191 out of 376 mutant alleles (50%) by resequencing the entire coding region and splice sites of MEFV. In addition, resequencing of the entire genomic region of 100 patients who had only one identifiable allele was carried resulting in the identification of specific haplotypes and we are currently investigating the phenotypic significance of these haplotypes. The spectrum of MEFV mutations in Arabs seems different from other ethnic groups commonly affected by FMF. The fraction of the identifiable disease causing alleles is the lowest amongst the commonly affected ethnic groups. The results of the genomic resequencing of MEFV may provide some insight into the role of non-coding sequences and may explain the molecular pathology of FMF. Thereby, we are currently working on the development of a low cost and high throughput technique to facilitate the resequencing of the entire genomic sequence of MEFV using the Next Generation sequencing technology.

Identifying causal mutations for Primary Immunodeficiencies (PIDs) in Southeast Asian region using whole exome sequencing. *J. Yang, W. Yang, PPW. Lee, S. Zeng, L. Zhang, PC. Sham, YL. Lau.* The University of Hong Kong, Pokfulam, Hong Kong.

PIDs are rare inborn errors of the immune system and vast majority of PIDs are monogenic diseases. Study of potential genetic defects of PID offers enormous opportunities to the understanding of host-pathogen interactions at the molecular and functional level. Like many other rare Mendelian disorders, disease genes of PIDs were mostly identified by linkage studies or candidate gene screening. Next generation sequencing, especially whole exome sequencing, provides an opportunity for identifying the causal mutations when linkage or candidate gene approach fail to identify the genetic cause. “Asian Primary Immunodeficiency Network (APID)” is a collaborative network with an on-line PID patient registry that contains a wealth of clinical and genetic data for researchers and clinicians. With this collection, we have reported the largest Chinese cohorts of common PIDs including chronic granulomatous disease, Wiskott-Aldrich syndrome and X-linked agammaglobulinemia, as well as rare genetic mutations which have not been described in the Chinese population. However, among the 259 patients tested, only 164 patients were confirmed to have molecular defects based on a candidate gene approach. We have selected about a dozen patients whose clinical and immunological phenotypes are definitive but no mutation in the currently known PID genes has been found through candidate gene screening for whole exome sequencing. These include agammaglobulinemia with absence of B cells and with BTK mutations excluded; severe combined immunodeficiency disorders; mendelian susceptibility to mycobacterial diseases; and autoimmune lymphoproliferative disorder. On average, we have around 70X coverage of the targeted exome, with about 94% of the regions covered 5X or above. Since for each patient, thousands of novel variants are identified, and pinpointing the causal mutations is a daunting challenge. The following approaches are adopted to help with the data analysis. Since recessive mutations and X-linked mutations in male patients are a strong possibility for some patients, homozygous mutations or compound heterozygous mutations, and mutations on the X-chromosome are preferentially considered. Several patients are from consanguineous marriage families, so homozygous mutations in long homozygous stretches in the genome (likely autozygous regions) are considered for causal mutation identification. Mutations with support from other affected members are also preferentially considered.

1086F

A rare case of trans-heterozygous autosomal dominant polycystic kidney disease with bilineal inheritance of PKD1 and PKD2 mutations. *M. Roifman[1], D. Chitayat[2], R. Teitelbaum[2], J.E. Murphy[3], K. Wang[4], N. He[4], C.F. Morel[3], Y. Pei[4].* 1) Division of Clinical and Metabolic Genetics, Department of Paediatrics, Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 2) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynaecology, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 3) Fred A. Litwin Family Centre in Genetic Medicine, University Health Network and Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 4) Divisions of Nephrology and Genomic Medicine, University Health Network and University of Toronto, Toronto, ON, Canada.

Autosomal dominant polycystic kidney disease (ADPKD) is a phenotypically variable disorder, characterized by progressive renal and extra-renal cyst formation, and typically leads to end stage renal disease (ESRD) by late middle age. The vast majority of cases are caused by mutations in either the PKD1 or PKD2 gene, with the former conferring more severe disease and earlier age of onset of ESRD by approximately 20 years. Trans-heterozygous mutations involving both genes have been shown in transgenic mouse models to be viable, but cause more severe disease than does either mutation alone. Bilineal disease and trans-heterozygosity in two human siblings has been previously documented based on demonstration of a protein-truncating PKD2 mutation and a putative disease PKD1 haplotype associated with a high lod score (Am J Hum Genet 68: 355-363, 2001). Human trans-heterozygotes with a PKD1 and PKD2 mutation confirmed by direct gene sequencing have not been previously described. We report a case of ADPKD in a patient with trans-heterozygosity for a protein-truncating PKD2 mutation (c.2160InsA; p.Asn720FS4X) inherited from the paternal lineage and a missense PKD1 mutation (c.8510C>T; p.2767R>C) of unknown significance that affects a highly conserved amino acid inherited from the maternal lineage. The PKD1 mutation R2767C is predicted to be probably damaging by Polyphen (PSIC score difference of 2.65) and is associated with very mild renal disease in the proband's affected mother and grandmother, suggesting that it may function as a hypomorphic allele. MRI-based total kidney volume measurement is currently being performed to further delineate the genotype-phenotype correlation of all the affected members of this family. Our findings of bilineal ADPKD with a trans-heterozygous individual affected by mutations in both PKD1 and PKD2 have important implications for genetic counseling of the at-risk subjects (i.e. the risk of disease in the proband's siblings and her children is ¾ at birth). Moreover, our documentation of mild renal disease associated with a putative hypomrophic allele suggests that not all PKD1 needs to be associated with severe renal disease.

1087F

Autosomal dominant adult Neuronal Ceroid Lipofuscinosis (Kufs disease) maps to chromosome 20q13.33. *M. Cadieux-Dion[1], P. Lachance-Touchette[1], C. Meloche[1], S. Leonberg[2], F. Andermann[3], E. Andermann[3], S.F. Berkovic[4], G.A. Rouleau[1], P. Cossette[1].* 1) CHUM Research Centre, Notre-Dame Hospital, Excellence Centre For Neurosciences of the University of Montreal, Montreal, Quebec Canada; 2) Clinical Neurophysiology, Medford, New Jersey, USA; 3) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada; 4) Epilepsy Research Centre, Austin Health, Victoria, Australia.

The neuronal ceroid lipofuscinosis (NCL) are a group of devastating neurodegenerative disorders with infantile (INCL, Santavuori-Haltia), late-infantile (LINCL, Jansky-Bielschowsky), juvenile (JNCL, Batten disease, Spielmeyer-Vogt) and adult (Kufs disease) onset. The clinical manifestations of NCLs include recurrent seizures, myoclonus, intellectual deterioration, vision impairments and early death. Pathology of NCLs is characterized by abnormal lysosomal accumulation of autofluorescent lipopigment in the neurons, and sometimes in the eye. Mutations in 8 genes have been so far associated with the various forms of NCLs in Humans. It has been recently shown that mutations in CLN6 gene, causing late-infantile onset NCL, are also associated with recessive forms of adult-onset NCL (Kufs disease). Although Kufs disease with autosomal inheritance has been described earlier (CLN4), the causative gene remains to be identified.

Microsatellite genome scan allowed us to localize the CLN4 locus on chromosome 20q13.33 with a maximal LOD score of 5.3 at SNP rs11204451 in a large North American family. This family contains 18 affected individuals over 4 generations and shows an autosomal dominant mode of inheritance. Analysis of haplotypes revealed key recombinants and allowed us to determine a 4 MB candidate region containing at least 80 genes. Based on a priorisation list, multiple candidate genes have been sequenced but, to date, no causative mutations have been found.

We now aim to identify the CLN4 gene by using Next Generation Sequencing. We captured the exome of 3 affected individuals from this CLN4 family with *Agilent SureSelect All Exon 50 MB kit* and underwent whole-exome sequencing using *Illumina Hiseq* platform. These later analysis are underway.

In situ detection of Globotriaosylceramide by MALDI MS-imaging in mouse model of Fabry disease. *R. Dobrovolny[1, 2], M. Volny[3], H. Faltyskova[3], P. Novak[3], V. Havlicek[3], J. Ledvinova[2], B. Asfaw[2], H. Hulkova[2], M. Elleder[2], L. Kuchar[2], R.J. Desnick[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) First Faculty of Medicine of Charles University, Institute of Inherited Metabolic Disorders, Prague, Czech Republic; 3) Institute of Microbiology, Czech Academy of Sciences, Prague, Czech Republic.

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism caused by the deficient activity of lysosomal (-galactosidase A ((-Gal A) leading to the progressive accumulation of glycosphingolipids with terminal (-galactosyl residues. In patients with the classical phenotype, who have little or no enzymatic activity, the disease presents in the childhood and progresses to renal failure, cardiac involvement, cerebrovascular disease and early demise. A murine (-Gal A knock-out model has been generated which has no enzymatic activity and accumulates major glycosphingolipid, globotriaosyceramide (GL-3). To investigate the nature of GL-3 accumulation in the mouse model, MALDI MS-imaging (MSI) was used to investigate the spatial distribution of GL-3 in kidney tissue sections from wild-type and Fabry mice. In MALDI MSI, compounds are ionized directly from the tissue slice, which is attached on a conductive surface moving in set raster steps under a laser beam with resolution up to 50 μm. Sampling of the ions directly from the tissue into the mass spectrometer provides very rich mass spectra with respect to the number of ions, enabling simultaneous detection of different analytes during a single measurement. In the mice, MSI identified different GL-3 isotypes accumulated preferentially in the outer cortex of the kidney. The results of the MSI correlated well with the immunochemical detection with GL-3 specific antibodies in adjacent kidney sections. The murine results also were compared with available results from human normal and Fabry specimens. The results confirm the feasibility of the MSI method for the study of various lipidoses and glycolipidoses helping to elucidate the mechanisms underlying the accumulation of the substrates, even in cases where good quality antibodies are not available and when subcellular resolution is not needed.

1089F

Mucopolysaccharidosis type II: thirteen novel mutations in the IDS gene of the Czech and Slovak patients. *L. Dvorakova[1], G. Storkanova[1], M. Hrebicek[1], L. Stolnaya[1], H. Vlaskova[1], H. Poupetova[1], E. Hruba[1], M. Magner[2], J. Zeman[2].* 1) Inst Inherit Metabol Disorders, Charles Univ, First F Med, Prague 2, Czech Republic; 2) Dept of Paediatrics and Adolescent Medicine, Charles Univ, First F Med, Prague 2, Czech Republic.

Mucopolysaccharidosis type II (MPS II, Hunter syndrome) is a rare X-linked recessive lysosomal storage disorder caused by the deficiency of the enzyme iduronate sulfatase (IDS). The clinical diagnosis of MPS II was confirmed biochemically both by the demonstration of an increased excretion of urinary dermatan and heparan sulfates and by the deficiency of iduronate sulfatase activity in 30 patients from 25 Czech and Slovak families. In 20 probands the material for DNA analysis was available and a causative mutation was identified in all cases. In two patients the IDS-IDS2 recombination leading to altered transcript lacking exons 8 and 9 (Rec B) was found. The other mutations were family specific and included only five missense mutations, while the rest were clearly pathogenic mutations (3 nonsense mutations, 4 small and 2 gross deletions, 3 small insertions, and 1 splicing error). Thirteen pathogenic changes including two missense mutations located at amino acid positions 333 and 335, respectively, were not described previously. The genotype/phenotype correlation was not straightforward as an insertion leading to frameshift caused an attenuated as well as severe phenotype in two patients from the same family. Three patients with genotypes c.[1181-1G>A], c.[1038delC] and [RecB], respectively, receive the ERT. Samples from twelve mothers of probands were available, one de novo mutation was observed. A total of fourteen heterozygotes were identified in the families, all of them were asymptomatic. Peripheral blood cells were inspected for X-inactivation by HUMARA method in 11 heterozygotes. X-inactivation was skewed in one clinically asymptomatic heterozygote (80/20), in who the non-mutated allele was preferentially inactivated. X-inactivation of another clinically asymptomatic carrier with low IDS activity (11% of controls) was random. Thus, X-inactivation status did not correlate neither with the clinical nor the biochemical phenotypes in our cohort of carriers. Grant support: VZ MSMCR0021620806, MZ0VFN2005.

Fabry disease: identification and characterization of 12 novel alpha-galactosidase A mutations causing variable phenotypes. *D.P. Germain[1, 2], C. Boucly[3], E. Caudron[4], F. Jabbour[3], X. Jeunemaitre[5], N. Miri[3], M. Piraud[6], P. Prognon[4], G. Reboul[2], K. Benistan[2].* 1) Division of Medical Genetics, University of Versailles, Garches, France; 2) Expert Centre for Fabry disease, CHU Raymond Poincare, Garches, France; 3) Laboratory of Biochemistry, CHU Raymond Poincare, Garches, France; 4) Pharmacy, HEGP, Paris, France; 5) Department of Genetics, HEGP, Paris, France; 6) Laboratory of Biochemistry, HCL, Lyon, France.

Background: Fabry disease (FD, OMIM 301500) is an X-linked lysosomal storage disease resulting from mutations in the alpha-galactosidase A (GLA) gene. The disease is phenotypically highly heterogeneous with classic and variant phenotypes. Identification of the GLA mutation in families enables confirmation of carrier status in females, accurate genetic counselling, precise prenatal genetic testing, and study of genotype/phenotype correlations (1). **Patients and Methods**: The nature of the molecular lesions in the GLA gene was determined in 22 unrelated families with FD from France (n=18), Algeria (n=1), Bulgaria (n=1), Greece (n=1) and Morocco (n=1). Genomic DNA was isolated from leukocytes or dried blood spot (DBS) obtained from hemizgous males or heterozygous females and all coding regions and flanking sequences were PCR-amplified and analyzed by direct automated sequencing. Extensive clinical work-up was done prior to initiation of enzyme replacement therapy (ERT) or enzyme enhancement therapy (EET) together with measurement of alpha-gal A residual activity and determination of baseline urinary Gb3. **Results**: Twelve novel mutations were identified : p.M42R (c.125T>G), p.G43S (c.127G>A), p.G132E (c.395G>A), p.K168N (c.504A>C), p.I198T, (c.593T>C), p.Q212X (c.634C>T), IVS4 C(-3)>G, p.F295C (c.884T>G), p.L300P (c.899T>C), p.G328E (c.983G>A), p.G411D (c.1232G>C), and c.1086-1098 del13bp. Sequences obtained from DNA eluted from DBS in the PCR mix were of good quality. All novel mutations were private to one given family. For some mutations, enzyme activity was enhanceable in response to incubation of mutant cells with active site specific chaperone (1-deoxygalactonojirymicin). Clinical severity scoring, using the DS3 instrument (2), revealed variable phenotypes within the study population. **Discussion**: Our results further expand the spectrum of GLA mutations causing FD, allow precise heterozygote detection in families, help defining genotype/phenotype correlations and facilitate identification of candidate patients for clinical trials of enzyme enhancement therapy. **References**: 1) Germain DP. Fabry disease. Orph J Rare Dis 2010 ; 5 : 30. 2) Gianini et al. A validated disease severity scoring system for Fabry disease. Mol Genet Metab 2010; 99: 283-290.

1091F

Identification of 83 novel alpha-mannosidosis-associated sequence variants: Functional analysis of *MAN2B1* missense mutations. *H.M.F. Riise Stensland[1], H.B. Klenow[1], L.V. Nguyen[1], G.M. Hansen[2], D. Malm[3], O. Nilssen[1,4].* 1) 1Department of Medical Genetics, Division of Child and Adolescent Health, University Hospital of North-Norway, N-9038 Tromsø, Norway; 2) Department of Medical Biochemistry, Faculty of Medicine, University of Tromsø, N-9037 Tromsø, Norway; 3) Department of Internal Medicine, Division of Medicine, University Hospital of North-Norway, N-9038 Tromsø, Norway; 4) Department of Clinical Medicine-Medical Genetics, University of Tromsø, N-9037 Tromsø, Norway.

The lysosomal storage disorder alpha-mannosidosis is caused by deficiency of the enzyme lysosomal alpha-mannosidase (MAN2B1), a lysosomal enzyme involved in the ordered degradation of N-linked oligosaccharides. In this study, 130 unrelated alpha-mannosidosis patients from 30 countries, mainly of European origin, were subjected to mutation analysis. A total of 96 putative disease-causing mutations were identified, of these 13 had been reported previously. Hence, this study provides a new delineation of the mutational spectrum in alpha-mannosidosis, increasing the number of known disease causing mutations from 42 to 125. The 83 novel variants included 29 missense mutations, 24 smaller frameshifting mutations (duplications/insertions/deletions), 16 nonsense mutations, 10 splice site mutations, three larger deletions and one small in-frame insertion. In total, 256 of the 260 mutant alleles (98.5 %) were identified. Most of the mutations (81%) were unique to each family, further demonstrating the allelic heterogeneity of alpha-mannosidosis. However, one missense mutation, c.2248C>T (p.Arg750Trp), was detected in 50 patients from 16 countries, and accounted for 27.3 % of the disease alleles. Haplotype analysis of all reported patients with c.2248T-alleles using 3 intragenic *MAN2B1* cSNPs revealed that the c.2248T variant was present on four *MAN2B1* haplotype backgrounds, of which one major haplotype accounted for 95 % of the alleles. The distribution of the c.2248T associated haplotypes differed remarkably from those of the control populations, suggesting that the c.2248C>T has occurred on a few ancestral haplotype backgrounds where the major haplotype subsequently has spread by founder effects. In order to investigate their effect on the MAN2B1 protein, the putative disease-associated missense mutations and other selected variants were introduced into the human *MAN2B1* cDNA, expressed in cell-culture and assayed for MAN2B1 activity. The majority of the variants were inactive, however, ten of the putative disease-associated missense mutants showed MAN2B1 activity above background, and more detailed studies are necessary to further evaluate the pathogenicity of these variants.

1092F

Exome sequencing of trios identifies *de novo* mutations in novel candidate genes for permanent neonatal diabetes. *H. Lango Allen, R.C. Caswell, S.E. Flanagan, A.T. Hattersley, S. Ellard.* Molecular Genetics, Institute if Biomedical and Clinical Science, Peninsula College of Medicine and Dentistry, University of Exeter, Exeter, United Kingdom.

INTRODUCTION: Permanent neonatal diabetes mellitus (PNDM), defined as diabetes diagnosed before the age of 6 months, is most commonly caused by mutations in the K_{ATP} channel genes *KCNJ11* and *ABCC8* (40%), and the insulin gene *INS* (12%), with about 40% of PNDM patients still awaiting genetic diagnosis. We sequenced the exomes of eight PNDM patients negative for *KCNJ11*, *ABCC8* and *INS* mutations, and their unaffected, unrelated parents, to search for novel causes of isolated PNDM. By sequencing trios we expected to identify *de novo* pathogenic mutations, although we also looked for homozygous and compound heterozygous mutations. **METHODS AND RESULTS:** We performed 76bp paired-end single-lane sequencing of 8 trios on the Illumina GAII platform, using SureSelect Human All Exon Kit to capture 1.22% of human genomic regions corresponding to the CCDS exons. We aligned an average of 60 million reads to the whole human genome using BWA tool, and obtained 4-5 billion aligned bases per sample, of which ~70% were on-target. The mean target coverage was 55-70X; 83-90% of targeted bases were covered by at least 10 reads, 73-83% by at least 20 reads, and 62-70% by at least 30 reads. We used GATK pipeline, with local realignment around indels, recommended quality filters, and minimum coverage of 10 reads, to call 20-25,000 variants per individual, of which between 600 and 1000 were not present in dbSNP131. Using in-house MySQL queries we discovered up to 20 putative novel *de novo* missense mutations per patient. After manual inspection of parents' sequence alignment files for presence of poorly captured variants, and Sanger sequencing of those not detected in parents, each patient had zero or 1 (total 5) missense substitutions, and one had an 8bp deletion within a protein-coding region. Follow-up studies of these candidate genes are in progress within a larger PNDM cohort. We also identified several novel homozygous variants, though most of these are now present, at <1% frequency, in the latest 1000Genomes calls. Interestingly, in two patients, candidate gene sequencing identified causal mutations that were missed by exome sequencing - one in an exon with no or very little coverage, the other in an untargeted regulatory region. **CONCLUSIONS:** Exome sequencing of trios is a successful approach for identifying novel candidate genes for a monogenic disease, by looking for *de novo* mutations of major impact in patients with other common causes of the disease excluded.

1093F

Frequency of SPG48 in autosomal recessive and sporadic spastic paraplegia patients. *N.A. Schlipf[1], P. Bauer[1], S. Klimpe[3], K.N. Karle[2], M. Synofzik[2], J. Schicks[2], O. Riess[1], L. Schöls[2], R. Schüle[2].* 1) Department of Medical Genetics, Institute of Human Genetics, Tübingen, Baden-Württemberg, Germany; 2) Clinical Neurogenetics, Department of Neurology and Hertie-Institute for Clinical Brain Research and German Center of Neurodegenerative Diseases, University of Tübingen, Tübingen, Germany; 3) Department of Neurology, University of Mainz, Germany.

Hereditary spastic paraplegias (HSPs) are a rare and highly heterogeneous group of neurodegenerative disorders. The main neuropathological feature is the progressive degeneration of the corticospinal tracts, which leads clinically to a progressive lower limb spasticity and pyramidal weakness. The most frequent causes of autosomal recessive HSP (ARHSP) are mutations in the SPG11-gene. However, ARHSP families as well as sporadic cases negative for such mutations present a significant diagnostic challenge. Mutations in a gene implicated in DNA repair (*KIAA0415*) have been recently reported to be associated with spastic paraplegia type SPG48. Our objective was to determine the relative frequency of *SPG48/KIAA0415* mutations in a large cohort of 133 HSP patients, including sporadic and familial cases with evidence of recessive inheritance. We applied a targeted next-generation amplicon sequencing (NGS) approach to analyze all coding exons of the *SPG48/KIAA0415*-gene. The *SPG48* target regions were covered with an overall average coverage of 112-fold by this comprehensive molecular screening. Sequencing fragments which failed completely (5%, 133 out of 2261) or covered insufficiently (<10-fold) (12%, 279 out of 2261 fragments) were sequenced by Sanger sequencing. All sequence variants detected by NGS were validated by Sanger sequencing, too. Currently, after excluding known polymorphisms or silent mutations, 5 single nucleotide variants with uncertain or unlikely pathogenicity remained. Subject to future investigation will be a multiplex ligation dependent probe amplification assay (MLPA) targeting SPG48 to investigate copy number variations.

Cluster headache: exome capture of the elusive causal variants. *L. Southgate[1], S. Scollen[2], M.A. Simpson[1], R. McEwen[3], B. Zhang[4], W. He[4], M.E. Weale[1], T. Schlitt[1], L. Xi[4], C.L. Hyde[4], B. Dougherty[5], J.C. Stephens[4], M. Leone[6], C. Sjöstrand[7], M.B. Russell[8], S.L. John[4], R.C. Trembath[1].* 1) Department of Medical and Molecular Genetics, King's College London, Guy's Hospital, London, United Kingdom; 2) Pfizer, Neusentis, PTx Precision Medicine, Granta Park, Cambridge, United Kingdom; 3) Pfizer, Molecular Medicine, Ramsgate Road, Sandwich, Kent, United Kingdom; 4) Pfizer, PTx Precision Medicine, Eastern Point Road, Groton, CT; 5) Pfizer, Molecular Medicine, Eastern Point Road, Groton, CT; 6) Carlo Besta National Neurological Institute, Milan, Italy; 7) Department of Neurology, Karolinska University Hospital Huddinge, Stockholm, Sweden; 8) Department of Neurology, Research Centre, Akershus University Hospital, Oslo, Norway.

Cluster headache (CH) is regarded as the most severe of the primary headache syndromes, characterised by recurrent, relatively short-lived attacks of excruciating pain, often with regular periodicity. It is widely considered to be a neurovascular disorder with activation of hypothalamic, trigeminovascular and cranial parasympathetic systems. Recent estimates suggest a lifetime prevalence of about 0.1% and, whilst CH typically presents as a sporadic disorder, familial clustering supports autosomal dominant inheritance with reduced penetrance. We have previously reported a genome-wide linkage scan in a large cohort of Northern European families, which identified a number of putative linkage loci and provided substantial evidence for genetic heterogeneity. To advance our search for causative genes, we have undertaken exome sequencing in ten autosomal dominant CH pedigrees. Exome capture was performed for two affected subjects from each family using the Agilent SureSelect Target Enrichment System and sequenced on an Illumina Genome Analyzer IIx. Paired-end sequence reads were aligned to the reference genome and variants identified and annotated using an in-house data analysis pipeline. Under the assumption that novel rare variants underlie CH predisposition, variants were filtered against dbSNP, 1000 Genomes and >200 in-house controls to exclude known or common variation. By isolating identical novel heterozygous variants, shared between the two related affected subjects in each family, we identified 196 genes. Our previous linkage data enabled further prioritisation of putative candidates on a family-specific basis and we are currently completing the cosegregation analysis of these variants in the extended pedigrees. The power of exome sequencing to identify mutations in rare Mendelian disorders is now well-established; however, few data exist on the utility of this approach to unravel the genetic architecture in the context of locus heterogeneity or complexities such as incomplete penetrance and phenocopies. Our initial analyses are confounded by such complexities, as well as by the assumption that causative variation will be novel. Given the reduced penetrance and population prevalence of CH, alternative analysis models may be more appropriate. This study points to the need to develop larger data sets together with pathway based analysis, work presently ongoing, in order to further our understanding of the genetic basis of this debilitating disorder.

1095F

Comparison of functional prediction methods for nonsynonymous SNPs in exome sequencing-based study of Mendelian diseases. *P. Wei[1,3], X. Jian[2], E. Boerwinkle[1,2], X. Liu[1,2].* 1) Human Genetics Center, University of Texas School of Public Health, Houston, TX; 2) Division of Epidemiology, Human Genetics and Environmental Sciences, UTSPH, Houston, TX; 3) Division of Biostatistics, UTSPH, Houston, TX.

Next-generation sequencing (NGS) technologies have allowed for sequencing of the whole-exome of a large number of individuals, but it remains a considerable challenge to identify disease-causing variants from thousands of background polymorphisms. Functional prediction algorithms of nonsynonymous SNPs (nsSNPs) have shown to be promising in filtering for pathogenic mutations. While many prediction methods have been proposed, it is unclear which to use in practical applications. We performed a comparative study of nine functional prediction algorithms (LRT, MutationTaster, PANTHER, PhD-SNP, PMut, PolyPhen-2, SIFT, SNAP, and SNPs3D), three conservation scores (GREP, phastCons, and PhyloP), and an ensemble prediction method (weighted average of the normalized scores (WAS)). With a primary focus on exome sequencing-based studies of Mendelian diseases, we evaluated the predictive performance of different methods on two manually curated test sets of non-functional nsSNPs and deleterious ones that cause Mendelian disorders, taking advantage of the Uniprot database and data from the 1000 Genomes Project. MutationTaster's prediction score had the highest discriminative power with an area under the ROC curve (AUC) of 0.86, whereas PolyPhen-2's qualitative prediction had the highest sensitivity, ranging from 83% to 90% across test sets. We suggest, as a practical guideline, using PolyPhen-2 to filter for nsSNPs causing Mendelian diseases followed by MutationTaster to quantitatively prioritize functional nsSNPs. Our study also sheds light on the use of functional predictions in NGS-based association studies of complex traits, and provides novel insights into the value of conservation scores and ensemble-based prediction methods.

1096F

The complex function of FMR2P and its paralogs: insights into the molecular pathology of FRAXE intellectual disability. *B. Bardoni[1], M. Bensaid[1], D. Douguet[1], J. Gecz[2], M. Melko[1].* 1) Dept Human Genetics, CNRS UMR 6097, Valbonne, PACA, France; 2) SA Pathology (Women's and Children's Hospital), 72 King William Road, North Adelaide, SA 5006 Adelaide, AUSTRALIA.

FRAXE intellectual disability (ID) is a mild form of mental retardation. This disease is caused by the expansion of a CCG trinucleotide repeat in the 5' untranslated region of FMR2 (Fragile X Mental Retardation 2), resulting in its silencing. FMR2-null mice display impairment in conditioned fear and enhanced long-term potentiation, suggesting a role for FMR2 in regulating synaptic plasticity and memory formation. FMR2 (also called AFF2) belongs to the AFF (AF4/FMR2) family of genes including other 3 members AFF1, AFF3 and AFF4. While the role in transcription of AFF proteins was described shortly after their identification, more recently we have shown that FMR2P has properties of an RNA-binding protein, modulating alternative splicing via the binding to a G-quadruplex RNA, a structure that is known to behave as an exonic splicing enhancer. In particular, FMR2P modulates the alternative splicing of the exon 14 (expressing the Nuclear Export Signal) of the mRNA encoded by FMR1, the gene silenced in the Fragile X syndrome, another form of ID. When splicing is blocked, FMR2P is localized in the nucleolus, suggesting a role of this protein also in intranuclear transport of mRNA and/or mRNA maturation. We explored some functional properties of the AFF family (functional domains, intracellular localization, RNA-binding ability) triggered by the observation that AFF3 and AFF4, similarly to the AFF2/FMR2 protein, are localized in nuclear speckles and that their overexpression affects the dynamics and/or biogenesis of these structures. We showed that these proteins specifically bind the G-quadruplex RNA and modulate the splicing efficiency of a minigene reporter containing a G-quadruplex RNA in one alternatively spliced exon. We also obtained findings showing that AFF family members are involved in biogenesis/dynamics of nuclear speckles. In conclusion, we provided new evidence concerning the function of members of AFF family and new insight into the molecular pathology of FRAXE ID since our results suggest that a functional redundancy among AFF proteins can explain the mild nature of the cognitive impairment observed in FRAXE patients. In support of this hypothesis, increased expression of the AFF4 gene was identified in fibroblasts from FRAXE patients. By a two-hybrid screening in yeast we identified 3 new interacting proteins of FMR2P. We will present new data showing the ability of the partners of FMR2P to modulate its function.

Modeling Mental Retardation in Cornelia de Lange Syndrome (CdLS) with *Drosophila melanogaster*. *D. Xu[1], J. Li[2], W. Chen[3], A. Bell[4], N. Ferrick[4], T. Jongens[4], I. Krantz[5].* 1) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA; 3) Dept of Neuronscience, University of Pennsylvania School of Medicine, Philadelphia, PA; 4) Dept of Genetics, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) Dept of Pediatrics/Human Gen, Children's Hosp Philadelphia, Philadelphia, PA.

Cornelia de Lange Syndrome (CdLS) is a dominant genetically heterogeneous diagnosis characterized by a striking constellation of cognitive impairment, growth delay and birth defects. Approximately 65% of CdLS probands have an identifiable mutation in cohesin structural (*SMC1A*, *SMC3*) or regulatory (*NIPBL* and *HDAC8*) genes. We, and others, have described a non-canonical role of cohesin in regulating gene expression, that is most likely the mechanism by which it manifests its phenotypic effect in CdLS. Homozygous mutation of cohesin genes in *Drosophila* (and other organisms) is embryologically lethal, while heterozygous loss has minimal, if any, reported phenotypic effect. Homozygous mutation of cohesin genes or disruption of cohesin structure has been shown to cause failure of . -neuron pruning, a post-mitotic event, during *Drosophila* brain development. It remains unclear if loss of one copy of these cohesin genes, more closely representing the gene dosage in CdLS probands, also causes any structural or functional brain differences in *Drosophila*. We investigated brain development in heterozygous fly mutants of *SMC1*, *Rad21*, *Rpd3* (*Drosophila HDAC8* homologue) and *Nipped-B*. . -neuron pruning defects have been observed in ~30% of the heterozygous mutant pupae. This indicates that heterozygous cohesin mutations indeed affect normal fly brain development, although the effect is not fully penetrant. Although showing normal locomotor activity, these heterozygous flies do display irregular sleep pattern, especially during dark periods. These mutants present decreased total sleep time consisting of a larger number of short sleep episodes compared with wild type flies. Preliminary courtship assay demonstrates a deficit in learning and memory function in the heterozygous mutant flies. Ongoing genome-wide expression analysis of the brain of these mutant flies will provide molecular insight into the effects on gene regulation of haploinsufficiency for cohesin genes. These experiments will be very important in understanding the alterations of the transcriptome in the *Drosophila* brain and how that translates into the cognitive status resulting from haploinsufficiency. These studies will help to validate if the heterozygous cohesin mutant flies echo the cognitive phenotype seen in CdLS probands and can serve as a valuable model to study the neurocognitive aspects of CdLS.

Identification of novel mutations in Xanthina dehydragenase gene in an Azorean family affected with hypouricemia. *I. Foroni[1,2], A.R. Couto[1,2], J. Bruges-Armas[1,2].* 1) Serviço Especializado de Epidemiologia e Biologia Molecular, Hospital de Santo Espírito de Angra do Heroísmo, Canada do Barreiro 9700-856 Angra do Heroísmo, Azores, Portugal; 2) Institute for Molecular and Cell Biology, Universidade do Porto, Portugal.

Background. Uric acid is the end-product of purine metabolism. It is converted in xanthine by the activity of the Xanthine oxidase enzyme. A deficiency of the enzyme causes low level of uric acid and the consequent accumulation of xanthine in blood serum. The disease, called Xanthinuria, is a rare autosomal recessive disorder that leads to renal lithiasis and in some cases renal failure. It is caused by mutations in the Xanthina deydrogenase gene located on chromosome 2p22. Methods. We examined an entire family composed of ten persons aged between 32 and 73 years. The proband and three siblings were affected with renal lithiasis and abdominal pain. The serum level of creatine clearance, urate clearance, and uric acid were analyzed. Mutational analysis on XDH gene was performed in order to find single-nucleotide polymorphism which can be associated to the desease. Results. The proband and the siblings showed low uric acid and high urate clearance levels. Within the analyzed coding region of XDH gene, a novel G to C base substitution at position 859 bp in exon 10 was identified in the proband and in the three siblings. The point mutation caused a CTG (Leu) to GTG (Val) nonsense mutation at codon 287. The healthy individuals of the family showed normal biochemical values and no base change. Conclusion. In the present study a novel point mutation was identified at the exon 10 of the XDH gene. This is the first report which associates a nonsynonimous mutation with a possible case of Xanthinuria in an Azorean family.

Mutation analysis in OTCD patients with emphasis on detection of large deletions. *G. Storkanova[1], H. Vlaskova[1], L. Stolnaya[1], H. Treslova[1], V. Stranecky[1], M. Hrebicek[1], R. Mihalova[2], L. Dvorakova[1].* 1) Inst Inherit Metabol Disorders, Charles Univ, First F Med, Prague 2, Czech Republic; 2) Inst Biol Med Genetics, First F Med, Charles Univ and General Univ Hospital, Prague 2, Czech Republic.

Ornithine transcarbamylase deficiency (OTCD, OMIM 311250) is the most common inherited defect of the urea cycle. Working diagnosis of OTCD is usually based on clinical signs, biochemical markers (elevated ammonia and glutamine in plasma, elevated urinary excretion of orotic acid) and results of the allopurinol loading test in females. As enzymological proof of OTC deficiency requires tissue sample from invasive liver biopsy, the diagnosis is commonly confirmed by mutation analysis. To detect the causative mutations we used sequencing of the X-linked OTC gene and its transcript, MLPA and SNP array technology. We have detected 26 hemizygotes and 44 carriers from 26 families. The found mutations included three large and two small deletions, two splicing defects, three nonsense mutations, 11 missense mutations, and one mutation abolishing the natural stop codon. The largest identified deletion was 444 kb deletion. This deletion included the whole OTC gene, TSPAN7 gene (Xp11.4) and larger part of RPGR gene (Xp21.1). The heterozygosity for the deletion was found in the proband's mother by MLPA. We have also revealed 9937 bp deletion including part of intron 4, whole exon 5, intron 5, exon 6 and part of intron 6 and 1 bp insertion in OTC gene. We have identified 5 heterozygotes in proband's family and the knowledge of this mutation was used for a prenatal diagnosis. Although OTCD is considered X-linked recessive disease, significant number of heterozygous females is clinically affected. In our cohort 9 heterozygotes manifest clinical symptoms. One of them carries a 24536 bp deletion/3 bp insertion. The deletion boundaries were detected by MLPA assay, DNA array analysis and direct sequencing of long range PCR product. The data shown here in accordance with results published by others show that large deletions are common in the OTC gene and sequencing of coding region of the gene alone is often not sufficient. Support: VZ MSMCR0021620806, MZ0VFN2005.

1100F

GENE EXPRESSION PROFILE IN AUTOSOMAL RECESSIVE CUTIS LAXA, TYPE 2. *D.Z. Scherrer, C.V. Maurer-Morelli, J.F. Vasconcellos, C.S. Rocha, A.H.B. Matos, C.E. Steiner.* Medical Genetics, Unicamp , Campinas, São Paulo, Brazil.

Autosomal recessive cutis laxa, type 2 (ARCL2), is a rare disorder of connective tissue in which the skin sags excessively, giving to the individual an aged aspect. It has been suggested that ARCL2 is the same entity described under the denominations of wrinkly skin syndrome and gerodermia osteodysplastica. Such confusion is caused, in part, by overlapping of the histological and clinical findings, thus nosology remains uncertain until the definitive elucidation of the molecular basis of these conditions. So far, there are only three genes implicated in several forms of cutis laxa; ATP6V0A2, SCYL1BP1, and PYCR1, however, they cannot explain the complete phenotype of this patients. The main aims of this study were to determinate the gene expression profile in ARCL2 by using microarray investigation and identify genes and pathways, which are possible altered in such condition in order to shed some light into the molecular mechanisms underlying this type of cutis laxa. Because cutis laxa is a rare condition, we performed gene expression profiling in skin tissue from two patients with ARCL2. This study was performed using the Human Genome U133 Plus 2.0 array (Affymetrix™), and analyzed using Affy and RankProd packages from Bioconductor. Genes were considered differentially expressed when the statistical significance was $p<0.01$. The analyses of overrepresented gene ontology categories were performed with the DAVID software, and the gene interactions and correlation networks were identified with the Ingenuity Pathways Analysis software. Transcriptional profiling by microarray analysis from ARCL2 patients detected 750 differentially expressed genes compared to healthy controls. The top enriched gene ontology categories analyzed by DAVID included the differentiation and development of keratinocytes, epidermis and ectoderms. Among the most activated signaling pathways analyzed by Ingenuity software were cancer, connective tissue development and function, skeletal and muscular systems as well as lipid metabolism, which include genes as GPX3, CCL27, TIMP3, and ADIPOQ. This is the first study using microarray investigation in the ARCL2 disease. Our results provide a complete view of cellular pathways differentially expressed in such condition and look forward to contribute to a better understanding of molecular mechanisms of ARCL2.

Apoptosome independent caspase 9 activation underlies Microphthalmia with linear skin defects (MLS) syndrome. *A. Indrieri[1], I. Conte[1,2], G. Chesi[1], D. Ghezzi[3], J. Quartararo[4], I. Ferrero[4], R. Tate[2], P. Goffrini[4], M. Zeviani[3], P. Bovolenta[5], B. Franco[1,6].* 1) TIGEM, Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Institute of Genetics and Biophysics (IGB) Adriano Buzzati Traverso CNR, Naples, Italy; 3) Unit of Molecular Neurogenetics, Fondazione Istituto Neurologico Carlo Besta, Milan, Italy; 4) Department of Genetics, Microbiology, Anthropology and Evolution, University of Parma, Parma Italy; 5) Centro de Biología Molecular Severo Ochoa. CSIC-UAM, Universidad Autónoma de Madrid, Madrid. Spain; 6) Medical Genetics Services, Department of Pediatrics, Federico II University, Naples Italy.

Microphthalmia with linear skin defects (MLS) is an X-linked dominant male-lethal neuro-developmental disorder associated to mutations in the holocytochrome c-type synthetase (HCCS) transcript. Female patients display microphthalmia and linear skin defects, additional features include CNS malformation, mental retardation and cardiac defects. HCCS codifies a mitochondrial protein that catalyzes the attachment of heme to apo-Cytochrome (Cytc) c and c1. Defects in the yeast homologous heme lyases result in loss of respiratory growth. Cytc is released from mitochondria in response to a variety of intrinsic death-promoting stimuli leading to caspase-dependent cell death. We generated an animal model to study the molecular mechanisms underlying this rare genetic disease in the medaka fish (Oryzia latipes, ol). Consistent with a respiratory role we find Medaka olhccs mRNA to be highly expressed in the muscles, heart, CNS and in the eye where high mitochondrial activity is required. To analyze the olhccs function during development, three different morpholinos have been designed and injected resulting in a pathological phenotype, which resembles the human condition. As expected, morphants displayed a severe ocular phenotype with microphthalmia and coloboma associated with microcephaly and cardiac defects. Characterization of morphants revealed impairment of mitochondrial functions, overproduction of reactive oxygen species (ROS) and a strong increase of apoptosis in the CNS and in the eyes. This data confirm the role of HCCS in mitochondria and suggest that MLS should be considered a mitochondrial disease. Interestingly, our data showed an activation of mitochondrial dependent cell death triggered by activation of Caspase9 (Casp9) in a Bcl-dependent but apoptosome-independent manner suggesting that at least in some tissues apoptosis can occur in a non-canonical way. Casp9 activation relies on the formation of apoptosomes, composed of Cytc, Apaf1, and Casp9. Our data provide evidences for an Apaf1- and Cytc-independent Casp9 activation in vivo and suggest a possible tissue specificity for this event. Our model provides strong evidences that mitochondrial mediated apoptotic events may underlie microphtalmia providing new insights into the mechanisms of this developmental defect.

Successful strategy for rapid molecular diagnosis in complex I deficiency with custom target capture associated to next generation sequencing. *A.S. LEBRE[1], M. JAMBOU[1], M. RIO[1], P. DE LONLAY[1], N. BODDAERT[1], V. PROCACCIO[2], J.P. BONNEFONT[1], A. MUNNICH[1], A. RÖTIG[1], Z. ASSOULINE[1].* 1) Université Paris Descartes, AP-HP Hôpital Necker-Enfants Malades et Inserm U781 et U797, Départements de Génétique, Radiologie pédiatrique, Neurologie pédiatrique et des Maladies du développement, Paris F-75015 France; 2) Department of Biochemistry and Genetics and UMR INSERM, U771-CNRS6214, Angers University Hospital, Angers, France.

Leigh Syndrome (LS) is a rare disorder characterized by degeneration of the central nervous system. LS has been associated with mutations in the mitochondrial DNA (mtDNA) as well as with numerous nuclear genes, highlighting the extreme genetic heterogeneity of the disease. A molecular diagnosis is still missing for a large majority of LS patients. The need of a good patient characterization and the large number of candidate genes in LS remains a great challenge for molecular diagnosis. Our goal was i) to better characterize the LS patients; ii) to use a high throughput approach for sequencing and identification of causative mutations. This study was focused on LS patients with complex I deficiency. The patient selection was based on criteria including i) a common pattern of brain MRI imaging; ii) isolated complex I deficiency in muscle; iii) mtDNA involvement excluded; iv) complex I assembly defect identified on patient skin fibroblasts with BN-PAGE analysis. A targeted resequencing assay including complex I genes was designed relying on custom target capture (SureSelect, Agilent) coupled to next-generation sequencing. Specifically, we captured the entire sequence of 87 known as causative or candidate genes in LS and re-sequenced them on Illumina GaII platform. A total of 8 LS patients with complex I deficiency were selected including a positive control. Over 99.5% of the targeted regions were captured and sequenced with appropriate coverage and quality. The depth of sequencing coverage was extremely high (mean x103). Filtering of novel variants was performed by comparison to dbSNP130, in-house database (composed of 32 exomes) and 8 HapMap exomes. Of the variants recognized, 1 to 9 % represented new alterations and only one candidate gene was identified in 7/8 patients. All pathogenic mutations identified were confirmed by Sanger sequencing. Of the seven new patients analyzed, one known mutation in *NDUFS4* gene and nine new mutations in *NDUFV1, NDUFA11, C8ORF38* and *NUBPL* genes were identified. This report demonstrates the power of our strategy for rapid molecular screening in complex I deficiency. This study indicates that the use of next generation sequencing technology holds great promise as a tool for molecular diagnosis of LS. Compared to the full exome sequencing, this approach has the potential to generate fewer variants and to rapidly focus on mutations in strong candidate genes in well characterized patients.

1103F

Exome sequencing for unraveling the molecular basis of complex I deficiency. *H. Prokisch[1,2], T. Haack[1,2], K. Danhauser[2], B. Haberberger[1,2], P. Freisinger[3], S. Eck[1], M. Zeviani[4], TM. Strom[1,2], T. Meitinger[1,2].* 1) HelmholtzZentrum Munchen, Inst fur Humangenetik, Neuherberg, Germany; 2) Technical University Munich, Institute of Human Genetics, Munich, Germany; 3) Klinikum am Steinenberg, Reutlingen, Germany; 4) The Foundation `Carlo Besta' Institute of Neurology, Milan, Italy.

Faulty energy supply due to defective oxidative phosphorylation is the biochemical signature of the genetically heterogeneous group of mitochondrial disorders. The molecular basis of the disorder remains unknown for a majority of patients and there is an urgent need for new diagnostic and therapeutic strategies. We applied exome sequencing (50 Mb capture, 100x coverage) in a group (n=15) of unrelated patients with isolated mitochondrial respiratory chain complex I deficiency to screen for pathogenic mutations. In a first step we analyzed known structural subunits and assembly factors of complex I and identified pathogenic mutations in five patients. In a second step we searched for two mutated alleles in genes coding for mitochondrial proteins and identified the potential pathogenic mutation in two patients. Next we screened for two loss of function alleles in any gene and identified one novel gene involved in complex I activity. In the remaining 6 patients, none of the above filters led to the identification of a pathogenic mutation. We established a lentiviral based complementation assay to validate the pathogenic role of novel variants in fibroblasts of patients. Complementation testing and mutation screening for the novel genes in 150 additional index patients is ongoing. In conclusion, exome sequencing in combination with functional assaying provides both an effective tool for molecular diagnosis and for discovery of new genes mutated in patients with complex I deficiency.

1104F

Defective NDUFA9 as a novel cause of neonatally fatal complex I disease. *B.J.C. van den Bosch[1,2], M. Gerards[1,2], W. Sluiter[3], A.P.A. Stegmann[1], E.L.C. Jongen[1], D.M.E.I. Hellebrekers[1], E.H. Lambrichs[2], H. Prokisch[4,5], K. Danhauser[4,5], K. Schoonderwoerd[6], I.F.M. de Coo[7], H.J.M. Smeets[1,2].* 1) Unit Clinical Genomics, Department of Clinical Genetics, Maastricht University, Maastricht, Netherlands; 2) School for Oncology and Developmental Biology, Maastricht University Medical Centre, Maastricht, The Netherlands; 3) Centre for Lysosomal and Metabolic Diseases, Erasmus MC, Rotterdam, The Netherlands; 4) Institute of Human Genetics, Technische Universität München, Munich, Germany; 5) Institute of Human Genetics, Helmholtz Zentrum München, German Research Centre for Environmental Health, Neuherberg, Germany; 6) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 7) Department of Neurology, Erasmus MC, Rotterdam, The Netherlands.

Mitochondrial disorders are associated with abnormalities of the oxidative phosphorylation (OXPHOS) system and cause significant morbidity and mortality in the population. The extensive clinical and genetic heterogeneity of these disorders due to a broad variety of mutations in either the mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) impedes a straightforward genetic diagnosis. Several approaches exist to identify the underlying gene defect, such as (large scale) screening of candidate genes, linkage analysis, homozygosity mapping and/or whole exome/genome sequencing. Here we present a single Kurdisch patient from consanguineous parents with neonatally fatal Leigh syndrome and complex I deficiency in which the gene defect was identified by homozygosity mapping and subsequent positional candidate gene analysis of complex I genes. A pathogenic mutation was identified in the complex I subunit encoding NDUFA9 gene, changing a highly conserved arginine at position 321 by proline, which is the first mutation reported for NDUFA9. Complex I activity was restored in fibroblasts of the patient by lentiviral transduction with wild type but not mutant NDUFA9, confirming that the mutation causes the complex I deficiency and related disease. Our data shows that homozygosity mapping and candidate gene analysis is still an efficient way to detect mutations in (single) consanguineous patients with OXPHOS deficiency, especially when the enzyme deficiency in fibroblasts allows appropriate candidate gene selection and functional complementation.

1105F

Zebrafish model of Poikiloderma with Neutropenia Syndrome: towards the function of the causative *C16orf57* gene. *E.A. Colombo[1], S. Carra[2], E. Bresciani[2], L. Volpi[3], F. Cotelli[2], L. Larizza[1].* 1) Dip. Medicina, Chirurgia e Odontoiatria, Università degli Studi di Milano, via A. di Rudinì 8, Milano, Italy; 2) Dip. di Biologia, Università degli Studi di Milano, via Celoria 26, Milano, Italy; 3) Dip. Biologia e Genetica per le Scienze Mediche , Università degli Studi di Milano, via Viotti 3/5, Milano, Italy.

Poikiloderma with Neutropenia (PN; OMIM #604173) is a rare autosomic recessive genodermatosis characterized by poikiloderma, telangiectasia, hyperkeratosis and pachyonychia, and by the hematological sign of neutropenia, which accounts for recurrent infections in the pediatric age and susceptibility to myelodysplastic syndrome at later stages. Other symptoms include short stature, osteoporosis, osteopetrosis and fragile carious teeth. A few PN patients display craniofacial dysmorphisms, mainly midface hypoplasia, depressed nasal bridge and mild prognathism. *C16orf57* has been shown to be the causative gene of PN, and eighteen inactivating mutations have been detected so far in forty PN patients. However, little is known about this gene and the function of its encoded protein. As *C16orf57* is highly conserved from plants to humans, we decided to employ zebrafish (*Danio rerio*), an ideal vertebrate model for the study of human developmental genetic diseases and haematological malignancies, to gain insights into the C16orf57 function and the consequences of its disruption. The human *C16orf57* gene has a unique ortholog in zebrafish (zc16orf57), with a high degree of conservation both in the intron-exon structure and in aminoacid sequence (73,4% similarity and 46% identity). Time course RT-PCR analysis on cDNA from 2-4 cell cleavage stage up to the swimming larva (3 dpf) showed zc16orf57 transcripts in all analyzed stages, consistent with the parallel widespread expression of the gene tested by whole-mount in situ hybridization assay. Moreover zc16orf57 was detected by RT-PCR in various tissues of adult zebrafish (brain, eye, gills, heart, liver, muscle, ovary and testis) in agreement with its ubiquitous expression in humans. To directly assess the function of zc16orf57 during development we performed loss-of-function experiments injecting specific antisense, morpholino-modified oligomers. Injection of the splice-morpholino in embryos at one cell stage induces an abnormal severe phenotype that partially recapitulate the PN defects. The morphants show: a decreased skin pigmentation, reduction or lack of blood circulation, a small head with defects in early cartilages of pharyngeal arches, as highlighted by Alcian blue staining, and edema in the pericardial area that expands to the whole embryo.

1106F

Selenoprotein N deficiency in mice is associated with lung emphysema. *B. Moghadaszadeh[1], B.E. Rider[1], M.W. Lawlor[1], C.A. Owen[2], A.H. Beggs[1].* 1) Division of Genetics and Program in Genomics, The Manton Center for Orphan Disease Research, Children's Hospital Boston, Harvard Medical School, Boston, MA, USA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA.

Mutations of the selenoprotein N gene, SEPN1, cause multiminicore myopathy, a rare congenital myopathy characterized by muscle weakness, spinal rigidity and respiratory insufficiency. Patients' muscle biopsies are characterized by the presence of minicores that are indicative of areas of mitochondria depletion and myofibrillar disruption. As with other members of the selenoprotein family, selenoprotein N incorporates selenium in the form of selenocysteine (Sec). Most selenoproteins that have been functionally characterized are involved in redox reactions, with the Sec residue being located at the catalytic site of the protein. To model multimincore myopathy and learn more about selenoprotein N function, we generated a Sepn1-knock-out (KO) mouse line in which exon 9, which carries the Sec codon, has been deleted. Homozygous Sepn1-KO mice are fertile and their weight and lifespan are comparable to wildtype (WT) animals. Furthermore, muscle histology of these mice under baseline conditions appears normal. Since the Sepn1-KO mice presented no apparent phenotype under normal conditions, and we anticipated SEPN1 to be involved in redox reactions, we fostered oxidative stress in these animals by feeding them a vitamin-E deficient diet for 8 months and subjecting them to an endurance running program for 5 days prior to sacrifice. Under these conditions both WT and Sepn1-KO mice developed minicores in their muscles, and while not statistically significant, the number of minicores was slightly higher in KO animals. We also investigated the spontaneous activity of these mice by quantifying the number of rearings and distance traveled in 10 minutes and found that Sepn1-KO mice were less active than the WT. This difference was more pronounced when animals were subjected to oxidative stress. Selenoprotein N deficiency in humans is associated with a respiratory insufficiency syndrome, which so far has been thought to be caused primarily by diaphragm weakness. Remarkably, Sepn1-KO mice presented enlarged alveoli, compatible with development of emphysema beginning as early as 4 weeks of life and progressing with age. Interestingly this pulmonary phenotype is present in KO mice under normal conditions in the absence of oxidative stress induction. Our findings in mouse lungs suggest that selenoprotein N deficiency directly affects lung function, which may have a potential impact on management of respiratory insufficiency in patients with multiminicore myopathy.

Update on the roles and functions of OPA1 in mitochondria: a never ending story? *P. Amati-Bonneau[1,2,7], V. Procaccio[1,2,7], G. Lenaers[3,7], C. Hamel[3,7], V. Carelli[4,7], A. Martinuzzi[4,7], B. Wissinger[5,7], D. Milea[1,2,6,7], M. Ferré[1,2,7], A. Chevrollier[1,2,7], V. Desquiret-Dumas[1,2,7], N. Gueguen[1,2,7], P. Reynier[1,2,7], D. Bonneau[1,2,7].* 1) Departement of Biochemistry & Genetics, CHU Angers, Angers, France; 2) UMR INSERM U771-CNRS6214, Angers, France; 3) INSERM U583, Institute for Neurosciences of Montpellier, Montpellier,France; 4) Departement of Neurological Sciences, University of Bologna, Bologna, Italy; 5) Molecular Genetics Laboratory, Institutefor Ophthalmic Research, University Clinics Tuebingen, Tuebingen, Germany; 6) Departement of Ophthalmology, CHU Angers, Angers France; 7) ERMIO-N:European Research Project on Mendelian Inherited Optic Neuropathies.

Inherited optic neuropathies are one of the most common causes of vision loss in childhood and early adulthood. Mutations in the mitochondrial fusion protein OPA1 cause autosomal dominant optic atrophy (ADOA). The OPA1 gene encodes a mitochondrial dynamin-related GTPase, located to the mitochondrial inner membrane. Originally, OPA1 has been shown to play a key role in mitochondrial fusion and mitochondrial network organization. As of today, our laboratory in Angers has identified more than 230 OPA1 mutations (refer to our website: http://lbbma.univ-angers.fr/eOPA1) in a large cohort of 1500 patients. The large majority of OPA1 mutations result in protein truncation suggesting that haploinsufficiency could be the prime pathomechanism. However, a dominant-negative effect of mutated OPA1 could also play a role as seen with the R445H mutation consistently resulting in severe optic atrophy associated with hearing loss. The pathophysiology of OPA1-related diseases is still largely unknown. A primary degeneration of retinal ganglion cells (RGC) has been hypothesized but the mechanisms leading to this degeneration require further investigations. Other OPA1 functions have been recently identified, related to oxidative phosphorylation and maintenance of membrane potential, maintenance of mtDNA, and cristae organization and control of mitochondrial apoptosis through the compartmentalization of cytochrome c. Biochemical investigations of patient fibroblasts carrying OPA1 mutations have revealed a common OXPHOS coupling defect together with a reduction of the mitochondrial membrane potential. Alterations of the mitochondrial network have been observed in patient fibroblasts bearing OPA1 mutations. The severity of the mitochondrial network fragmentation seems to be well correlated with the most severely affected patients suggesting a link between OXPHOS impairment and mitochondrial alterations. Finally, significant mtDNA alterations have been reported in OPA1 patients as a strong indicator of the role of OPA1 in mtDNA maintenance. Recently, mouse models carrying OPA1 mutations have been generated exhibiting pathological features similar to ADOA including a progressive RGCs and optic nerve axon degeneration. This model should substantially help us to clarify the genetics and pathophysiology of OPA1 related disorders and useful to evaluate candidate therapeutic strategies.

1108F

Identification and functional analysis of SOX10 missense mutations in different types of Waardenburg syndrome. *A. Chaoui[1,2], Y. Watanabe[1,2], R. Touraine[3], V. Baral[1,2], M. Goossens[1,2,4], V. Pingault[1,2,4], N. Bondurand[1,2].* 1) INSERM U955, Creteil, France; 2) Université Paris-Est, Faculté de Médecine, Créteil, France; 3) CHU-Hôpital Nord, Service de Génétique, Saint Etienne, France; 4) AP-HP, Groupe Hospitalier Henri-Mondor, Service de Biochimie et Génétique, Créteil, France.

Waardenburg syndrome (WS) is an auditory-pigmentary disorder that exhibits varying combinations of sensorineural hearing loss and pigmentation defects. Four subtypes are clinically defined based on the presence or absence of additional symptoms. In particular, the absence of additional features characterizes WS2, whereas the association with Hirschsprung disease defines WS4. WS is genetically heterogeneous with six genes already involved, including SOX10. Since 1998, about 50 heterozygous mutations or deletions of this gene have been described in patients presenting with WS2 or WS4, with or without myelination defects of the peripheral and central nervous system (PCWH). The mutations characterized so far are mostly truncating mutations, removing part of the protein. Only 3 missense mutations were described. Here, we report the identification of new SOX10 missense mutations in 11 patients, associated with a variety of phenotypes ranging from WS2 to PCWH, and describe the functional consequences of each of these mutations on the main SOX10 characteristics and functions. Altogether, our functional assays highlight deleterious effects of all the mutations tested. Some mutants present with partial cytoplasmic and/or subnuclear redistribution, some lose their DNA binding and/or their transactivation capacities on various tissue specific target genes. Intriguingly, several mutants were redistributed in nuclear foci. To our knowledge, such redistribution was not described so far during functional studies of patients' mutations identified in other SOX genes. Whether it is a cause or a consequence of the mutant pathogenicity remains to determine, but it could help identify new SOX10 function and mode of action.

1109F

Characteristics of hepatic proteome expressions in Wilson disease. *B.H. Lee[1,2,3], J.M. Kim[2,3], S.H. Heo[2], J. Kim[4], J.H. Kim[2], G.H. Kim[1,2], J.H. Choi[1], H.W. Yoo[1,2,3].* 1) Pediatrics, Asan Med Ctr, Seoul, Korea; 2) Genome Research Center for Birth Defects and Genetic Disorders, Asan Med Ctr, Seoul, Korea; 3) Medical Genetics Center, Asan Med Ctr, Seoul, Korea; 4) Department of Pathology, Asan Med Ctr, Seoul, Korea.

Wilson's disease (WD) is an autosomal recessive disorder caused by a deficiency of the P-type copper-transporting ATPase (ATP7B). The most pathognomic feature of WD is copper accumulation, starting in hepatic tissue and progressing to extrahepatic tissues including the brain, which induce oxidative injury and pro-apoptotic conditions. Using Long-Evans Cinnamon (LEC) rats, an animal model of WD, the study was undertaken to identify proteins involved in the process of WD and to investigate their functional roles in copper-induced hepatotoxicity. LEC rats and LEA (Long-Evans Agouti) rats, a non-diseased LEC rats, aged 6, 12 and 24 weeks (3 each per group) were used. Their clinical and histopathological features were compared. Their protein profiles were comparatively analyzed using 2-DE and MALDI-TOF-MS, and validated by immunoblotting. In early stages, mitochondrial matrix proteins including agmatinase, isovaleryl coenzyme A dehydrogenase, and cytochrome b5 were down-regulated. As mitochondrial injuries progressed, along with subsequent apoptotic processes, expressions of malate dehydrogenase 1, annexin A5, transferrin, S-adenosylhomocysteine hydrolase, and sulfite oxidase 1 were differentially regulated. Notably, the expression of malate dehydrogenase 1 was down regulated while the annexin A5 was over-expressed in an age-dependent manner, indicating that these proteins may be involved in the WD process. In addition, pronounced under-expression of S-adenosylhomocysteine hydrolase in elderly LEC rats, also involved in monoamine neurotransmitter metabolism, indicates that this protein might be related to the development of neurological manifestations in WD. The results of our study help to understand the pathogenic process of WD in hepatic tissues, identifying the important proteins associated with the disease process of WD, and to investigate the molecular pathogenic process underlying the development of neurological manifestations in WD. Further investigations are needed whether the similar differential expression patterns of these proteins are also noted in other easily-accessible tissues, blood or urine, in WD patients with the demonstration of their disease-specific expressions, which will ultimately help to utilize them as potential biomarkers for the prediction of WD progression.

HRAS mutants identified in Costello syndrome patients have the ability to induce cellular senescence: possible association with the pathogenesis of Costello syndrome. *T. NIIHORI[1], Y. AOKI[1], N. Costello syndrome (CS) is characterized by a distinctive facial appearance, failure to thrive, mental retardation and cardiomyopathy. In 2005, we discovered that heterozygous germline mutations in HRAS caused CS. Several studies have shown that mutations causing CS are clustered in codons 12 and 13, and mutations in other codons have also been identified. The functional profiling of HRAS mutations causing CS remains to be elucidated. In the current study, we identified G12S, G12A, G12C and G12D mutations in 21 patients and analyzed the clinical manifestations in these patients. To examine the functional difference among the mutations identified in CS, we characterized a total of nine HRAS mutants, including seven mutants in codon 12 or 13, K117R and A146T. The A146T mutant demonstrated the weakest Raf-binding activity, and the K117R and A146T mutants had weaker effects on downstream JNK signaling than mutants in codon 12 or 13. We demonstrated that HRAS mutants had the ability to induce senescence when overexpressed in human fibroblasts. Oncogene induced senescence is a cellular reaction that controls cell proliferation and is driven by oncogenic mutation, and it has been considered one of the tumor suppression mechanisms in vivo. Our findings suggest that the HRAS mutations identified in CS are sufficient to cause oncogene induced senescence and cellular senescence might contribute to pathogenesis of CS.

1111F

BMP2-Smad-Runx2 overexpression provides evidence for the involvement of a pro-osteogenic signalling pathway in pseudoxanthoma elasticum. *O. Vanakker[1], M. Hosen[1], P. Coucke[1], O. Le Saux[2], A. De Paepe[1].* 1) Center for Medical Genetics, Ghent Univiversity Hospital, Ghent, Belgium; 2) Department of Cell and Molecular Biology, John A. Burns School of Medicine, University of Hawai'i.

Aims. Pseudoxanthoma elasticum (PXE) is characterized by oculocutaneous and cardiovascular manifestations, due to mineralization and fragmentation of elastic fibers. The causal ABCC6 gene encodes a transmembrane transporter; however, the pathogenetic link with the elastic fiber abnormalities remains unknown. Current pathophysiological hypotheses include a role for oxidative stress and an unidentified PXE serum factor. We have previously shown that PXE patients have a diminished vitamin K (VK) serum concentration, leading to inefficient .-carboxylation or activation of VK-dependent inhibitors of mineralization, such as matrix gla protein (MGP). MGP is known to inhibit Bone Morphogenetic Protein 2 (BMP2), a master regulator of osteogenesis. Several pathways are associated with BMP2, one of which is the BMP2-Smad-RUNX2 pathway in which RUNX2 acts as a transcriptional regulator of proteins involved in mineralization or osteogenesis. We aimed to study the role of this signalling pathway in the PXE pathogenesis. **Methods & Results.** Alizarin red calcium stains were performed to detect mineralization around the whiskers of ABCC6 knockout mice and human PXE dermis. Immunohistochemical stains on calcium-positive adjacent slides for BMP2, Smad 1-4-5-8 and RUNX2 showed positive labeling, co-localizing with mineralization, in all tissues compared to controls. These qualitative results were quantitatively confirmed via qPCR on human PXE fibroblasts. Comparable qPCR results were obtained on control fibroblasts inoculated with human PXE serum. **Discussion & Conclusion.** Our results indicate the involvement of the pro-osteogenic cellular BMP2-Smad-RUNX2 pathway in PXE. Calcification-specific upregulation of RUNX2 provides a pathophysiological mechanism for the up- or downregulation of proteins previously implicated in PXE (such as osteocalcin, alkaline phosphatase, osteopontin, bone sialoprotein and VEGF-A), leading to ectopic mineralization or neovascularisation. In addition, our results for the first time merge three principal pathophysiological observations in PXE. Indeed, besides VK-deficiency also oxidative stress has been shown to contribute to RUNX2 overexpression and we show a similar effect of PXE serum on RUNX2 expression. Thus, our results provide evidence that vitamin K deficiency, oxidative stress as well as the PXE serum factor co-operate in an integrated pathophysiological process leading to ectopic mineralization in PXE.

Cohesin complex regulator ESCO2 and Replisome Progression complex Timeless and TIPIN constitute a complex that links establishment of sister chromatid cohesion and the replication stress checkpoint. *H. Vega[1,2], M. Gordillo[2,3], N. Sakai[4], HS. Rho[5,6], J. Boeke[5,7], H. Zhu[5,6,7,8], K. Inui[4], K. Ozono[4], EW. Jabs[2].* 1) Molecular Biology, Cell Biology, and Biochemistry, Brown University, Providence, RI; 2) Department of Genetic and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 3) Department of Surgery, Cornell University, New York, NY; 4) Department of Pediatrics, Osaka University, Osaka, Japan; 5) The Center for High-Throughput Biology, Johns Hopkins University, Baltimore, MD; 6) Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, MD; 7) Department of Pharmacology and Molecular Sciences, Johns Hopkins University, Baltimore, MD; 8) The Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins University, Baltimore, MD.

ESCO2 mutations cause Roberts syndrome (RBS). ESCO2 is member of the Eco1 family of acetyltransferases that is central to the establishment of sister chromatid cohesion, a process intimately linked to the passage of the replisome. Eco1 is aided during cohesion establishment by a number of non-essential factors associated to the replisome. However, little is known about how the replisome and the cohesion factors affect each other. Using a human protein chip we found that ESCO2 and ESCO1 physically interact with the replication stress checkpoint proteins Timeless and TIPIN members of the replisome progression complex. ESCO2 exist in two different complexes in the replisome, one with Timeless and other with PCNA. Timeless and PCNA siRNA depletion indicates that the Timeless-ESCO2 complex plays a more important role in sister chromatid cohesion than the PCNA-ESCO2 complex. RBS cells, deficient in ESCO2 activity showed increased spontaneous chromosome fragilities, reduced proportion of cells in the S phase without reduction in BrdU incorporation and faster progression through S phase. Under replication stress conditions RBS cells showed hypersensitivity to hydroxyurea, reduced levels of Timeless, abnormal electrophoretic mobility of TIPIN, deficient phosphorylation of Chk1 and histone H2AX, impair .H2AX, MDC1 and MRE11 foci formation while ATR foci are efficiently formed. Our results demonstrate a new role for ESCO2 in signal transduction and unravel a link between sister chromatid cohesion and the replication stress checkpoint.

1113F

Severe myopathy due to cofilin-2 deficiency in a knockout mouse model. *P.B. Agrawal[1,2], T. Savic[1], Z. Chen[1], M. Joshi[1], A.H. Beggs[1,2].* 1) Dept. of Medicine, The Manton Center for Orphan Disease Research, Program in Genomics, Children's Hospital Boston, Boston, MA; 2) Harvard Medical School, Boston, MA.

Background: Congenital myopathies (CMs) are rare, genetic skeletal muscle disorders that present with muscle weakness, delayed motor milestones, feeding/breathing difficulties. We have identified cofilin-2 (CFL2) to be the sixth gene mutated in nemaline myopathy, the most common CM. Cofilin-2 belongs to the AC family of actin-binding proteins that include cofilin-1 and destrin. The role of cofilin-2 in muscle development and thin filament dynamics is unknown. Objective: To create a cofilin-2 conditional knockout (KO) mouse model (COFI). To breed the COFI mice with various cre-recombinase expressing mice to create constitutive and striated muscle-specific Cfl2-KOs and to evaluate the KO phenotype. Design/Methods: COFI mice were created and bred with various cre-mice including those expressing it in zona pellucida (Zp3-cre) for a constitutive KO, cardiac and skeletal muscles-specific (Acta1-cre, Ckmm-cre with postnatal cre expression) and skeletal muscle-specific (Mef2c-cre). Results: Loss of cofilin-2 was associated with severe myopathy in the KO mice. The Cfl2-KO mice died by day 8 (constitutive KO, Cofi/Cofi:Acta1-cre/+, Cofi/Cofi:Mef2c-cre/+) and day 31 (Cofi/Cofi:Ckmm-cre/+) after birth. KO animals were significantly smaller in both length and weight compared to their wild type (WT) siblings. Their muscles demonstrated extensive areas of degeneration on H&E and NADH staining. On ATPase staining, slow fibers were significantly increased in the KO mice. On qRT-PCR, slow-fiber specific gene transcripts were significantly higher and fast-fiber specific gene transcripts lower in the KO mice compared to WT. Electron microscopy showed myofibers with minicores, nemaline bodies, absent Z lines, disrupted sarcomeres and actin accumulations. Immunofluorescence using phalloidin and anti-actin antibody showed actin accumulations in several fibers. Increased amounts of actin and alpha-actinin-2 were present in the KO mice compared to control on the Western blot analysis. Further, the skeletal muscle did not show any defects in the KO fetuses (E18.5) suggesting that cofilin-2 plays a critical role in muscle maintenance, but not in myofibrillogenesis. Conclusions: Cofilin-2 deficiency in mice causes severe myopathy and markedly reduced life span, and is associated with myofiber degeneration, nemaline bodies, cores and actin accumulations. Cofilin-2 is critical for the muscle maintenance.

1114F

Anoctamin 5 (ANO5) skeletal muscle subcellular localization is preserved in a LGMD2L patient carrying a splicing mutation. *V. Bolduc[1], T.C. Conte[1], R. Larivière[1], K.M. Boycott[2], H. Inoue[3], M. Itakura[3], Y. Robitaille[4], N. Leblanc[5], E. O'Ferrall[6], B. Brais[1,6].* 1) Laboratoire de neurogénétique, Centre de Recherche du CHUM, Montreal, Que, Canada; 2) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ont, Canada; 3) Institute for Genome Research, The University of Tokushima, Tokushima, Japan; 4) CHU Ste-Justine, Montreal, Que, Canada; 5) Department of Pharmacology, University of Nevada, School of Medicine, Reno, NV, USA; 6) Department of Neurology and Neurosurgery, McGill University, Montreal Neurological Institute, Montreal, Que, Canada.

Recessive mutations in Anoctamin 5 (*ANO5*) were recently found to cause a limb-girdle muscular dystrophy type 2L (LGMD2L; MIM 611307). LGMD2L is characterized by late-onset progressive weakness of proximal limb muscles with prominent quadriceps atrophy and high serum creatine kinase levels. A total of 16 published and unpublished ANO5 mutations were uncovered to date, consisting of 8 missense, 2 nonsense, 2 splice site mutations, 1 single base pair duplication, and 3 indels. ANO5's function and localization in muscle is still unknown, but Ano1 and Ano2 function as calcium-activated chloride channel (CaCC) in other tissues. Our immunofluorescence data support that ANO5 localizes to intracellular membranes in a striated pattern in close proximity to Z-disks, with a partial co-localization with SERCA1 (a sarcoplasmic reticulum marker) and OPA1 (a mitochondrial marker). On a LGMD2L muscle section from a patient homozygous for a splice site mutation, we could observe preservation of the striated ANO5 signal, despite that this mutation was previously demonstrated to trigger the degradation of transcripts via the nonsense-mediated mRNA decay pathway. *ANO5* transcripts analyses from this LGMD2L patient using TA-cloning revealed that alternative splicing events occur, and that the coding frame is restored in a proportion of the transcripts. This result suggests that myocytes may use alternative splicing to produce truncated ANO5 isoforms in LGMD2L which may be partially functional, and may explain the preserved ANO5 staining observed in additionnal LGMD2L patients as well. A better understanding of ANO5 isoforms in normal and pathological states will help elucidate the pathophysiology of the anoctaminopathies.

1115F

A molecular genetic approach to the diagnosis of limb-girdle muscular dystrophies. *D. Monies[1], S. Majid[1], M. Al Muhaizea[2], H. Al Hindi[3], I. Al Homoud[2], A. Al Azami[1], D. Jaroudi[1], B. Baz[1], E. Naim[1], S. Al Haibey[1], BF. Meyer[1], S. Bohlega[2].* 1) Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Neurosciences, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Department of Pathology & Laboratory Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia.

Autosomal recessive limb-girdle muscular dystrophy (LGMD2) is a genetically heterogeneous disorder. So far 15 genes have been identified which are responsible for LGMD2. Due to such a large number of genes and their size (e.g. TTN has 312 exons) the genetic diagnosis can be very costly and laborious. We have studied eighteen consanguineous LGMD2 families. The fifteen candidate genes were screened for homozygosity using the Affymetrix Cyto v.2 array and Chromosome Analysis Suite (ChAS) software. We excluded all but one candidate gene in ten families and 2 or 3 loci were identified in four and three families respectively. In one family none of the LGMD2 loci were homoallelic. This family was reclassified as having facioscapulohumeral muscular dystrophy (FSHD) and confirmed by a microdeletion of DUX4. To date the underlying mutations were identified for eight LGMD2 families. These consisted of six novel mutations in four genes with two of these being shared by more than 1 family. Our results demonstrate that in consanguineous populations, homozygosity screening is a much faster and less expensive molecular approach to the diagnosis of genetically heterogeneous disorders like LGMD2.

1116F

Molecular diagnosis of neuromuscular diseases by next generation sequencing. *N. VASLI[1], J. BOEHM[1], S. LEGRAS[2], J. MULLER[1], F. PLEWNIAK[2], C. KEIME[2], S. VICAIRE[3], B. JOST[3], JL. MANDEL[1,4], V. BIANCALANA[1,4], J. LAPORTE[1].* 1) Department of Translational Medicine and Neurogenetics, IGBMC, Illkirch-Graffenstaden, Alsace, France; 2) Bioinformatics platform , IGBMC, Illkirch-Graffenstaden, France; 3) Microarrays and sequencing platform, IGBMC, Illkirch-Graffenstaden, France; 4) Laboratoire de diagnostic gÉnÉtique, FacultÉ de MÉdecine, Strasbourg, France.

Introduction : Neuromuscular diseases (NMD) are debilitating disorder with a strong impact on the individuals and society. Despite tremendous research and clinical efforts, the molecular causes of NMD are still unknown for about 40% of patients and additional genes remain to be found. In order to provide a faster and cheaper molecular diagnosis for NMD patients and to detect different types of mutations, we have validated sequence capture and next generation sequencing using Agilent Sureselect liquid capture kit following by Illumina GAIIx sequencing. Results: Using targeted re-sequencing of 270 genes implicated in most of neuromuscular disorders in 7 patients with known mutations, we successfully retrieved the deleterious mutations in all of them (covering point mutations, intronic mutation 10nt from the exon, a small indel and a large hemizygous deletion). The coverage for one of the mutations was low and led to improvement of our protocol. In the second part of the project, after improving the capture step for uncovered regions in first trial, we pooled 4 tagged DNAs in each lane of Illumina GAIIx. In total we sequenced 16 patients (4 pools of 4 patients) with different types of mutations where we knew the mutations in half of them. We could successfully detect all the disease-causing variants in the 8 patients with known mutations. For patients with unknown mutations we prepared a list of candidate genes and are checking them by direct sequencing. More experiments are ongoing to prove these changes as disease-causing mutations. Conclusion: We conclude that next generation sequencing is a powerful approach to identify potential disease-causing variants, a prerequisite for genetic counseling and better healthcare. Although this technique is still in its infancy, it should allow reducing the time to genetic diagnosis and its cost. It might represent a first screening without the need for very detailed clinical criteria for inclusion that may be absent in atypical forms of the diseases or when the disease begins. In addition, the analysis might be proposed before the need of more invasive investigations such as biopsy. This emerging strategy is very likely to become a standard tool for routine genetic diagnosis.

1117F

Application of massive parallel sequencing to the detection of somatic *NLRP3* mutations in cryopyrinopathies. *E. Gonzalez[1], M. Ibañez[2], R. Merino[3], F. Rius[1], S. Plaza[1], J. Yague[1].* 1) Immunology Service (CDB), Hospital Clinic de Barcelona, Barcelona, Spain; 2) Pediatric Reumathology Dpt., Hospital del Niño Jesús, Madrid, Spain; 3) Pediatric Reumathology Dpt., Hospital de la Paz, Madrid, Spain.

Chronic infantile neurologic, cutaneous and articular syndrome (CINCA), also known as neonatal-onset multisystem inflammatory disease (NOMID), represents the severest phenotype among the cryopyrynopathies, which also includes Familial Cold Autoinflammatory Syndrome (FCAS) and Muckle-Wells syndrome. CINCA/NOMID is a severe, early-onset inherited autoinflammatory disease characterized by an urticaria-like rash, arthritis/arthropathy, neurologic involvement, and dysmorphic features. CINCA/NOMID has been associated with dominantly inherited *NLRP3* mutations, most of them located at exon 3. During the past years, *NLRP3* mutational analysis has been the only test to achieve a definitive diagnosis of cryopyrinopathies. However, Sanger-based sequencing analyses detect germline, disease-causing mutations in only 55-60% of CINCA/NOMID patients, suggesting for the presence of genetic heterogeneity. In a previous study, we found the novel and de novo p.D303H *NLRP3* variant in a Spanish CINCA/NOMID patient as the responsible of his disease. Interestingly, it was detected as a somatic mutation in hematopoietic and nonhematopoietic cell lineages. This work included subcloning and Sanger-sequencing of exon 3 of *NLRP3* as well pyrosequencing to quantify the amount of cells presenting the mutation. However, this strategy is expensive and time-consuming to apply as diagnostic tool in patients with a moderate clinical suspicious of cryopyrinopathies. The recent incorporation of massive parallel sequencers to research and clinic opens a new perspective to study the presence of somatic mutations in an easier way. We used a 454 GS Junior sequencer to test if this system could identify known germline and somatic mutations in exon 3 of *NLRP3* gene that were previously identified and quantified by traditional methods. For this proposal, we run three samples: -Sample 1: p.G307V in ~12% of cells -Sample 2: p.D303H in ~20% of cells -Sample 3: p.D303N in germline The test gave us the expected results finding ~10.5% of cells with the somatic mutation p.G307V in sample 1, ~16.7% of cells with the somatic mutation p.D303H in sample 2 and 46,7% of cells in sample 3 with the germline p.D303N mutation. Regarding the good results obtained in this first test, we are currently performing massive parallel sequencing of exon 3 of *NLRP3* in patients who have a clinical suspicious of cryopyrinopathies . We expect that we will be able to explain the molecular basis underlying their disease.

1118F

Molecular analysis in four Greek patients with retinal degeneration establishes a spectrum of clinical diagnosis: identification of four novel mutations in CHM, RS1, SPATA7 and RDS genes. *S. Kamakari[1,2], G. Koutsodontis[1,3], C. Tsika[3], I. Datseris[1], M. Tsilimbaris[3].* 1) Ophthalmic Genetics Unit, OMMA Institute of Ophthalmology, Halandri Athens, Greece; 2) School of Medicine, University of Athens, Athens, Greece; 3) Department of Ophthalmology, School of Medicine University of Crete, Iraklion, Greece.

Purpose: To identify the molecular cause in 4 Greek retinal dystrophy patients with uncertain clinical diagnosis. Methods: PCR amplification and sequencing of the full coding sequence and splice junctions of CHM,OAT,RS1,SPATA7 and RDS genes was selectively performed on 4 patients. LCA chip analysis was used in 1 case. Results: Case 1 was a 57 year old male patient diagnosed with either gyrate atrophy or chorioderemia. Pedigree analysis did not confirm the pattern of inheritance. No mutations were detected in the gyrate atrophy OAT gene, whereas a novel frameshift mutation c.223_224dupTG (p.Trp75Cysfsx52) in exon 4 was detected in the chorioderemia gene, CHM. Case 2 was a 10 year old male patient with possible diagnosis of Stargardt's disease. Thorough pedigree investigation revealed 8 male patients on the maternal side indicating a possible X-linked inheritance. A decision was made to analyse the proband for the X-linked retinoschisis gene, RS1, and a novel missense mutation, c.175T>G (p.Cys59Gly) was detected in exon 3. Case 3 was a 34 year old simplex patient diagnosed with retinitis pigmentosa. She had light perception at the time of seeking genetic testing and suffered from vision loss since birth. LCA chip analysis was selected rather than ARRP and led to the detection of the known heterozygous mutation c.322C>T (p.R108X) in exon 5 of the SPATA7 gene. Subsequent sequencing of the entire coding sequence of this gene revealed a second novel heterozygous splice mutation c.373-1G>C in intron 5. Case 4 was a 30 year old male patient who was diagnosed with Best disease, had choroidal neovascularisation and his pedigree analysis showed an autosomal dominant pattern of inheritance. Due to late age of onset, the peripherin/RDS gene was selected for analysis since mutations in this gene are the major cause of multifocal pattern dystrophy. A heterozygous 1bp deletion c.163delT (p.Ser55LeufsX10) was detected in exon 1 of the gene. The 4 mutations were not found in 92 control subjects. Conclusion: We established the molecular diagnosis in 4 Greek patients with retinal degeneration and uncertain clinical diagnosis by analysing the best candidate gene for each patient. All 4 identified potentially pathogenic mutations in the analysed genes CHM, RS1, SPATA7 and RDS gene were novel. An accurate molecular diagnosis predicts the patients' visual prognosis, allows carrier identification and genetic counseling and may be important for future gene-specific therapies.

1119F

A novel mutation at F9 gene Iranian hemophilia B patient. *L. Kokabee, M. Kokabee, S. Zeinali, M. Karimipoor.* Molecular Medicine Group, Biotechnology Department, Pasteur Institute of Iran, Tehran, Tehran, Iran.

Hemophilia B is an X-linked bleeding disorder caused by the defect or functional deficiency of coagulation factor IX. The disease is due to heterogeneous mutations in the factor IX gene (F9), located at Xq27.1. It spans about 34 kb of genomic DNA. In this study, mutation in F9 gene of an Iranian patient with severe hemophilia B was analyzed. For this purpose, after obtaining informed consent, genomic DNA was extracted from blood (referred from Esfahan Hemophilia Center) by standard methods. PCR amplification and single strand conformation polymorphism (SSCP) technique were performed for scanning of the all functional-important regions of the F9 gene. Abnormal SSCP profile was identified in exon 8 of this patient. Then, direct sequencing was done according to Sanger method. DNA sequencing of the fragment with definite band shift in SSCP showed a single base insertion at nucleotide 30845insT. This frame shift mutation causes premature stop codon at residue 242 (242X). This mutation has not been reported previously in the hemophilia B mutation database and due to producing premature termination codon causes severe form of the disease, as observed in the patient.

1120F

A family of oculofaciocardiodental (OFCD) syndrome with a novel *BCOR* mutation and genomic rearrangements involving *NHS*. *Y. Kondo[1], H. Saitsu[1], K. Nishiyama[1], Y. Tsurusaki[1], H. Doi[1], N. Miyake[1], T. Miyamoto[2], N.K. Ryoo[3], J.H. Kim[3], Y.S. Yu[3], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Department of Obstetrics and Gynecology, Asahikawa Medical College, Asahikawa, Japan; 3) Department of Ophthalmology, Seoul National University College of Medicine, Seoul, Korea.

Oculofaciocardiodental syndrome (OFCD) is an X-linked dominant disorder, presenting congenital cataract, microphthalmia, dysmorphic face, dental radiculomegaly, and septal heart defects in affected female. Mutations in *BCOR* (encoding BCL-6-interacting corepressor) cause OFCD syndrome. Here, we report on a Korean family with common features of OFCD syndrome including congenital cataract, hypodontia, bilateral 2nd-3rd syndactyly, and septal heart defects in three affected females (mother and two daughters). Through the mutation screening and copy number analysis using genomic microarray, we identified a novel heterozygous mutation, c.888delG, in the *BCOR* gene and two duplications at Xp22.2-22.13 and Xp21.3 in all the three affected females in this family. The *BCOR* mutation may yield a premature stop codon (p.N297IfsX80) likely to be associated with nonsense mediated mRNA decay. The duplication at Xp22.2-22.13 partially involved the *NHS* gene causative for Nance-Horan syndrome, which is an X-linked disorder and shows similar clinical features with OFCD syndrome such as bilateral congenital cataracts, dental anomalies, facial dysmorphism and mental retardation in affected males, and in carrier females with milder presentation. X-inactivation study using peripheral blood leukocyte DNA indicated that normal allele, which was inherited from the healthy father, was mostly expressed. Considering the presence of bilateral 2nd-3rd syndactyly and septal heart defects, which is unique to OFCD syndrome, the mutation in *BCOR* is likely to be the major determinant of the phenotypes in this family.

1121F

Exome sequencing reveals a homozygous mutation in *DPH1/OVCA1* associated with syndromic craniosynostosis with ectodermal and developmental abnormalities. *C.M. Loucks[1], A.M. Innes[1], F.P. Bernier[1], D.R. McLeod[1], E.G. Puffenberger[2], K.M. Boycott[3], S.J. Childs[4], J.S. Parboosingh[1].* 1) Dept of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Clinic for Special Children, Strasburg, PA, USA; 3) Dept of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 4) Dept of Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, Canada.

Cranioectodermal dysplasia (CED) is a rare autosomal recessive disorder characterized by short stature, sagittal craniosynostosis and ectodermal abnormalities. In addition, the majority of patients have developed renal and retinal disease clinically consistent with CED being a ciliopathy, a classification supported by the identification of three genes involved in intraflagellar transport as causative for the disorder: *IFT122*, *IFT43* and *WDR35*. We ascertained three Hutterite children with a CED-like phenotype without significant renal or retinal disease but with intellectual disability. Given the known consanguinity in this population, a single nucleotide polymorphism array was performed on the patients to identify a homozygous region on chromosome 17 of approximately 10 Mb, containing 310 genes. Coding and flanking intronic regions throughout the genome were captured in one of these patients, followed by next generation sequencing to reveal over 50 000 variants. Looking at only variants present in the homozygous region on chromosome 17 reduced the number of variants to just over 500. Common variants were then excluded leaving 15 variants, most of which were intronic, intergenic or changes at poorly conserved positions. Subsequently, an additional Hutterite patient was identified with the same phenotype. Upon sequencing of coding or highly conserved variants, this patient was homozygous for only one variant surrounded by a small haplotype shared by all four patients. This variant results in the loss of the likely start codon of *DPH1/OVCA1*, a gene responsible for a post translational modification on a protein involved in translation elongation, characterized as a tumour suppressor in ovarian/breast cancer and associated with developmental abnormalities in the knockout mouse. Currently, work is being done to prove pathogenicity of this variant using zebrafish with initial studies suggesting evidence of perturbed sonic hedgehog signaling. Identifying the causative gene for CED in the Hutterites will allow for diagnostic testing within the population and will further our understanding of the complexities of ciliopathies in both the Hutterites and the general population.

MLL2 haploinsufficiency and nonsense-mediated mRNA decay as pathological mechanisms for the Kabuki syndrome. *G. Merla, C. Fusco, B. Augello, M.N. Loviglio, E.V. D'Addetta, A. Calcagni, L. Micale.* Medical Genetics Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy.

Kabuki syndrome (KS), also known as Niikawa-Kuroki syndrome, is a rare, multiple congenital anomalies/mental retardation syndrome, mainly characterized by a very distinctive facial appearance and other clinical signs such as developmental delay, short stature, persistent fingerpads, and urogenital tract anomalies. We and others demonstrated that a large number of Kabuki patients carry mutations in MLL2 gene, the majority of which results in premature stop codon termination. MLL2 encodes an H3K4 histone methyl transferase which acts as an epigenetic transcriptional activator during growth and development. In our study we assessed whether the MLL2 protein haploinsufficiency may be a molecular mechanisms that causes Kabuki syndrome. We assayed whether MLL2 truncating mutations lead to non-functional MLL2 proteins or can result in mutant mRNA degradation through the nonsense-mediated mRNA decay (NMD), leading to MLL2 protein haploinsufficiency. Using Kabuki patients lymphoblastoid cell lines, expressing detectable levels of both MLL2 mRNA and protein, we tested whether selected nonsense mutations were substrate of NMD. By QPCR analysis we highlighted that the treatment of patient cell lines with the well-known NMD inhibitors puromycin and emetine significantly increased the steady-state levels of mutant MLL2 transcripts. Consistently, western blot analysis on patients total lysate detected a decrease MLL2 protein level. To date no functional studies have been carried out to elucidate the molecular events causing this syndrome. Our findings provide the first evidence that MLL2 transcripts carrying PTC mutations undergo NMD, which in turn reduces MLL2 expression, and further strengthen the model of haploiunsufficiency as a pathomechanism of the disease, at least in a subset of Kabuki patients.

Molecular Investigation into Cystic Fibrosis in Omani Patients. *A. Ouhtit[1], H. Al-Kindy[1], Q. Al-Salmi[2], S. Al-Yahyaee[1], M. Al-Bimani[1], M. Al-Nabhani[1].* 1) Genetics, College of Medicine & Health Sciences, Sultan Qaboos University, Al-Khod (Muscat), Al-Seeb, Oman; 2) Royal Hospital, Ministry of Health, Oman.

Introduction. Cystic fibrosis (CF) is the most common lethal autosomal recessive disorder among Caucasians (1: 3,000), and the CFTR gene is the most common mutated gene for CF, with ΔF508 as the most common mutation in Caucasians. Our preliminary pilot study in Omani population revealed a CF prevalence of 1:2,738. Objective. The objective of the present study was to determine the most common CFTR mutations in the Omani patients to establish a proper molecular genetics diagnosis of CF in Oman. Methods. Blood Genomic DNA samples from Omani patients were examined by PCR and sequencing analyses of the entire coding sequence of the CFTR gene. Results. While ΔF508 is the most common mutation in the west, S549R was the most common mutation in Oman (79%; for S549R and 16%; for ΔF508), but the rest of the patients (5%) showed 2 novel mutations in the CFTR gene. Conclusion. The common mutations identified in Omani patients will be further validated for the establishment of molecular genetic testing of CF in Oman.

1124F

A germline mutation in a family with Gaucher disease. *N. Tayebi[1], H. Saranjam[1], S. Chopra[2], H. Levy[2], E. Sidransky[1].* 1) Medical Genetics Branch, NHGRI, NIH Bethesda MD; 2) Children's Hospital Boston, Harvard Medical School, Boston, MA.

Gaucher disease (GD), the most common lysosomal storage disorder, results from the inherited deficiency of the enzyme glucocerebrosidase (GCase). Over 300 unique mutations have been identified in GBA, the gene encoding glucocerebrosidase. GD is autosomal recessively inherited, so affected individuals inherit mutations from both parents. We investigated a family with a baby diagnosed with type 2 GD. Direct sequencing of GBA demonstrated that the child's genotype was T323I /L444P. We also sequenced parental DNA. Mutation T323I was inherited from the father, but no mutation was detected in a DNA sample from the mother. This was confirmed by sequencing GBA in DNA from different maternal cells, including blood, skin fibroblasts, and buccal cells. Further analysis demonstrated that the mother's somatic cells had normal levels of GCase expression and enzymatic activity. Studies of 32 additional markers evaluated in the child and parents confirmed maternity. Based on the experiments performed, we propose that the L444P mutation is likely present only in the mother's germ line cells, and was passed on to the proband. This is the first report of the presence of a germ line mutation in Gaucher disease, and can have significant implications for genetic counseling in recessive disorders.

1125F

Complete scanning of the HFE gene in Dutch hereditary hemochromatosis patients. *M.J. van Belzen, S. Smith, E. Bakker.* Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands.

Hereditary hemochromatosis (HH) type 1 is an autosomal recessive disorder caused by mutations in the HFE gene. The disease is characterized by accumulation of iron, which mainly occurs in the liver and in a number of other tissues including the pancreas, joints, skin and heart. Clinical symptoms include fatigue, liver cirrhosis, diabetes mellitus due to pancreatic islet cell failure, arthritis, pigmentation of the skin and cardiomyopathy. Three mutations are frequent in Caucasian populations: p.Cys282Tyr (3%), p.His63Asp (15%) and p.Ser65Cys (1.4%). Our general testing strategy for patients suspected of having HH is to perform sequence analysis of exons 2 and 4 of the HFE gene for detection of these three mutations. In this study we performed sequence analysis of the remaining 4 exons of the HFE gene in 74 Dutch patients in whom only one of these mutations was identified in heterozygous form. All patients had increased ferritin levels and increased transferrin saturation. No other mutations were present in exons 2 and 4. To test for the presence of heterozygous deletions, MLPA for all six exons was performed with the commercial P347-A1 kit (MRC-Holland). Sequence analysis revealed the presence of one other mutation, the previously reported p.Leu183Pro in exon 3. This mutation was detected in heterozygous form in only one patient. Iron indices of this patient were highly increased, liver enzymes were elevated and clinical symptoms included arthritis and tanned skin. MLPA analysis did not detect any deletion or duplication of one or more exons of the HFE gene. The frequency of other HFE mutations proved to be low in the Dutch population. In only one patient in this cohort a second mutation could be identified (0.14%), and this patient showed several characteristics of manifest HH. Targeted mutation detection for the three most frequent mutations seems to be an adequate strategy in our population. Complete mutation scanning of the HFE gene should only be considered in those patients with a strong clinical suspicion of HH but without homozygosity or compound heterozygosity for the mutations in exons 2 and 4.

1126F

Candidate gene functional analysis in nonsyndromic sagittal craniosynostosis. *G. Yagnik[1], J. Liu[1], C. Stevens[1], A. Ghuman[1], S. Kim[1], J. Kim[1], E. Cherkez[1], D. Soung[2], H. Drissi[2], M. Buckley[3], T. Roscioli[3], S.A. Boyadjiev[1].* 1) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento CA,95817; 2) New England Musculoskeletal Institute, Department of Orthopaedics, Farmington, CT; 3) Department of Human Genetics, Radboud University Medical Centre, Nijmegen, Netherlands.

Premature fusion of one or more cranial sutures is a common malformation (~4 per 10,000 live births) known as craniosynostosis (CS). Approximately 85% of cases present as nonsyndromic craniosynostosis of unknown etiology. The remaining 15% are syndromic (i.e. associated with other anomalies) and follow Mendelian inheritance patterns. Previous work has shown that loss-of-function mutations in ALX4 and RUNX2 result in hypoossification of the skull, manifest as parietal foramina or large fontanels in the context of cleidocranial dysplasia. Overexpression of NELL1 results in isolated craniosynostosis while loss of its function results in skeletal hypoossification in mice models. In addition, LRIT3 was identified as a candidate gene for nonsyndromic CS via exome sequencing. Based on these data, we hypothesize that gain-of-function mutations in ALX4, RUNX2, NELL1 and possibly LRIT3 will accelerate osteoblast differentiation and result in premature suture fusion (craniosynostosis). In order to test this hypothesis, we sequenced the DNA of more than 200 sagittal probands for each of the four candidate genes. The sequencing identified a total of 21 highly conserved, rare, familial nonsynonymous variants, consisting of 18 SNPs and 3 deletions. Some of these variants have already been tested via dual-luciferase assays and have demonstrated the expected gain-of-function effect. Further functional analyses are underway.

1127F

Exome sequencing reveals a novel homozygous mutation in adult-onset autosomal recessive spinocerebellar ataxia with psychomotor retardation. *H. Doi[1,2], K. Yoshida[3], Y. Tsurusaki[1], N. Miyake[1], H. Saitsu[1], H. Sakai[1], Y. Kuroiwa[2], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University, Yokohama, Kanagawa, Japan; 2) Department of Clinical Neurology and Stroke Medicine, Yokohama City University, Yokohama, Kanagawa, Japan; 3) Division of Neurogenetics, Department of Brain Disease Research, Shinshu University, Matsumoto, Nagano, Japan.

Autosomal recessive cerebellar ataxias (ARCAs) are clinically and genetically heterogeneous disorders associated with diverse neurological and non-neurological features that occur before the age of 20. Currently, more than 20 causative genes for ARCAs have been identified, but approximately half of the ARCA patients remain genetically unresolved. Here, we present a Japanese family with two siblings showing psychomotor retardation and the slowly progressive type of ARCA without involvement of pyramidal tracts or peripheral nerves. To find a causative mutation, whole exome sequencing combined with homozygosity mapping was performed on both cases. As a result, only one homozygous missense mutation remained as a candidate for both cases. Expression analysis of the gene using a TaqManTM assay confirmed that the transcripts were highly expressed in human fetal and adult brain tissues as well as in the mouse brain (especially in the cerebellum). An immunohistochemical analysis clearly showed that the gene product is specifically localized in Purkinje cells of the cerebellum in humans and mice. These results strongly suggest that the mutation contributes to the degeneration of the cerebellum seen in both patients.

1128F

The role of the JAK-Stat3 signaling pathway in inherited photoreceptor (PR) degenerations (IPDs). *K.C. Jiang[1], M.J. Szego[1], A.N. Bramall[1], K.L. Wright[1], L.R. Pacione[1], W.W. Hauswirth[2], S.E. Egan[1], R.R. McInnes[1,3].* 1) Program in Stem Cell and Developmental Biology, Hospital for Sick Children Research Institute, Toronto, M5G1L7; 2) Department of Ophthalmology, University of Florida, Gainesville, Florida 32610-0284, USA; 3) The Lady Davis Institute, Jewish General Hospital, McGill University, Montreal H3T1E2.

The biochemical pathways that promote or resist PR death in IPDs are largely unknown. We previously reported identification of 9 up-regulated mRNAs encoding proteins that constitute a putative JAK-Stat3 cytokine signaling pathway in the retinas of *Rds*$^{+/-}$, *TgRHO(P347S)* and *Rd1*$^{-/-}$ mouse IPD models. By immunoblotting, we found the active forms of STAT3, pSTAT3^{Tyr705} and pSTAT3^{Ser727}, to be elevated from 2-8 fold in the retinas of these three models. Immunostaining of retinas from all three models showed the increased STAT3 and pSTAT3 to be predominantly in Müller glia, but *Stat3* mRNA expression was also found to be increased in mutant PRs using laser capture microdissection of the PR layer and qPCR: 2.4 fold (n=3, p<0.05) in 7 week old *Rds*$^{+/-}$ PRs and 5.4 fold (n=3, p<0.05) in postnatal (PN) day 12 *Rd1*$^{-/-}$ PRs. To determine the significance of up-regulated *Stat3* in mutant PRs, we first used subretinal injections of an AAV2-CBA-Cre virus, whose expression is PR-specific, to delete *Stat3* from *Stat3*$^{flox/flox}$; *Rd1*$^{-/-}$ mutant PRs. AAV2-CBA-Cre injected retinas had an average increased PR survival of 30%±6.5% (n=22; p<0.05) at PN13. In addition, when we crossed mice with PR-specific Cre expression (*Opsin-iCre* mice) to *Stat3*$^{flox/flox}$ mice with the *Rd1*$^{-/-}$ mutation, we observed 42% (n=12; p<0.001) and 44% (n= 11; p<0.001) increases in PR survival at PN13 and PN15, respectively. These results suggest that the increased *Stat3* expression in *Rd1*$^{-/-}$ PRs is pathogenetic. In distinct contrast, however, when PR *Stat3* was deleted from *TgRHO(P347S)* mice by crossing *Opsin-iCre* mice to *Stat3*$^{flox/flox}$ mice with the *TgRHO(P347S)* mutation, 40% (n=6; p<0.01) and 67% (n=5; p<0.001) decreases in PR survival were seen at PN20 and PN30, respectively. These results suggest that the increased *Stat3* expression in *TgRHO(P347S)* PRs is protective, a finding confirmed by a 38% increased survival at PN30 (n=4, p<0.05) of *TgRHO(P347S)* PRs over-expressing *wt Stat3* from a *ROSA26* transgene. We conclude that i) comparable changes in gene expression in mutant retinas can have strikingly different mechanistic effects on PR survival in different IPD models, and ii) over-expression of PR *Stat3* may have potential as a general therapy for IPDs, assuming that the *TgRHO(P347S)* model is more representative of IPDs as a whole, vs. the aggressive degeneration seen with *Rd1* mutations.

1129F

Mechanism and clinical severity of FIG4 mutations in Charcot-Marie-Tooth Disease. *M.H. Meisler[1], G.M. Lenk[1], S. Reddel[2], A.E. Grant[1], C.J. Ferguson[1], C. Towne[3], J.M. Jones[1], L.G. Biesecker[4], S.D. Batish[3], G. Nicholson[2].* 1) Dept Human Gen, Univ Michigan, Ann Arbor, MI; 2) University of Sydney, ANZAC Institute, Concord Hospital, Sydney, Australia; 3) Athena Diagnostics, Worcester MA; 4) NIH Intramural Sequencing Center, NHGRI, NIH, Bethesda MD.

Charcot-Marie-Tooth type 4J (CMT4J) is a severe recessive form of CMT caused by mutations of the lipid phosphatase FIG4. Eight new cases were identified through screening with the CMT gene panel. Three additional cases were found in a small cohort characterized by early onset and proximal as well as distal muscle weakness. These 11 previously unreported patients exhibited variable onset and severity, assymetric proximal as well as distal muscle weakness, EMG findings indicative of denervation in proximal and distal muscles, and frequent progression to severe amyotrophy and wheelchair dependence. Among the 16 known cases, fifteen have the compound heterozygous genotype FIG4I41T/null. The I41T mutation impairs interaction between the FIG4 protein and the associated scaffold protein VAC14 that is required for in vivo stability of the FIG4 protein, as demonstrated by the loss of FIG4 protein in mice homozygous for a null mutation of VAC14. FIG4-I41T is thus a hypomorphic allele encoding a protein that is unstable in vivo. A transgenic mouse model of CMT4J was generated by expression of the I41T mutant cDNA as a transgene in Fig4 null mice. Expression of only 10% of the normal level of FIG4 protein was sufficient to rescue survival and prevent neurodegeneration in the null mouse. A mouse line with lower expression survives for 3 to 6 months and provides a model of CMT4J that can be used to test therapeutic intervention to increase the abundance of the I41T protein above the threshold for survival. The observations in the mouse model suggest that up-regulation of the I41T allele in CMT4J patients could be therapeutic.

1130F

Demyelinating sensory-motor neuropathy with secondary axonopathy: a novel mutation in Connexin32. *A. Patitucci[1], C. Tortorella[2], M. Liguori[1], A. Magariello[1], R. Mazzei[1], FL. Conforti[1], W. Sproviero[1,3], L. Citrigno[1], A. Morabito[1], C. Ungaro[1], A. Gambardella[1,3], M. Muglia[1].* 1) Institute of Neurological Sciences, CNR, Mangone (CS), Italy; 2) Institute of Neurology, Department of Neurological and Psychiatric Sciences, University of Bari, Italy; 3) Institute of Neurology, University Magna Graecia, Catanzaro, Italy.

Charcot-Marie-Tooth (CMT) disease is a heterogeneous disorder of hereditary motor and sensory neuropathies characterized by progressive muscle wasting, distal muscle weakness, sensory loss, and hypo/areflexia. According to the inheritance pattern, CMT is classified as autosomal dominant, autosomal recessive, or X-linked CMT (CMTX). CMTX is the second most common form of neuropathy after CMT1A, with a frequency of approximately 20%; it is due to mutations in connexin 32 (Cx32). Cx32 protein is expressed in myelinating Schwann cells where it forms the functional channels that allow the rapid transport of ions and small nutrients between coupled cells. We report about a 55-year-old man who complained for progressive gait abnormalities started when he was 11 years old. In the following years he developed a moderate muscular hypothrophy in both his thenar and ipothenar eminences, bilateral steppage gait, and recently a subjective dysestesia in his upper and lower limbs. Electrophysiological exam revealed a generalized sensory-motor demyelinating neuropathy with secondary axonopathy. His mother and grandmother also have showed similar neurological symptoms and signs. Genomic DNA was extracted after receiving informed consent from the patient. The CMT1A duplication was tested by Real Time PCR using the relative method. Point mutations in Peripheral Myelin Protein 22 (PMP22), Myelin Protein Zero (MPZ) and Cx32 were screened by Polimerase Chain Reaction followed by direct sequencing. Duplications of 1.5 Mb on 17p11.12 locus responsible for CMT1A, PMP22 and MPZ mutations were excluded. The analysis of Cx32 gene revealed a c.171 G>T variation that leads to a glutammin-hystidin substitution at codon 57 (p.Gln57Hys); unfortunately the genetic diagnosis was not confirmed in the other relatives since they were not available for the DNA sampling. However the same nucleotide substitution was not found in 100 genotyped controls. In order to verify the pathogenic role of this Cx32 mutation, the PolyPhen program was used: the PSIC (Position-Specific Independent Counts) score difference for the two aminoacids Gln and Hys was 2.859 (>2.0), resulting in a probable damaging effect of the identified mutation. This is in line with previous evidence reporting the same substitution (p.Gln57Hys) but resulting from a different nucleotide change (c.171 G>T instead of c.171 G>C) as causative of a CMTX phenotype. Functional studies are needed in order to confirm this finding.

1131F

Identification of the genetic defect causing pontine autosomal dominant microangiopathy and leukoencephalopathy using exome sequencing. *S. Appenzeller, G. Kuhlenbäumer.* UKSH Campus Kiel, Exp. Medicine, Arnold Heller Str. 3, Building 41 24105 Kiel, Germany.

Statement of purpose: Purpose of this study is to identify the genetic defect causing pontine autosomal dominant microangiopathy and leukoencephalopathy (PADMAL) using exome sequencing. PADMAL is characterized by a leukencephalopathy with an inflammatory component, pontine lesions, slowly progredient dementia, tetraparesis and early death. The age of onset is between 12 and 60 years [1]. PADMAL is of great research interest because the pathology resembles that of the sporadic form of cerebral microangiopathy. Therefore the identification and functional analysis of the underlying genetic defect of PADMAL will help to further elucidate the pathomechanisms of PADMAL as well as contribute to a better understanding of more common sporadic forms of microangiopathies. Methods used: Linkage analysis, CNV analysis, exome sequencing, Sanger sequencing Summary: We ascertained a large multigeneration family with a new inflammatory form of microangiopathy called PADMAL. Variants in known genes causing microangiopathies (NOTCH3; TREX1, HTRA1) were excluded as causing PADMAL using linkage analysis and Sanger sequencing. We did not find Copy Number Variants >10 kb using Affymetrix Genome-Wide Human SNP Array 6.0 in two distantly related patients. Exome sequencing has previously been successfully applied in identifying the cause of monogenic diseases not amenable to linkage analysis (summarized in [2]). Exome sequencing of two distantly related individuals who share only a fraction of their genome is underway. Results will be available at the end of June. Conlusion: Recent studies have shown that exome sequencing can be successfully carried out to identify the cause of monogenic diseases. The results of the exome sequencing will be shown at the meeting. Literature: [1] MRI features of pontine autosomal dominant microangiopathy and leukoencephalopathy (PADMAL). 1132F

Whole-exome sequencing to tackle genetic heterogeneity in cortical malformations associated with eye and muscle defects. *M.C. Manzini[1], R.S. Hill[1], J. Rodriguez[1], J.N. Partlow[1], B. Barry[1], W.B. Dobyns[2], M.A. Salih[3], C.A. Walsh[1].* 1) Division of Genetics, Children's Hospital Boston, Boston, MA; 2) Genetic Medicine, Pediatrics, University of Washington, Seattle, WA; 3) Pediatric Neurology, King Kahlid University Hospital, King Saud University, Riyadh, Saudi Arabia.

Cobblestone lissencephaly and polymicrogyria (PMG) are cortical malformations sometimes associated with ocular defects and muscular dystrophy and appear to be caused by a disruption of normal cellular interactions with the extracellular matrix (ECM) in the basal lamina. The best-studied example are alpha-dystroglycanopathies, a group of disorders with a wide spectrum of heterogeneous brain, eye and muscle symptoms, where the transmembrane glycoprotein dystroglycan is not appropriately glycosylated perturbing its interactions with ligands in the ECM. Eight different genes, mostly involved in glycosylation, have been identified to date in alpha-dystroglycanopathies, explaining only 30-40% of cases. Several additional genes remain to be identified in the remaining 60-70% of cases and a different group of genes may be involved in patients with similar presentation where dystroglycan glycosylation is normal. In addition to extreme genetic heterogeneity, these disorders are also clinically heterogenous and the severity of the symptoms in the affected children often limits the ability to collect DNA from multiple cases in the same family to narrow the size of the linkage regions. Next-generation sequencing approaches allow us to bypass heterogeneity by analyzing each family individually. We have collected a large cohort of patients affected by cobblestone lissencephaly and/or PMG with ocular malformations and muscle defects and generated genome-wide SNP genotyping data on all affected individuals and family member. Since several of our families were consanguineous and showed likely autosomal recessive inheritance, we used homozygosity mapping to identify candidate regions. Because a large percentage of the genome resulted homozygous (3-10%) we then employed whole-exome sequencing to sequence all coding sequences in the genome and focused on the genes in the candidate regions. Multiple candidates were identified and as expected they displayed little overlap between different families with similar phenotypes underlining the genetic heterogeneity in these disorders.

1133F

Linkage and single exome analyses identify *ADCY5* as the gene for Familial Dyskinesia with Facial Myokymia. *W.H. Raskind[1,2], Y-Z. Chen[1], M.M. Matsushita[1], P.D. Robertson[3], M. Rieder[3], S. Girirajan[3], H. Lipe[4], E.E. Eichler[3,5], D.A. Nickerson[3], T.D. Bird[1,4,6].* 1) Dept Med, Univ Washington, Seattle, WA; 2) Dept Psychiatry and Behavioral Sciences, Univ Washington, Seattle, WA; 3) Dept Genome Sciences, Univ Washington, Seattle, WA; 4) Dept Neurology, Univ Washington, Seattle, WA; 5) Howard Hughes Medical Institute; 6) VISN-20 Mental Illness Research, Education, and Clinical Center, Department of Veteran Affairs, Seattle, WA.

Objective: Familial dyskinesia with facial myokymia (FDFM) is an autosomal dominant disorder that progresses from paroxysmal episodes to constant and is exacerbated by anxiety. In a five-generation family we previously mapped FDFM to chromosome 3p21-3q21. Although the 72.5 Mbp minimal linkage region was too large for traditional positional gene-by-gene mutation identification, we reasoned that the exome sequence of a single affected individual would be sufficient for this purpose. **Methods:** We performed whole exome sequencing in one affected individual and used a series of bioinformatic filters, including functional significance and presence in dbSNP or 1000Genomes databases, to reduce the number of candidate variants. Nine affected and three unaffected at-risk individuals in three generations of the family were used for co-segregation analyses. **Results:** The exome contained 23428 single nucleotide variants, of which 9391 were missense, nonsense or splice site alterations. The critical region contained 323 single nucleotide variants, five of which were not present in either of the sequence-databases. Adenylate cyclase 5 (*ADCY5*) was the only gene in which the variant (A726T) cosegregated perfectly with disease status and was not present in 1200 control exomes. This residue is highly conserved evolutionarily and the change is predicted to be damaging by both PolyPhen and Sift. **Interpretation:** ADCY5 is highly expressed in striatum, a major brain coordinator of movement. Striatal dysfunction is common in many movement disorders, including Huntington disease. Mice deficient in Adcy5 develop a movement disorder that is worsened by stress. We conclude that FDFM in this family results from a missense mutation in ADCY5. This study demonstrates the power of a single exome sequence in combination with linkage information to identify causative genes for rare autosomal dominant diseases.

1134F

Mutation in the Neurofilament Light Chain Gene (NEFL) associated with facial diplegia and marked elevation of creatine kinase. *B. Rautenstrauss[1, 2], N. Garcia-Angarita[1], B. Schlotter-Weigel[1].* 1) Friedrich-Baur-Institute, Ludwig-Maximilians-University, Munich, Bavaria, Germany; 2) Medizinisch Genetisches Zentrum, Munich, Bavaria, Germany.

Objective: to present a family with an unusual phenotype of CMT2E, caused by a known pathogenic heterozygote mutation Gln332Pro in the Neurofilament Light Chain gene (NEFL). Background: NEFL gene mutations gene are found in about 2% of the cases in a large cohort of CMT patients and cause autosomal dominant neuropathies classified either as axonal Charcot-Marie-Tooth (CMT) type 2E or demyelinating CMT type 1 (CMT1F). Methods: 3 affected members of a family with CMT2E neuropathy underwent clinical and electrophysiogical examination. Results: Age of onset was reported at age 17-25. In one case first symptoms started in the upper limbs. At presentation distal weakness and atrophy was found in variable degree dependent on disease duration. The oldest patient (> 60 years) was wheelchair bound and showed a severe phenotype with disabling proximal weakness in the lower limbs and marked atrophy distal in lower and upper limbs. As additional symptom he presented a striking facial diplegia unable to blow his cheeks or to whistle. Eyeclosure was still possible. Dysarthria and swallowing difficulties were absent, the tongue motility preserved. Sporadic fasciculations were noticed in the facial muscles. The youngest patient (28 years) was only mildly affected with slightly reduced foot extension (MRC 4/5+) but complained about myalgia and fasciculations in the lower limbs after physical activity. A blood test revealed a markedly elevated creatin kinase (CK) up to 1414 U/l whereas in the other patients CK was moderately elevated (500 U/l). There was no evident ataxia and only mild sensory deficits were documented. Tendon reflexes were decreased or absent. Electrophysiological studies of the mildly affected patient confirmed a purely axonal neuropathy with normal motor nerve conduction velocity (NCV) in upper and lower limbs, normal distal motor latencies (dmL) and low amplitudes. In the more affected patients demyelinating motor NCV ranging from 32-38 m/s were recorded pronouncly in the lower limbs. Conclusion: CMT neuropathies are genetically very heterogeneous. Up to date 13 different NEFL gene mutations have been identified and no definite phenotype-genotype correlation exists. Prominent ataxia, plantopalmar hyperkeratosis and hypakusis are described as particular features. To our knowledge this is the first report of facial diplegia in a family with CMT2E neuropathy. Furthermore the elevated CK seems a point of interest regarding the function of NEFL.

1135F

Identification and functional studies of MLC1 mutations in Chinese patients with megalencephalic leukoencephalopathy with subcortical cysts (MLC). *J. Wang[1], H. Xie[1], A. Dhauchak[2], J. Shang[1,3], H. Wei[1,3], Y. Wu[1], H. Xiong[1], Q. Gu[1], C. Ding[4], L. Wang[5], Z. Gao[5], D. Colman[2], X. Wu[1], Y. Jiang[1].* 1) Peking University First Hospital, Beijing, China; 2) Montreal Neurological Institute, Montreal,Quebec,Canada; 3) Shanxi Medical University, Taiyuan, Shanxi, P. R. China; 4) Department of Neurology, Beijing Children's Hospital Affiliated to Capital Medical University, Beijing, China; 5) Department of Neurology, Children's Hospital, Capital Children's Research Institute, Beijing, China.

Megalencephalic leukoencephalopathy with subcortical cysts (MLC, MIM# 604004) is an autosomal recessively inherited disease resulting from a deficiency of MLC1 protein. This study was to identify MLC1 mutations and perform their functional studies in Chinese patients with megalencephalic leukoencephalopathy with subcortical cysts (MLC). Methods The analysis of clinical features and MLC1 mutation screening were performed in 13 Chinese patients. The functional study of MLC1 variants was carried out by western blot, real-time PCR and confocal microscope. U373MG cells transfected by p.cDNA3.1-HA-MLC1 wildtype and mutants were immunoassayed with antibodies of HA and calnexin, an ER marker. Results A total of 10 MLC1 mutations were identified in these patients, including five novel missense mutations (c.65G>A, p.R22Q; c.95C>T, p.A32V; c.218G>A, p.G73E; c.823G>A, p.A275T; c.832T>C, p.Y278H), one novel splicing mutation (c.772-1G>C in IVS9-1), one novel small deletion (c.907_930del, p.V303_L310del), one known nonsense mutation (c.593delCTCA, p.Y198X) and two known missense mutations (c.206C>T, p.S69L; c.353C>T, p.T118M). Compared with the protein expression in WT, the protein expression in mutants A32V, G73E, S69L, T118M, Y198X, A275T and C278R were reduced in different level (all $p<0.05$), but no statistic differences was found for protein expression in mutant R22Q.Compared with mRNA expression in WT, that in mutants G73E, T118M, Y198X and A275T were at a lower level ($p<0.05$). WT MLC1 was at arstrocyte borders, whereas MLC1 mutants R22Q and A32V are mainly intracellularly localized, and S69L, G73E, T118M are mildly retained at ER. Besides, other mutations are mainly at cell borders. Conclusion Ten DNA variations of MLC1 gene were identified including seven novel mutations. MLC1 mutants associated with MLC likely disrupt MLC1 protein and mRNA expression and locolization. This would be the first report about MLC1 mutations in patients with megalencephalic leukoencephalopathy with subcortical cysts in China.(We thank the patients and their parents for their support and cooperation. This work was supported by the National Key Research Project `11-5' (2006BAI05A07), `973' Project of the Science and Technology Ministry of China (2007CB5119004), the National Natural Science Foundation of China (30973227), the International Collaborative Genetic Research Training Grant (NIH/FIC, No. D43 TW06176)) .

Genetic analysis and exome sequencing in Amyotrophic Lateral Sclerosis. *K.L. Williams[1,2], J.A. Solski[1], J.C. Durnall[1], A.D. Thoeng[1,3], S. Waraich[1,2], G. Rouleau[4], G.A. Nicholson[1,5], I.P. Blair[1,2].* 1) Northcott Neuroscience, ANZAC Research Institute, Concord, NSW, Australia; 2) Sydney Medical School, University of Sydney, NSW, Australia; 3) Department of Physiology, University of Sydney, NSW, Australia; 4) Ste-Justine Hospital Research Centre, Montreal, Canada; 5) Molecular Medicine Laboratory, Concord Hospital, NSW, Australia.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder that causes the progressive degeneration of motor neurons. Familial ALS (FALS) accounts for approximately 10% of ALS cases with the remainder being sporadic (SALS). We aim to investigate known ALS genes and identify new ALS genes in a large cohort of Australian ALS families (n=165) using a combination of traditional genetic linkage approaches together with next-generation sequencing strategies. We also aim to develop a user-friendly pipeline for analysis of the raw exome sequencing data. We analysed 165 ALS families for mutations in known ALS genes and determined that mutations in these genes account for 26% of Australian ALS families, and comprise *SOD1* (17.0%), *FUS* (4.8%), *ANG* (1.8%), and *TARDBP* (2.4%) mutations. None of the identified mutations were present in a screen of 492 control chromosomes. To identify new loci for familial ALS, genome-wide linkage scans were performed in a subset of families that were negative for all known genes. An 8cM genome-wide microsatellite scan was carried out by deCODE-Iceland using 166 individuals (affected, unaffected and obligate carriers). Subsequent analyses have yielded significant and suggestive linkage to several chromosomal regions. Exome capture-sequencing (Agilent capture, SOLiD4 sequencing) has been performed among 39 individuals across 11 families. Bioinformatic analysis has required the development of a user-friendly pipeline, resulting in several new candidate ALS genes currently being screened through control cohorts. The genetic defects are yet to be identified among 74% of ALS families (122/165 families) within our cohort. The chromosomal regions implicated from our genome-wide linkage scans do not overlap previously identified loci, implicating substantial genetic heterogeneity. Linkage analysis in combination with exome capture and sequencing allows us a greater opportunity to identify novel ALS genes. The identification of these novel ALS genes will give insights into the biological basis of both familial and sporadic motor neuron degeneration, allow development of new disease models and provide new targets for therapeutic development.

Role of IL-1) in NLRP12-associated autoinflammatory disorders and resistance to anti-IL-1 therapy. *I. Jéru[1, 2, 3], V. Hentgen[4], S. Normand[5], P. Duquesnoy[1], E. Cochet[3], A. Delwail[5], G. Grateau[6], S. Marlin[7], S. Amselem[1, 2, 3], JC. Lecron[5].* 1) U.933, INSERM, Paris, France; 2) UMR S933, Université Pierre et Marie Curie-Paris6, Paris, France; 3) Service de Génétique et d'Embryologie médicales, Hôpital Trousseau, Assistance Publique Hôpitaux de Paris, Paris, France; 4) Service de Pédiatrie, Centre Hospitalier de Versailles, Le Chesnay, France; 5) EA 4331, Université de Poitiers, France; 6) Centre de référence Amyloses d'origine inflammatoire et Fièvre méditerranéenne familiale, Hôpital Tenon, Assistance Publique Hôpitaux de Paris, Paris, France; 7) Centre de référence des surdités congénitales et héréditaires, Hôpital Trousseau, Assistance Publique Hôpitaux de Paris, Paris, France.

Background. A new class of autoinflammatory syndromes called NLRP12-associated disorders (NLRP12AD) has been associated with mutations in the NLRP12 gene. Conflicting data on the putative role of NLRP12 in IL-1) signaling have been generated in vitro. Aim. This prospective study was undertaken to assess the secretion of IL-1) and three IL-1) -induced cytokines (IL-1Ra, IL-6 and TNF-( ) in patients' PBMC cultured ex vivo and to evaluate the patients' response to recombinant IL-1 receptor antagonist (IL-1Ra, anakinra), a major drug in the treatment of autoinflammatory disorders. Methods. Patients' disease manifestations and cytokine measurements were recorded before anakinra treatment was started, during 14 months of therapy, and after discontinuation of anakinra treatment. Results. Spontaneous secretion of IL-1) by patients' PBMC was found to be dramatically increased (80 to 175-fold) compared to controls. Consistently, anakinra initially led to a marked clinical improvement and to a rapid near-normalization of IL-1) secretion. However, a progressive clinical relapse occurred secondarily, associated with an increase in TNF-(secretion, persistent elevated levels of IL-1Ra and IL-6 and a reactivation of IL-1) secretion. Anakinra was discontinued after 14 months of therapy. Conclusion. Our findings provide in vivo evidence of the crucial role of IL-1) in the pathophysiology of NLRP12AD. This is the first time anakinra has been used to treat this disorder. This study provides new insights into the mechanisms underlying resistance to anti-IL-1 therapy observed in few patients with autoinflammatory syndromes. Our data also point to the potential interest of cytokine ex vivo measurements as predictors of response to treatment.

Arteriosclerosis, emphysema and abnormal elastogenesis in Schimke immuno-osseous dysplasia. *M. Morimoto[1,2], Z. Yu[3], J.M. Clewing[4], K. Choi[1,2], B. Najafian[5], C. Mayfield[6], G. Hendson[7], J.G. Weinkauf[8], A.K. Gormley[9], D.M. Parham[3], T. Lücke[10], C.F. Boerkoel[1,2].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Rare Disease Foundation, Vancouver, BC, Canada; 3) Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 6) Warren Clinic, Tulsa, OK; 7) Department of Anatomic Pathology, University of British Columbia and Children's and Women's Health Centre of British Columbia, Vancouver, BC, Canada; 8) Department of Medicine, University of Alberta, Edmonton, AB, Canada; 9) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 10) Department of Neuropediatrics, Children's Hospital, Ruhr-University Bochum, Germany.

Background SWI/SNF-related matrix-associated actin-dependent regulator of chromatin,
subfamily A-like protein 1 (SMARCAL1) deficiency diffusely alters gene expression yet
causes pathognomonic features characteristic of Schimke immuno-osseous dysplasia (SIOD),
an autosomal recessive multisystem disorder. We have hypothesized that SMARCAL1
deficiency causes disease by pathologically altering the expression of specific genes in affected
tissues.

Methods To study the arteriosclerosis and emphysema observed in SIOD, we analyzed the gene expression
and tissue morphology of SMARCAL1-deficient patient and mouse aorta and lung by
quantitative PCR, gene expression arrays, histopathology and immunohistochemistry.

Results SMARCAL1-deficient patient and mouse aorta and lung have markedly reduced
elastin mRNA and protein expression and abnormal organization of elastin fibers in the aorta.
Although the decreased expression of elastin could be arising from a direct effect of
SMARCAL1 deficiency on the elastin gene, we also find markedly reduced expression of
known transcriptional regulators of elastin expression.

Conclusion These observations provide one explanation for the arteriosclerosis and
emphysema of SIOD and a model for understanding other features of SIOD.

1139F

Clinical, Molecular, and Diagnostic Features of Hermansky-Pudlak Syndrome Type 3. *T. Gahl[1,2], R. Hess[2], T. Markello[2], E. Doherty[1], K. O'Brien[2], H. Doward[2], B. Gochuico[2], N. Cardillo[2], A. Cullinane[2], W. Gahl[2,3], M. Huizing[2].* 1) Virginia Tech Carilion School of Medicine, Roanoke, VA; 2) Medical Genetics Branch, NIH/NHGRI, Bethesda, MD; 3) Intramural Clinical Director NHGRI, OCD, NIH/NHGRI, Bethesda, MD.

Hermansky-Pudlak syndrome (HPS) is a heterogeneous disorder of albinism, bleeding and sporadic other features including recurrent infections, granulomatous colitis and pulmonary fibrosis. There are 8 human HPS subtypes. All subtypes are caused by mutations in genes coding for proteins that are organized into four complexes, designated adaptor complex-3 (AP3; HPS subtype 2), Biogenesis of Lysosome-related Organelles Complex (BLOC)-3 (HPS subtypes 1 and 4), BLOC-2 (subtypes 3, 5, and 6), and BLOC-1 (subtypes 7, 8, and 9).

After analyzing our NIH HPS cohort of 266 individuals with albinism and absent platelet dense bodies, HPS-3 was the most common subtype after HPS-1. More patients were affected with HPS-1 (195 patients; 148 with north-west Puerto-Rican 16-bp founder duplication, 47 with other mutations) than HPS-3 (34 patients; 9 with central Puerto-Rican 3,9-kb deletion, 25 with other mutations). And there were more unique mutations in *HPS1* (26) than in *HPS3* (23), but both these genes harbored significantly more mutations than other HPS genes: *HPS2* (4), *HPS4* (15), *HPS5* (14), *HPS6* (11), *HPS8* (1), *HPS9* (1). These findings classify HPS-3 as a major HPS subtype.

We report 16 novel *HPS3* mutations, including missense, nonsense, frameshift, and splice site mutations, located throughout the *HPS3* gene. We show that BLOC-2 deficiency can be diagnosed by Western blotting of patients' cell extracts using HPS5 antibodies, assisting in subtyping HPS-3 patients. Clinical analysis of the 12 unreported HPS-3 patients carrying these mutations confirmed the relatively milder phenotype of HPS-3. In contrast to AP3 and BLOC-3 deficient patients, there are no cases of molecularly subtyped HPS-3 patients (or other BLOC-2 patients) with abnormal lung findings consistent with pulmonary fibrosis, death from respiratory failure, or need for lung transplant. However, HPS-3 patients are at risk, like all other HPS subtypes (15-20%), for an inflammatory bowel disease which includes granulomatous colitis distinctive from but as severe as Crohn's disease.

1140F

Oligogenic Disease Models and `Clan Genomics'. *J. Lupski[1, 2, 3], J. Belmont[1,2], E. Boerwinkle[4,5], M. Bainbridge[1,5], C. Gonzaga-Jauregui[1], R. Gibbs[1,5].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, 77030; 2) Department of Pediatrics, Baylor College of Medicine, Houston, Texas, 77030; 3) Texas Children's Hospital, Houston, Texas, 77030; 4) Genome Sequencing Center, Baylor College of Medicine, Houston, Texas, 77030; 5) University of Texas Health Sciences Center, Houston Tx 77030.

With increasing DNA data and consideration of phenotypic heterogeneity, the dichotomous view of genetic disease as Mendelian versus common/chronic can be replaced by general oligogenic models. Using whole genome sequencing and whole exome DNA capture reagents, we have characterized more than 30 families with Mendelian disease and ~3,000 samples with common disease. The allele discovery supports oligogenic models as we have found genetic effects that add or modify the impact of primary disease mutations. In an individual with Charcot-Marie-Tooth disease we identified a pair of causative, recessive alleles in SH3TC2, and were able to correlate the single alleles with additional phenotypes: one subclinical axonal neuropathy; and the other with predisposition to carpal tunnel syndrome. Next, we identified the genetic cause of a DOPA Responsive Dystonia by discovering compound heterozygous, rare, deleterious mutations in SPR. The discovery altered patient management by the addition of a serotonin precursor that subsequently has alleviated symptoms which were not addressed by L-DOPA therapy alone. Interestingly, co-segregation with an apparent heterozygous null allele for SPR suggests a possible role for a haploinsufficiency in SPR activity in fibromyalgia; a condition that responds to SSRI. In studies of left ventricular non compaction (LVNC) we have found mutations in multiple genes - some with early onset and some that do not present before the age of 30. Both extremes may be present in a single family-in one such `solved' case we find a rare mutation is primarily responsible for the LVNC, but is modified by a common, protein changing mutation to yield a more severe phenotype. We have articulated similar models in multiple syndromes (Noonan syndrome, ciliopathies) and in restricted data sets from complex disorders e.g. autism. With the current pace of systematic collection and characterization of Mendelian families, it will be possible to complete and generalize these models, and to potentially associate overlapping phenotypes between the models by utilizing variant data from genome-wide studies. The impact of rare variants in these models means that the most important thing for individuals regarding inherited alleles is what their near relatives gave to them - the population from which you come is not that relevant. We term this `clan genomics', and postulate the general emergence of family data that govern clusters of disease predispositions.

1141F

Carrier screening in Romanian population for GJB2-35delG gene mutation causing non-syndromic deafness. *E. Severin[1], C. Dragomir[2], A. Stan[2], N. Scribann[3], L. Savu[2].* 1) Dept Human Genetics, Carol Davila Univ Med Pharm, Bucharest, Romania; 2) Genetic Lab SRL - Bucharest, Romania; 3) Georgetown Univ.Medical Ctr, Washington, DC, U.S.A.

Objective. The aim of carrier screening was to estimate the carrier frequency of the GJB2-35delG gene mutation in Romanian population. The 35delG mutation is known to be the leading one involved in hereditary hearing loss in European populations. Design. We performed a carrier screening to identify carriers of a hearing loss gene mutation among fetuses with normal hearing parents using prenatal molecular testing procedures. Samples of amniotic fluid (N=366) and chorionic villi (N=11) were taken from an unselected group of 377 unrelated pregnant women. Genomic fetal DNA was extracted and analyzed by PCR multiplex assays. Results. The rate of carriers for 35delG GJB2 mutation was 3.45% (13/377 or 1 in 29)) comparable to that of the most South-Eastern European populations. The genetic tests were considered for carrier detection and early diagnosis and not for termination of pregnancy. Conclusions. The study suggests a need for detecting the carriers. This is the first step for the construction of a national database, and provides information for health planners and policy makers to help them in planning programs and allocation resources. The impact of carrier screening results was good. No women regretted having had the test even their unborn child was identified as carrier.

1142F

5'UTR region mutations in *ENG* gene cause hereditary hemorrhagic telangiectasia. *K. Damjanovich[1], C. Langa[2], C. Bernabeu[2], F.J. Blanco[2], J. McDonald[1,3], D.A. Stevenson[4], P. Bayrak-Toydemir[1,5].* 1) ARUP Laboratories, Salt Lake City, UT, USA; 2) Centro de Investigaciones Biologicas, Madrid, Spain; 3) University of Utah, Department of Radiology, Salt Lake City, UT, USA; 4) University of Utah, Department of Pediatrics, Salt Lake City, UT, USA; 5) University of Utah, Deptartment of Pathology, Salt Lake City, UT, USA.

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant vascular disorder characterized by arteriovenous malformations, epistaxis, and telangiectasias, caused by mutations in the coding regions of activin A receptor type II-like (*ACVRL1*) and endoglin (*ENG*) genes. However, in approximately 15% of cases mutations have not been found in the coding regions of these genes, by sequencing and deletion/duplication testing. Non-coding regions, particularly the 5'UTR region, are important in gene regulation. Knowing this importance, we reviewed our HHT clinical database and found an *ENG* variant, c.1-9G>A in two cases; homozygous in one of the cases. This variant is predicted to affect translation, yet not alter the reading frame. Expression analyses indicated the c.1-9G>A variant is a hypomorphic mutation. This prompted us to screen 154 cases for variants in the 5'UTR region that could affect transcription. These cases, with 2 or more HHT clinical criteria, had been found to be negative for mutations in the coding regions of *ACVRL1* and *ENG*. We found a c.1-127C>T mutation, which is predicted to affect translation initiation, and alters the reading frame. This mutation was found to be in a family linked to the *ENG* gene, which previous sequencing and deletion/duplication analysis revealed no mutations in the coding regions of *ACVRL1* and *ENG*. We performed a segregation study for this family, and found the mutation only in affected individuals. The mutation was found in two other cases, in one of which the mutation was found in an affected sibling. In vitro expression studies with mutant constructs indicated downregulation of the endoglin protein, which emphasizes the importance of the 5'UTR region of the *ENG* gene in the disease pathogenesis of HHT. We sequenced 134 normal cases in which our mutations were not found, further supporting the role of these mutations in the disease, and underscoring the necesary inclusion of the 5'UTR region of the *ENG* gene in clinical testing for hereditary hemorrhagic telangiectasia.

1143F

Minor splicing defect in Microcephalic Osteodysplastic Primordial Dwarfism type 1 (MOPD1, Taybi-Linder syndrome). *P. Edery[1], C. Marcaillou[2], M. Sahbatou[3], A. Labalme[1], J. Chastang[1], R. Leutenegger[13].* 1) Dept Gen, Biol Est Ctr, Lyon-Bron, France; Inserm U1028, CNRS UMR5292, University Lyon 1, CRNL, TIGER, Lyon, France; 2) Integragen, Evry, France; 3) Fondation Jean Dausset, CEPH, Paris, France; 4) Genetics Service, CHU Saint-Etienne, France; 5) Dept Pediatrics, Division Med Genetics, Wilmington, USA; 6) Dept Ped Genetics, Amrita Institute Med Science, Cochin, India; 7) Genetics and Procreation Dept, CHU Grenoble, France; CNRS UMR5525, University Joseph Fourier, Grenoble, France; 8) Dept Pediatrics, University Hosp Innsbruck, Austria; 9) Section Clin Genetics, Dept Pathology, St Olavs Hospital, Trondheim, Norway; Center Med Genetics Mol Medecine, Haukeland University Hospital, Bergen, Norway; 10) Genetics Service, Bretonneau Hospital, CHRU Tours, France; Inserm U930, François Rabelais University, Tours, France; 11) Center Musculoskeletal Research, Texas Scottish Rite Hospital Children, Dallas, USA; 12) Inserm U669, Villejuif, France; Paris Sud University, UMR-S669, Villejuif, France; 13) Inserm U946, Paris, France; Hematology Institute, Paris Diderot University, UMR-S946, Paris, France.

The spliceosome, a ribonucleoprotein complex that includes proteins and small nuclear RNAs (snRNAs), catalyses RNA splicing through intron excision and exon ligation to produce mature messenger RNAs, which, in turn serve as templates for protein translation. Using targeted massively parallel sequencing, we identified mutations in the *U4atac* snRNA component of the minor spliceosome in patients with brain and bone malformations and unexplained postnatal death (MOPD1, Taybi-Linder syndrome, Leutenegger A.-L. et al, Am J Hum Genet 2006;79:62-6; Edery P. et al, Science 2011;332:240-3). We also showed that minor splicing efficiency is affected in fibroblasts derived from Taybi-Linder patients and that expression of several genes containing minor introns, but not all of them, is decreased in patients' cells. We are currently performing RNA-seq (whole transcriptome) analysis in patients fibroblasts to identify signalling pathways linked to the disease phenotype. We shall present our preliminary results on new candidate pathways for abnormal neuronal migration defects and unexplained early death, which are two important features of the disease.

1144F

Mutations in SERPINF1 cause Osteogenesis Imperfecta Type VI. *E. Homan[1], F. Rauch[2], I. Grafe[1], C. Lietman[1], J. Doll[3], B. Dawson[1], T. Bertin[1], D. Napierala[1], R. Morello[4], R. Gibbs[1], L. White[1], R. Miki[5,6], D. Cohn[5,6], S. Crawford[3], R. Travers[2], F. Glorieux[2], B. Lee[1,7].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Genetics Unit, Shriners Hospital for Children and McGill University, 1529 Cedar Avenue, Montreal, Quebec, Canada H3G 1A6; 3) Department of Surgery, NorthShore University Health System Research Institute, Evanston, IL 60201, USA; 4) Department of Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, Arkansas, USA; 5) Departments of Molecular, Cell and Developmental Biology and Orthopaedic Surgery, University of California, Los Angeles, CA 90095, USA; 6) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA 90048, USA; 7) Howard Hughes Medical Institute, Houston, TX 77030, USA.

Osteogenesis Imperfecta (OI) is a spectrum of genetic disorders characterized by low bone mass and fragility. It is caused by dominant mutations affecting the synthesis and/or structure of type I procollagen or by recessively inherited mutations in genes responsible for the post-translational processing/trafficking of type I procollagen. In all but one class of OI, the histopathological and clinical features cannot predict the causative gene or functional defect among affected individuals. However, recessive OI type VI is characterized by a pathognomonic increase in the amount of unmineralized osteoid, thereby suggesting a distinct disease mechanism. OI type VI is of unknown etiology and identifying the disease gene will add to our understanding of matrix mineralization and identify potential therapies. To identify the gene region, homozygosity mapping was carried out using the genomic DNA of 3 members of a consanguineous French Canadian family. A single region of homozygosity was shared by all three of these related OI VI patients defined by the markers rs8074026 and rs1362761. Next generation sequencing of one patient from this family identified homozygosity for a stop mutation in exon 4 (g.4130C>T, p.R99X) of serpin peptidase inhibitor, clade F, member 1(SERPINF1) which was confirmed by Sanger sequencing in all affect family members. The stop codon mutation was predicted to result in nonsense mediated decay (NMD) of the SERPINF1 transcript and realtime RT-PCR of patient fibroblasts confirmed that this is the case. Sanger sequencing the 8 exons of SERPINF1 in 10 unrelated patients identified additional mutations. Interestingly, the g.4130C>T mutation was identified in additional patients of French Canadian origin, suggesting the presence of a founder allele in the population. SERPINF1 encodes the 50kDa secreted protein, Pigment Epithelium-derived Factor (PEDF). Serum PEDF levels were undetectable in OI type VI patients in contrast to classical OI patients (caused by mutations affecting type I collagen) in whom PEDF serum levels were comparable to normal controls. These data suggest that mutations in SERPINF1 resulting in loss of PEDF cause OI type VI. This provides an avenue for proper OI diagnosis of patients, whereas PEDF could be measured in serum for confirmation. In addition, PEDF is a secreted protein, suggesting that therapy with recombinant PEDF could be used as a potential therapy for OI type VI patients.

1145F

Spondylothoracic dysostosis, spondylocostal dysostosis type 2, and the mutational spectrum of MESP2: protein modelling helps explain phenotypic differences from the genotype. *P.D. Turnpenny[1], M. Owens[2], K. Stals[2], E. Young[2], S. Phadke[3], I. Verma[4], O. Braaten[5], M. Nielsen[6], L. Bonafé[7], A. Cornier[8], R. Caswell[9], S. Ellard[2,9].* 1) Clinical Genetics Department, Royal Devon & Exeter Hospital, Exeter, United Kingdom; 2) Molecular Genetics Laboratory, Royal Devon & Exeter Hospital, Exeter, United Kingdom; 3) Department of Medical Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, India; 4) Center of Medical Genetics, Sir Ganga Ram Hospital, Rajinder Nagar, New Delhi, India; 5) Department of Paediatrics, Ullevål University Hospital, Oslo, Norway; 6) Department of Clinical Genetics, Leiden University Medical Center, Leiden, Belgium; 7) Laboratory of Molecular Paediatrics, Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 8) Department for Molecular Medicine, La Concepción Hospital, San Germán, Puerto Rico; 9) Institute if Biomedical and Clinical Science, Peninsula College of Medicine & Dentistry, University of Exeter, Exeter, United Kingdom.

The mesoderm posterior 2 (MESP2) gene (MIM 605195) is a key component of the Notch signalling pathway and is integral to the determination of segmental boundary formation in axial skeletal development. It is a small gene of 2 exons with a bHLH transcription domain located within exon 1. There are two very different phenotypes associated with recessive mutations in the MESP2 gene, though both affect all vertebral segments: 1. A mild form of spondylocostal dysostosis—type 2 (SCD02, MIM 608681, the closest phenotype to `Jarcho-Levin syndrome')—with limited truncal shortening and good lung capacity; 2. The severe phenotype—spondylothoracic dysostosis (STD)—giving rise to the classical `crab-like' appearance on a chest radiograph, which is sometimes lethal in early childhood due to respiratory insufficiency. Both give rise to generalised segmentation defects of the vertebrae and an early radiological `tramline' effect of ossified vertebral pedicles that is not seen in SCD cases due to the more commonly mutated DLL3 gene (SCD01). We report a wide range of 11 published and unpublished mutations alongside the radiological phenotypes. Severe, STD cases generally had frameshift or nonsense mutations in exon 1 that result in a truncated protein that is susceptible to degradation by the nonsense-mediated decay (NMD) pathway. Two SCD02 cases had the same 4-bp duplication mutation (c.500_503dup, p.Gly169fs) in exon 1, creating an open reading frame and premature termination codon in exon 2; another SCD02 case is a compound heterozygote for substitution mutations within the bHLH domain, predicted to reduce DNA binding and transcriptional MESP2 activity. One non-lethal STD phenotype is homozygous for a deletion (c.776delC, p.Pro259fs) resulting in an open reading frame and extended termination codon at 480 in exon 2. Various mechanisms may explain the severe phenotype, including the possibility that the additional sequence interacts functionally with transcriptional coactivators, resulting in the sequestration of such factors away from functional sites of transcription. In general the genotype-phenotype correlation depends on mutational site, effect on BHLH binding, and NMD. This new MESP2 developmental gene data aids our understanding and recognition of the SCD/STD axial skeletal phenotypes.

Biochemical and Molecular data of Patients with Osteogenesis Imperfecta type II-IV in the Netherlands 1991-2011. *F.S van Dijk[1], D. Micha[1], N. Ameziane[1], M. Huizer[1], E.D. Setijowati[1,2], T. Uithuisje[1], A. Maugeri[1], G. Pals[1].* 1) Clinical Gen, VU Med Ctr, Amsterdam, Netherlands; 2) Center of Biomolecular Research, Faculty of Medicine, Diponegoro University, Indonesia.

Objectives: OI (Osteogenesis Imperfecta) is currently known to be genetically heterogeneous with an estimated 90% due to heterozygous causative variants in the COL1A1 or COL1A2 gene and approximately 10% due to causative variants in recessive OI-related genes and other unknown genetic causes. Methods: In order to determine the proportion dominant versus recessive causes of OI types II-IV in our diagnostic laboratory, we studied the molecular and biochemical data from all index patients referred to us with from 1991 until 2011, with a clinical diagnosis of OI type II, II/III, IV, I/IV. Results : More than 500 causative variants were found in COL1A1 or COL1A2. In 9 index patients bi-allelic recessive variants in CRTAP, LEPRE1, PPIB and FKBP10 were found. Not all patients were analyzed for all currently known OI-related genes. Currently, we are performing targeted exome sequencing for known and candidate genes of OI to complete the molecular data on all patients. Conclusions: We present an overview of molecular and biochemical data of patients referred to our DNA laboratory with a clinical diagnosis of OI type II-IV. Several patients with a clear clinical/radiological diagnosis of OI type II/III/IV without causative variants in the known genes for OI will be discussed more extensively.

1147F

Targeted re-sequencing of the remaining 22q11.2 region in atypical DiGeorge patients. *B.A. Nowakowska[1,2,7], J.K.J. Van Houdt[1], A. Swillen[1], K. Devriendt[1], S. Bouquillon[3], F. Novara[4], C. Le Caignec[5], M. Piotrowicz[6], W. Hawula[6], A. Kutkowska-Kazmierczak[7], E. Obersztyn[7], J.R. Vermeesch[1].* 1) Center for Human Genetics, K.U. Leuven, Belgium; 2) Foundation for Polish Science (FNP), Poland; 3) Hôpital Jeanne de Flandre, CHRU de Lille, France; 4) Genetica Medica, Universita` di Pavia, Italy; 5) CHU Nantes, Service de Génétique Médicale, Nantes, France; 6) Department of Genetics, Polish Mother's Memorial Hospital - Research Institute, Lodz, Poland; 7) Institute of Mother and Child, Warsaw, Poland.

The 22q11.2 deletion syndrome, also called the DiGeorge syndrome (OMIM 188400) is the most common chromosomal deletion syndrome in humans with an incidence of 1 in 2-4000 live births. Although the clinical presentation of 22q11.2 syndrome is variable, the major clinical characteristics of the syndrome are intellectual disability, congenital heart anomalies, velopharyngeal abnormalities and characteristic facial appearance. In addition, to the variability amongst patients with the “typical” phenotypic features, occasionally (about 1/100) 22q11.2 deletion carriers present atypical malformations. Despite intensive studies it remains unclear what causes this phenotypic variability of patients with the same deletion. We hypothesize that the distinct rare features are caused by unmasking a recessive allele which occurs at low frequency in the general population. In our study we focused on patients with 22q11.2 deletion and one of the phenotypic features outside the traditional 22q11.2 spectrum, like anorectal malformation, arthrogryposis, polymicrogyria, eye anomalies, inner ear malformations and laryngeal web. For identification of the functional role of genes within the common deletion we captured coding parts of the remaining 22q11.2 region using custom designed Nimblegen capture arrays, and re-sequenced the enriched samples with 454 GS FLX Titanium chemistry. SNP analysis of the remaining 3 Mb region, in 26 individuals with deletion and rare, atypical phenotypic feature, showed surprising high diversity of genomic variants in re-sequenced genes. The recurrent deleted region harbors approximately 50 genes. Each patient carried five to eighteen non-synonymous mutations. Overall, mutations were identified in an astonishing 29 genes and several patients carried stop mutations (which are thus nullisomic). For some of those, the nullisomic mice were shown to be embryonic lethal. Further analysis performed based on comparison of variants present in patients with the same phenotypic feature against variants found in patients without that characteristic and candidate genes responsible for particular feature, will be presented.

Phage display predicts regions on MMACHC that bind its partner MMADHC in human intracellular cobalamin metabolism. *I.R. Miousse[1], M. Plesa[2], D.S. Rosenblatt[1], J.W. Coulton[2].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Microbiology and Immunology, McGill University, Montreal, Canada.

Protein-protein interactions are essential in human vitamin B_{12} (cobalamin) intracellular metabolism. Two key proteins involved in the early part of this pathway, MMACHC and MMADHC, have recently been shown to interact *in vitro* and *in vivo*. Mutations in *MMACHC* and *MMADHC* are the cause of rare inborn disorders characterized by a defect in the synthesis of methylcobalamin and adenosylcobalamin, cofactors for methionine synthase and methylmalonyl-CoA mutase, respectively. The human *MMADHC* gene, cloned as a fusion to maltose binding protein plus a hexahistidine tag, was expressed in *Escherichia coli*. The protein was purified on FPLC with Ni^{2+}-NTA and the tag removed with TEV protease. After immobilizing homogeneous MMADHC protein, its surface was probed with a library of bacteriophages displaying random sequences on their tail proteins (phage display). Unbound phages were washed off and bound phages were eluted and amplified for a second round of affinity-selection. From two commercially available phage libraries, 181 unique sequences with affinity for MMADHC were identified. By aligning affinity-selected sequences with the amino acid sequence of MMACHC, we assembled four regions that are predicted to interact with MMADHC. Three of these four regions are located in the C-terminal domain of MMACHC, corresponding to amino acids 221 to 238, 232 to 250 and 261 to 280. The C-terminus of MMACHC shares similarity with the C-terminus of TonB, a protein that mediates import of cobalamin in gram-negative bacteria. Interestingly, this region of TonB also mediates protein-protein interactions in bacteria, highlighting a potential similarity in function between the two proteins.

DFNB59 gene mutation screening using PCR-SSCP/HA technique in non-syndromic genetic hearing loss in province of Iran. *F. Azadegan-Dehkordi[1], E. Farrokhi[2], M. Saedi-Marghmaleki[3], M. Abolhasani[1], Gh. Banetalebi[3], M. Montazer-Zohouri[4], M. Hashmzadeh-Chaleshtori[5].* 1) Human Genetics, Cellular and Molecular Reserch Center, Shahrekord, Chaharmahal va Bakhtiyari, Iran; 2) MSc of Biochemistery, Cellular and Molecular Reserch Center, Shahrekord University of Medical Sciences, Iran; 3) BSc of Laboratory Sciences, Cellular and Molecular Reserch Center, Shahrekord University of Medical Sciences, Iran; 4) PhD Student of Medical Genetics, school of Medical Sciences-Tarbiat Modares University, Iran; 5) Professor of Human Genetics, Cellular and Molecular Reserch Center, Shahrekord university of Medical Sciences,Iran.

Background and aim: Hearing Impairment (HI) is the most prevalent Neurosensory disorder which is heterogenous and can also occur due to environmental causes. The majority of hearing deficiencies are of genetic origin affecting about 60% of the HI cases. A novel gene DFNB59 encods pejvakin has been recently shown to cause deafness. This study aims to determine the frequency of DFNB59 gene mutations in coding region the gene in Booshehr province. Method: In this descriptive experimental study, we investigated the presence of DFNB59 gene mutations in Exons (2-7) of the gene in 80 deaf subjects. DNA was extracted using standard phenol -chloroform method. The screening of gene mutations was performed by PCR-SSCP/HA procedure. Finally, the possible mutations were confirmed by direct sequencing. Results: In all, 9 polymorphisms 793C>G were found in 80 non-syndromic, genetic hearing loss subjects studied. However no DFNB59 gene mutation was identified. Conclusion: We conclude that the association of DFNB59 gene mutations with hearing loss is very low in samples studies.

Ubiquitous Expression of Glucosylceramide-Synthesizing Enzyme Accelerates Disease Phenotype in a Gaucher Disease Mouse Model. *S. Barnes[1], Y-H. Xu[1,3], Y. Sun[1,3], W. Zhang[2], K. Setchell[2,3], G. Grabowski[1,3].* 1) Dept Human Gen, Children's Hosp Med Ctr, Cincinnati, OH; 2) Div Path Lab Med, Children's Hosp Med Ctr, Cincinnati, OH; 3) Dept Pediatrics Univ of Cincinnati Coll Med, Cincinnati, OH.

Several viable mouse models of GD have been generated by introducing point mutations into the mouse GCase (gba1) locus that are common in Gaucher patients, including N370S, V394L or D409H, or D409V. Disease phenotypes in these mouse models have somewhat milder phenotypes than their human counterparts. We hypothesized that increasing substrate synthesis in these mice should produce phenotypes that more closely resemble those in humans. We created transgenic mice overexpressing the mouse glucosylceramide-synthesizing enzyme, UDP-glucose:ceramide glucosyltransferase (GCS) driven by a ubiquitous ROSA promoter and cross bred these mice into the D409V/null (9V/null) line. RT-PCR and Northern blot showed high levels of transgenic GCS expressed in all tissues tested compared with endogenous GCS. Western blot analyses detected substantial increases in GCS protein above WT levels, particularly in the lung and liver. This correlated with 2-fold increases in GCS activity compared to non-transgenic controls by in vitro assays using NBD-ceramide as a substrate. Glycosphingolipids analyses by LC/MS revealed ~2 fold increases in tissue-specific glucosylceramide species in brain, liver, spleen and lung tissues of 9 week old 9V/null mice expressing transgenic GCS (tgGCS). Increased CD68 immunostaining (markers of activated macrophage) was observed in the liver and lung of 9V/null mice expressing transgenic GCS compared to their non-transgenic littermates, mild effects were observed in brain. Overall, the presence of transgenic GCS increased the substrate load to levels comparable to 20 week old mice and accelerated the disease phenotype at least 3 weeks earlier than expected for 9V/null mice. This mouse model may be useful in determining the threshold level of substrate flux that influences phenotypic development and to test the efficacy of newer therapeutic approaches including pharmacological chaperones and substrate reduction.

1151F

Transgenic mouse model for MADA disease displays severe pathology in skin organization and a specific transcriptional profile in cutaneous fibroblasts. *M.R. D'Apice[1], A. Vielle[2], M. Bertoli[3,4], S. Sambucini[5], S. Mariani[4], S.M. Lepore[4], D. Minella[4], B. Testa[4], G. Rossi[6], G. Chillemi[7], G. Prosperini[7], S. Bueno[7], M. Federici[8], A. Botta[4], F. Amati[4], G. Novelli[1,3,4].* 1) Laboratory Medicine , Policlinico Universitario Tor Vergata, Rome, Italy; 2) The Gurdon Institute, University of Cambridge, Cambridge, UK; 3) Ospedale San Pietro Fatebenefratelli UOSD di Genetica Medica, Rome, Italy; 4) Department of Biopathology, University of Rome Tor Vergata, Rome, Italy; 5) Istituto di Ricerche di Biologia Molecolare, Pomezia, Italy; 6) Department of Public Health and Cell Biology, Tor Vergata University, Rome, Italy; 7) CASPUR, Consortium for Supercomputing Applications, Rome, Italy; 8) Department of Internal Medicine, University of Rome Tor Vergata, Rome, Italy.

Mandibuloacral Dysplasia type A (MADA; OMIM#248370) disease is characterized by postnatal growth retardation, craniofacial dysmorphism, skeletal and cutaneous features, lipodystrophy, and metabolic complications. Affected patients have a homozygous p.R527H mutation in the LMNA gene encoding nuclear lamin A/C. Since the pathogenic mechanisms of this mutation are still unknown, we generated a MADA transgenic mouse model by the random insertion of the human p.R527H LMNA cDNA. We evaluated the effects of p.R527H over-expression by pathological, histological, cellular and molecular examination. The LMNA mutation determines some aging phenotypes in adult transgenic mice. These include decreased body weight and skin thinning and disorganization. A mild significant glucose intolerance and insulin resistance was revealed when the animals were undergone to a diet rich in fat. Investigations of growth rate, life span, wound healing, and ossification ability of transgenic mice not showed significant differences compared to wild-type littermate. Mutant MADA fibroblasts, isolated from dorsal skin, showed alteration of nuclear shape, delayed cellular proliferation and increase of senescence. Additionally, their transcriptional profile showed significant alterations in the expression of gene involved in different cellular pathways. Although these data suggest that our MADA mouse model summarizes only some characteristics of the complex human phenotype, transgenic fibroblasts show an altered nuclear and cellular phenotype and a specific gene expression confirming the role of lamin A in signalling pathways affecting transcription regulation.

1152F

Pathogenic orphan transduction created by a non-reference, rare LINE-1 retrotransposon. *S. Solyom[1], A.D. Ewing[1], D.C. Hancks[1], M. Matsuo[2], Y. Takeshima[2], H. Awano[2], H.H. Kazazian[1].* 1) Institute for Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Kobe University, Kobe, Japan.

Retrotransposons ("jumping genes") are highly abundant mobile genomic elements. In particular, the long interspersed element-1 (LINE-1) class comprises 17% of the human genome. These autonomous non-long terminal repeat retrotransposons move by a potentially mutagenic "copy and paste" mechanism via an RNA intermediate that is reverse transcribed and inserted into the genome. Recently, the retrotransposition-mediated insertion of a new transcript was described as a novel cause of genetic disease, Duchenne muscular dystrophy, in a Japanese male (Awano et al. 2010). In this work, it was presumed that the inserted sequence was a single-copy, non-coding RNA transcribed from chr. 11q22.3 that was reverse transcribed and integrated into exon 67 of the dystrophin gene on chr. X. Because LINE-1 insertions are often associated with 3' transduction of adjacent genomic sequences, we suspected that the insertion might result from a 3' transduction of a LINE-1. However, no LINE-1 was present in the DNA upstream of the single copy sequence from chr. 11q22.3 in the human reference genome. Here we demonstrate through PCR-based analysis that a polymorphic, non-reference full-length LINE-1 is situated in the maternal and proband genomes at chr. 11q22.3 directly upstream of the sequence that was inserted into the dystrophin exon. This full-length LINE-1 is rarely present in the Japanese population. Thus, the likely explanation for the mutagenic insertion in the proband is a LINE-1-induced 3' transduction event with a severe 5' truncation upon insertion, such that only the 3' transduced sequence was inserted. This is the first example of LINE-1-induced human disease caused by an "orphan" 3' transduction, without insertion of the LINE-1 sequence. Therefore, any insertion of a non-repetitive sequence bearing the hallmarks of retrotransposition should be further investigated for a LINE-1 mediated transduction event.

A Novel Gene Controls Macular Retina Development, Corpus Callosum and Hippocampus Morphogenesis as well as Immune Function. *P. Bitoun[1], E. Pipiras[2], B. Benzacken[2], A. Delahaye[2].* 1) Medical Genetics, CHU Paris-Nord, Jean Verdier Hospital, Bondy, France; 2) Embryo-Cytogenetics CHU Paris-Nord, Jean Verdier Hospital, Bondy, France.

Background: Childhood Macular dystrophy usually presents around age 5-15 as Stargardt disease associated with ABCA4 mutations. The authors report a consanguineous family with a congenital syndromic macular dystrophy. Materials and Methods: Patients were examined using ocular biomicroscopy, color vision, ERG, VEP, Multifocal ERG, retinal Optical Coherescence Tomography (OCT), brain MRI karyotyping, ABCA4 sequencing, screening for known AR retinitis pigmentosa gene mutations and 105k Agilent Array CGH platform. Results: This 5 year-old proband presented with congenital nystagmus and visible macular dystrophy without auto-fluorescence, 20/200 distance vision and absent macular formation on Optical Coherence Tomography. ERG was normal while 15' and 30' pattern VEP absent response pointed to macular bundle dysfunction. She had complete corpus callosum agenesis discovered prenatally and an MRI showed hippocampi hypoplasia, she had severe liver infection manifesting as fatigue and daily afternoon sleep attacks at school with normal EEG and cytolytic hepatitis with 20x N elevation of ASAT and ALAT associated with infectious mononucleosis combined with group A beta streptococcal infection lasting for 4 months. Her 10 year-old brother with reportedly normal vision was found to have absent foveal peak on multifocal ERG bilaterally and slight hypoplasia of the junction of the posterior third of the corpus callosum. The younger 4 year-old sister was also found to have macular dystrophy without nystagmus and 20/60 vision bilaterally. The Proband was found to carry a small 115kb homozygous deletion of the 3q25 region on array CGH also present in both siblings while parents carried the same heterozygous deletion. Proband was found to harbour a double variant ABCA4 allele in cis with missense S2255I and c.6282 + 7G>A (IVS45 + 7 G>A) the pathogenicity of which are widely debated in the literature and inherited from father but not present in the other siblings. Discussion: The contribution of this ABCA4 variant in explaining the more severe proband phenotype is discussed while the macular dystrophy of the sister and, to a lesser degree, the brother confirms the role of the gene deletion alone in the etiology of the macular dystrophy . This observation identifies a developmental gene involved in retinal macular specification and development as well as corpus callosum and hippocampus morphogenesis as well as immune function.

1154F

Novel mutations in CNGA3 and CNGB3 cause Achromatopsia in the Newfoundland Population. *L. Doucette, J. Green, C. Black, G. Johnson, TL. Young.* Discipline Gen, Memorial Univ Newfoundland, St. John's, NF, Canada.

Intro: Achromatopsia is an autosomal recessive (AR) congenital disease of the cone photoreceptor affecting 1-50,000 individuals worldwide. This disorder causes severely reduced visual acuity, loss of colour vision, photophobia, and nystagmus. The majority of cases are caused by mutation of one of three genes, CNGB3 (50% of cases), CNGA3 (20-30%), and GNAT2 (2%). This study aimed to identify the molecular etiology of AR achromatopsia in five families from Newfoundland. Methods: We obtained 13 samples (eight affected; five unaffected) from five families and performed direct sequencing of three previously associated achromatopsia genes, CNGB3, CNGA3, and GNAT2. Identified variants were checked in dbSNP, underwent segregation analysis where possible, and were compared to ethnically matched controls. Mutated amino acids were checked for conservation to assess pathogenicity. Results: This approach revealed 18 variants (14 were SNPs). Two variants (CNGA3 c.1580 T>G; and CNGB3 c.887_896del) were novel and were absent in ethnically matched population controls. The CNGA3 c.1580 T>G mutation causes the replacement of a leucine residue at position 527 with an arginine (L527R). This mutation was homozygous in family 1491 and conservation analysis of the L527 residue found that it is completely conserved across 15 species. This mutation was also identified as a compound heterozygote with the previously described c.1479 T>C: p.R427C allele in family 1723. The second novel mutation, c.887_896del, was found in CNGB3 and is predicted to cause a frameshift, creating a stop codon nine amino acids downstream (p.T296NfsX9). This 10 bp deletion in CNGB3 was found to be compound heterozygous in family 1713 with the commonly reported c.1148delC mutation. We also identified the c.1148delC in the homozygous state in two other families (1442, and 1492). This study has identified two novel mutations and two previously described mutations, solving a total of five families. This observed heterogeneity confirms the complexity of achromatopsia and illustrates that different genes and mutations can be responsible for this disorder even in a genetically isolated population such as in Newfoundland.

1155F

RD3 mutations are responsible for GUCY2D-like LCA. *I. PERRAULT[1,2], S. HANEIN[1,2], N. DELPHIN[2], S. GERBER[1,2], N. ABOUSSAIR[1,3], A. MEGARBANE[4], C. EDELSON[5], C. LEOWSKI[6], J.-L. DUFIER[7], O. ROCHE[7], A. MUNNICH[1,2], J. KAPLAN[1,2], J.-M. ROZET[1,2].* 1) Genetics and epigenetics of metabolic, sensorineural diseases and birth defetcs, INSERM U781-Paris Descartes University & Institute of genetic diseases IMAGINE, Necker - Enfants Malades University Hospital, Paris, France; 2) Genetics Department, Necker - Enfants-Malades University Hospital, Paris, France 3Institute for Medical Genetics, Rabat, Morroco; 4Department of Medical Genetics, Saint Joseph University Hospital, Beyrouth, Lebanon, 5Ophthalmo-Pediatric Department, Fondat; 3) Institute for Medical Genetics, Rabat, Morroco; 4) Department of Medical Genetics, Saint Joseph University Hospital, Beyrouth, Lebanon; 5) Ophthalmo-Pediatric Department, Fondation Ophtalmologique Adolphe de Rothschild, Paris, France; 6) Institut National des Jeunes Aveugles, Paris, France; 7) Ophthalmology Department-Paris Descartes University, Necker - Enfants Malades University Hospital, Paris, France.

Purpose: Leber congenital amaurosis (LCA) is the earliest and most severe retinal degeneration. It may present as a congenital stationary cone-rod dystrophy (LCA type I) or a progressive yet severe rod-cone dystrophy (LCA type II). Fifteen LCA genes have been identified which account for approximately 70% of cases. A unique splice-site mutation in the gene RD3 was reported to cause LCA. The purpose of this study was to assess the involvement of RD3 in a large cohort of unrelated patients affected with LCA and to look for possible genotype-phenotype correlations. Families and Methods: We selected 190 unrelated LCA patients originating worldwide with no mutation in known LCA genes. The two coding exons and intron-exon boundaries of the RD3 gene were screened using direct sequencing. The clinical files of patients harbouring RD3 were revisited to search for genotype-phenotype correlations. Results: Two original RD3 mutations were identified in 5 families originating from countries on the Shores of the Mediterranean (Algeria, Morocco n = 2, Lebanon and Turkey). The two mutations are expected to truncate severely the protein. They segregated with the disease in all five families and were not found in a control panel of 113 unrelated healthy individuals, 25/113 of who originated from Mediterranean countries. One of the 2 mutations segregated with the disease in 4/5 families. Segregation analysis of microsatellite markers flanking the mutation supported the hypothesis of a founder effect in 3/4 families by showing the transmission of a small common haplotype (1Mb) with the disease. Haplotype studies and Bayesian calculations suggested that the mutation occurred 100-150 generations ago. All Patients presented with LCA type I but with moderate or absent hyperopia. Discussion and conclusion: This study gives support to the implication of RD3 in LCA families. Yet, the identification of homozygous mutations in consanguineous families originating from closely-related populations suggests that rare population-specific mutations might exist. All patients presented with LCA type 1. Interestingly, this phenotype was originally described in patients with mutations in the gene encoding GUCY2D which trafficking in photoreceptors depends on RD3. Finally, none of the patients (2-31 yrs) had renal failure, neurological symptoms or mental retardation. Owing to the retina-specific pattern of expression of RD3, it is likely that the disease may remain restricted to the retina.

1156F

Transcriptional Regulation of B°AT1 (Slc6a19), the Gene Mutated in Hartnup Disorder. *E. Tumer, S. Broer, T. Juelich.* Research School of Biological Sciences, The Australian National University, Canberra, Australia.

Hartnup disorder is an autosomal recessive disorder caused by mutations in the B°AT1 (Slc6a19) gene encoding the major transport system for neutral amino acids across the intestinal brush-border membrane. B°AT1 protein is expressed at the apical membrane of intestinal villus enterocytes along the villus-crypt axis. Mechanisms regulating B°AT1 expression along crypt to villi tips are still unknown. In this study a combination of experimental approaches were used to identify potential factors of mouse B°AT1 transcriptional regulation. Potential binding sites of transcription factors within the promoter region of B°AT1 gene were predicted with Genomatix Matinspector (genomatix.de), and the compared with changes in global gene expression pattern between crypts and villus cells using Microarray. We co-transfected these transcription factor candidates into Hek293 with B°AT1 promoter constructs of different sizes. Co-transfection of Hnf4(-expression plasmid increased B°AT1 promoter activity by 20 times when compared to the basal luciferase activity. Also, Hnf1(co-transfection showed 3 to 5 fold higher luciferase activity to a promoter only construct. The binding sites for this transcription factors are confirmed by site-directed *in vitro* mutagenesis. Both transcription factors are highly expressed in the crypt and villus cells. Sox9 is another possible transcription factor candidate; Sox9 co-transfection was sufficient to abolish the promoter activation caused by Hnf1(and Hnf4(. We hypothesize that Sox9, a transcription factor known to be involved in the differentiation of stem cells into mature enterocytes, plays a crucial role in the repression of B°AT1 in the crypt, while Hnf1a and Hnf4a were shown to interact readily with the B°AT1 promoter *in vitro*..

1157F

Expression and characterization of the ALAS2 carboxy-terminal gain-of-function mutations causing X-linked protoporphyria. *D.F. Bishop, V. Tchaikovskii, I. Nazarenko, M. Balwani, D. Doheny, R.J. Desnick.* Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY.

X-Linked Protoporphyria (XLP) (MIM #300752) is a cutaneous porphyria resulting from deletions in the last exon of the erythroid-specific 5-aminolevulinate synthase gene (ALAS2). These exon 11 deletions result in either a carboxy-terminal truncation or a replacement of the carboxy-terminus with a different polypeptide sequence. They are expressed as “gain of function” mutations that increase the enzymatic activity of ALAS2, leading to the accumulation of nearly equal amounts of free- and Zn-protoporphyrin IX in erythrocytes. The subsequent release from erythrocytes results in protoporphyrin accumulation in other tissues, particularly in the vasculature of the skin and liver. Patients exposed to light experience a painful burning sensation, due to the photosensitivity of the porphyrin in the skin vasculature. To date, the reported studies of XLP-causing mutations have used assays of crude extracts of recombinantly-expressed mutant proteins fused to the maltose binding protein (MBP) (Whatley et al., Am. J. Hum. Genet. 83:408-414, 2008). To further characterize the functional consequences of these mutations, the two previously reported ALAS2 exon 11 mutations, c.1706_1709delAGTG and c.1699_1670delAT, and a third, new XLP mutation, c.1734delG, were expressed in *E. coli*, the MBP fusion protein removed, and the mutant recombinant enzymes purified to homogeneity. The novel c.1734delG mutation resulted in a carboxy-terminal replacement of the last 7 residues with 12 new residues; SMSPPMPEKPAA. In contrast to the previous report of up to a 200-fold increase of ALAS2 activity *in vitro*, the c.1706_1709delAGTG and c.1699_1670delAT enzymes had 2- to 3-fold increases in both specific activity and the V_{max} for glycine. Both had a 1.5-fold increase in the V_{max} for succinyl CoA. Surprisingly, the homogeneous c.1734delG mutant enzyme had normal specific activity, a 25% reduced V_{max} for glycine, and a 50% reduced V_{max} for succinyl CoA. The affinity constants for both substrates were normal, as were the thermostabilities at 45°C for all three enzymes. Wild-type ALAS2 had two bands on SDS PAGE, the expected band of ~54 kDa and a proteolytically clipped band of ~52 kDa that was enzymatically active *in vitro*, but predictively less active *in vivo*. The c.1734delG mutation led to reduced proteolysis, increasing the amount of the ~54 kDa form that is active *in vivo*, thereby providing a different gain-of-function mechanism for this XLP mutation.

1158F

Mutational screening of ARID/BRIGHT and JmJC domains in *JARID1C/KDM5C* gene in Brazilian men with intellectual disability of unknown etiology. *A.P. Gonçalves, N.F. Rodrigues, M. Campos Jr, J.M. Santos, M.M.G. Pimentel, C.B. Santos-Rebouças.* Department of Genetics, State University of Rio de Janeiro, Rio de Janeiro, Brazil.

X-linked intellectual disability (XLID) is a heterogeneous set of genetic conditions caused by mutations in more than 90 different genes located at X chromosome, which affects approximately 2-3 males per 1000. Among these genes, mutations in the *Jumonji AT-rich interactive domain 1C* (*JARID1C*) gene were recently identified as potential etiologic candidates for XLID. *JARID1C* gene encodes a transcriptional regulator that has histone demethylase activity specific for di- and trimethylated histone 3 lysine 4 (H3K4) and is indispensable for epigenetic regulation. JARID1C protein contains several conserved motifs, including ARID/BRIGHT and JmJC domains. ARID/BRIGHT displays a possible involvement in the modification of the chromatin structure, whereas JmJC domain catalyzes novel histone modifications, being responsible for the demethylase activity of JARID1C. In this study, we investigated mutations in the *JARID1C* gene by screening exons 3, 4 and 5 (ARID/BRIGHT domain) and exons 11, 12 and 13 (JmJC domain) in 115 patients with ID of unknown etiology (103 from families with possible XLID and 12 from ID affected sib pairs). Genomic DNA was extracted from peripheral blood and samples were amplified by PCR, followed by direct Sanger sequencing analysis. All patients had normal karyotypes and mutations in *FMR1*, *FMR2* and *MECP2* genes were ruled out. We identified two silent mutations: the variant c.564G>A (Lys188Lys), located at exon 5 and the variant c.1794C>G (Pro598Pro), situated at exon 13. While the former was previously described in both XLMR families and control samples, being considered benign, the latter has never been reported. Nonetheless, a silent mutation at the same 1794 position (c.1794C>T; Pro598Pro) was previously found among probable XLID families, but was absent in controls. *In silico* analyses were performed to verify if the c.1794C>G variant could affect possible Exonic Splicing Enhancers (ESEs) of splicing. Rescue-ESE software did not identify any ESE in the region flanking the c.1794C>G mutation, whereas ESE finder software predicted modifications of the ESE pattern from the wild type sequence to the mutated one. Evidence have demonstrated possible harmful role of silent variants, suggesting that they could interfere, in some situations, with mRNA folding, translation speed, besides altering ESEs pattern. In this sense, the c.1794C>G mutation should not be definitively classified as benign and more investigative studies are needed.

1159F

Disease-associated NEMO mutations as a tool to unravel the key molecular mechanisms in NF-2B activation. *A. Pescatore[1], E. Esposito[1], J. Gautheron[2], G. Courtois[2], M.V. Ursini[1].* 1) Human Molecular Genetics , IGB-ABT-CNR, Naples, Italy; 2) INSERM U781, Hôpital Necker, Paris, France.

NF-2B is a ubiquitous transcription factor implicated in a wide array of physiological and pathological processes such as development, immunity tissue homeostasis and inflammation. The genetic disease that mainly contributed to elucidate of the role of NF-2B alteration in human disorder is Incontinentia Pigmenti (IP, OMIM #308300), an X-linked dominant genodermatosis caused by mutations in NEMO. IP presents with skin lesions appearing at birth and evolving in four typical stages. In addition, other neuroectodermal tissues are affected and often, a severe clinical presentation involving mental handicap was reported. NEMO is the essential subunit of the kinase complex IKK, the regulatory complex required for the canonical NF-2B activations. Further progress on the comprehension of the IP physiopathology depends on a deeper insight into the mechanisms of action of NEMO mutated protein in the context of IP pathology. Starting from the NEMO screening in a large cohort of IP patients from EU we identified few missense NEMO mutations. Among them we will present a complete analysis of two NEMO missense mutations and one short internal deletion found in IP patients. Studying the selected mutations in several cell lines: (1) we identified the lysine residues of NEMO, which are targeted by TRAF6-dependent non-degradative ubiquitination, a posttranslational regulatory modification that is essential for NEMO function; (2) we characterized the domains participating in NEMO/TRAF6 interaction and we provide genetic and molecular evidences supporting the role of this physical interaction in NF-2B activation; (3) we produced exciting new information concerning the identity of the NF-2B-dependent signaling pathways such as IL-1beta and TNF-alfa that play a critical role in the manifestations of the disease. More important, dissecting specific molecular interactions within the NEMO-mediated NF-2B activation could suggest new targets for the development of potentially effective therapeutic strategies, not only for this specific pathology but also for more common pathologies resulting from NF-2B dysfunction. Regulation of Dendritic Spine Characteristics in Mouse Brains by Members of the Fmr1 Gene Family. *R. Zong[1], Z. Fang[1], D. Parghi[2], D. Nelson[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Intellectual and Developmental Disabilities Research Center (IDDRC), Baylor College of Medicine, Houston, TX.

Absence of the RNA-binding protein FMRP (Fragile X Metal Retardation Protein) causes Fragile X syndrome, the most common form of inherited mental retardation. Abnormal dendritic spine development was observed in both human patients and in mice lacking FMRP. There is increasing evidence to support that FMRP modulates synaptic plasticity by negatively regulating translation of mRNAs, however specific targets and molecular mechanism in vivo for this action remain largely unknown. Qualitative examination of human brain autopsy material has shown that fragile-X patients exhibit abnormal dendritic spine lengths and shapes on parieto-occipital neocortical pyramidal cells. In animals, similar quantitative results have been obtained in Fmr1 knockout mice as dendritic spines were examined by using the Golgi-Cox method. We have examined dendritic spines in mice with mutations in Fmr1, as well its paralogs Fxr1, and Fxr2 using the Golgi method, and carried out quantitative analysis of dendritic spine length, morphology, and density to demonstrate the regulation of dendritic spine development by FMRP, FXR1P, and FXR2P. Behavioral studies have also suggested that Fxr1 and Fxr2 share functional overlap with Fmr1 in mice. In this study, we demonstrate that mice lacking any of these proteins (FMRP, FXR2P, or FXR1P) individually exhibit abnormal dendritic spines in the visual cortex. Phenotypes include increased spine length, elevated spine density, and an immature morphology. To further demonstrate the functional overlap of these proteins, abnormal dendritic spine phenotypes were found to be exaggerated in Fmr1/Fxr2 double knockout mice. We also found elevated spine densities in Purkinje neurons of mutant mice. Our data are consistent with the concept that this class of RNA binding proteins together plays an important role in normal spine structural maturation and possibly in pruning. Finally, we demonstrate the ability to establish and/or rescue dendtitic spine abnormalities in adult mice that have alleles which allow condition expression or ablation of FMRP. This finding suggests that this aspect of the Fragile X phenotype may be amenable to treatment beyond the juvenile period.

The Role of Methylation in Reversible Gene Expression in The Airways of Former Smokers. *GL. Stewart[1], EA. Vucic[1], R. Chari[2], S. Lam[1], WL. Lam[1].* 1) Dept. of Integrative Oncology, BC Cancer Research Centre, Vancouver, BC, Canada; 2) Dept. of Genetics, Harvard Medical School, Boston, MA.

Background: Smoking related disease including lung cancer (LC) is a leading cause of morbidity and mortality, and by 2030, it is predicted to kill one in every 6 people in the world. Surprisingly, half of newly diagnosed LC patients are former smokers (FS), who remain at an elevated risk of LC years after quitting. Cigarette smoke induces DNA damage in airway and lung tissues at the genomic and epigenomic levels, where it is associated with changes to gene expression. Upon smoking cessation, both reversible and irreversible changes in gene expression have been described in studies on current (CS), FS, and never smokers. As DNA methylation is both a heritable and reversible epigenetic gene regulatory mechanism that is highly altered in cells lining the airways of smokers, we hypothesize that the reversible nature of genes differentially expressed in bronchial epithelial cells in the airways of CS and FS, may be due to changes in DNA methylation Methods: Bronchial epithelial cells were obtained from brushings of small airways (< 2mm diameter) during bronchoscopy from CS (n=12) and FS (n=6). Global gene methylation profiles were generated using the Illumina Infinium Human Methylation27 platform. Methylation results were aligned to the set of reversibly expressed genes described in previous studies, and genes that were differentially expressed and methylated upon smoking cessation were selected for further study. Results: Methylation and expression analysis identified 9 genes to be overexpressed and hypomethylated, and 3 genes to be underexpressed and hypermethylated in CS relative to FS. The former 9 included GPX2 and GSTA2, genes involved in central metabolic pathways activated in response to halogenated and polycyclic aromatic hydrocarbons, and detoxification of reactive oxygen intermediates. These pathways have been previously shown to be upregulated in CS. The latter 3 included SYF2 and CXCL6, involved in cell cycle regulation and inflammatory disease, respectively. Conclusion: The identification of differentially methylated and expressed genes between CS and FS may provide insight into the mechanism of smoking related disease. Significantly, as DNA methylation is a reversible gene regulatory mark, this knowledge may lead to the application of preventative epigenetic therapeutics for CS and FS and help reduce the burden of smoking related disease.

Genome-wide association analysis of genetic determinants for lethal prostate cancer. *R. Szulkin[1], S. Benlloch[2], A. Amin Al Olama[2], D. Easton[2], R. Eeles[3], Z. Kote-Jarai[3], M. Guy[3], K. Govindasami[3], H. Grönberg[1], F. Wiklund[1], PRACTICAL.* 1) Department of Medical Epidemiology and Biostatistics,Karolinska Institutet, Stockholm, Sweden; 2) Centre for Cancer Genetic Epidemiology, University of Cambridge, Strangeways Laboratory, Cambridge, UK; 3) The Institute of Cancer Research, Sutton, Surrey UK.

Given a prostate cancer diagnosis today, it is hard to predict how the disease develops. Prognostic tools, such as clinical stage (T), pathological grade (Gleason) and prostate-specific antigen (PSA) levels perform suboptimally in distinguishing those who will develop a lethal prostate cancer from those with a less aggressive disease. Thus, there is an urgent need for improved tools to guide clinicians in treatment decisions. There is a strong genetic component in prostate cancer development and several risk susceptibility regions have been identified. However, none of these have been proven to discriminate between lethal and non-lethal prostate cancer. We have performed a genome-wide association study (GWAS) to identify inherited genetic variants associated with prostate cancer mortality. In the first stage, we examined the association between SNPs (Single-nucleotide Polymorphisms) and mortality in a combined analysis of a Swedish study, CAPS (Cancer of the Prostate in Sweden) and a British study, UK 1. The CAPS study included 1,932 prostate cancer cases of whom 422 had died from the disease at the end of follow-up (June 2009), genotyped using the Affymetrix 500k array. UK1 included 1820 patients, of whom 206 patients were deceased, genotyped using the Illumina 550k array. Imputation using Hapmap CEU as reference was used to estimate genotypes for a common set of 1.6 million SNPs for analysis. In the combined analysis 10 SNPs were associated at p<10-5 and 78 SNPs at p<10-4. The strongest associations were found in chromosomal regions 7q11 (SNP rs17139313, p=4.3*10-8) and 7q31 (SNP rs2299556, p=9.1*10-7). These were genotyped in a further 18,194 prostate cancer patients, of which 712 had died from the disease, within the PRACTICAL (PRostate cancer AssoCiation group To Investigate Cancer Associated aLterations in the genome) consortium. Neither association replicated in PRACTICAL. Genotyping of the 5,000 top survival associated SNPs, from the first stage is currently ongoing. These results emphasise that large sample sizes are required to reliably identify genetic determinants of cancer survival.

1163F

The Role of Notch Signaling in the Pathogenesis of Osteosarcoma. *J. Tao[1], M. Jiang[1,4], T. Bertin[1], F. Gannon[2], L. Donehower[3], B. Lee[1,4].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pathology and Immunology, Baylor College of Medicine, Houston, TX; 3) Molecular Virology and Microbiology, Baylor College of Medicine, Houston, TX; 4) Howard Hughes Medical Institute, Houston, TX.

Human osteosarcoma (OS) is the most common primary bone cancer, comprising approximately 20% of all bone tumors and about 5% of pediatric tumors overall. Most OS occurs sporadically and our understanding of its molecular basis is still limited. Recently, we found that human and mouse p53 mutant osteosarcoma tumor samples show evidence of upregulated Notch signaling. Moreover, chemical or genetic inhibition of Notch signaling decreased tumor growth in a xenograft mouse model of human osteosarcoma. Notch signaling plays an important role in the developmental processes and tissue homeostasis. Altered Notch signaling has been associated with several cancers in which Notch can act both as an oncogene and tumor suppressor depending on its spatiotemporal expression. To generate a mouse osteosarcoma model and examine the role of Notch signaling in bone tumorigenesis, we utilized a bitransgenic mouse model that constitutively expresses a single copy of Notch NICD in osteoblasts. The resulting bitransgenic Notch gain-of-function (GOF) mice developed osteosclerosis at early age. Histomorphometric and molecular analysis of cavarial and long bones indicated that Notch could stimulate proliferation of immature osteoblasts while inhibiting their differentiation into mature osteoblasts. This gain of function phenotype was reminiscent of osteoblastic tumors. Indeed, aging studies of these GOF mice showed that they spontaneously developed bone tumors with complete penetrance and had a survival mean time of 9.5 months. To explore a genetic interaction of Notch and p53 pathways in the pathogenesis of OS, the GOF mice were bred with p53-conditional mice. We found that p53-null GOF mice showed significantly shortened latency prior to tumorigenesis, as mice developed OS at a mean time of 5 months. This result suggests that the genetic interaction of Notch and p53 plays a critical role in OS development. Together, our data support that p53-Notch interaction may be a dominant mechanism in OS pathogenesis.

Molecular Study of PCA3 gene variations in Iranian patients affected with prostate cancer. *A. TAVAKOLI TAMEH, S. MATOO, A. YASARI MAZANDARANI, B. SEDAGHATI KHAYAT, N. HATAMNEJADIAN, SH. ABADPOUR, M. MAHDAVI, A. RASHID FARROKHI, A. EBRAHIMI.* Dr. Ahmad Ebrahimi Molecular Genetics , PhD Parseh Medical Genetics Counselling Center, Floor 7, No.75, Royan Alley,Keshavarz Bolv. Tehran, Iran Tel-Fax: +98 21 88966579 ,88996889 E-mail: ae35m@yahoo.com.

Introduction: Prostate Cancer is the most common cancer in men over 35 years old. Using biomarkers for early diagnosis in this cancer could be useful. Early researches show that increasing PCA3 expression in patients with prostate cancer could be a remarkable diagnostic biomarker in decision-making for biopsy. So studying the molecular changes of PCA3 gene in prostate cancer can be helpful. Materials and methods: Fifty patients and 100 healthy people were chosen according to the clinical examinations and preclinical work ups. After genetic counseling and preparing consent information, the proband blood samples were collected and DNA samples were extracted. The PCR product using intronic primers were amplified and then analyzed by direct sequencing. Results: The analysis showed various sequence, including some new SNPs and mutations. Studies also suggest that patients with prostate cancer have a rational pattern of STR population in exon 3 of PCA3 gene. This study same as previous molecular studies in Iranian population, revealed that there is a high level of heterogeneity in Iranian multi-ethnic population. Key words: Prostate cancer, PCA3, STR, PCR.

Exploring a *PALB2* c.3113G>A breast cancer multiple-case family for other genetic risk factors via exome sequencing. *Z.L. Teo[1], D.J. Park[1], F. Odefrey[1], F. Hammet[1], T. Nguyen-Dumont[1], H. Tsimiklis[1], B.J. Pope[2], A. Lonie[2], G.G. Giles[3], J.L. Hopper[4], M.C. Southey[1], ABCFS.* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria, Australia; 2) Victorian Life Sciences Computation Initiative , Victoria, Australia; 3) Cancer Epidemiology Centre, The Cancer Council Victoria, Victoria, Australia; 4) Centre for Molecular Environmental Genetic and Analytical Epidemiology, School of Population Health, The University of Melbourne, Carlton, Victoria, Australia.

PALB2, the binding partner of BRCA1 and BRCA2, is involved in homologous recombination repair. Studies of multiple-case breast cancer (BC) families have reported that mono-allelic *PALB2* mutations, on average, increase BC risk two to six fold. Proven genetic modifiers of BC risk for *BRCA1* and *BRCA2* mutation carriers are now numerous. Despite being associated with small changes in risk individually, collectively they may account for considerable risk modification for some women. In a population-based study of BC we used five population-based families and estimated the cumulative BC risk of carrying the *PALB2* c.3113G>A mutation to be 91% (95%CI=41-100) by age 70, similar to 65% (95%CI=44-78) and 45% (95%CI=31-56) average risk estimates for *BRCA1* and *BRCA2* mutation carriers respectively. One of these pedigrees, negative for *BRCA1*and *BRCA2* mutations, has ten diagnoses of BC (5 under the age of 50 years). The pedigree structure does not allow for all cases to be explained by a single genetic factor and two affected women do not carry the *PALB2* mutation (both maternal side). In view of such a high risk estimate and observations of non-*PALB2* mutation carrier cases in this pedigree, we hypothesise that there may be other genetic risk factors segregating through this family. Presence of other genetic risk factors, in addition to *PALB2* c.3113G>A, could alter the risk for mutation carriers and/or convey BC risk to family members who are not *PALB2* mutation carriers. These additional factors could further explain the BC cases in non-*PALB2* mutation carriers, the multiple cases of early onset BC and the high estimated risk of c.3113G>A in this family. We performed whole exome capture followed by massively parallel sequencing on four strategically selected affected females of this family: the proband, her sister and their paternal and maternal cousin. In this family, we have identified 15 predicted protein damaging variants in genes with plausible relevance to cancer aetiology. Eight such variants are protein truncating or are mutations predicted to have strong effects on splicing efficiency, two of which have been observed in key DNA repair genes. In summary, six of the genes have roles in DNA repair, three in cell cycle checkpoints regulation, one controls telomerase activity and another has been reported to predispose to prostate cancer. Further analyses of these candidate genes to determine their relevance to BC predisposition will be presented.

Chanock[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland, USA; 2) Medical Service, Veterans affairs Medical Center, Washington, DC.,USA; 3) Core Genotyping Facility at the Advanced Technology Center of the National Cancer Institute, NIH, SAIC-Frederick Inc., National Cancer Institute-Frederick, Frederick, Maryland, USA; 4) International Agency for Research on Cancer (IARC), Lyon, France; 5) N.N. Blokhin Cancer Research Centre, Moscow, Russia; 6) Karmanos Cancer Institute and Department of Family Medicine, Wayne State University, Detroit, Michigan, USA; 7) Department of Epidemiology, Institute of Occupational Medicine, Lodz, Poland; 8) Division of Epidemiology and Biostatistics, School of Public Health, University of Illinois at Chicago, Chicago, USA; 9) Charles University in Prague, First Faculty of Medicine, Institute of Hygiene and Epidemiology, Prague, Czech Republic; 10) Palacky University, Olomouc, Czech Republic; 11) Department of Cancer Epidemiology and Genetics, Masaryk Memorial Cancer Institute, Brno, Czech Republic; 12) Division of Cancer Prevention, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland, USA; 13) Epidemiology Research Program, American Cancer Society, Atlanta, Georgia, USA; 14) Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland.

In follow-up of a recent genome-wide association study (GWAS) that identified a locus in chromosome 2p21 associated with risk for renal cell carcinoma (RCC), we conducted a fine mapping analysis of the 120kb region flanking the EPAS1 gene. We genotyped 59 tagged common single nucleotide polymorphisms (SNPs) across a 120kb region flanking the EPAS1 gene in 2,278 RCC cases and 3,719 controls of European background. Genotypes surrounding EPAS1 were imputed using two publicly available reference data sets: 1000 Genomes Project March 2010 release and Phase III HapMap. To validate the association signals, top hits were genotyped in five studies (2,480 RCC cases and 4,203 controls). A conditioned analysis was performed to determine if the effect for new SNPs was independent of the previously reported markers in the GWAS. In an analysis of controls, SequenceLDhot was used to identify recombination hotspots between two signals. We observed a novel signal for rs9679290 (P= 5.75x10-8; OR= 1.27, 95% CI: 1.17-1.39 per allele). Imputation of common SNPs surrounding rs9679290 using HapMap III and 1000 Genomes data yielded two additional signals, rs4953346 (P= 8.66 x 10-10; OR=1.31, 95% CI: 1.20-1.43 and rs12617313 (P = 9.82 x 10-9; OR=1.33, 95% CI: 1.31-1.46, both highly correlated with rs9679290 (r2 greater than 0.95), but interestingly did not correlate with the two SNPs reported in the GWAS: rs11894252 and rs7579899 (r2 =0.05 and 0.08 with rs9679290). Genotype analysis of rs12617313 confirmed an association with RCC risk (P=1.72 x 10-9; OR= 1.28, 95% CI: 1.18-1.39 per allele), which could be independent of the previously reported GWAS association signal based on a conditional analysis and the presence of an intervening recombination hotspot detected using SequenceLDhot software. Cases with germline EPAS1 variants in the new region were more likely to have tumor VHL alterations, with the strongest association observed for rs4953346 (P= 0.01, OR= 2.41, 95% CI, 1.24-4.67). Our investigation suggests a second locus separated by a recombination hotspot in the chromosome 2p21 and a more complex genetic architecture for common variants in this region associated with RCC.

1167F

Prevalence of *BRCA* mutations among black South African women with breast cancer. *E.J. van Rensburg, M.D. Sluiter, C.M. Dorfling, N. Roelofse.* Dept Human Genetics, University of Pretoria, Pretoria, South Africa.

Cancer of the breast is the most common cancer in South African women. When arranged by population group, breast cancer ranks first in white and Asian women and second in black females. Overall the lifetime risk for developing cancer of the breast is 1 in 27 for all South African women, ranging from 1 in 12 for white women to 1 in 51 for black women (Mqoqi et al., 2004: Incidence of histologically diagnosed cancer in South Africa, 1998-1999, National Cancer Registry). It has been estimated that 15 - 20% of female breast cancers are due to inheritance of highly penetrant mutations in either of two breast cancer susceptibility genes, *BRCA1* and *BRCA2*. Germ-line mutations within the *BRCA*-genes are responsible for different proportions of inherited susceptibility to breast cancer in different populations. To date there is little information regarding the prevalence of *BRCA* mutations in black South Africans. In order to determine the proportion of black South African women who carry *BRCA* gene mutations we screened a hospital-based cohort of 287 black women (unselected for family history of cancer), using PTT and PCR-SSCP/Hetero-duplex analysis. MLPA analysis was carried out to detect large rearrangements in BRCA1. The ages at diagnosis of breast cancer ranged from 18 - 85 years, with 202 of the women diagnosed at or before age 55. Three frame-shift mutations (with one recurring 4 times), one novel large genomic rearrangement in *BRCA1* and, four frame-shift and one nonsense mutation in *BRCA2* were identified in 13/287 (4,5 %) of the women - all of whom were diagnosed before age 55 (13/202; 6,4%). In this group, 13,6% of women diagnosed with breast cancer at 18 - 35 years of age carried a *BRCA* mutation. Only one of the 13 women with a *BRCA* mutation reported a family member with breast cancer (an affected sister), thus family history of cancer is not an indicator of *BRCA* mutation status in this cohort. Using this data one can calculate the incidence of *BRCA*-associated breast cancer among black women in South Africa. With the lifetime risk of breast cancer for black women at 1 in 51, this would translate to approximately 1 in 1150 persons of the general population.

1168F

Novel Tools to Study of the EGFR/HER2 Pathway Utilizing Targeted Integration via Zinc Finger Nucleases and an SH-2 Domain Based Biosensor. *D. Vassar, H. Zhang, N. Zenser, F. Zhang, A. Samsonov, J. Fetter, D. Malkov.* R&D, Cell Based Assays, Sigma-Aldrich, St Louis, MO.

HER2 and EGFR are both members of the ErbB family of receptor tyrosine kinases.The study of this receptor family,especially HER2,is of high therapeutic interest as their overexpression has been associated with numerous types of cancer. We have developed novel genetically engineered cell lines as unique research tools to study these receptors. Zinc finger nucleases(ZFNs) are synthetic proteins engineered to bind DNA at a sequence-specific location and create a double strand break. The cell's natural machinery repairs the break in one of two ways: non-homologous end joining or homologous recombination. We utilized the homologous recombination pathway to insert a transgene into a defined location of the specific genes.In this case, the desired location was the near the C-terminus of HER2 and/or EGFR and the transgene chosen was a fluorescent reporter protein.The fluorescent protein was stably integrated into the cells preserving endogenous regulation of gene expression and protein function. The specificity of the target integration process allows for the integration of multiple reporter genes into a single cell line. We therefore tagged both EGFR and HER2 in the human ovarian adenoma cell line, SKOV-3,to permit study of their interactions in cellular processes and develop cell based assays for efficient screening of compound libraries. In addition to endogenous tagging of specific genes, we also designed a natural domain-based, genetically encoded biosensor for EGFR by transduction with lentivirus. The biosensor is composed of a protein-binding domain, derived from natural domain-binding proteins,fused to a fluorescent protein that serves as a reporter.Specifically, a biosensor consisting of the SH2 domain of the adaptor protein,Grb2,fused to GFP was developed and tested in human cell lines having endogenous EGFR expression such as the A549. The biosensor was either transiently transfected or stably expressed in the cells using an exogenous promoter.In each case the EGFR biosensor showed robust redistribution towards the cell membrane indicative of receptor activation. Unlike biochemical assays and immunohistochemical staining, both approaches described here allow for live cell imaging studies of endogenous EGFR and HER2 activity making them ideal for high content analysis assays.Our findings suggest that both strategies can be applied to the study of other receptor tyrosine kinases and possibly additional cellular signaling pathways.

1169F

Interleukin-10 Promoter Polymorphism (-1082 G/A) and Gastric Cancer. *A. Venkateshwari[1], B. Amar Chand[1], D. Krishnaveni[1], B. Prabhakar[2], K. Pandu Ranga Rao[2], P. Anitha[2], N. Pratibha[3], A. Jyothy[1].* 1) Cell Biology, Institute of Genetics and Hospital for Genetic Dis, Hydrabad, Andhra Pradesh, India; 2) Department of Gastroenterology, Osmania General Hospital, Hyderabad - 500 001, India; 3) Department of Genetics, Osmania University, Hyderabad, India.

Gastric cancer (GC) is one of the most commonly diagnosed malignancies and remains a considerable public health problem worldwide. Gastric cancer is a genetic disease developing from a multifactorial, multigenetic and multistage process with the involvement of both genetic and environmental risk factors. Genetic variation in genes encoding cytokines and their receptors, determine the intensity of the inflammatory response, which may contribute to individual differences in the outcome and severity of the disease. Interleukin (IL)-10, an important anti-inflammatory and immuno-suppressive cytokine produced by T-lymphocytes, down-regulate the expression of Th1 cytokines and acts as co-stimulatory molecule and regulate angiogenesis in various cancers. In the present study, we investigated the association between the IL-10 -1082 G/A polymorphism and the susceptibility to gastric cancer in south Indian population. A total of 164 endoscopically and histopathologically confirmed gastric cancer patients and 160 healthy control subjects were included in the study. The genotyping of IL-10 -1082 G/A polymorphism was carried out by amplification refractory mutation system-polymerase chain reaction (ARMS-PCR). Statistical analysis was applied to test for the significance of the results. The distribution of IL-10 genotypes at -1082 G/A were GG 19.51 %, GA 36.59% and AA 43.9 % in gastric cancer patients and GG 31.25 %, GA32.5 % and AA36.25 % in control subjects. We observed increased frequency of low expresser allele A in GC patients in comparison to controls [OR = 1.49 (CI = 1.089-2.036), p value = 0.0156]. Thus, the allele A of IL-10 gene promoter polymorphism may be one of the important genetic risk factor in the development of gastric cancer.

1170F

TP53 Codon 72 Polymorphism and risk of Acute leukemia. *S. Vure[1], N. Dunna[1], K. Sailaja[1], D. Surekha[1], S. Rajappa[2], D. Raghunadharao[2], S. Vishnupriya[1].* 1) Department of Genetics, Osmania UNiversity, Hyderabad, AP,; 2) Department of Medical Oncology, Nizams Institute of Medical sciences, Hyderabad, India.

TP53 is the mostly commonly mutated gene in many cancers. The TP53 tumor suppressor protein is involved in multiple cellular processes, including transcription, DNA repair, genomic stability, senescence, cell cycle control and apoptosis. A common single nucleotide polymorphism located within the proline rich region of TP53 gene at codon 72 in exon 4 encodes either proline or arginine. TP53 Arg 72 is more active than TP53 Pro 72 in inducing apoptosis. The frequency of TP53 Arg 72 allele is higher than TP53 Pro72 allele. This might indicate that the hyper mutability observed for TP53 Arg allele might lead to unstable protein and lack of tumor suppressor ability leading to myeloid malignancies. The aim of the study was to understand the association of 72 codon polymorphism with acute leukemia development and prognosis of the disease. The present study includes 288 acute leukemia cases comprising of 147 acute lymphocytic leukemia (ALL), 141 acute myeloid leukemia (AML) and 245 control samples for analysis of TP53 Codon72 polymorphism using PCR-RFLP method. Significant association of homozygous arginine genotype with acute leukemia was observed (χ2-133.53; df-2, p - < 0.000). When data was analyzed with respect to clinical variables, the elevation in Mean WBC, Blast %, LDH levels and slight reduction in DFS in ALL cases with arginine genotype was observed. AML patients with Pro/Pro had elevated WBC, Blast%, LDH levels with slightly reduced DFS. Unlike other polymorphisms, the genotype association with respect to clinical variables was found to be different in ALL and AML. Hence our study indicates that Arg/Arg genotype might confer increased risk to development of acute myeloid leukemia.

1171F

Genome-wide analysis of genetic alterations in a mouse mutagenesis model of acute lymphoblastic leukemia. *L. Wei[1], J. Dang[1], J. Zhang[2], L. Janke[1], L. Weyden[3], A. Rust[3], D. Adams[3], J. Downing[1], C. Mullighan[1].* 1) Department of Pathology, St. Jude Children's Research Hospital, Memphis, TN; 2) Department of Computational Biology and Bioinformatics, St. Jude Children's Research Hospital, Memphis, TN; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1HH, U.K.

Genome-wide profiling studies of acute lymphoblastic leukemia (ALL) have identified multiple novel recurring genetic alterations of unknown pathogenic significance. Alterations of PAX5 (encoding the lymphoid transcription factor PAX5) by heterozygous mutations in over 30% of B-ALL cases, suggesting that PAX5 is a haploinsufficient tumor suppressor. To test this hypothesis, we mutagenized Pax5+/+ and Pax5+/-) mice with the alkylating agent ENU or Moloney murine leukemia virus (MLV), and performed genome-wide analysis of genetic alteration in the resulting tumors. Pax5 haploinsufficiency significantly increased the penetrance and reduced the latency of B-ALL in both models including Array-CGH, Sanger sequencing, exome sequencing (39 tumors), and retroviral integration site (RIS) sequencing (128 tumors) identified additional genetic alteration in B lymphoid transcriptional regulators in the tumors, notably Pax5 sequence mutations identical or similar to those in human ALL in 60% of ENU tumors of 128 tumors. We also identified recurring (>2 samples) non-silent mutations in 86 genes in addition to Pax5, 11 of which are known to be mutated in cancer. For these known cancer genes, most of the mutations were identical to mutations previously observed in human cancer and leukemia, including (known/total) Jak1 (4/5), Jak3 (9/11), Ptpn11 (7/7), Kras (4/4), Nras (3/3). Indel mutations were identified in Cdkn2a (n=1) and Notch1 (n=1) in T-lineage ALL. Sh2b3 (Lnk) encodes a negative regulator of JAK2 signaling that is mutated in myeloproliferative disease, and harbored non-silent mutations in 4 cases (1 frameshift, 2 nonsense, and 1 missense). As expected, tumors from ENU-treated mice had a higher burden of sequence mutations (23.1±12.5 mutated genes/case) than the MLV-induced tumors (7.7±3.8 mutated genes/case, $P<0.01$). Grouped by tumor type, myeloid tumors harbor the fewest mutations (8.8±9.5 mutated genes/case), compared with B-cell tumors (20.2±12.5 mutated genes/case) or the single T-cell tumor studied (37 mutated genes). These results confirm the role of PAX5 in leukemogenesis and show that leukemogenesis commonly requires the acquisition of multiple mutations. Our data also suggest that screening of human leukemia samples for the novel mutations identified in these studies may identify new genes and pathways contributing to the development of ALL.

Genetic Variation in the APC gene associates with moderate APC allele-specific expression and is correlated with increased susceptibility to common forms of colorectal cancer. *M.J. White[1], M. Curia[2,3], S. De Iure[2], L. De Lellis[2,3], S. Veschi[3,4], S. Mammarella[2], J. Bartlett[1], A. Di Iorio[5], C. Amatetti[6], M. Lombardo[6], P. Di Gregorio[7], P. Battista[4], R. Mariani-Costantini[2,3], S.M. Williams[1], A. Cama[2,3].* 1) Department of Molecular Physiology and Biophysics, Vanderbilt Univ, Nashville, TN; 2) Department of Oncology and Experimental Medicine, “G.d'Annunzio” University, Chieti-Pescara, Chieti, Italy; 3) Aging Research Center (Ce.S.I) University, “G.d'Annunzio” Foundation, Chieti, Italy; 4) Department of Human Movement Sciences, “G.d'Annunzio” University, Chieti-Pescara, Chieti, Italy; 5) Department of Medicine and Sciences of Aging, University “G.d'Annunzio” Foundation, Chieti, Italy; 6) Division of Oncology, “S.Spirito” Hospital, Pescara, Italy; 7) Division of Immunotransfusion, “SS. Annunziata” Hospital, Chieti, Italy.

Although germline variation in allele-specific expression (ASE) has been shown to associate with highly penetrant familial cancers, its role in sporadic common cancers is less well-defined. ASE of the adenomatous polyposis coli (APC) gene plays a role in familial adenomatous polyposis (FAP), a familial colon cancer. We hypothesized that moderate ASE variation in the APC gene contributes to susceptibility to common forms of colorectal cancer (CRC). There were two main aims of this study: First, we investigated whether APC ASE was associated with sporadic cancer by performing germline analysis in CRC cases (n=53) and controls (n=68) using denaturing high performance liquid chromatography (DHPLC). We compared the means, medians, and variances of ASE between cases and controls. Our results showed that while there was no significant difference in average ASE values between cases and controls (mean p=0.57, median p=0.45), there were significant differences in the distribution of ASE values between cases and controls; cases had a significantly larger variance (p=0.0004). Further analyses confirmed that cases had a significantly higher proportion of individuals more than 1.0 (p=0.001, OR=3.97) or 1.645 (p=0.005, OR=13.46) standard deviations from the mean than controls, confirming that deviations of ASE values from the overall mean were associated with increased risk of CRC. Second, we investigated whether genetic variants in the APC gene were associated with its ASE. Twenty-three tag SNPs were genotyped in the APC gene, and eight passed quality control and were polymorphic. Four markers were significantly associated with APC ASE in the case/control analyses, rs41115 (additive model p=0.0091), rs41115 (dominant model p=0.0030), rs467033 (dominant model p=0.0427), rs971517 (additive model p=0.0010), and rs2431507 (p=0.0247). Three markers were significantly associated with APC ASE in case-only analyses, rs41115 (p=0.0058), rs41115 (p=0.0013), and rs971517 (p=0.0103). None of the markers showed significant association with APC ASE in controls. In conclusion, our study detected a wider distribution in APC ASE among CRC cases compared to CRC controls, found that CRC risk seemed to increase with the degree of ASE, and discovered genetic variants in APC that were associated with ASE. Our combined results support the conclusion that APC, a gene that predisposes to FAP, also plays an important role in sporadic cancer via ASE.

1173F

Role of NEU1 deficiency in cancer development and progression. *S.J. White-Gilbertson, E. Machado, D. van de Vlekkert, S. Moshiach, E. Bonten, A. d'Azzo.* Genetics, St. Jude Children's Research Hospital, Memphis, TN.

Deficiency of the lysosomal sialidase NEU1 results in the lysosomal storage disease sialidosis. Type I sialidosis is a catastrophic pediatric disease while Type II, or adult onset sialidosis, is a relatively mild condition caused by gene mutations which preserve residual activity of NEU1. A recent paper reported on a family with three siblings with Type II sialidosis, who all developed a different type of cancer. This genetic study suggests a link between NEU1 deficiency and cancer susceptibility, prompting us to dissect possible links between NEU1 and cancer. Our own research into NEU1 deficiency, performed in the mouse model of sialidosis, has revealed a novel function of NEU1 as an inhibitor of lysosomal exocytosis. In the absence of NEU1, its substrate LAMP-1 accumulates, increasing the number of lysosomes docked at the PM and ready to engage in lysosomal exocytosis. As a result, lysosomal contents, including active proteases such as cathepsins, are aberrantly released extracellularly, most likely impacting the extracellular matrix structure and composition. We hypothesized that this phenotype could be advantageous for cancer cells, which are known to extensively modify their extracellular matrix. We have therefore examined the expression of NEU1 in a variety of cancer cell lines from four cancer types: breast carcinoma, colon carcinoma, Ewing's sarcoma, and alveolar rhabdomyosarcoma. For each type of cancer examined, lower levels of NEU1 activity correlated with increased expression of over-sialylated LAMP-1, as our model would predict. Here we report on a correlation between a low-NEU1, highly exocytic phenotype and the invasive capacity of cells. In some cases, the invasiveness of tested cell lines was known. For instance, the syngeneic system of SW480 and SW620 colon cancer lines is composed of cells derived from a primary or metastatic tumor, respectively, from the same patient. In other cases, such as for Ewings sarcoma and rhabdomyosarcoma, invasive potential of the tested cell lines was determined in our hands using an ex vivo model of peritoneal invasion. These studies establish a new paradigm for understanding the spread of cancer: invasive potential is enhanced by degradation of extracellular matrix via lysosomal exocytosis of active proteases. (Supported in part by NIH grant RO1 GM060950 and ALSAC).

Patient satisfaction survey of a comprehensive *BRCA* information resource. *J.L. Wiggins, K. Kohut, E.K. Bancroft, R.A. Eeles, K. Myhill, A. Stormorken, S. Thomas, S. Shanley.* Cancer Genetics, The Royal Marsden NHS Foundation Trust, Sutton, United Kingdom.

Families with *BRCA* gene mutations have expressed a need for reliable and evidence-based information. We developed a comprehensive *BRCA* resource pack as a pilot project aiming to empower *BRCA* mutation carriers to make informed decisions and help them discuss genetic issues with at-risk relatives. Method: Charity funding was obtained for production of a resource pack. The format was a small, plain binder including information on the *BRCA* genes; screening options, reducing risk, sharing information with at-risk relatives and information sources. The information pack was distributed to 150 consecutive *BRCA* mutation carriers attending either their annual genetics follow-up appointment or the department-run *BRCA* support group over a six month period. A feedback form was included in the pack, to be returned by post after reading the resource. Results: Thirty-three individuals returned the feedback form (response rate 22%). Ninety-one per cent of respondents were female, 84% were over 40 years of age, 79% had known about their *BRCA* mutation status for more than a year and 46% had a personal history of cancer. Overall satisfaction with the resource pack was very high. Comments from patients included `Wonderful resource to reduce sense of fear and isolation' and `Clear, easy to understand and informative. Will keep referring to it time and again'. Action was taken by 85% of patients as a result of receiving the information resource including identifying and sharing information with at-risk family members and investigating options for risk-reducing surgeries. Patients almost exclusively thought the pack should be presented when receiving their genetic test result. Conclusion: The patients who received this pack have attended the genetics clinic for follow up on an annual basis since their diagnosis. The feedback suggests that there is a role for a detailed written resource and ongoing genetic support even among a well educated group of *BRCA* patients. Additional funding has been obtained have the resource pack available in our clinic for all eligible patients.

1175F

Somatic mutations in GRM1 alter receptor activity and promote tumor progression. *M. Willard[1], J. Esseltine[2], M. Lajiness[1], I. Wulur[1], S. Ferguson[2], T. Barber[1].* 1) Translational Science, Eli Lilly and Company, Indianapolis, IN; 2) Robarts Research Institute and Department of Physiology and Pharmacology, University of Western Ontario London, Ontario, Canada.

Emerging data indicates that GPCRs have a critical role in cancer. Specifically, accumulating evidence suggests that modulation of GPCR function may promote cancer progression and metastasis. Metabotropic glutamate receptor type 1 (GRM1) and its role in physiological processes in the nervous system have been well-documented. Recently, the role of GRM1 in cancer progression has emerged. Somatic mutations altering the coding region of GRM1 have been detected in colorectal cancer, glioblastomas, and lung cancer but the functional significance of these mutations is unknown. Here we demonstrate that cancer-associated mutations of GRM1 lead to altered receptor localization, interactions, and activity, and consequently, abnormal cellular behavior. These findings suggest that somatic mutations in GRM1 promote tumor progression through deregulated receptor activity, and highlight the importance of evaluating GRM1 antagonists to block both the normal and mutant forms of the receptor.

1176F

A replication study and genome-wide scan of single nucleotide polymorphisms associated with pancreatic cancer risk and overall survival. *J.A. Willis[1], S.H. Olson[2], S. Mukherjee[1], M. Gönen[2], R.C. Kurtz[3], R.J. Klein[1].* 1) Program in Cancer Biology and Genetics, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Department of Epidemiology and Biostatistics, Memorial Sloan-Kettering Cancer Center, New York, NY; 3) Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY.

Background: Pancreatic adenocarcinoma is a rapidly fatal disease with a poor long-term prognosis. To better understand the role of inherited genetic variations in this disease, we performed a combined replication and discovery study of single nucleotide polymorphisms (SNPs) associated with pancreatic cancer risk and overall survival (OS). **Experimental Design:** Germline DNA from 495 pancreatic cancer cases and 285 healthy controls was genotyped at SNPs previously reported to be associated with pancreatic cancer risk or clinical outcome. We analyzed putative risk SNPs under a logistic regression model (adjusted for age and gender) for replication of their reported effects on risk, as well as under a Cox Proportional Hazards model for the discovery of novel effects on OS. Similarly, we analyzed putative “clinical outcome” SNPs for replication of their reported effects on OS as well as for novel effects on risk. Further, we performed a two-stage genome-wide association study (GWAS) of OS using a subset of 252 cases genotyped by whole-genome SNP arrays. **Results:** Seven putative risk SNPs were analyzed in our study. At a nominal significant threshold of $p < 0.05$, we replicated the known risk effects of SNPs rs505922 (*ABO*) ($p = 0.002$, per-allele OR = 1.67, 95% CI 1.20-2.31) and rs9543325 ($p = 0.03$, per-allele OR = 1.39, 95% CI 1.03-1.88). Of the 24 putative “clinical outcome” SNPs analyzed in our study, we replicated the effects of SNPs rs9350 (*EXO1*) ($p = 0.005$, per-allele HR = 1.29, 95% CI 1.08-1.53) and rs2953993 (*POLB*) ($p = 0.05$, per-allele HR 1.39, 95% CI 1.01-1.92). However, no putative risk SNPs or putative “clinical outcome” SNPs were found to be associated with OS or risk, respectively. To discover novel SNPs associated with OS, we conducted a GWAS of ~300k SNPs in 252 cases (stage 1), followed by validation of 27 candidate SNPs in 226 additional cases (stage 2). We identified a novel SNP rs16867625 located in a non-genic region of chromosome 8q22 to be putatively associated with OS (combined stage 1 and 2 $p = 5.66 \times 10\text{-}6$, per-allele HR = 2.04, 95% CI 1.50-2.78). **Conclusions:** The effects of SNPs on pancreatic cancer risk and overall survival were replicated in our study, though further work is necessary to understand the functional mechanisms underlying these effects. More importantly, the putative association with OS identified by GWAS suggests that GWAS may be useful in identifying SNPs associated with clinical outcome in pancreatic cancer.

1177F

Colorectal and other cancer risks for carriers and non-carriers of a DNA mismatch repair gene mutation from mutation carrying families: a prospective cohort study. *A.K. Win[1], D.D. Background: Carriers of germline mutations in DNA mismatch repair (MMR) genes are known to have substantially increased risk of colorectal, endometrial and some other cancers. However, cancer risk for their non-carrier relatives is not established. The aim of this study was to determine whether cancer risks for carriers and non-carriers from families segregating an MMR gene mutation are increased above that of the general population. Methods: We prospectively followed a cohort of 446 unaffected carriers of an MMR gene mutation (161 in *MLH1*, 222 in *MSH2*, 47 in *MSH6* and 16 in *PMS2*) and 1029 unaffected relatives without mutations every five years at recruitment centers of the Colon Cancer Family Registry. For comparison of cancer risk with the general population, we estimated country-, age- and sex-specific standardized incidence ratios (SIRs) of different cancers separately for carriers and non-carriers. Results: Over a median follow-up of 5 years, mutation carriers had an increased risk of colorectal cancer (SIR 20.48, 95% confidence interval, CI 13.08 - 33.42, P <0.001), endometrial cancer (SIR 30.62, 95% CI 14.37 - 76.57, P <0.001), pancreatic cancer (SIR 10.68, 95% CI 2.25 - 106.11, P = 0.02), gastric cancer (SIR 9.78, 95% CI 2.07 - 95.85, P = 0.02), renal cancer (SIR 11.22, 95% CI 3.92 - 48.23, P <0.001), bladder cancer (SIR 9.51, 95% CI 2.38 - 38.04, P = 0.001) , ovarian cancer (SIR 18.81, 95%; CI 6.26 - 85.19, P <0.001) and breast cancer (SIR 3.95, 95% CI 1.95 - 9.17, P = 0.001). Their non-carrier relatives had no increased risk of any cancer, including colorectal cancer (SIR 1.02, 95% CI 0.43 - 3.06, P = 0.97). Conclusions: Despite their family history of cancer and the presence of an MMR gene mutation in their families, we found no evidence that the relatives who did not harbor their family specific mutation were at increased risk of colorectal or other cancers and, therefore, may be considered at similar risk as the general population.

Further support for *RAD51C* gene's contribution to hereditary breast and ovarian cancer susceptibility. *R. Winqvist[1], M. Vuorela[1], J.M. Hartikainen[2], K. Sundfeldt[3], A. Lindblom[4], A. von Wachenfeldt Wäppling[5], M. Haanpää[1], U. Puistola[6], M. Anttila[7], V.-M. Kosma[2], A. Mannermaa[2], K. Pylkäs[1].* 1) Lab of Cancer Genetics, Dept of Clinical Genetics and Biocenter Oulu, Univ of Oulu, Oulu Univ Hospital, Oulu, Finland; 2) School of Medicine, Inst of Clinical Medicine, Pathology and Forensic Medicine, Univ of Eastern Finland, and Dept of Clinical Pathology, Kuopio Univ Hospital, Kuopio, Finland; 3) Inst of Clinical Sciences, Dept of Obstetrics and Gynecology, Sahlgrenska Academy at Gothenburg Univ, Sweden; 4) Dept of Molecular Medicine and Surgery, Karolinska Inst, Stockholm, Sweden; 5) Dept of Oncology-Pathology, Karolinska Univ Hospital, Karolinska Inst, Stockholm, Sweden; 6) Dept of Obstetrics and Gynecology, Univ of Oulu, Oulu Univ Hospital, Oulu, Finland; 7) Dept of Obstetrics and Gynecology, Univ of Eastern Finland, Kuopio Univ Hospital, Kuopio, Finland.

Currently known susceptibility genes such as *BRCA1* and *BRCA2* explain less than 25% of familial aggregation of breast cancer, which suggests the involvement of additional susceptibility genes. RAD51C, a RAD51 paralogue involved in homologous recombination, was recently identified as a predisposing factor both in Fanconi anemia and breast cancer. In the initial report, *RAD51C* (alias *FANCO*) mutations were shown to confer a high risk for both breast and ovarian tumors, but most of the replication studies published so far have failed to identify any additional susceptibility alleles. Here, we report a full mutation screening of the *RAD51C* gene in 147 Finnish familial breast cancer cases and in 232 unselected ovarian cancer cases originating from Finland and Sweden. Additionally, in order to resolve whether common *RAD51C* SNPs are risk factors for breast cancer, we genotyped five tagging single nucleotide polymorphisms, all located within the gene, from 993 Finnish breast cancer cases and 871 controls for cancer associated variants. Whereas none of the studied common SNPs associated with breast cancer susceptibility, mutation analysis revealed two clearly pathogenic alterations. *RAD51C* c.-13_14del27 was observed in one familial breast cancer case and c.774delT in one unselected ovarian cancer case, subsequently shown to have a background of cancer in the family, thus confirming that *RAD51C* mutations are implicated in breast and ovarian cancer predisposition, although their overall frequency seems to be low. Independent identification of the very recently reported *RAD51C* c.774delT mutation in yet another patient originating from Sweden suggests that it might be a recurrent mutation in that population and should be studied further. The reliable estimation of the clinical implications of carrying a defective *RAD51C* allele still requires the identification of additional mutation positive families.

1179F

Chromosome 17 anomalies inferred by high-density genotyping of benign, borderline and malignant serous ovarian cancer specimens. *P.M. Wojnarowicz[1], S.L. Arcand[2], K. Klein Oros[3], D. Provencher[4,5], A.-M. Mes-Masson[4,6], C. Greenwood[3,7], P.N. Tonin[1,2,8].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) The Research Institute of the McGill University Health Centre; 3) Division of Clinical Epidemiology, Lady Davis Research Institute, Jewish General Hospital, Montreal; 4) Centre de recherche du Centre hospitalier de l'Université de Montréal/ Institut du cancer de Montréal; 5) Department of Obstetrics and Gynecology, Université de Montréal; 6) Department of Medicine, Université de Montréal; 7) Department of Epidemiology, Biostatistics and Occupational Health, McGill University; 8) Department of Medicine, McGill University.

Epithelial ovarian cancer (EOC) of the serous histopathological subtype is the most lethal gynecological malignancy, and current knowledge of EOC pathogenesis is limited. Tumours are classified based on pathology as benign (BOV), borderline or low malignant potential (LMP), low-grade (LG) or high-grade (HG) tumours, which may represent distinct disease states or progressive phases of a continuum. Chromosome 17 (Chr17) aberrations occur frequently in EOC, with partial loss of specific genomic regions or complete loss of heterozygosity (LOH) occurring in 50-70% of HG tumours. Molecular genetic, functional and transcriptome analyses also have implicated a number of Chr17 genes in EOC, including *TP53* (17p13.1), which is the most frequently mutated gene in HG tumours. We have applied the Illumina 610-Quad BeadChip SNP array to further investigate Chr17 abnormalities across these disease states, namely 33 BOV, 59 LMP, 12 LG, and 87 HG serous EOC tumour samples. We found that 100% of the BOV samples were heterozygous for Chr17, whereas allelic imbalance (AI), LOH and/or interstitial breaks were found in LMP, LG, and HG tumour samples at frequencies of 5.1%, 50%, and 94.3%, respectively. We found 100% of the BOV samples as well as 100% of the heterozygous LMP, LG, and HG tumours to be *TP53* mutation negative, while 83.33 % of LG and 96.3% HG tumour samples that exhibited AI, LOH and/or interstitial breaks anywhere on Chr17 were mutation positive. Other loci of interest such as the *BRCA1*, *ERBB2*, and *NF1* regions were also surveyed for aberrations as these regions are implicated in EOC. Low frequency of *ERBB2* amplification and homozygous deletion affecting *NF1* were also observed in two and four HG cases, respectively. Interestingly, one LMP sample also showed deletion of the *NF1* region, this sample was also the only LMP to be *TP53* mutation positive. Thus Chr17 genomic content may be a good indicator of disease state and also aid in identifying those LMP samples that may progress to more aggressive disease.

1180F

MicroRNA-93 inhibits colorectal tumorigenesis and decreases early relapse of human colorectal cancer. *I. Yang[1,2], H. Tsai[3,4,6], K. Chen[1], P. Tsai[1], S. Huang[1,6], W. Chou[1,6], J. Wang*[1,3,4,6], S. Juo*[1,5].* 1) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Nursing, Shu Zen College of Medicine and Management, Kaohsiung, Taiwan; 3) Department of Surgery, Faculty of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Cancer Center and Division of Gastroenterology and General Surgery, Department of Surgery, Kaohsiung Medical University Hospital, Kaohsiung Medical University, Kaohsiung, Taiwan; 5) Cancer Center and Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 6) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

MicroRNAs are short noncoding RNAs that serve an important role in post-transcriptional regulation. Accumulating evidence has demonstrated that deregulation of miRs participates in the cancer development and outcomes. Using microRNA arrays, we identified that microRNA-93 has substantially different expression levels between early (recurrence within 12 months after surgery) and non-early relapse of colorectal cancer (CRC). The replication study including 35 early relapsed and 42 non-early relapsed CRC further confirmed over-expressed microRNA-93 in non-early relapsed samples. Cellular studies showed that over-expression of microRNA-93 inhibited colon cancer cell proliferation and migration but not invasion. The cell cycle studies revealed that microRNA-93 caused accumulation of the G2 population. However, microRNA-93 could not induce cell apoptosis or necrosis. Functional studies showed that microRNA-93 could suppress CCNB1 protein expression leading to cell cycle arrest in the G2 phase. Moreover, microRNA-93 could repress expression of ERBB2, p21 and VEGF, all of which are involved in cell proliferation. We also demonstrated that microRNA-93 suppressed tumor growth in null mice. Taken together, the present study including human, cell and mouse data consistently demonstrated that microRNA-93 can inhibit tumorigenesis and reduce CRC early recurrence, which may have potential clinical applications for the prediction and intervention of CRC patients.

1181F

DNA methylation in lung cancer. *H. Zamakhshari, M. Abdalla, Y. Haj-Ahmad.* Norgen Biotek Corp, Thorold, Ontario, Canada.

Lung cancer has the highest rate of mortality in both genders due to the late diagnosis. The current method of diagnosis is mainly based on biopsy which is Invasive and can be done only after visualizing the tumor by x-ray. Early detection of the lung cancer can make a big difference in the life expectancy of the patient therefore a new approach is needed. Cancer biomarker has been the main focus over a last decade. A biomarker can be any molecule (DNA, RNA or protein) that can indicates an alteration in physiology from normal. These alterations can be generated from genetic and epigenetic abnormalities of certain genes. The objective of this study is to identify the epigenetic changes including the DNA methylation in lung cancer cell lines which can be used as potential biomarker for the early diagnosis of Lung Cancer. This was based on the hypothesis that a difference may be found between the cancerous and normal cell lines and such a difference may lead to the identification of a biomarker(s) for the early detection of lung cancer. DNA was isolated from two Small cell lung cancer (SCLC) and two Non-small cell lung cancer (NSCLC) cells lines as well as from a normal lung cells line. Four tumour suppressor genes (RASSF1-A,RAR) , APC and P53) were studied for their aberrant methylation using Methylation Sensitive Restriction Enzymes PCR. The isolated DNA was digested with DpnI that will cleave DNA only when its recognition site is methylated and a set of primers were designed to amplify the region flanking the DpnI - recognition site. The housekeeping gene GAPDH was used as a control where the designed GAPDH primer will amplify a region that doesn't have a DpnI - recognition site. Digesting the DNA did not affect the amplification of the tumour suppressor genes as it was amplified by house keeping gene GAPDH. The tumour suppressor gene RASSF1, RAR-) , APC and p53 was not methylated in the lung cancer cell line when digesting with the enzyme DpnI. The same approach was also tested by digesting DNA with two different restriction enzymes HapII and HhaI. It was found that p53 was methylated in H164 and A549 cell line when digesting with the enzymes HapII and HhaI.

1182F

Spontaneous metastasis in a mouse model of testicular germ cell tumours. *J. Zechel[1], G. MacLennan[2], J. Heaney[1], J. Nadeau[1,3].* 1) Department of Genetics, Case Western Reserve University School of Medicine, Cleveland, OH; 2) University Hospitals Case Medical Center, Institute of Pathology, Cleveland OH; 3) Institute for Systems Biology, Seattle, WA.

Testicular germ-tumours (TGCTs) are the most common cancer in men between the ages of 15 and 35 and worldwide incidence has doubled in the last 40 years. TGCTs have a high rate of metastasis, which increases mortality rates and treatment-associated morbidity. Despite the importance of metastasis in human TGCTs and in part because of the lack of a suitable animal model, little is known about acquisition of metastatic potential or modes of dissemination. Here we describe a new model of spontaneous TGCT metastasis the 129 family of mice and demonstrate that these are true metastases from primary testicular cancers, rather than independent extragonadal germ cell tumours. Among males from six genetically distinct strains that had a primary TGCT, similar rates of metastases were found. Additionally, metastases were found in anatomical sites that are consistent with TGCT metastasis in humans. Various lines of evidence support their germ cell origin and the pluripotent nature of these metastases, including the existence of several tissues of endodermal, mesodermal and ectodermal origin, and presence of OCT4 and SSEA-1 pluripotency markers. Moreover, metastases were never observed in males in the absence of a primary testicular cancer. Genetic analysis of pairs of primary TGCTs and metastases from individual mice revealed shared DNA copy number variants, implying that metastases originated from a primary TGCT. Together these results provide the first evidence for spontaneous TGCT metastasis in mice and show that these metastases originate from primary TGCTs rather than independently from ectopic stem cells.

1183F

Next-generation sequencing of multiple samples derived from the same BRCA1-positive patient with ovarian carcinoma. *J. Zhang[1], E. Lalonde[1], L. Li[2], W. Gotlieb[3], A. Ferenczy[4], W. Foulkes[2], J. Majewski[1].* 1) The Department of Human Genetics, McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 2) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Quebec,Canada; 3) Departments of Obstetrics & Gynecology and Oncology, McGill University, Montreal, Quebec,Canada; 4) Departments of Pathology and Obstetrics and Gynecology, McGill University and Jewish General Hospital, Montreal, Quebec, Canada.

In contrast to the whole human genome sequencing, exome sequencing targets only protein-coding sequences of the genome, and provides a more efficient strategy to search for genetic variants underlying rare monogenic diseases. Metastasis to distant tissues is the leading cause of cancer mortality, but the mechanism underlying this process remains unknown. We are interested in investigating the genetic causes of metastatic tumors using high-throughput sequencing. For the purpose of this project, we have collected three separate tumour samples from one patient: a primary ovarian tumour, a pre-treatment metastatic tumour and a post-chemotherapy residual metastatic tumour in the stomach region (in the omentum and peritoneum). The samples have been subjected to whole exome capture and sequencing to detect mutations, such as SNVs and small indels at the DNA level. We hope to identify how mutations appear and disappear during the progression of the disease. This work could lead to improved understanding of the key events leading to recurrence and could potentially affect treatment for the affected patients.

Neural teneurins are expressed in human tumors and tumor-derived cell lines. *A. Ziegler[1], G. Di Capua[1], J.E. Oyarzún[1], I.E. Roa[2], J.A. Brañes[3], P. Casanello[3], G. Repetto[1].* 1) Center for Human Genetics, Faculty of Medicine, Clínica Alemana-Universidad del Desarrollo; 2) Division of Pathology, Clínica Alemana de Santiago; 3) Perinatology Research Laboratory (PRL) & Cellular and Molecular Physiology Laboratory (CMPL), Division of Obstetrics and Gynaecology, School of Medicine, Pontificia Universidad Católica de Chile.

Teneurins are a family of transmembrane proteins involved in embryonal development of the central nervous system, where they promote axonal guiding and neural networking. In a previous proteomics-based study, we had identified differential expression of teneurin-2 in malignant pleural mesothelioma versus lung adenocarcinoma, and had proposed that teneurin-2 could be a potential biomarker for tumor discrimination. Purpose: We evaluated 12 human tumor-derived cell lines to identify additional tumor types that could express teneurin-2 or teneurin-4. Based on the evidence obtained, we analyzed human ovarian tumors for the presence of teneurin-2 and teneurin-4 mRNA and protein to assess the patterns and frequency of expression. Methods: In cell lines, expression of teneurin mRNAs and their transcript variants was assessed by RT-PCR. Teneurin protein expression was detected by immunohistochemistry. Expression of teneurins in frozen tumors and control biopsies was determined by comparative real-time RT-PCR and immunohistochemistry. The study was approved by the participating institutions' Ethical Committees, and tissues were obtained with informed consent of patients. Results: In cell lines, teneurin-2 and teneurin-4 mRNA were expressed in ovarian and breast cancer cells, but infrequently in gastric cancer cells. Characterization of teneurin transcripts in Skov3 ovarian cells revealed multiple alternative splicing sites, and that expression of exons does not always coincide with the structure postulated in public sequence sources. The presence of teneurin mRNAs correlated with expression of teneurin proteins, as evidenced by immunohistochemical detection. In contrast to cell lines, we found differential expression of teneurins in a preliminary set of 8 ovarian tumors. While expression of teneurin-2 was seldom, teneurin-4 was detected in 6/8 tumors. Immunohistochemistry revealed a membrane localization pattern in tumors but not in surrounding stroma. Experiments are ongoing to analyze additional ovarian tumors and non-malignant controls for presence of teneurin-4. Conclusions: We describe for the first time the expression of teneurins in ovarian and breast cancer cell lines. Seventy five percent of human ovarian tumors expressed teneurin-4. Our data suggest that some teneurins might harbor potential as tumor biomarkers. Studies into functional contribution of teneurins to the tumor phenotype are underway. Supported by Fondecyt 1100605.

Identification of a novel *NBN* truncating mutation from targeted next-generation sequencing of men with familial prostate cancer. *K.A. Zuhlke[1], A.M. Ray[1], C.M. Robbins[3], W.D. Tembe[3], C.A. Salinas[1], J.D. Carpten[3], E.M. Lange[4], W.B. Isaacs[5], K.A. Cooney[1,2].* 1) Department of Internal Med, Hem/Onc, University of Michigan Medical School, Ann Arbor, MI; 2) Department of Urology, University of Michigan, Ann Arbor, MI; 3) Translational Genomics Research Institute, Phoenix, AZ; 4) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC; 5) Department of Urology, The Johns Hopkins University School of Medicine, Baltimore, MD.

Nibrin (*NBN*), located on chromosome 8q21 is a gene involved in DNA double-strand break repair that has been implicated in the rare autosomal recessive chromosomal instability syndrome known as Nijmegan Breakage Syndrome. Nijmegan Breakage Syndrome is characterized by microcephaly, growth retardation, immunodeficiency, and cancer predisposition. Individuals who are heterozygous for *NBN* mutations are clinically asymptomatic, but display an elevated risk for certain cancers including, but not limited to, ovarian and prostate cancer as well as various lymphoid malignancies. In this study, 94 unrelated familial prostate cancer cases from the University of Michigan Prostate Cancer Genetics Project (n= 54) and Johns Hopkins University (n=40) were subjected to targeted next-generation sequencing of the exons and UTRs of *NBN*. One individual diagnosed with prostate cancer at age 52 was identified to have a heterozygous 2117 C>G mutation in exon 14 of the gene, which results in a premature stop at codon 706 (S706X). Sanger sequencing of three additional male relatives revealed that the father, who has prostate and bladder cancer, also carries the S706X allele as does the proband's brother who has no cancer at this time. A paternal uncle, who was diagnosed with prostate cancer at age 70, does not carry the S706X allele. NBN is involved in double-strand break repair as a component the MRE11/RAD50 genomic stability complex. The S706X mutation truncates the protein in a highly conserved region of NBN near the MRE11 binding site, thus suggesting a role for *NBN* mutations in prostate cancer susceptibility.

Cytogenetic and molecular 11q23/MLL findings in infants with acute leukemia. *M.S. Gallego[1], M.C. Coccé[1], C. Alonso[2], J. Rossi[3], A. Bernasconi[3], E. Alfaro[2], M.S. Felice[2].* 1) Genetics Department, Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina; 2) Hemato-Oncology Department,Buenos Aires, Argentina. Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina; 3) Immunology Department, Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina.

Acute leukemia in infants (<1 year of age) is an infrequent disease with unique epidemiological, biological and clinical features, and the frequency of 11q23/MLL rearrangements has been described in about 50% and 80% of these rare cases with “de novo” acute myeloid leukemia (AML) or acute lymphoblastic leukemias (ALL) respectively. On the other hand, chromosomal rearrangements involving band 11q23 occur in 5-6% of all AML as well as in 5-10% of all ALL cases and in 85% of the secondary therapy-related myeloid We present the 11q23/MLL rearrangements detected in 167 infants diagnosed and treated in our Hospital from 1990 to 2011. Cytogenetic studies were performed by G-banding and in situ fluorescence hybridization (FISH) and characterized by RT-PCR for MLL/AF4, MLL/AF9 and MLL/ENL fusion genes. Patients were treated according to the Interfant-99/06 (n=76) and AML-99 (n=78) protocols. Chromosomal 11q23 abnormalities and/or MLL rearrangements were identified in 52(64)% of ALL and in 24 (28)% of AML patients, being t(4;11)/MLL-AF4, t(9;11)/MLL-AF9 and t(11;19)/MLL-ENL the most frequent translocations. We also found complex structural rearrangements, atypical t(4;11) translocations, inversion 11q, insertions and uncommon translocations involving 11q23. Some of these rearrangements were clarified by FISH using painting probes and split FISH. Since the incorporation of molecular techniques, the comparison between cytogenetic and molecular studies has shown high reciprocal agreement. In 14% and 6%, the alterations were detected either only by cytogenetic or by molecular studies, respectively. Response to induction of infants with 11q23/MLL abnormalities was: for ALL: 44 complete remission (CR) (90%), 3 deaths and 2 null responses, and for AML: 14 CR (68%), 7 deaths and 1 null response. From 44 ALL who achieved CR, 17 relapsed and 13 died in CR, and from 14 AML who achieved CR, 9 relapsed and 1 died in CR. The 5 years pEFS(SE) was 28 (6)% for ALL and 15 (8)% for AML (p= 0.122). Our findings emphasize the value of performing both, molecular and cytogenetic studies, including split FISH, to improve the detection of MLL rearrangements, taking into account the importance of its prognosis impact.

1187F

Genomic imbalances detected by oligoarray CGH in clear cell renal cell carcinoma (CCRCC). *F. Gong[1,2], C. Wang[2], X. Wang[1], S. Li[1], J. Lee[1].* 1) OUHSC, Oklahoma City, OK., USA; 2) The First Hospital of Jilin University, Changchun 130021, P.R. China.

Renal cell carcinoma (RCC) accounts for about 3% of all new cancer cases and the incidence rates for all stages have been steadily rising over the last 3 decades. Despite the introduction of new treatment regimens, surgical resection remains the only curative therapy for CCRCC. Unfortunately, up to 50% of patients undergoing nephrectomy for clinically localized CCRCC will develop local recurrence or distant metastasis. These statistics highlight the need for detecting CCRCC at early stages and identifying markers that can predict prognosis and response to therapy. Application of array CGH to identify chromosomal imbalances of CCRCC tumor specimens may help to differentiate relevant subsets of tumors, which would allow better prognostic and therapeutic decision. After obtaining the patients' signed consent forms, total genomic DNA was isolated from 50 fresh CCRCC tumor tissues by using commercial kits. Eleven out of 50 samples were Fuhrman stage I, 24 were stage II and the rests were stage III. Oligoarray CGH was performed on the 720k oligonucelotide chip (Roche/NimbleGen System Inc.) and experimental procedures were performed according to the manufacturer's protocols with minor modifications. Our data showed that all the samples had genomic imbalances, either losses or gains. The common regions with losses were 3p (45/50), 8p (14/50), 4q (8/50), 6q (7/50), 10q (6/50), 13q (6/50), plus monosomy of chromosomes 9 (10/50) and 14 (15/50). The regions with gains were 5q (35/50), 8q (9/50), 1q (8/50), plus gain of extra chromosomes 12 (9/50), 16(8/50), 20(8/50), and 22(6/50). Interestingly, no single case with stage I had a loss or gain of chromosome 1, but 17 out of 39 cases with stage II and III had either loss or gain involving chromosome 1. The result shows the 3p lose and 5q gain were the most significant imbalances detected in our 50 CCRCC samples, which were likely due to the fact that the unbalanced chromosome rearrangements involving the chromosomes 3 and 5. It also showed that cases with early stage did not have chromosome 1 rearrangement, but high frequency of rearrangement of chromosome 1 in the late stage of tumor. The findings warrant further investigation of whether stability of chromosome 1 could serve as a maker for tumor subtype classification of the CCRCC or not.

1188F

Definition of chromosome 8q copy number changes in paediatric solid tumors. *N.Y. Martin[1], D. Belluoccio[2], G.B. Peters[3], J.A. Byrne[1].* 1) Children's Cancer Research, KRI at Children's Hospital at Westmead, Sydney, NSW 2145, Australia; 2) 347 Burwood Hwy, Forest Hill, VIC 3131, Australia; 3) Department of Cytogenetics, The Children's Hospital at Westmead, Sydney, NSW 2145, Australia.

Chromosome 8q gain is one of the most common cytogenetic events in cancer. As either the entire chromosomal arm or different focal regions can be gained, chromosome 8q likely harbors multiple oncogenes. Proposed amplification targets include *MYC*, *MAL2*, *WWP1*, and *TPD52*, but others remain to be identified. It is not known whether the same or different genes are targeted in different tumour types. Chromosome 8q gain has also been poorly characterized in paediatric tumours, relative to more common adult cancers.

Methods: Genomic DNA was extracted from 19 paediatric solid tumours (3 osteosarcomas, 7 Ewing sarcomas, 3 rhabdomyosarcomas and 6 neuroblastomas) and 6 breast cell lines as controls. The SALSA Multiplex ligation-dependent probe amplification **(MLPA)** P014-A1 kit (MRC-Holland) was used to detect possible exonic amplifications or deletions. This includes probes with target sequences in 22 chromosome 8q genes, 8 chromosome 8p genes, and 10 reference genes. Agilent **array CGH** analyses will also be performed to refine and extend the results obtained using **MLPA** analyses.

Results: All 19 tumour samples showed increased copy number at one or more chromosome 8q loci. Increased copy number was most frequently noted at *SLA* (at 134.1 MB) and *RECQL4* (at 145.7 MB) which were gained in 12/19 (63%) and 14/19 (74%) tumours, respectively, and 4/6 breast cell lines. The *SLA* gene was predominantly gained in Ewing sarcoma (5/7 cases) and osteosarcoma (3/3 cases), whereas *RECQL4* was predominantly gained in Ewing sarcoma (6/7 cases), neuroblastoma (5/6 cases) and rhabdomyosarcoma (2/3 cases). *TPD52* (at 81.1 MB) was gained in 3/3 osteosarcoma cases and 4/6 breast cell lines, which is consistent with previous reports. Although *MYC* (at 128.8 MB) showed increased copy number in 6/6 breast cell lines analysed, only 2/19 (11%) tumours (2 neuroblastoma cases) showed *MYC* gain.

Conclusion: Increased copy number at chromosome 8q loci is a common finding in pediatric solid tumours, and of the chromosome 8q loci examined, *SLA* and *RECQL4* were most frequently gained. Analyses of these tumour samples using **array CGH** may provide further information about chromosome 8q genes which are specifically or commonly targeted in different paediatric solid tumours.

1189F

Does transient abnormal myelopoiesis occur in the absence of Down Syndrome, or is it really AML? *E.M. Tegg[1,2,4], C.E. Wren[2], A.G. De Paoli[3], A.M. Johnston[4], C. Williams[3].* 1) Haematology, Menzies Research Institute, Hobart, Australia; 2) Cytogenetics Department, Royal Hobart Hospital, Hobart, Australia; 3) NPICU, Royal Hobart Hospital, Hobart, Australia; 4) Haematology Department, Royal Hobart Hospital, Hobart, Australia.

Case history A well 1 day old preterm male neonate, born at 34 weeks gestation with a birth weight of 2740 g, was noted to have a petechial rash. Full blood examination revealed anaemia (Hb 109 g/L), thrombocytopenia (22 x 109/L), and a large proportion of pleomorphic blasts (40%). Immunophenotyping confirmed these as myeloblasts (CD13, CD33, CD56 and some expressing CD117). The differential diagnosis included transient abnormal myelopoiesis (TAM) associated with Down syndrome (DS) or acute myeloid leukaemia (AML). The infant had no compelling clinical features of DS. Mild hypotonia was consistent with his stated gestation and epicanthic folds were in keeping with the South-East Asian background of his mother. Cytogenetic analysis on unstimulated cells in the peripheral blood confirmed the sole abnormality as trisomy 21 in the blast cell line. A phytohaemagglutinin (PHA) stimulated culture of T lymphocytes and analysis of 100 cells from a buccal smear both revealed a normal male karyotype in all cells (46,XY). A provisional diagnosis of non-DS TAM was made and supportive treatment included red cell transfusion and multiple platelet transfusions. Two weeks after diagnosis, the platelet count had not improved with the blast count remaining at approximately 10%. At four weeks post diagnosis, there were no circulating blasts, the platelet count had recovered (106 x 109/L) and the child was discharged home. Discussion: Although the current World Health Organisation classification of haematological malignancies describes TAM as a unique disorder of DS, it is clear from this case and other cases in the literature that TAM can occur in infants in the absence of DS. In this case trisomy 21 was identified only in the peripheral blast line. The most appropriate long-term follow-up for infants with TAM remains unclear. Whilst there is a well recognized increased risk for subsequent development of leukaemia in these infants there is currently no treatment to lower this risk. The longer-term follow up of this case and a systematic review of the literature will be presented.

1190F

The role of pregnancy on hemangioblastomas in von Hippel-Lindau disease: a retrospective French study. *C. Abadie[1, 4], I. Coupier[1, 2, 4], S. Bringuier-Branchereau[3], S. Deveaux[4], S. Richard[4, 5], French National Cancer Institute network "VHL disease and inherited predisposition to kidney cancer.* 1) Service de Génétique Médicale, Unité d'Oncogénétique, CHU Montpellier, Montpellier, France; 2) Service d'Oncogénétique, CRLCC Val d'Aurelle, Montpellier, France; 3) Département d'Information Médicale, CHU Montpellier, France; 4) Réseau National et Centre Expert National Cancers Rares PREDIR, Service d'Urologie, AP-HP, Hôpital de Bicêtre, Le Kremlin-Bicêtre, France; 5) Laboratoire de Génétique Oncologique EPHE, CNRS FRE 2939, Faculté de Médecine Paris-Sud, Le Kremlin-Bicêtre et Institut de cancérologie Gustave Roussy, Villejuif, France.

Von Hippel-Lindau disease (VHL) is a dominantly inherited disorder predisposing to highly vascularized tumors including hemangioblastomas of the central nervous system (CNS) and the retina. The disease results from germ-line mutations in the VHL tumour-suppressor gene that plays a key role in the cellular response to tissue hypoxia and angiogenesis. CNS and retinal hemangioblastomas occur in about 75% and 60% patients, respectively. Only a few case reports and one study on a small population of VHL patients (Grimbert et al., Am. J. Gyn. Obst. 1999,180:110-1) were previously interested in a potential deleterious role of pregnancy on hemangioblastomas which express progesterone receptors. We present a retrospective and comparative French study in 269 women from 172 families coming from the national VHL clinical database. The aim was to analyse the onset of new hemangioblastomas and potential tumoral complications in patients according to their gestational status. Available data of imaging follow-up of CNS and retina were collected in 176 women with at least one pregnancy and 93 women with none. When taking account of the relative frequency regarding the period of follow-up, more significant complications of previous hemangioblastomas were seen in women during pregnancy (P=0.022) and it was also significant during a period of 3 months postpartum (P<0.001). To our knowledge, this work represents the first study analysing the effect of pregnancy in a very large series of women with VHL. This study underlies the necessity of follow-up patients closely during pregnancy. Thus, a magnetic resonance imaging without injection is systematically required during the fourth month of pregnancy in each patient with previously known CNS lesions.

1191F

Global gene expression profiles in ovarian cancer linked to Lynch syndrome. *K. Bartuma[1], K. Harbst[1, 2], S. Malander[1], M. Jönsson[1], Z. Ketabi[3], A. Måsbäck[4], G. Jönsson[1, 2], M. Nilbert[1, 3].* 1) Department of Oncology, Institute of clinical sciences, Lund University, Lund, Sweden; 2) CREATE health strategic center for translational cancer research, Lund University, Lund, Sweden; 3) Clinical Research Center, Hvidovre Hospital, Copenhagen University, Hvidovre, Denmark; 4) Department of Pathology, Institute of Laboratory Sciences, Lund University, Lund, Sweden.

Lynch syndrome is caused by defective DNA mismatch repair and has been associated with an increased risk of ovarian cancer with a particular overrepresentation of endometrioid and clear cell tumors. The more common colorectal cancers in Lynch syndrome show distinct genetic profiles related to mismatch repair, which led us to investigate gene expression profiles in hereditary ovarian cancer. Ovarian cancers from 25 Lynch syndrome mutation carriers and 42 sporadic cases were included in a case-control design. The Illumina Whole Genome DASL assay was used for expression profiling and significance analysis of microarrays was performed to identify differentially expressed genes. Differential expression between Lynch syndrome-associated and sporadic ovarian cancers involved 335 genes with up-regulation of the mTOR and MAPK/ERK pathways. Clear cell cancers are overrepresented in Lynch syndrome and this subset showed a distinct expression profile with 668 differentially expressed genes with up-regulation of the HER2 signaling and apoptosis signaling pathways. Global gene expression profiles differ between hereditary and sporadic ovarian cancer and demonstrate distinct profiles linked to clear cell histologies. These data identify key signaling pathways as potential therapeutic targets in ovarian cancer linked to Lynch syndrome.

1192F

Endometrial cancer as a red flag for Lynch syndrome identification. *P.O. Chappuis[1,2,3], M. Genevay[4], P. Petignat[5], S. Myit[6], P. Benusiglio[1], S. Arcioni[3], L. Fonteneau[1], R. Suchy[3], L. Rubbia-Brandt[4], P. Hutter[3,7].* 1) Division of Oncology; University Hospitals of Geneva; Switzerland; 2) Division of Genetic Medicine; University Hospitals of Geneva; Switzerland; 3) Unit of Medical Genetics; Institut Central des Hôpitaux Valaisans, Sion; Switzerland; 4) Division of Clinical Pathology; University Hospitals of Geneva; Switzerland; 5) Division of Gynaecology; University Hospitals of Geneva; Switzerland; 6) Division of Histocytopathology; Institut Central des Hôpitaux Valaisans, Sion; Switzerland; 7) Laboratory of Molecular Oncology; University Hospitals of Geneva; Switzerland.

BACKGROUND: Women carrying germline mutations in DNA mismatch repair (MMR) genes responsible for Lynch syndrome (LS) have a 40-60% lifetime risk of developing endometrial cancer. According to the Amsterdam criteria and Bethesda guidelines, identification of LS is mostly determined by personal/family history of colorectal cancer. Tumor pre-screening with immunohistochemistry (IHC) for detection of the main MMR proteins and search for microsatellite instability (MSI) in incident cases of endometrial cancer is presented. **METHODOLOGY:** A population-based study designed for patients with colorectal and endometrial cancer diagnosed < age 75 in the Geneva and Valais cantons, Switzerland has been set up in 05.2009. After written consent, a phone interview collected detailed personal/family history and a complete pedigree is drawn. Tumor tissue pre-screening is based on IHC for MLH1, MSH2, MSH6, PMS2, the main MMR proteins, and search for MSI using 3 monomorphic microsatellites (BAT-25, BAT-26, CAT-25). *BRAF* c.1799T>A/p.V600E is searched when MLH1 protein is not expressed. In case of positive pre-screening, a genetic counselling is proposed and selective testing for germline mutations in MMR genes is discussed. **RESULTS:** Between 05.2009 and 05.2011, 26 endometrial cancers have been pre-screened for LS. Mean age at diagnosis was 58.3 (31-73.4) years and 3 (11.5%) patients were < age 50. Endometrioid carcinoma is the most frequent (96%) subtype of endometrial cancer and 22 patients had FIGO stage I/II disease, 4 stage III/IV. Three (11.5%) cases fulfilled Bethesda guidelines and 1 (3.8%) the Amsterdam criteria. Five (19.2%) tumors demonstrated loss of expression of ⁄ 1 MMR proteins and/or MSI. All patients with positive pre-screening have been seen in genetic counselling and one patient declined testing. Three genetic tests for germline MMR mutations have been completed. One *MSH2* pathogenic mutation (c.367-?_645+?del) has been identified in a 36 years old patient who did not meet any clinical criteria for LS. Moreover, one *MLH1* unclassified variant (c.545+61T>C) has been characterised is another index case. **CONCLUSION:** Endometrial cancer can be the single familial presentation of LS. Pre-screening of all endometrial cancer using IHC for MMR proteins and/or search for MSI should be considered given the limitations of the Amsterdam criteria and Bethesda guidelines in gynaecologic population. *Supported by a Swiss Cancer League grant and the Dumont-Moerlen fund.*

Determining a role for germline mutations in intermediate risk breast and ovarian cancer susceptibility genes in the Belgian population. *K. De Leeneer, A. De Jaegher, B. Crombez, I. Coene, A. De Paepe, B. Poppe, K. Claes.* Center for Medical Genetics, Ghent University Hosp, Ghent, Belgium.

Germline mutations in the coding and splice regions of BRCA1&2 are identified in approximately 15% of patients selected for genetic testing in the Belgian population. It is estimated that germline mutations in intermediate risk genes like PALB2, ATM, CHEK2, BRIP1 and BARD1 account for an elevated breast and ovarian cancer risk in approximately 5% of familial breast cancer. In this study we evaluated the mutation prevalence of PALB2 mutations in 285 Belgian patients from 256 independent BRCA1/2 mutation negative families with a young age at onset and/or family history of breast and/or ovarian cancer. The complete UTR, coding and splice site regions of PALB2 were analyzed with High resolution melting followed by Sanger sequencing of the aberrant melting curves. In silico predictions of variants with an unclear clinical significance was performed with the Alamut software. In total we identified 20 unique sequence variants in PALB2 of which 6 are previously unreported. Three novel unequivocal mono allelic mutations (PALB2 c.2834+1G>T c.2888delC and c.3423del4) were detected and shown to segregate with the disease in the families. PALB2 c.2834+1G>T is a splice site mutation which undoubtedly will lead to aberrant splicing; c.2888delC and c.3423del4 are both frame shift mutations in the WD40 protein domain, responsible for the interaction with BRCA2. Furthermore, we detected in nine patients 4 novel sequence variants (PALB2 c.-158G>C, c.498T>C, c.995T>A and c.1520C>G) of which the clinical significance is currently unknown. Several in silico analyses predict that PALB2 c.995T>A (p.Leu332His) could affect protein function. However, segregation analysis revealed that the mother of the patient, diagnosed with breast cancer at the age of 45 years did not carry the sequence variant. Deleterious PALB2 mutations were only identified in familial breast cancer patients (3/208= 1.4%) and not in 48 sporadic patients with early onset or bilateral breast cancer. Interestingly, the average age at diagnosis for the mutation carriers (62y; range 48-71) was significantly higher compared to the average age at diagnosis (39y, range: 25-78) of the non carriers. This limited role for PALB2 germline mutations in the Belgian population, suggests locus heterogeneity and further investigations in other intermediate risk breast and ovarian cancer susceptibility genes (ATM, CHEK2, BRIP1 and BARD1) will be undertaken.

1194F

Characterization of unclassified variants in DNA mismatch repair genes in Lynch syndrome. *M. Dominguez Valentin[1], LJ. Rasmussen[2], C. Therkildsen[3], T. Van Overeem Hansen[4], I. Bernstein[5], M. Nilbert[1,3].* 1) Department of Oncology, Institute of Clinical Sciences, Lund University, 22100 Lund, Sweden; 2) Center for Healthy Aging, Copenhagen University, Copenhagen, Denmark; 3) Clinical Research Centre, Hvidovre University Hospital, Copenhagen University, 2650 Hvidovre, Denmark; 4) Department of Clinical Biochemistry, Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark; 5) HNPCC Register, Department of Gastroenterology, Hvidovre University Hospital, Copenhagen University, 26550 Hvidovre, Denmark.

Lynch syndrome (LS) is the most common form of hereditary colorectal cancer (CRC) and accounts for 2-5% of all CRC (Lynch et al. 2005). LS is caused by germline mutations in mismatch repair (MMR) genes. Patients suffering from this syndrome inherit mutations in one allele of any of four MMR genes, most frequently MSH2, MLH1 or MSH6 and more rarely in PMS2 (Couch et al. 2008). The majority of the disease-predisposing MMR gene alterations cause truncations and thus loss of function of the affected protein (Lützen et al. 2008). A significant proportion of DNA variants found in patients suspected of having LS are unclassified variants (UV) (32%, 18% and 38% for MLH1, MSH2 and MSH6, respectively), whose pathogenicity remains unclear (Castillejo et al. 2011). Our previous study on suspected Danish LS population, found 36% of UV, being 26% of MLH1, 30% of MSH2 and 44% of MSH6 (Nilbert et al. 2009). This study aims to evaluate the pathogenicity of 15 UV found in 20 suspected Danish LS families (3 UV of MLH1 in 6 families, 5 UV of MSH2 in 5 families and 7 UV of MSH6 in 9 families) by applying co-segregation analysis, co-occurrence analysis (other MMR gene mutation in the family), biochemical diagnosis (IHC and MSI analysis), in silico predictions (SIFT, Polyphen, MAPP-MMR and P-mut programs) and functional assays. We analyzed the pedigrees and performed IHC, MSI and in silico analysis of all the families. In order to characterize the subcellular localization of the mutant proteins, we evaluated the co-localization of the mutant proteins by confocal laser scanning microscopy. Our results suggest normal subcellular localization of the 4-tested MSH2 and all tested MSH6 proteins. Based on the characterization of protein-protein interactions in MMR complexes containing MSH2 and MSH6 mutant proteins, we performed yeast-two hybrid and GST fusion protein (pull-down) assays for all 5-tested MSH2. We observed that all tested MSH2 UV were able to interact with MSH6. Currently, we are developing specific functional assays for MLH1 and MSH6 UV. Using these approaches, evidence for pathogenicity will be collected, which has clinical implications for recommendations for surveillance.

Background: Germline mutations in the DNA mismatch repair genes MLH1 and MSH2 are associated with substantially increased risks of colorectal cancer (CRC), endometrial cancer (EC) and certain other cancers. Due to the rarity of these mutations, previous studies have been underpowered to provide precise estimates of risks. **Methods:** We studied 167 MLH1 and 225 MSH2 mutation-carrying families comprising 17,352 members from the Colon Cancer Family Registry. Probands were recruited either because they had a family history of cancer (n=274) or from cancer registries independently of family history (n=118). Hazard ratios (HRs) of cancer risks for carriers compared with the general population and age-specific cumulative risks for carriers (penetrance) were estimated using modified segregation analysis conditioned on ascertainment. Heterogeneity in risks for carriers was modeled with a polygenic risk modifier (as in the BOADICEA model). **Results:** The age-specific incidence of CRC for male MLH1 mutation carriers was estimated to be 222 times (95% CI: 152-324) that for the population at ages 40 years and younger but only 6.1 times (95% CI: 2.4-15.5) after age 60 years. This decline ($p<0.0001$) in the CRC HR with age was also evident for female MLH1 mutation carriers ($p=0.002$) but was less marked. Male MLH1 mutation carriers on average had higher CRC HRs than female carriers ($p=0.004$). The estimated CRC HRs for MSH2 mutation carriers were similar to those for MLH1, with any differences consistent with chance ($p>0.3$). The estimated EC HRs also decreased sharply with age ($p=0.0004$ and 0.001 for MLH1 and MSH2, respectively) and no difference by gene was observed ($p=0.7$). There was strong evidence for an unmeasured polygenic modifier of risk ($p<0.0001$). The estimated average cumulative risks (95% CI) of CRC to age 70 years were 44% (35-54) for male carriers and 38% (30-48) for female carriers, and corresponding EC risks were 22% (14-31). However for carriers in the lowest vs. highest quartiles of polygenic risk (respectively) these were 4.9% vs. 93% for male CRC, 3.5% vs. 88% for female CRC and 1.5% vs. 59% for EC. **Conclusions:** This international study shows that, although the average cancer risks for MLH1 and MSH2 mutation carriers are similar, there is substantial unexplained variation in risks due to differences by mutation or by genetic or environmental modifiers. This finding has implications for the counseling and clinical management of mutation carriers.

From 2000-2010 - A Review of the First Pediatric Cancer Genetics Program in North America. *H. Druker[1,2], S. Meyn[1,2], N. Parkinson[1,2], D. Malkin[1,2].* 1) Hospital Sick Children, Toronto, ON, Canada; 2) University of Toronto, Toronto, ON, Canada.

The Cancer Genetics Program at The Hospital for Sick Children was created in July of 1999. It is the first of its kind in North America. It is housed in the second largest pediatric oncology department in North America with an average of 295 new cancer diagnoses made every year. Individuals are seen if the primary risk is NOT for breast/ovarian cancers, familial GI cancers in adults, or retinoblastoma. Referrals are accepted if at least one member of the extended family has/had a childhood cancer or may be at risk for developing cancer. From July 1, 1999 to December 31, 2010, the Cancer Genetics Program registered 1842 patient-visits. Of those 69.5% were new referrals and 29.5% were follow-up appointments. Of the new referrals, 68.0% underwent genetic testing that yielded an interpretable result. Variants of unknown significance were excluded. 78.6% received negative results, while 21.4% received positive results. Individuals with a positive result or with a suggestive family history of cancer were provided with screening guidelines in accordance with published literature or expert judgment. The most commonly tested condition was Li-Fraumeni Syndrome (41.3%), followed by VHL (9.8%), FAP (7.6%), Hereditary Wilms (5.1%), MEN2 (4.7%), Rhabdoid Tumour Syndrome (4.5%), PGL (3.4%), Gorlin (3.2%), Fanconi Anemia (2.5%), NF2 (2.5%), CCHS Syndrome (2.3%), MEN1 (2.3%) and other (10.8%). The highest number of positive results was identified amongst those tested for MEN1 (54.6%), followed by Gorlin (53.3%), Fanconi Anemia (50%), VHL (45.7%), CCHS (45.5%), PGL (25.0%), Rhabdoid Tumour Syndrome (23.8%), FAP (22.2%), NF2 (16.7%), HLRCC (16.7%), Hereditary Wilms (12.5%), and LFS (11.8%). No mutations were identified amongst those tested for Cowden Syndrome or Familial Neuroblastoma. In summary, 68.0%; of new referrals underwent genetic testing that yielded an informative result. This number is expected to rise as more hereditary cancer predisposition genes are identified.

1197F

Characterisation of Genetics Aspects of Paragangliomas and Pheochromocytomas in the Quebec French-Canadian Population. *N. Dumas[1], M. Edmont[1], S. Grunenwald[2], I. Lévesque[2], M. Binet[1], N. Burnichon[3], A. Gimenez-Roqueplo[3], I. Bourdeau[2,1].* 1) Service de Médecine Génique, Centre hospitalier de l'Université de Montréal (CHUM), Montreal, QC, Canada; 2) Service d'endocrinologie, Département de médecine et Centre de recherche, Centre hospitalier de l'Université de Montréal (CHUM), Montréal, Québec; 3) Service de génétique, Assistance Publique - Hôpitaux de Paris, Hôpital Européen Georges Pompidou, Paris, France.

Background: Paragangliomas (PGL) and pheochromocytomas (PCC) are rare tumors that may affect children and adults. To date, mutations in various genes have been identified as a risk factor for developing PGL and PCC including *VHL* (Von Hippel Lindau), *RET* (Multiple Endocrine Neoplasia type 2) and *NF1* (neurofibromatosis) and the genes encoding 3 of the 4 subunits of the mitochondrial enzyme succinate dehydrogenase (*SDHB*, *SDHC*, and *SDHD*). A mutation in one of the *SDHx* genes is present in 40% of individuals affected by head and neck PGL, and 10% of individuals with sympathetic PGL and PCC. Approximately 4% of hereditary PGL/PCC can be attributed to mutations in the *SDHC* gene. Methods: Following genetic counselling, 26 French Canadian patients (10 PCC, 16 PGL) consented to genetic testing of germline DNA. The 4 exons of the *SDHD* gene, the 8 exons of the *SDHB* gene, the 3 exons of the *VHL* gene, the 6 exons of the *SDHC* gene, and 7 exons (8, 10, 11, 13, 14, 15, 16) of the *RET* gene were amplified and directly sequenced. MLPA was performed for the *VHL* and *SDHx* genes. Results: One patient with PCC (10%) had a mutation in the *SDHB* gene (c.725G>A). Six patients with PGL (37%) were carriers of an *SDHx* mutation: two patients (33%) had an *SDHD* mutation (c.112C>T, c.119_125del), the same heterozygous non-sense mutation at codon 133 of exon 5 of the *SDHC* gene (c.397C>T, p.Arg133X) was found in 4 patients (67%). This genetic alteration leads to an amino acid change from arginine to a stop codon, causing premature truncation of the protein. These results are in contrast to the higher frequency of *SDHB* or *SDHD* mutations reported in other populations. Pedigrees were constructed and analysed for common ancestors for the patients with the *SDHC* mutation using a database containing information on residents of Québec since the 17th century (Balsac). Initial data from the genealogical research shows 10 possible common ancestors (5 couples) to the 4 index-cases with the *SDHC* mutation. Conclusion: Further genealogical studies including comparison to a control group, are needed to determine whether the *SDHC* mutation identified in our population truly represents a founder mutation. Haplotype analysis will also be used to further characterise this apparent *SDHC* founder mutation and to confirm the unique genetic distribution of *SDHC* mutations in French Canadians.

1198F

BRCA1 and BRCA2 mutational spectrum and evidence for a BRCA1 founder mutation in Luxembourg families with breast-ovarian cancer. *H. Grootkoerkamp[1], C. Bock[1], M. Sand[1], F. Lemoine[2], S. Meyer[2], S. Rauh[3], JL. Guarin[4], P. Hilbert[5], K. Dahan[5,6].* 1) ZithaKlinik, Luxembourg, L-2763 Luxembourg, Tumor Klinik; 2) Centre Hospitalier Emile Mayrisch , L-4240 Esch-sur-Alzette, Service d'Oncologie; 3) Centre Hospitalier Emile Mayrisch , L-4602 Niederkorn, Service d'Oncologie; 4) Centre de Génétique Humaine, Université Catholique de Louvain, B-1200 Brussels; 5) Centre de Génétique, Institut de Pathologie et de Génétique, B- 6041 Gosselies; 6) Laboratoire National de Santé, L-1911 Luxembourg Division d'Hématologie, Service de Conseil Génétique.

Genetic testing for inherited mutations in BRCA1 and BRCA2 has become integral to the care of women with a severe family history of breast or ovarian cancer, but in comparison with other European countries the prevalence of BRCA1/BRCA2 mutation in Luxembourg isn't well established. Here, we performed a multicenter study to determine the mutational spectrum and identify possible BRCA1 and BRCA2 founder mutations in the Luxembourg population. Between 2002-2010, 122 families were selected on the following criteria ; (i) two or more breast cancers under the age of 50 years, or (ii) three cases of breast cancer (BC) at any age or (iii) both breast and ovarian cancer (OC) cases or (iv) one BC diagnosed under the age of 35 years. Small mutations were screened by genomic sanger sequencing (/) or by amplicon sequencing with Multiplicom (www.multiplicom.com) using GS-FLX 454 standard chemistry (Roche) and large rearrangements using multiplex ligation dependent probes. A total of 15 mutations in the BRCA1/2 genes were identified in 122 families studied (15/122, 12%). All but four of the mutations were detected within the BRCA1 gene (11/15, 73,3%). Majority of mutations are unique nucleotide changes except for the large BRCA1 deletion comprising exons 13-15 which was identified in 4 unrelated families (4/15, 26%). No other rearrangement was detected. Mutational analysis of BRCA1/2 genes showed a relative low frequency of causing-disease changes in Luxembourg and illustrated the dominant role of the BRCA1 exon 13-15 deletion, a change previously observed in Asian population and found in 4 of 122 high-risk families referred for genetic counseling.

Differential effects of Pot1b and telomerase deficiency in adrenocortical dysplasia (*acd*) mice. *C.E. Keegan, H. Kocak, E.L. Macke, K.W. Wilson, G.A. Osawa.* Departments of Pediatrics and Human Genetics, Univ Michigan, Ann Arbor, MI.

Telomeres are nucleoprotein structures that solve both the end-replication problem and the end-protection problem. Dysfunctional telomeres can result from critically short telomeres or unprotected telomeres, leading to genomic instability. While telomerase prevents critical telomere shortening, the shelterin complex protects telomeres by suppressing DNA damage responses. In humans, Dyskeratosis Congenita (DC) is a rare genetic disorder characterized by extremely short telomeres, bone marrow failure, and mucocutaneous manifestations, caused by mutations in telomerase and its associated proteins and in the shelterin complex member *TINF2*. Mouse knockouts of *Terc*, the telomerase RNA component and *Pot1b*, a shelterin component, have been proposed as models for DC. Adrenocortical dysplasia (*acd*), a hypomorphic mutation encoding the shelterin component Tpp1, has overlapping features with *Terc* and *Pot1b* deficient mice, including growth retardation, infertility, and reduced survival. To better understand the *in vivo* interactions of Tpp1 with Pot1 and telomerase, we generated crosses of these three existing viable mouse models with known telomere dysfunction and features of DC. In our cross of *acd* mice to *Pot1b* null mice, *acd* mutant mice in the F_2 generation exhibited a slower growth rate than mice with other genotypes, as expected from prior studies. However, there were no surviving *acd/acd*, *Pot1b*$^{-/-}$ or *acd/acd*, *Pot1b*$^{+/-}$ mice, suggesting that deficiency of both Tpp1 and Pot1b is incompatible with survival. Furthermore, *acd/acd*,*Pot1b*$^{-/-}$ embryos were absent at E13.5, when homozygous *acd* mutant embryos are present in Mendelian ratios, suggesting a synergistic interaction. In addition, it has previously been shown that *Terc* haploinsufficiency significantly exacerbates the *Pot1b* null phenotype. Thus, to determine the effect of Terc deficiency on the *acd* mutant phenotype, we crossed early generation (G1) *Terc* deficient mice to *acd* mice, and we found that double mutant mice in the F_2 generation are viable and appear to have a phenotype resembling adult *acd* mutant mice. Future work will include isolation of MEFs from *acd* mutant mice with *Terc* deficiency and with *Pot1b* deficiency to investigate the cellular consequences of these mutations. Our data thus far indicate that *Pot1b* deficiency exacerbates the *acd* mutant phenotype, while *Terc* deficiency does not have a significant effect. This work was supported by American Cancer Society RSG GMC-115995 to CEK.

A large intragenic duplication in the Folliculin (*FLCN*) gene causing Birt-Hogg-Dubé syndrome with an interesting phenotype. *D.H.K. Lim[1,2], C. Morgan[2], P.K. Rehal[2], F. Bond[2], L. Walker[3], D. Halliday[3], F. Macdonald[2], E.R. Maher[1,2].* 1) Department of Medical & Molecular Genetics & Centre for Rare Diseases and Personalised Medicine, University of Birmingham, United Kingdom; 2) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Edgbaston, Birmingham, United Kingdom; 3) Department of Clinical Genetics, Churchill Hospital, Oxford, United Kingdom.

Birt-Hogg-Dubé syndrome (BHD), caused by germline mutations in Folliculin (*FLCN*), is an autosomal dominant cancer predisposing genodermatosis characterised by fibrofolliculomas (benign tumours of the hair follicles), lung cysts +/- spontaneous pneumothorax and an increased lifetime risk of renal cancer. The function of Folliculin remains to be fully understood but it has been shown to be involved in the mammalian target of rapamycin (mTOR), AMP-activated protein kinase (AMPK) and transforming growth factor (TGF-)) signalling pathways.

In collaboration with the European Birt-Hogg-Dube Consortium, we previously established a locus specific database (LSDB) for *FLCN* variants available at www.lovd.nl/flcn. Most mutations reported to date have been point mutations and small insertions/deletions. Recently large genomic deletions and a single small duplication in *FLCN* have been reported.

We present a family with 5 affected individuals over 2 generations with a clinical diagnosis of BHD. The proband presented with typical histologically confirmed fibrofolliculomas and developed an unusual renal cell carcinoma at age 36 years. The phenotypic features of the other affected individuals of the family will be presented along with other interesting findings including a carcinoma of the caecum in the proband's father and chronic inflammatory conditions in the other affected individuals.

Sequencing of the *FLCN* gene identified a novel exon 11 missense variant (c.1198G>A, p.Val400Ile) that did not segregate with the disease in the family. Multiplex Ligation-dependant Probe Amplification (MLPA) revealed a large duplication of exons 2 to 11, which was subsequently confirmed to be in tandem by long range PCR (LR-PCR) on genomic DNA and RNA studies.

The identification of a large duplication of the *FLCN* gene further expands the mutation spectrum in BHD. We recommend MLPA analysis in patients who show clinical features of BHD, but in whom a disease causing mutation cannot be identified on routine sequencing. MLPA analysis of the *FLCN* gene will improve the diagnostic yield of mutation screening and allow more accurate genetic counselling.

1201F

Tumor suppression in *Apc*$^{Min/+}$ mice by prostaglandin D_2. *H. Lin[1], B. Tippin[1], A. Kwong[1], J. Park[1], A. Materi[1], V. Buslon[2], S. French[2], S. Narumiya[3], Y. Urade[4], E. Salido[5].* 1) Division of Medical Genetics, Harbor-UCLA Medical Center, Torrance, CA; 2) Department of Pathology, Harbor-UCLA Medical Center, Torrance, CA; 3) Department of Pharmacology, Faculty of Medicine, University of Kyoto, Japan; 4) Department of Molecular Behavioral Biology, Osaka Bioscience Institute, Japan; 5) CIBERER, Hospital Universitario Canarias, La Laguna, Tenerife, Spain.

Prostaglandin D_2 (PGD_2) appears to prevent intestinal tumors, as shown by more adenomas in *Apc*$^{Min/+}$ mice that lack hematopoietic prostaglandin D synthase (HPGDS) and fewer tumors in mice that over-express this enzyme (Park et al. Cancer Res 2007; 67: 881-9). PGD_2 binds to receptor PTGDR, and PGD_2 metabolites bind to peroxisome proliferator-activated receptor gamma (PPARG). Therefore, we hypothesized that knockouts of the genes for PPARG or PTGDR may reduce tumor suppression by PGD_2. Two sets of experiments were used to test these predictions. First, we produced *Apc*$^{Min/+}$ mice with transgenic lipocalin-type prostaglandin D synthase (PTGDS), with and without heterozygous *Pparg* knockouts (104 mice, including controls). Next, in separate experiments, we produced *Apc*$^{Min/+}$ mice with *Ptgdr* knockouts (40 mice, including controls). Mice were sacrificed at 14 weeks. Intestines were removed in one piece, cleaned, opened lengthwise, fixed in formalin, coiled into “Swiss rolls,” embedded, sectioned, and mounted on slides for histology. To score adenomas, we used 24 Swiss roll sections spaced 150 μm apart for experiments on *PTGDS* transgenic mice and *Pparg* knockout mice. We used 10 Swiss roll sections spaced 250 μm apart for experiments on *Ptgdr* knockout mice. We grouped tumors into 3 size categories: intravillar lesions; other small tumors (seen on only one section); and large tumors (seen on multiple sections). Compared to results from our earlier report, transgenic PTGDS was less tumor suppressive than transgenic HPGDS. Nonetheless, *PTGDS* transgenic mice had lower median numbers of large adenomas (50% of control; $P = 0.022$) and lower levels of MYC mRNA in the colon. Heterozygous *Pparg* knockouts alone did not affect numbers of tumors, but *Pparg* knockouts blunted the suppression of large tumors by transgenic PTGDS. More dramatically, *Ptgdr* gene knockouts (homozygous or heterozygous) raised the median number of tumors 2-fold, compared to the median number among *Apc*$^{Min/+}$ controls ($P = 0.0005$). The increase was 2.6-fold for homozygous *Ptgdr* knockouts (8 knockout mice and 9 controls; $P = 0.0015$). The data establish the concept of PGD_2 as a tumor suppressing molecule, whose effect is mediated through receptor PTGDR in *Apc*$^{Min/+}$ mice. Inflammatory mechanisms involving T cells and dendritic cells may be involved. The results may suggest ways to prevent tumors in familial adenomatous polyposis and sporadic colorectal neoplasia by use of PTGDR agonists.

1202F

Gynecologic phenotypes in women with PTEN Hamartoma Tumor Syndrome. *J. Mester, C. Eng.* Genomic Med Inst, Cleveland Clinic, Cleveland, OH.

PTEN Hamartoma Tumor Syndrome (PHTS) is a molecularly-defined umbrella term used to describe individuals with Cowden syndrome (CS), Bannayan-Riley-Ruvalcaba syndrome, and other conditions who have germline mutations of the PTEN tumor suppressor gene, localized to 10q23. Genotype-phenotype analysis, not designed to look at gynecologic phenotypes, and case reports suggest increased, but unknown, prevalence of endometrial carcinoma of the uterus (EC) in CS patients. By expert opinion, EC was included as a major criterion towards the clinical diagnosis of CS. Other gynecologic (GYN) tumors and anomalies count towards minor diagnostic criteria. However, the prevalence and natural history of GYN findings have not been systematically studied in a prospectively accrued series of CS patients. In our series of 122 PTEN pathogenic mutation-positive females recruited by relaxed CS diagnostic criteria (CS or CS-like) or presence of a known germline PTEN mutation, 85 were adults >18 yrs. Of these 85, 15 (18%) were found to have EC. Median age at EC diagnosis was 47 yrs (range 20-64), compared to 61 yrs in the general population. Based on SEER data, 0.194 cases were expected, giving an age-adjusted Standardized Incidence Rate (SIR) of 77.4 (95% CI 44.95-124.7, p<0.001). All EC with documented histology were endometrioid lesions, FIGO grade I or II . While most patients were overweight or obese (average BMI 31.6 kg/m2), patients with EC trended towards having even higher BMI (p=0.055). Of the 85 mutation positive adult females, 40 had fibroid tumors, which was not significantly associated with obesity (p=0.14). Among all 122 mutation positive females 10 (8.2%) had 11 ovarian tumors, 2 of which were malignant, and 6 had GYN developmental anomalies (4 bicornuate uterus, 1 duplicated cervix, 1 hypoplastic ovary). Current National Comprehensive Cancer Network screening guidelines for CS, which are utilized for patients with PHTS, advise patient education and prompt response to symptoms of EC. Prophylactic hysterectomy or uterine surveillance is not mentioned but we would advise clinicians to have a low threshold to offer these options to PHTS patients given both high prevalence and high SIR of EC in this population. Based on these data, we would not add a recommendation for ovarian cancer screening or oophorectomy, but would advise physicians to closely follow adnexal masses and understand the potential for malignancy.

1203F

Genetic testing for BRCA1 and BRCA2 mutations in women with hereditary predisposition to breast and ovarian cancer in Croatia. *V. Musani[1], M. Levacic Cvok[2], I. Susac[3,4], P. Ozretic[1], M. Sabol[1], D. Car[1], D. Eljuga[4], Lj. Eljuga[4], S. Levanat[1].* 1) Rudjer Boskovic Institute, Zagreb, Croatia; 2) Rudjer-Medikol Diagnostics, Zagreb, Croatia; 3) Croatian League Against Cancer, Zagreb, Croatia; 4) Eljuga polyclinic, Zagreb, Croatia.

Among women, breast cancer is the most commonly diagnosed cancer after non-melanoma skin cancer, and it is the leading cause of cancer deaths in Croatia. Ovarian cancer is in the fifth place, both in incidence and mortality. Epidemiological data indicates that 5-15% of breast cancer and 10% of ovarian cancer cases are hereditary, and germline mutations in the tumor suppressor genes Breast Cancer Gene 1 (BRCA1) and Breast Cancer Gene 2 (BRCA2) account for the majority of hereditary breast and ovarian cancers. BRCA1 and BRCA2 are involved in a variety of cellular processes, including maintenance of genome stability, DNA repair via homologous recombination, transcriptional regulation, cell cycle control, chromatin remodeling and ubiquitinylation. Mutations are scattered throughout both genes and include disease-causing mutations as well as unclassified variants. The contribution of BRCA1 and BRCA2 mutations to hereditary breast and ovarian cancer in Croatia is unknown. The purpose of this study was to estimate the incidence and spectrum of pathogenic mutations in BRCA1 and BRCA2 genes in high risk women in Croatia. The screening was performed with high resolution melting analysis, direct sequencing and semi-quantitative multiplex PCR method (Cvok et al. Clin Chem Lab Med 2008;46(10):1376-83). Protocols were certified by EMQN (European Molecular Genetics Quality Network). The complete coding sequences and exon-intron boundaries analyses of both genes were carried out on 160 women with family history of breast and ovarian cancer. Up to now 13 pathogenic mutations were detected, eight in BRCA1, with one previously unpublished, and five in BRCA2 (three previously unpublished). 22 BRCA1 and 36 BRCA2 unclassified variants and polymorphisms were also identified, of which two in BRCA1 and eight in BRCA2 were not previously published. This is the first molecular investigation of the hereditary predisposition to breast and ovarian cancer in BRCA1 and BRCA2 genes in Croatia. Samples were collected from different regions of the country and the level of pathogenic mutations and distribution of polymorphic variants will contribute to population statistics for 4.5 million population of Croatia. This study was funded by The Terry Fox Run 2009 donation and supported by The Terry Fox Foundation and Croatian League Against Cancer.

Birt-Hogg-Dubé syndrome in a large Hutterite family. *R. Perrier[1], K. Dornan[2], J. Parboosingh[1], W. Davidson[3].* 1) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 2) Division of Medical Genetics, Alberta Health Services, Calgary, AB, Canada; 3) Division of Respirology and Department of Community Health Sciences, University of Calgary, Calgary, AB, Canada.

Birt-Hogg-Dubé syndrome (BHD) is an autosomal dominant condition characterized by cutaneous manifestations (fibrofolliculomas, trichodiscomas, and achrocordon-like growths), cystic lung disease and spontaneous pneumothoraces, and predisposition to renal cell carcinoma. We describe a large Hutterite family, originally descended from a Mennonite couple, with 33 affected individuals. The proband in this family was diagnosed with BHD after presenting with a personal and family history of multiple spontaneous pneumothoraces. A heterozygous mutation in the *FLCN* gene (c.59delT) resulting in premature protein truncation was identified. Following the diagnosis of BHD, cascade testing was offered to at-risk relatives in the extended family with 63 people agreeing to formal testing. The familial *FLCN* mutation was identified in 33 people over 3 generations with an age range of 24-71 years at the time of testing. There was a history of spontaneous pneumothoraces in 21% (N=7). The average age at first diagnosis of pneumothorax was 35.9 years (range 20-47 years). In the 28 people who had a chest CT scan, the degree of lung parenchymal cystic changes varied from normal parenchyma to extensive, bilateral cystic disease. The prevalence of cystic lung disease was 89%. Fibrofolliculomas were present in 54%. One incident renal cancer (an unclassified renal cell carcinoma) was diagnosed by screening abdominal CT scan in a healthy 40 year old male. The only other malignancy was a lung adenocarcinoma in an obligate carrier diagnosed at age 37. As consanguineous marriages are common in the Hutterite population, one couple was identified in which both partners were found to carry the *FLCN* mutation, giving rise to the possibility of offspring with homozygous *FLCN* mutations. This couple has three healthy young children who have not been offered genetic testing given their age. Animal data from mice suggests that homozygous loss of *FLCN* would likely cause an embryonic lethal phenotype, so it is unlikely that there would be any reproductive consequences for this family with the exception of possible reduced fertility. This large Hutterite cohort with Birt-Hogg-Dubé syndrome provides a unique opportunity to describe the variable phenotype associated with the c.59delT *FLCN* mutation, and in the future will allow for study of the natural history of BHD in a prospective manner.

Use of Whole Exome Sequencing to Identify the Molecular Basis of Susceptibility to Lymphoid Malignancies in Childhood. *B.C. Powell[1,2], M. Delario[2], L. Jiang[3], L. Trevino[3], R. Zabriskie[2], M. Kimmel[4], L.C. Strong[5], D.A. Wheeler[1,3], R.A. Gibbs[1,3], S.E. Plon[1,2].* 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Dept. of Pediatrics, Texas Children's Cancer Center, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Dept. of Statistics, Rice University, Houston, TX; 5) Dept. of Pediatrics, University of Texas M.D. Anderson Cancer Center, Houston TX.

Introduction: Knowledge of cancer susceptibility genes impacts prevention, surveillance and treatment for patients and their at-risk family members. These same genes and their signaling pathways are also important in sporadic cancers. However, the underlying genetic basis of many childhood cancers remains unknown. Aims and Methods: Our goal is to identify novel high risk cancer susceptibility genes by analysis of germline DNA from small cohorts of childhood cancer families enrolled in research protocols through three pediatric cancer genetics programs in Texas. Variants are discovered by sequencing of all gene coding regions (using coding exons from VEGA, CCCDS and RefSeq on a capture platform comprising 42 Mb of target followed by sequencing on Illumina HiSeq). We have used this whole exome sequencing of constitutional (non-tumor) DNA to study 7 kindreds in which multiple closely related individuals have developed lymphocytic leukemia or lymphoma. Relationships among affected individuals in these kindreds suggest inheritance that is autosomal dominant (AD, 4 kindreds), AD vs. X-linked (2 kindreds) or indeterminate (1 kindred). Variants are further characterized based on segregation with cancer in family, informatic prediction of pathogenicity of missense changes and presence in both control and tumor sequencing datasets. Results and Conclusions: Greater than 20X coverage was obtained for 91-95% of each targeted exome. One early finding is a nonsense variant of *TP53* (c.916C>T; p.R306X) in a kindred containing 5 cases of high-risk ALL and only one other solid tumor. This result is surprising in that prior studies have found that p53 does not underlie familial leukemia/lymphoma and leukemia is not a major feature of Li Fraumeni syndrome suggesting that a leukemia modifier may also segregate in the family. In another kindred, we analyzed variants shared among 3 individuals with cancer. 95% of these variants were previously reported in dbSNP. The remaining 54 novel SNVs were further reduced to 33 by subtraction of variants also found in the healthy non-transmitting parent, 7 of which are predicted by bioinformatic analysis to be functionally important. Integration of data across similarly-affected kindreds will provide a means for identification of novel susceptibility genes for rare and common cancer types, as well as identification of unexpected cancer phenotypes due to mutations in known genes. Linkage Analysis and Whole-Exome Sequencing on Families with Multiple Lipomatosis. *F. Probst[1], R. Corrigan[1], R. Zabriskie[2], D. Murdock[3], R. Hamid[4,5], G. Tiller[6], J. Phillips[4], N. Kramer[7], J. Graham, Jr.[7], M. Bainbridge[3], W. Jin[2], L. Wang[2], R. Gibbs[3], S. Plon[1,2].* 1) Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Pediatrics - Hematology & Oncology, Baylor Col Med, Houston, TX; 3) Human Genome Sequencing Center, Baylor Col Med, Houston, TX; 4) Pediatrics, Vanderbilt University School of Medicine, Nashville, TN; 5) Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN; 6) Genetics, Kaiser Permanente, Los Angeles, CA; 7) Medical Genetics Institute, Cedars-Sinai Medical Center, UCLA School of Med, Los Angeles, CA.

Multiple lipomatosis (OMIM %151900) is an autosomal dominant condition that leads to the development of multiple encapsulated lipomas, predominantly on the trunk and limbs. We have recently ascertained two large families that exhibit this genetic disorder in several living generations. Most affected family members did not develop tumors until later in life, typically in the late teens or early 20s in males, or in the late 20s or early 30s in females. One individual was affected in infancy and by age 4 years had undergone two major surgical procedures to remove large lipomas from his back. Two (out of eight) of the affected women in the larger pedigree developed breast cancer, one in her 40s and the other in her 50s, suggesting that multiple lipomatosis may confer an increased risk for breast cancer. Conversely, the gene that is responsible for multiple lipomatosis may also be involved in the pathogenesis of sporadic breast cancers. Linkage analysis on the larger family was performed on data from 700K SNP arrays using MERLIN software, which revealed a single linkage peak with a LOD score of greater than 3.0, located on the short arm of chromosome 1. However, an additional peak with a LOD score in the range of 2.5 to 3.0 was also noted, as were nine peaks with LOD scores between 2.0 and 2.5. Exome capture of four affected family members from the larger family was performed with the Roche NimbleGen SeqCap EZ Human Library v2.0 capture reagent, and sequencing of the output DNA was performed on the Applied Biosystems SOLiD platform. The data were aligned to the hg18 reference genome using BFAST v0.4.6d, and variants were called with SAMtools. This analysis yielded two potential candidate mutations that were seen in all four individuals, one of which was under the main linkage peak. Candidate gene sequencing and linkage analysis on the second family are currently in progress, as is candidate gene sequencing in several smaller families, in order to determine the underlying gene (or genes) responsible for this disorder.

Does age at cancer diagnosis depend on parent of origin of BRCA mutation? *I. Shapira, D. Budman, M. Akerman, L. Weiselberg, V. Vinciguerra, J. D'Olimpio, C. Devoe, C. Chavez, K. Cheng, L. Donahue, S. Cohen.* Hofstra North Shore LIJ School Of Medicine New York.

Background: Recently reported epidemiologic evidence shows that daughters who inherit Lynch syndrome mutations from their fathers get cancer at an earlier age than those inheriting mutations from their mothers suggesting that autosomal dominant DNA mismatch repair genes may be subject to imprinting effects. Biallelic expression is not the norm for all genes in humans. Imprinting effect evident in autosomal dominant hereditary paraganglioma leads to tumors only if inherited from paternal germline. Cancer penetrance in carriers of BRCA mutation may be determined by the parental origin of mutation Methods: From 2004-2010 we analyzed 1456 consecutive patients who presented for genetic counseling. In 168 patients with BRCA 1 or BRCA 2 the parent of origin for the mutation was known. Of 168 patients 2 had both BRCA1 and BRCA2 mutated paternally inherited. The mean age of BRCA mutation diagnosis was 44 years of age with a range of 21-67 years of age. All the patients in our cohort were born after 1940. 75 inherited the deleterious BRCA mutation from their fathers (53 affected) and 91 individuals inherited the deleterious mutation from their mother (61 affected). No ovarian cancers were identified in our cohort of BRCA 2 mutations of maternal inheritance. Two-sample t-test was used to compare the mean age at diagnosis in patients with BRCA 1 or 2 mutations of paternal or maternal inheritance. Results: Maternal Paternal 2 sample t-test p-value Br Ca BRCA1 46 + 11 39 + 7 p< 0.0281 Br Ca BRCA2 51 + 10 41 + 5 p< 0.0007 Ov Ca BRCA2 56 + 7 44 + 3 p< 0.0080 Significantly younger age at breast and ovarian cancer diagnosis was observed in paternal inheritance of BRCA mutations. Conclusion: Maternal and paternal inherited BRCA alleles may not be exchangeable. Women with paternally inherited mutations in BRCA gene mutations have cancers diagnosed at earlier age compared with women who inherit the gene mutations from their mothers. In this small sample clear differences at age of cancer diagnosis are apparent in paternal inheritance of BRCA gene mutation. If this observation duplicates in larger cohorts results will have important implications for recommendation of surgical risk reduction in BRCA mutation carriers.

A founder XPD mutation among Iraqi Jews: Estimation of the most recent common ancestor (MCRA). *H. Slor[1,2], S. Orgal[1], Z. Keren[3], S. Koka[3], O. Bittermann Deutch[4], E. Azizi[5], F. Pavlotzki[5], R. Yaniv[5], M. Korostishevsky[1], K.H. Kraemer[6], P.C. Hanawalt[7], G. Spivak[7], T.C. Falik-Zaccai[3,8].* 1) Dept Human Gen, Tel Aviv Univ Sch Med, Tel-Aviv, Israel; 2) Biotechnology, Tel Hai Academic College, Upper Galilee,Israel; 3) Institute of Human Genetics, Western Galilee Hospital, Naharia, Israel; 4) of Dermatology, Western Galilee Hospital, Naharia, Israel; 5) Department of Dermatology, Sheba Medical Center, Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 6) National Cancer Institute, NIH, Bethesda, MD, USA; 7) Department of Biology, Stanford University, Palo Alto, Ca, USA; 8) Rappaport Faculty of Medicine, Technion, Israeli Institute of Technology, Haifa Israel.

Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by hypersensitivity to UV irradiation due to a defect in nucleotide excision repair (NER). XP patients have a high frequency of squamous and basal cell carcinomas as well as malignant melanomas appearing at a very early age (Kraemer et al., 2007). The prevalence of XP in western European population was estimated to be 0.9 per million live births (Kleijer et al., 2008) . Certain geographically isolated populations have a higher prevalence, especially where consanguinity is common; in Japan the rate is 1 in 22,000 (Hirai et al., 2006). Among the 450,000 Iraqi Jews in Israel, we estimate the incidence of XPD to be 1 in 10,000. We describe a cohort of 13 unrelated XP patients representing 13 families with a total of more than 40 XP patients. All the patients are of Kurdistani and Iraqi Jewish origin. They exhibit mild to medium sun sensitivity, and a relatively low frequency of skin tumors (basal cell and squamous cell carcinomas) compared to other XP patients. There were no eye abnormalities, No hearing loss, and no XP type neurological abnormalities except for loss of tendon reflexes. All patients were found to belong to the XP-D complementation group by host cell reactivation and cell fusion assays. Sequence analyses revealed that all the patients were homozygous for a p.R683Q mutation in the XPD gene. These patients did not have the neurological abnormalities seen in XP patients with the common p.R683W mutation at the same amino acid site (Lehmann, 2001). All the Jewish Iraqi XP patients carry the same homozygous haplotype along 420 kb downstream and 503 kb upstream of the XPD gene as determined by SNP analysis. These data suggest a founder mutation. Further SNP analysis further away from the above distances identified several different variations indicating recombination events from which the most common recent ancestor (MRCA) was estimated to be about 60 generations ago, which correspond to about 1500 years. This large cohort might expand our understanding of the genotype-phenotype correlations for the p.R683Q mutation in the XPD gene. Further phenotypic characterization of segmental neurofibromatosis type 1 in a large patient cohort. *J.S. Solomons[1], J. Jamieson[1], S. Huson[2], D. Shears[1], U. Kini[1].* 1) Clinical Genetics, Oxford Radcliffe NHS trust, Oxford, United Kingdom; 2) Genetic Medicine, St. Mary's Hospital, Manchester, United Kingdom.

Introduction: Segmental Neurofibromatosis type 1 (SNF1) is a rare variant of NF1 characterised by limited, segmental distribution of cutaneous NF1 lesions. Somatic mosaicism caused by post zygotic mutation of the NF1 gene leads to an SNF1 phenotype. The phenotype in SNF1 can be variable with usually unilateral and rarely bilateral and either symmetric or asymmetric distribution. There is a paucity of reports in literature on phenotypic characterization, complications, malignancy and reproductive risks on large cohorts of patients with SNF1. **Aim**: To study phenotypic variation, complications, risk of malignancy and reproductive risks in a large cohort of patients with SNF1. **Methods**: Review of case notes of all patients with SNF1 referred to Oxford regional genetics NF1 centre from 1993 to date. **Results**: Eighty one patients with SNF1 were reviewed at the Oxford regional NF1 centre over a period of 17 years. Some of the complications diagnosed in our patient cohort included 22 patients with plexiform neurofibromas , 3 spinal Neurofibromas, 3 optic gliomas and 2 sphenoidal wing dysplasias. Six of our patients were diagnosed with other forms of benign and malignant tumours not commonly associated with NF1 such as teratomas, breast tumours, lymphomas, lipomas and hemangiomas. We present a detailed report of further phenotypic characterization, malignancy and reproductive risks based on observations in our patient cohort. **Conclusion**: We present here the phenotypic variability of SNF1 seen in the largest cohort of patients to our knowledge reported so far. A larger cohort of patients need to be studied in order to determine more accurate reproductive and malignancy risks.

1210F

Novel mutation in tp53 I195S in a patient with Li-Fraumeni. *T. Wegman-Ostrosky[1,2], L. Taja-Chayeb[3], J. Sanchez-Corona[1], C. Moran-Moguel[1], C. Migues-Muñoz[3], S. Vidal-Millan[4].* 1) Medicina Molecular, CIBO, IMSS, Guadalajara, Jalisco, Mexico; 2) CUCS, Universidad de Guadalajara; 3) Investigación Básica , Instituto Nacional de Cancerología , México; 4) Investigación Clínica, Instituto Nacional de Cancerología México.

Li Fraumeni Syndrome (LFS) is a dominantly inherited cancer syndrome characterized by a high risk of developing soft tissue sarcoma, osteosarcoma, pre-menopausal breast cancer, brain tumors, adrenocortical carcinoma, and a variety of other neoplasms. The main cause of LFS is a germline mutation in the p53 gene, and there are nearly 600 mutations reported word wild. Individuals with LFS have increased risks for developing cancer at younger ages. In individuals who have a TP53 mutation, the median age of diagnosis of cancer is 25 years. We present a case of 9 years old boy with multiple primary tumors and family background of several members who had cancer. A previously healthy boy of 9 years old, had history of rounding of her face, acne on her forehead and signs of virilization were noted. On admission he had acne on the forehead and increased oiliness of the facial skin. A mass of 4 x 4 cm was palpable on left torax. There was axillary hair and genitalia showed signs of virilization. Abdominal computed tomography confirmed the finding of a right adrenal mass and a second mass on the 5th rib. The biopsies of both tumors confirm adrenocortical carcinoma in the first mass and osteosarcoma in the biopsy from the rib. DNA was isolated from peripheral blood leukocytes. Five pairs of primers were used to amplify exons 2-9 of p53. After corroborating a correct amplification, samples were analyzed in a DHPLC (Transgenomics™) device. Heterozygote profiles were identified in the amplicon of the exon 5/6 by visual analysis of the chromatograms, comparing peak shapes with a wild-type sample. Samples were sequenced to identify sequence change in samples with an aberrant DHPLC profile in these fragments. Electropherograms were analyzed in both sense and antisense direction for presence of mutations and a point mutation in the codon 195 was detected. The sequences obtained were compared with the reference TP53 (GenBank X54156). Results were compared with the following three databases: International Agency for Research on Cancer (IARC) database; and the P53 Knowledgebase. In the nucleotide 13344 a trasvertion T -> G was detected. This mutation, I195S, is located in the DNA binding domain of P53 therefore destroys the ability of the protein to bind to its target DNA sequences, and thus prevents transcriptional activation of these genes. I195S has not been reported has a germline mutation, so is the first case of Li-Fraumeni Syndrome inflicted by the mutation I195S.

1211F

Mutation analysis of the *Rak* gene in Finnish breast cancer families. *T. Heikkinen[1], LM. Pelttari[1], K. Aittomaki[2], C. Blomqvist[3], H. Nevanlinna[1].* 1) Department of obstetrics and gynecology, Helsinki university central hospital, Helsinki, Finland; 2) Department of clinical genetics, Helsinki university central hospital, Helsinki, Finland; 3) Department of oncology, Helsinki university central hospital, Helsinki, Finland.

Inherited susceptibility to breast cancer consists of germline mutations in various genes, most notably in *BRCA1* and *BRCA2*. High breast cancer risk is also a part of rare cancer syndromes such as Cowden Syndrome caused by mutations in the *PTEN* gene. PTEN (phosphatase and tensin homolog) is a regulator of the PI3K/Akt oncogenic pathway that is often dysregulated in cancer. Rak (FRK, Fyn related kinase) is a kinase protein belonging to Src family which directly interacts with PTEN by phophorylating it on amino acid residue Tyr336 thus stabilizing the protein. The *Rak* gene is located on the chromosomal region 6q21 overlapping with the recently published Nordic breast cancer linkage region 6q14.2-21.3 (Arason et al. Breast Cancer Res 2010). We sequenced the protein coding regions, exon-intron boundaries, and 5'UTR of the Rak gene in 116 breast cancer patients belonging to 111 non-BRCA1/2 families. *CHECK2* 1100delC and *PALB2* 1592delT mutations were also excluded. We identified 10 variants on the *Rak* gene of which four have not been reported previously. Two variants changed the amino acid sequence of the protein product: a common polymorphism c.364GA (rs3756772), p.Gly122Arg, and in two families a novel variant c.1451GA, p.Arg484His. Neither of these missense variants however had predicted functional consequences on the protein in SIFT, Polyphen, or SNPs3D prediction tools and were not evolutionarily conserved. The two novel 5'UTR variants -239TC and -160CG, both found in single families, were evolutionary conserved among primates, but not among other mammals. The -160CG variant was not present in another breast cancer patient (cousin) from the same family. The fourth novel variant was an intronic variant IVS6+42AG found in three unrelated patients. Mutations in the *Rak* gene seem unlikely neither to contribute in a large scale to hereditary breast cancer nor to explain the 6q linkage.

1212F

Association of Variants in Estrogen-Related Pathway Genes with Prostate Cancer Risk and Prognosis. *S.K. Holt[1], E.W. Kwon[2,3], R. Fu[1,4], S. Kolb[1], Z. Feng[1,4], E.A. Ostrander[2], J.L. Stanford[1,5].* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Program in Human Genetics and Molecular Biology, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Department of Epidemiology, University of Washington, Seattle, WA.

Estrogen signaling plays a key role in prostate cancer (PCa) development and progression. Through mediation by its receptors, estrogen has been shown to have both carcinogenic and anti-carcinogenic effects on the prostate, as well as defining distinct molecular subclasses of PCa cells. Thus, genetic variation within this pathway may contribute to both disease risk and outcomes. We report results from a hypothesis testing population-based genetic association study of single nucleotide polymorphisms (SNPs) in estrogen-related candidate genes ESR1, ESR2, CYP19A1 CYP1A1, and CYP1B1. We evaluated PCa risk conferred by 73 tagSNPs genotyped in 1,453 incident PCa cases and 1,351 age-matched controls using logistic and multinomial regression. Assessment of recurrence/progression and PCa-specific mortality after an average of 10 years of follow-up was carried out using adjusted Cox proportional hazards regression. PCa risk was associated with 12 SNPs found in ESR1, CYP1A1, and CYP1B1. Only the association with CYP1B1 rs1056836 (OR CC vs. CG or GG = 1.3, 95% CI 1.3 95% CI 1.1-1.5) remained significant after adjustment for multiple comparisons. As secondary analyses, we examined SNP genotypes by dietary phytoestrogen intake, body mass index, and family history of PCa. For outcomes analyses, there were 331 cases with recurrence/progression events and 88 cases who died of PCa. Analyses of outcomes are underway, with preliminary findings suggesting that genomic variation in ESR1, ESR2, CYP1A1, and CYP19A1 are associated with PCa-specific mortality. Complete results with respect to prognosis will be shown at conference presentation. These data provide strong evidence that germline genetic variation of CYP1B1 is associated with risk of PCa and that germline genetic variation may contribute to PCa outcomes. Future studies are needed to understand the functional consequences of these genetic variations. Larger studies are needed to confirm these associations with PCa risk and prognosis and to identify genetic predictors in the estrogen pathway for specific subsets of patients with distinct environmental exposures or genetic backgrounds.

1213F

Association of Genetic Polymorphisms in the Androgen Pathway and Prostate Cancer Risk. *E.M. Kwon[1,2], S.K. Holt[3], R. Fu[3,4], S. Kolb[3], Z. Feng[3], J.L. Stanford[3,4], E.A. Ostrander[2].* 1) Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD, USA; 2) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD, USA; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA; 4) Dept. of Epidemiology, School of Public Health, University of Washington, Seattle, WA, USA.

Prostate cancer (PC) is the most frequently diagnosed solid tumor and second leading cause of cancer deaths in U.S. men. Multiple genome-wide association studies (GWAS) have identified over 40 single nucleotide polymorphisms (SNPs) that are significantly associated with PC risk, including genes in the androgen pathway (e.g., *KLK3*). Androgens play a central role in mediating prostate carcinogenesis and genes involved in the androgen pathway are therefore important candidates for PC susceptibility. In this hypothesis-testing study, we evaluated risk of PC in association with variants in 22 genes that are either involved in androgen metabolism or have been shown to interact with AR. Using samples from a population-based case-control study of Caucasian and African American men, 187 SNPs were genotyped in 1,458 cases and 1,351 age-matched controls. PC risk was estimated using adjusted unconditional logistic regression and multinomial regression models. Our single SNP analyses showed suggestive evidence (p<0.05) for an association of PC risk with 13 SNPs in 8 genes: *NKX3.1, HSD17B3, AKR1C3, CYP17A1, KLK3, JAK2, NCOA4* and *STAT3*. The most significant effect on risk was seen with rs2253502 in *HSD17B3* (odds ratio, OR=0.57, 95% CI: 0.39-0.84). In addition, 60 SNPs in 15 genes were associated with clinical features of PC such as stage, Gleason score, and a composite aggressive score; of these, 5 SNPs in 4 genes (*CYP17A1, HSD17B4, NCOA4*, and *SULT2A1*) were associated with more aggressive disease with p<0.01. Pathway-based association analysis is currently underway to test cumulative effect from multiple SNPs within the androgen metabolism pathway. Our preliminary findings show significant gene-gene interactions (p<0.0001) between a SNP rs10883783 in *CYP17A1* and a SNP rs7039978 in *HSD17B3* conferring 1.44-fold increased risk of PC. These results confirm that variants in genes involved in the androgen metabolism pathway are associated with risk of PC. Our results replicate previously reported associations of SNPs in *NKX3.1, HSD17B3, ARK1C3, CYP17A1* and *KLK3*. In addition, novel associations were observed for SNPs in *JAK2, NCOA4, HSD17B4*, and *SULT2A1*. The latter results as well as those for SNPs associated with clinical features and gene-gene interactions need further replication in larger studies.

1214F

Frequency of *BRCA1* and *BRCA2* mutations in prostate cancer. *D. Leongamornlert[1], E. Saunders[1], M. Tymrakiewicz[1], N. Mahmud[1], E. Castro[1], C. Goh[1], T. Dadaev[1], M. Guy[1], L. O'Brien[1], E. Sawyer[1], A. Hall[1], R. Wilkinson[1], The. UKGPC Collaborators[1], D. Easton[2], D. Goldgar[3], R. Eeles[1,4], Z. Kote-Jarai[1].* 1) Oncogenetics, The Institute of Cancer Research, Sutton, Surrey, United Kingdom; 2) Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge, UK; 3) Department of Dermatology, University of Utah, Salt Lake City, US; 4) The Royal Marsden NIH Foundation Trust, London, UK.

The aetiology of prostate cancer (PrCa) is poorly understood. A family history of prostate cancer, particularly at a young age, is a strong risk factor for the disease, indicating that inherited factors are important in PrCa. Relative risk of prostate cancer (PrCa) in *BRCA1* and *BRCA2* mutation carriers ≤ 65 years has been estimated to be up to 1.85 and 7.3-23, respectively. We previously estimated that 2.3% of PrCa cases diagnosed ≤ 55 years harbour a *BRCA2* mutation and PrCa among *BRCA2* carriers has been shown to be more aggressive, with poorer survival. To further evaluate the role of *BRAC1* and *BRCA2* genes in PrCa predisposition we screened 914 cases for *BRCA1* mutation and 1821 for BRCA2 mutation. Patients were recruited through the UKGPCS (UK Genetic Prostate Cancer Study Collaborators) aged 36 to 86 years but the study was enriched for cases with an early age of onset, (~88% men diagnosed ≤ 65 years). We analyzed the entire coding region of the *BRCA1* gene using Sanger sequencing and the *BRCA2* gene using a novel high-throughput multiplex fluorescent heteroduplex detection system developed for the ABI3130xl genetic analyser BRCA1 was also analysed for large re-arrangements by MLPA for 460 cases. We identified 4 deleterious mutations and 33 unclassified variants (UV) in *BRCA1* and 19 deleterious mutations and 69 UVs in *BRCA2*. Based on studies in breast/ovarian cancer families, most UVs in these genes are likely to be non-pathogenic. Three of the *BRCA1* mutation carriers were affected at age ≤ 65 years and one developed PrCa at 69 years, whilst all the carriers of frameshift mutations in *BRCA2* were affected at age ≤ 65 years. The frequency of deleterious *BRCA1* mutation in this study is 0.43% and the frequency of *BRCA2* mutation is 1.05 % for all ages and 1.20 % for cases diagnosed ≤ 65 years. Using previously estimated carrier frequencies germline *BRCA1* mutation confers an increased relative risk of PrCa approximately 3.6 fold (95% CI 1.0-9.3) and this translates to a ~7.6% cumulative risk by age 65. We estimate that germline *BRCA2* gene mutation confers an increased relative risk of PrCa by age 65 of approximately 7 fold (95% CI 4.5-11), corresponding to a cumulative risk of ~15% by age 65. This study indicates a rationale for routinely testing young onset PrCa cases for germline *BRCA2* mutations, to enable the delivery of targeted treatments.

1215F

Evidence for a *hTERT* repressor gene on human chromosome 3p21.3 by using chromosome engineering. *T. Ohhira[1], S. Abe[2], H. Tanaka[2], T. Notsu[3], S. Horike[4], D-L. Qi[1], C. Fujisaki[1], G. David[2], M. Oshimura[1], H. Kugoh[1].* 1) Biomedical Science, Regenerative Medicine, Yonago, Tottori, Japan; 2) Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, Indiana , USA; 3) Regenerative Medicine and Therapeutics, Graduate School of Medical Science, Tottori University, Tottori, Japan; 4) Frontier Science Organization, Institute for Gene Research, Kanazawa University, Kanazawa, Japan.

Telomeres are the repeated sequence located on both ends of chromosomes in eukaryotes, which protect the end of the chromosome from deterioration or from fusion with neighbouring chromosomes and their eventual loss is thought to result in cellular senescence. Unlike normal somatic cells, most tumor cells had an activation of telomerase, which stably maintains telomere length by adding DNA sequence repeats (”TTAGGG” in all vertebrates) to the 3' end of DNA strands in the telomere regions. The RCC23 cell line derived from human renal cell carcinoma had telomerase activity and loss of heterozygosity on the short arm of chromosome 3. We and others have previously demonstrated that the introduction of a human chromosome 3 into RCC23, via microcell-mediated chromosome transfer (MMCT), repressed transcription of the *hTERT* gene, that is a key component and controlling factor required for telomerase activity. In this study, we performed an analysis of hTERT expression level in RCC23 cells transferred truncated chromosome 3 fragments (RCC23 #3del), to identify chromosomal region that carry *hTERT* suppressor gene. By development of chromosome engineering, we found a telomerase repressor region located within a 7-Mb interval on chromosome 3p21.3. These results provide important information regarding *hTERT* regulation and a unique method to identify *hTERT* repressor elements. Ref; S. Abe et al., Genome Integrity., 1., 2010.

Frequency of haplotype (C667T/A1298C polymorphisms) of MTHFR in Mexican breast cancer patients. *AM. Puebla[1], A. Solorzano[2], A. Ramos[2], LE. Figuera[3], MP. Gallegos[1].* 1) Inmunofarmacologia, CUCEI, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) Laboratorio de Genetica Molecular, Division de Medicina Molecular, CIBO, IMSS; 3) Division de Genetica, CIBO, IMSS.

The methylenetetrahydrofolate reductase (MTHFR) gene is important for folate metabolism, and the polymorphisms, C677T and A1298C, have been observed to reduce the enzymatic activity; C677T is present at high penetrance in Mexican populations. These polymorphisms has been associated with breast cancer in other population but no included the Mexican population. In the present study we determinate the frequency of haplotypes of C667T/A1298C polymorphism of MTHFR gene in 110 patients with breast cancer and 249 healthy controls from Mexican population. The frequency observed of 10% (23/220) and 16.6 % (83/492) of CC haplotype; 36% (79/220) and 37% (182/492) of CA haplotype; 40%(88/220) and 29% (142/492) of TA haplotype; similar frequency was observed in the TC haplotype 11% (24/220; 54/492) in both study groups; 3% (6/220) and 8% (38/492) heterozygous haplotype in cases and controls respectively. The statistically different ($p<0.05$) was observed in the TA haplotype with OR 1.64(95%CI 1.16-2.32). These results suggest that the TA haplotype of C667T/A1298C polymorphism on the MTHFR is associated with Mexican breast cancer patients.

1217F

Rapid and Precise Inference of Copy Number Alterations using Graphics Processing Units. *G.K. Chen[1], C. Curtis[1], K. Wang[1,2].* 1) Dept of Preventive Medicine, University of Southern California, Los Angeles, CA 90089, USA; 2) Zilkha Neurogenetic Institute, Dept of Psychiatry, University of Southern California, Los Angeles, CA 90089, USA.

Heritable copy number variations (CNVs) in the human genome have been extensively characterized, and numerous computational approaches are available for robustly detecting such variants in germline DNA. Somatic alterations in cancer genomes present a landscape of variation that differs from germline CNVs in that these copy number alterations (CNAs) tend to be more abundant and are typically broader. In addition to the general challenges in assigning copy number states, methods for detecting CNAs must deal with issues that are unique to tumor samples. For example, tumor specimens frequently exhibit aneuploidy as a result of genomic instability and those of epithelial origin (e.g. breast, colon) often contain a significant fraction of normal cells, known as stromal contamination. While stromal contamination can be ameliorated by techniques such as laser capture microdissection, such an approach is laborious and seldom applied in large-scale genomic studies. A second issue is that there are many possible copy number states and stromal contamination levels, which presents computational challenges if investigators are interested in precise characterization of CNAs. As such, modeling the true allelic copy number states as an estimated mixture of normal and tumor copy numbers, with the estimate of the magnitude of stromal contamination in a locus-specific manner, can lead to more precise CAN inference. We propose a continuous time Hidden Markov Model for high-resolution SNP genotyping arrays that allows users to specify an arbitrary number (up to several thousand) of hidden states, dictated by the maximum number of states, possible genotypes, and the granularity of mixture estimates. Our algorithm exploits massively parallel computing cores on graphics processing units (GPUs), enabling HMM training to proceed in a matter of minutes in contrast to days or months using a serial implementation. Our software, written in OpenCL, allows for portability across a wide range of target platforms such as multi-core CPUs, and GPU adapters from vendors like ATI or nVidia. We present results that demonstrate that our method performs as accurately as the current state of the art methods (which also model stromal contamination), but achieves results using only a fraction of the memory and CPU time required by these methods, allowing investigators who may not have access to a large computing cluster to feasibly carry out analyses on a large number of tumor samples.

Copy number variation analysis in 134 unrelated patients with mutation negative adenomatous polyposis. *S. Horpaopan[1], S. Vogt[1], I. Spier[1], A.M. Zink[1], K. Wöllner[1], S. Herms[1,2], M. Draaken[1,2], A. Kaufmann[1], D. Stienen[1], S. Uhlhaas[1], E. Holinski-Feder[3,4], M.M. Nöthen[1,2], P. Hoffmann[1,2], S. Aretz[1].* 1) Institute of Human Genetics, University of Bonn, Germany; 2) Dept. of Genomics, Life & Brain Center, University of Bonn, Germany; 3) University Hospital of the Ludwig-Maximilians-University, Campus Innenstadt, Munich, Germany; 4) MGZ - Center of Medical Genetics, Munich, Germany.

Background: Adenomatous polyposis syndromes are characterised by multiple colorectal adenomas and a high lifetime risk of colorectal cancer. Germline mutations of the APC and MUTYH genes cause the autosomal dominant Familial Adenomatous Polyposis (FAP) and autosomal recessive MUTYH-associated Polyposis (MAP), respectively. However, in up to 50% of families no germline mutation could be identified although a genetic cause is likely. Copy number variants (CNVs), in particular, heterozygous microdeletions, contribute significantly to the mutation spectrum of known hereditary tumor syndromes and thus it could be hypothesised that those heterozygous deletion CNVs might also be the underlying cause in yet unidentified genes responsible for monogenic adenomatous polyposis syndromes. **Methods:** Genomic DNA from 134 unrelated mutation negative polyposis patients was used for genome-wide SNP genotyping with the HumanOmni1-Quad BeadArray (Illumina). Putative CNVs were identified by the QuantiSNP v2.2 algorithm, filtered according to various criteria by use of the Cartagenia Bench™ software, by in-silico-analysis, and by comparison with 531 healthy controls, and validated by qPCR. **Results:** 35 unique heterozygous deletion CNVs (size: 10-613 kb) containing 38 protein coding genes could be validated in 33 of 134 patients (25%) but not in healthy controls. 25 genes are partly or completely deleted, in 13 more the deletion affects intronic regions only. Additionally, 47 unique duplication CNVs (size: 25-856 kb) from 38 patients (28%) were validated by qPCR. 49 out of the 106 involved genes are partially duplicated which might point to potential loss-of-function effects. 9 of 25 partial/whole deleted genes and 30 of 49 partial duplicated genes are expressed in the intestine. All CNVs are present only once in the whole cohort; all except eight patients harbor just one CNV. Candidate adenoma genes include protein kinases, transcription factors, and potential tumor suppressors. **Conclusions:** By applying stringent filter criteria, we identified a group of rare deletion and duplication CNVs which might contain predisposing genes for adenoma formation. After prioritization of the included genes according to function and pathway, upcoming work is sequencing the coding regions of the most interesting candidates in all patients to look for pathogenic point mutations. The study was supported by the German Cancer Aid (Deutsche Krebshilfe).

Cutaneous Somatic Mosaicism in Hereditary Leiomyomatosis and Renal Cell Cancer. *B.G. Hammond[1], R. Madani[1], M. Pithukpakorn[2], G.M. Glenn[2], C. Cabala[2], O. Toure[2], W.M. Linehan[2], M.H. Wei[2], J.R. Toro[1,2].* 1) Dermatology, Washington, DC Veterans Affairs Medical Center, Washington, DC, USA; 2) National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland, USA.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is the autosomal dominant predisposition to uterine and cutaneous leiomyomas (CL) and renal cell cancer. Patients with HLRCC develop solitary, segmental and/or disseminated CLs. Our objective was to investigate the frequency of inactivation of the second FH allele in CL and compare the pattern of loss of heterozygosity (LOH) in segmental and non-segmental CL. Two or more skin biopsies were obtained from CLs in a segmental distribution and at least one skin biopsy from a non-segmental CL from each patient. DNA was extracted from microdissected CL and normal tissues, and genotyped with one intragenic FH marker and 12 polymorphic markers surrounding the FH locus covering a 17 kb region. DNA sequencing was conducted to screen for FH somatic and germline mutations. A total of 87 CLs were biopsied from 47 individuals with HLRCC. 87% (76/87) of CLs had a somatic mutation or LOH. LOH at the FH locus was detected in 84% (73/87) of CLs of which 74% (57/77) showed deletions > 8.3 kb. In every case of LOH, the germline mutation was retained, and the wild-type sequence was lost. Three CLs that did not show LOH revealed a frameshift FH mutation. Only a single alteration was found in each CL and no somatic mutations were found in matched normal fibroblasts and peripheral blood leukocytes DNA. To investigate the functional consequences of second allele inactivation, the FH enzyme activity in 10 CLs from three HLRCC patients was measured. All CLs showed almost absent FH enzyme activity compared to fibroblasts from unaffected skin from the same patient. DNA specimens (2-7 per lesions) obtained from a segmental CL showed the same LOH pattern (size and polymorphic markers) in each patient (N=11). In contrast, DNA from a non-segmental CL (N=12) showed a unique LOH pattern distinct from segmental or other non-segmental CLs on the same patient. This is the largest molecular and genetic investigation of CL from HLRCC patients. The high frequency of second allele genetic alterations and nearly absent FH enzyme activity in CLs strongly supports that FH is a tumor suppressor gene. Our findings suggest that segmental CL may arise from a second hit in an early progenitor cell. In contrast, second hits in independent lesions occur later and randomly in smooth muscle-like differentiated cells. Therefore, the timing of the loss of second FH allele may predict the pattern and distribution of CLs.

Description of BRCA mutations, UVs, SNPs and haplotypes in North-Eastern Romanian population. *L. NEGURA[1], D. AZOICAI[1], M. MATEI[1], G. POPOIU[2], A. CONEAC[3], N. UHRHAMMER[4], Y.-J. BIGNON[4], A. NEGURA[2].* 1) Immunology, University of Medicine and Pharmacy Gr. T. Popa, IASI, IASI, Romania; 2) Biochemistry and Molecular Biology, Alexandru Ioan Cuza University, IASI, Romania; 3) University of Medicine and Pharmacy Iuliu Hatieganu, Cluj-Napoca, Romania; 4) Centre Jean Perrin, Clermont-Ferrand, France.

Breast cancer is the most common cancer in women worldwide, including Romania, where its annual incidence has increased significantly to 14,000 during the last decade. In 30% of all cases there is a familial segregation, while in at least 10% a clear Mendelian inheritance is usually shown in different genetic backgrounds/populations. Germinal mutations in predisposition genes like BRCA1 or BRCA2 are responsible for up to 90% of cancer cases in hereditary breast and ovarian cancer (HBOC) families. Screening for BRCA mutations and polymorphisms is nowadays standard practice in the western world, allowing medical follow-up and genetic counseling of risk patients from HBOC families. Currently, most laboratories performing diagnostic analysis of the BRCA genes proceed to PCR amplification of exons and intron-exon boundaries, coupled to a pre-screening step to identify anomalous amplicons. The techniques employed for the detection of mutations and SNPs have evolved over time and vary in sensitivity, specificity and cost-effectiveness. We adapted several pre-screening techniques and imagined new ones in order to reduce the number of sequenced BRCA amplicons. MLPA screen was implemented for detecting large gene deletions or duplications. Multiplex-PCR and allele-specific PCR were used for rapid identification of known recurrent mutations in our region. In-house PCR-RFLP targeted novel BRCA mutations. Heteroduplex analysis by mismatch-specific endonuclease was used to pre-screen unknown mutations and to identify anomalous amplicons prior to sequencing. All detected variations were confirmed by forward and reverse dideoxy sequencing. We combined all these techniques in a pre-screening model. We present the first study regarding BRCA mutations and SNPs in Romanian population. We observed a variety of BRCA mutations, which may place the North-Eastern Romanian population somewhere between western populations (few recurrent, many rare or unique mutations) and eastern ones (recurrent mutations responsible for the majority of predisposed families, very few novel or unique mutations). Two missense variants of unknown significance (UVs) were observed. We used 14 prevalent SNPs to define BRCA1 alleles, and identified 7 different BRCA1 haplotypes in our population, with 5 canonical previously described and 2 novel haplotypes. This study was possible with partial financial support from the Romanian Ministry for Education and Research, by the CNCSIS grant PN-II-PD-557/2010.

1221F

Prostate Cancer predisposition loci and risk of metastatic Prostate Cancer in Asian Indians. *Y. TAN[1], J. AHN[2], T. REBBECK[3], R. MITTAL[4], A. MANDHANI[4], B. MITTAL[4], R. HAYES[2], H. RENNERT[1].* 1) Department of Pathology, Weill Cornell Medical College, New York, NY; 2) NYU School of Medicine, New York, NY; 3) University of Pennsylvania, Philadelphia, PA; 4) Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Objectives: Prostate cancer varies widely by geographic location and ethnicity. American men have a high prostate cancer (PC) risk, but most have localized disease. In contrast, Asian Indians have a low PC risk, but most are diagnosed with metastatic disease. Genetic contribution to PC risk is well-established, but less is known about gene variation-associated PC in low-risk populations. The objective of this study was to investigate the role of selected susceptibility single nucleotide polymorphisms (SNPs) based on their genome-wide association with PC in the Cancer Genetic Markers of Susceptibility (CGEMS) in Asian-Indian men with advanced PC. Methods: DNA samples obtained from 121 cases and 216 age-matched controls from Asian Indians (Northern India) were genotyped for 15 SNPs at 11 different loci (JAZF1, 11q13, MSMB, 10q23, IL16, 8q24, HNF1B, CDH13, CPNE3, CTBP2, and 8p21). The association between SNPs and the risk for metastatic PC was analyzed by logistic regression. Age adjusted Odds Ratios (OR) were estimated under each possible genetic model, and the best fitted model was selected. Results: Six SNPs are significantly associated with risk for metastatic prostate cancer in Asian Indian. Among those six, four are located on 8q24: rs4242382 (OR=2.34, 95% CI=1.44-3.80); rs1447295 (OR=1.93, 95% CI=1.19-3.15); rs1016343 (OR=1.67, 95% CI= 1.09-2.57); rs6983561 (OR=1.89, 95% CI=1.13-3.14), one from MSMB rs10993994 (OR=1.82, 95% CI=1.14-2.88), and the other one from JAZF1 rs10486567 (OR=0.54, 95% CI=0.34-0.86) . The best fitted genetic model for the six significant SNPs is either Dominant or Log-additive. Conclusions: Our results support the role of selected susceptibility SNPs in 8q24, MSMB, and JaZF1 in metastatic PC in Asian-Indian men. This study warrants additional investigations of these genes in PC etiology to identify markers that can better predict individuals that are more likely to develop lethal PC.

1222F

Spatio-temporal dynamics of ATM protein at DNA damage sites define a distinct sub-pathway of the DNA double strand break response network. *M.S. Meyn[1,2,3], P. Bradshaw[1,2].* 1) Prg in Gen & Genomic Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada.

Human cells use complex signaling networks to detect and respond to DNA damage in genomic DNA. ATM, the protein kinase inactivated in the cancer syndrome Ataxia-Telangiectasia, controls the major DNA Double Strand Break (DSB) response pathway. Current models assume that ATM is a critical component of . H2AX-associated megabase-sized chromatin complexes that develop around induced DSBs and serve as a platform for DSB repair. To better understand the behavior of ATM at DNA breaks we use UVA light + Hoechst dye to introduce spatially-defined DNA breaks within chromatin in human fibroblasts.

Photo-induction of DNA damage, equivalent to ~10 Gy . -radiation, causes rapid recruitment of ATM to damage sites. ATM recruitment occurs after MRE11/Rad50/NBS1 (MRN) and prior to DNA damage response factors . H2AX, 53BP1 and MDC1. Unlike . H2AX, ATM accumulation peaks 10-30 minutes post damage, then declines with kinetics paralleling those of DSB rejoining. While induced foci of . H2AX and many other DSB response proteins enlarge and diffuse with time, ATM forms discrete non-diffusible, MDC-1 independent foci. ATM foci formation requires MRN, but at 1 hr post damage, ATM foci are spatially separate from MDC1-independent MRN foci which themselves colocalize with homologous recombination (HR) proteins RPA, Rad51 and FANCD2. The non-diffusible nature of DNA damage-associated endogenous ATM foci is confirmed by FRAP analysis of GFP-tagged ATM. Auto-phosphorylation of serine 1981 is key for ATM foci formation, as mutating serine 1981 to alanine impairs GFP-ATM accumulation and over-expression of the telomeric protein TRF2, an ATM kinase inhibitor whose binding spans the S1981 residue, also attenuates GFP-ATM accumulation at DNA damage sites. Further, transient depletion of the chromatin regulator HMGN1 results in serine 1981 phosphorylation and activation of ATM signalling. Our results argue against current DSB response models as they indicate that at least 3 classes of complexes form at DSBs: . H2AX-associated megabase complexes; discrete foci of HR proteins; and discrete foci of ATM. ATM foci dynamics suggest ATM is not a major component of . H2AX-associated megabase complexes and does not directly facilitate HR-mediated repair. Rather, our findings suggest that ATM rapidly accumulates at localized sites of damage in an MRN-dependent manner, then is displaced as DNA breaks are either rejoined or processed for recombinational repair.

Single-cell RT-PCR cDNA subtraction and expression profiling of putative bipotential B-macrophage progenitors improves the identification of both normal and leukaemic haematopoietic development. *E. Sakhinia[1,2], Y. Heshmat[2], G. Brady[3].* 1) Molecular Medicine Division, Tabriz university of Medical Science, Tabriz, Iran; 2) 2- Tabriz Genetic Analysis Centre (TGAC), Sheikh Alraeis Clinic, Specialized & Subspecialized Outpatient Clinic of Tabriz Medical Sciences University, Tabriz, I.R.Iran; 3) Novel Therapies Division, EpiStem Ltd , Manchester,UK.

The molecular mechanisms underlying haematopoiesis are as yet unclear, but they will certainly be reflected and often driven by changes in gene expression. Identification of changes in gene expression accompanying haematopoietic differentiation is, therefore, likely to further our understanding of both normal and leukaemic haematopoietic development. In recent years, there has been increasing evidence for the existence of naturally occurring haematopoietic precursors, which are restricted to B cells/macrophages (B/M precursors) and are also a target for neoplastic transformation. Further understanding of B/M precursors would therefore provide potential insights into the regulation of both normal and leukaemic haematopoietic developments. The aim of this study was to examine early haematopoietic precursors in order to evaluate whether B cells and macrophages share a common restricted development precursor and if this is reflected at the molecular level. Our approachs were 1) Enrich for B/M specific genes by applying cDNA subtraction to foetal liver fractions enriched for B/M precursors. 2) Identify and characterise individual B/M precursors 3) Use cDNA subtractions, cloning and sequencing to analysis putative B/M specific genes. Analysis of the first set of cDNA subtractions indicated that B/M specific transcripts were rare in cDNA prepared from pools of enriched cells and an initial screen of cDNA clones failed to identify useful B/M markers. To further refine the approach single cell analysis was performed and resulted in the identification of three individual putative B/M precursors. The DNA sequencing showed that three of the subtracted clones have no similarities in the gene bank suggesting that subtraction is more reliable for discovering unknown stage specific and rare genes. But this does not negate the fact that the single cell approach alone is capable of identifying novel genes. Generally, the sequencing results confirm that the cDNA being used is still sound and that the whole approach is working, including sequencing. The approach taken is also enriching for rare unknown genes.

Tavtigian[5].* 1) Queensland Institute of Medical Research, Herston, Queensland, Australia; 2) International Agency for Research on Cancer, Lyon, France; 3) Department Genetics, University Medical Center Groningen, Groningen, The Netherlands; 4) Genetics of Breast Cancer Team, Cancer Research Center of Lyon, Centre Leon Berard, Lyon, France; 5) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, UT; 6) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 7) School of Informatics and Computing, Indiana University, Bloomington, IN; 8) Buck Institute, Novato, CA; 9) Department of Genetics, University Hospital and Inserm U614, Institute for Biomedical Research and Innovation, Rouen University, Rouen, France; 10) Department of Internal Medicine, University of Utah School of Medicine, Salt Lake City, UT; 11) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, UT; 12) Department of Medicine, University of Vermont, Burlington, VT.

Clinically useful classification of rare missense substitutions observed during genetic testing is one of the outstanding problems in clinical genetics. Perhaps the most developed solution is the Bayesian “integrated evaluation” used to assess substitutions observed during testing of the breast cancer susceptibility genes BRCA1 and BRCA2. Here we take an important step towards an analogous system for the mismatch repair (MMR) genes (MLH1, MSH2, MSH6, PMS2) that confer colon cancer susceptibility in Lynch syndrome. We calibrated in silico methods to estimate probabilities of pathogenicity for MMR gene missense substitutions. We developed a qualitative MMR gene missense substitution classification system based on the IARC five-class system. After excluding uncertain variants, there were 81 missense substitutions that 1) could be classified as pathogenic, likely pathogenic, likely not pathogenic, or not pathogenic and 2) had no evidence of causing a splice defect. In parallel, we built and curated protein multiple sequence alignments for each of the four MMR genes, with all four alignments based on a fixed tree of metazoan sequences. We used six different missense substitution analysis tools (Align-GVGD, MAPP, MutPred, PolyPhen-2.1, SIFT, and Xvir) to score the missense substitutions. The tools' outputs were calibrated by regression against the classifications of the 81 missense substitutions. All six tools were reasonably effective at missense substitution analysis, generating correlation coefficients (R^2) of 0.39 - 0.54, regression P-values of 10E-10 and lower, and areas under the ROC curve of 0.85 - 0.91. MAPP was the most accurate stand-alone tool tested. Benefits of combining two tools into a single classification model were explored. Taking into account problems of colinearity and the requirement that secondary tools make a significant contribution to combined models, we found MAPP + MutPred to make the best combined model and, excluding those two tools, PolyPhen-2.1 + Align-GVGD to make the second best combined model. Because the integrated evaluation can accept prior probabilities as a continuous variable, our in silico models avoid binary classification in either their inputs or outputs. By design, their outputs are interpretable as probability in favor of pathogenicity. The best model has an area under the ROC curve of 0.93, and 54% of input substitutions receive probabilities of either >90% or <10% with only one apparent classification error.

1225F

The GWAS-identified prostate cancer associated SNP, rs10993994, transcriptionally regulates microseminoprotein-beta (MSMB) levels. *X. Xu[1], J.E. Hayes[1], H.G. Lilja[2,3,4], R.J. Klein[1,2].* 1) Cancer Biol & Gen, Sloan-Kettering Cancer Ctr, New York, NY; 2) Department of Laboratory Medicine, Division of Clinical Chemistry, Lund University, Malmö University Hospital, 205 02 Malmö, Sweden; 3) Reproductive Medicine Centre, Lund University, Malmö University Hospital, 205 02 Malmö, Sweden; 4) Department of Clinical Laboratories, Surgery (Urology) and Medicine (GU-Oncology), Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA.

Background: Recent genome wide association screens have identified a single nucleotide polymorphism (SNP), rs10993994, as a locus that confers genetic predisposition to prostate cancer. This SNP is located in the proximal promoter of micro-seminoprotein beta (*MSMB*). *MSMB* codes for one of major secretory products of the prostate,) -MSP/PSP94. Though the function of) -MSP is unknown, the protein and a peptide derivative have properties suggestive of tumor suppressors. We have previously shown that rs10993994 genotype is strongly correlated with physiological) -MSP levels in the serum and semen of young healthy men.

Objectives: We hypothesize that rs10993994 is the functional variant responsible for the prostate cancer association signal, and acts through reducing *MSMB* levels, a putative tumor suppressor. Consequently, our objective is to elucidate the regulatory mechanisms underlying rs10993994's influence on *MSMB*/) -MSP levels.

Results: Through promoter reporter activity analysis, we have determined that single nucleotide difference at rs10993994 causes a reduction in in vitro transcriptional activity. We also find evidence for allele-specific expression of *MSMB* in a cell line heterozygous for rs10993994. We have found several transcription factors with differential in silico predicted binding potential to the rs10993994 locus. We are currently testing each of these in turn through chromatin immunoprecipitation and siRNA-mediated knockdown of predicted transcription factors.

Conclusions: Our results support the hypothesis that rs10993994, a prostate cancer associated SNP identified from recent GWAS studies, is the functional variant responsible for the association signal. One criticism of genome wide association studies has been the lack of functional follow-up to association signals. Our preliminary findings suggest a compelling possible causal pathway, in the case of rs10993994's association with) -MSP levels and subsequent prostate cancer development. Our ongoing studies will resolutely determine the role of rs10993994 in *MSMB* regulation.

1226F

Genes with Novel SNPs and Indels in the Early-onset Female Breast Cancer Identified through Whole Exome Sequencing. *C. Lee[1], N. Leng[2], W. Kuo[3], H. Yang[4], K. Nobuta[2], Y. Lu[5], C. Chang[1], C. Lin[5], C. Chen[6], W. Yao[6], K. Chiu[1], A. Cheng[5], C. Shen[6], K. Chang[3,7], C. Haudenschild[2], C. Chen[1].* 1) Genomics Research Center, Academia Sinica, Taipei, Taiwan; 2) Genomic Services, Illumina, Inc., Hayward, CA, US; 3) Department of Surgery, National Taiwan University Hospital, Taipei, Taiwan; 4) Molecular and Genomic Epidemiology Research Center, China Medical University Hospital, Taichung, Taiwan; 5) Department of Oncology, National Taiwan University Hospital, Taipei, Taiwan; 6) Institute of BioMedical Sciences, Academia Sinica, Taipei, Taiwan; 7) Department of Surgery, Cheng Ching General Hospital, Taichung, Taiwan.

The incidence rates of early-onset breast cancer has been increasing strikingly in Taiwan in last two decades. Clinical characteristics of early-onset breast cancer are very different between patients in Taiwan and Western countries. The proportion of estrogen receptor (ER)-expressed breast cancer with good prognosis is much higher in Taiwan than in Western countries. Whole exome sequencing was used in this study to explore novel single nucleotide polymorpgisms (SNPs), and insertions and deletions (indels) involved in the development of early-onset breast cancer in Taiwan. Paried blood and tumor tissue samples were collected from 68 patients with breast cancer diagnosed at ages 40 years old or younger. They were classified into five subtypes by the expression of ER, progesterone receptor (PR), human epidermal growth factor receptor 2 (HER2) and Ki67 antigen. There were 37 luminal A [ER(+), PR(+/-), HER2(-), Ki67 low], 10 luminal B [ER(+), PR(+/-), HER2(-), Ki67 high], 12 luminal/HER2(+) [ER(+), PR(+/-), HER2(+)], 4 HER2(+) [ER(-), PR(-), HER2(+)] and 5 triple negative [ER(-), PR(-), HER2(-)] cases. Whole exome sequencing was performed by Illumina GAIIx system, with more than 8GB data in each sample. Using hg19 as a reference, SNPs and indels were identified by CASAVA 1.7 software; and genes with novel SNPs and indels were annotated by ANNOVAR software. Synonymous or non-frameshift mutations were excluded. Novel SNPs and indels were further ascertained by removing variations that were reported in 1000 Genome Project and dbSNP database. The remaining novel SNPs and indels in paired blood and tumor tissues of each patient were compared to find genes with novel somatic mutations. A total of 2881 genes with novel SNPs and indels were identified in 68 patients. One gene with novel mutation was found in 21 patients (31%), and another 10 genes with novel mutations were found in 14 (21%) to 19 (28%) patients. There were 13 genes with novel mutations observed in six or more patients affected with luminal-related subtypes only. There was one gene with novel mutations identified in all patients affected with HER2(+) subtype and another gene with novel mutations was also observed in all patients of triple(-) subtype. The findings suggest different genetic mutations are involved in the carcinogenesis of various subtypes of breast cancer. These common mutated genes in specific subtypes might provide new therapy targets.

1227F

The genomic landscape of childhood pre-B acute lymphoblastic leukemia. *J. Spinella[1], V. Saillour[1], J. Healy[1], M. Larivière[1], A. Alter[1], C. Richer[1], M. Bourgey[1], S. Busche[2], B. Ge[4], A. Montpetit[4], T. Pastinen[2,4], D. Sinnett[1,3].* 1) Sainte-Justine UHC Research Center, University of Montreal, Montreal, Qc, Canada; 2) Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada; 4) McGill University and Genome Quebec Innovation Centre, Montreal, QC, Canada.

Precursor B-cell acute lymphoblastic leukemia (pre-B ALL) is the most frequent pediatric cancer. Increased understanding of the pathobiology of B-cell ALL has led to risk-targeted treatment regimens and increased survival rates. However, the underlying causes of this pediatric cancer are still unclear. We are using next-generation sequencing technology to better understand the genomic landscape of pre-B ALL and to build a catalogue of variations involved in pediatric ALL onset and/or progression. Using a unique “quartet” design that involves matched tumor (at diagnosis) and normal (remission) samples, as well as DNA from both parents, we will be able to identify germline variations (which can modify the risk of disease and/or therapeutic responses) and somatic mutations. Here, we report the deep-sequencing of the whole exomes and the partial miRNomes of 30 childhood B-cell ALL quartets. Using the Agilent SureSelect Kit combined with multiplex paired-end sequencing (ABI SOLiD 4), we captured over 4.0 Gb of sequence on average per sample with a mean coverage of 40X. Genome-wide genotyping (Illumina's Omni 2.5 array) was also performed on all samples for quality control. For each individual, approximately 97% of the targeted bases were covered ⁄ 1X and 80% of the targeted bases passed our thresholds for variant calling (⁄ 8X coverage, MQV ⁄ 30). According to these criteria, about 30,000 SNPs were found per individual. Using this quartet design we were able to incorporate parental sequence information to reduce sequencing errors and facilitate the identification of overlapping candidate disease-causing variants. From the identified repertoire of germline variants and based on several criteria (PolyPhen annotation, known allele frequency etc.), we were able to highlight both rare (about 80 missense variants per individual) and common variants that are strong functional candidates for association testing. We also investigated the somatic mutation profiles and identified both recurrent and private leukemia-specific mutations; our goal now is to validate potential driver mutations that could play a direct role in leukemogenesis through functional assessment. Ultimately, this work will provide invaluable insights to understand the genetic mechanisms underlying pediatric ALL which could lead to the development of powerful clinical tools to improve detection, diagnosis and treatment of this childhood cancer.

1228F

A genome-wide association study to identify genetic markers associated with endometrial cancer grade. *T.A. O'Mara[1,2], D. Duffy[2], D.J. Thompson[3], S. Ahmed[4], K. Ferguson[2], C.S. Healey[4], G. Montgomery[2], M. Shah[4], J. Morrision[3], P.P. Pharoah[3,4], A.M. Dunning[4], P.M. Webb[2], D.F. Easton[3,4], A.B. Spurdle[2], ANECS.* 1) Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, QLD, Australia; 2) Division of Genetics and Population Health, Queensland Institute of Medical Research, Brisbane, QLD, Australia; 3) Department of Public Health and Primary Care, University of Cambridge, Strangeways Research Laboratory, Cambridge, UK; 4) Department of Oncology, University of Cambridge, Strangeways Research Laboratory, Cambridge, UK.

Endometrial cancer is the most malignancy of the female genital tract. Although endometrioid endometrial cancer (80% of cases) generally carries a good prognosis, some patients with this tumour subtype relapse within two years. Identification of genetic markers associated with prognosis could inform clinical decision-making for management at diagnosis, and inform development of chemotherapeutic agents targeting aggressive disease. Genome-wide association studies (GWAS) have been successful in identifying common genetic variation involved in cancer susceptibility. Presently there are limited published studies using GWAS data to identify single nucleotide polymorphisms (SNPs) associated with tumour prognostic indicators, such as grade. We used case data from an endometrial cancer case-control GWAS to assess association of SNPs with endometrial cancer grade. Genome-wide genotyping of 1285 Australian and British women with endometrioid endometrial cancer and reporting Caucasian ethnicity was performed using the Illumina 610K BeadChip. After applying quality control measures, data on 583,366 SNPs for 1220 cases with grade information were used in the analysis. Regression analyses assessing SNP association with grade (1, 2 or 3), adjusting for study group (Australian or British) were performed using PLINK software. Gene-based analysis was performed using the Versatile Gene-Based Association Study (VEGAS) program. Fifty-seven SNPs were found to be significant at <10 4. Two genes were identified by VEGAS as having a p-trend<10-6. Validation is underway of two variants with evidence of association with higher endometrial cancer grade (p-trend<10-6) in 10 independent datasets from Australia, UK, Belgium, Sweden, Norway and Germany. These SNPs are located in or near genes not previously reported to be involved in cancer aetiology or prognosis and, if confirmed, would represent novel gene targets. Neither of these SNPs fall into the top 1500 SNPs prioritised for validation of association with risk. Results to date suggest that genetic alleles associated with prognostic features, such as cancer grade, may be distinct from those associated with predisposition. GWAS analysis of tumour prognostic features is thus likely to improve understanding of biological pathways influencing outcome for endometrial cancer patients.

1229F

Precise Characterization of Stromal Transcriptional Response to Developing Tumors Using RNAseq. *R.O. Bainer[1], C. Frankenberger[2], J. Menon[2], C. Chavarria[1], K. Michelini[1], P. Melsted[1], Y. Gilad[1], M.R. Rosner[2].* 1) Human Genetics, The University of Chicago, Chicago, IL; 2) Ben May Department for Cancer Research, University of Chicago, Chicago, IL.

The ability of cancer cells to survive and grow at primary and metastatic sites is influenced to a large degree by the surrounding cells in the tumor environment. In this process, tumor cells secrete signals that recruit specific cell types to their immediate vicinity and induce these cells to produce factors critical to tumor development, while the surrounding normal tissue, or stroma, detects and responds to developing lesions. While the clinical importance of this complex dialogue between the tumor and the surrounding tissue has long been appreciated, its molecular basis is not well understood. In particular, studies attempting to characterize interactions between tumors and the surrounding tissue have been confounded, largely due to technical reasons relating to the difficulty of precisely identifying and separating the developing tumor cells from normal cells nearby. Recent developments in massively parallel sequencing technology offer an opportunity to overcome this difficulty and precisely identify factors associated with the stromal response to developing tumors on a genomic scale. By sequencing RNA from a mouse xenograft model whereby human tumor cells are introduced into a murine stromal background, we were able to identify changes in gene expression levels at the tumor-stromal interface. Using this strategy we were able to unambiguously assign reads to either the tumor or stromal transcriptomes, with an estimated misassignment rate approaching 0.01%. These methods have allowed us to directly compare transcript levels in stroma containing developing tumors to those levels observed in naive stroma, and subsequently identify a set of candidate factors likely involved in the stromal response to developing lesions. We then extended this method to contrast stromal responses to near-isogenic tumors with differing metastatic potential and invasive phenotype, thereby identifying candidate factors likely to be specifically relevant to metastatic colonization. In this experiment we utilize RNA sequencing technology in an innovative way to increase our understanding of the interplay between tumors and their local environment.

1230F

Somatic Mutation of *GNA11* in an Optic Nerve Sheath Dural Melanoma. *S.C. Benes[1,2], M.H. Abdel-Rahman[2], E. Dosunmu[3], E. Craig[2].* 1) Eye Center of Columbus, 262 Neil Ave. Suite 210, Columbus, OH 43215; 2) The Ohio State University, Department of Ophthalmology, 915 Olentangy River Rd. Columbus, OH 43212; 3) Mayo Clinic, Department of Ophthalmology, Rochester, MN.

In this study we investigated the molecular genetics of a case of optic nerve dural melanoma. We also report the biological behavior of two additional cases of optic nerve dural melanoma. Molecular genetic alterations in chromosomes 3, 6p, 8q were studied by genotyping. Somatic mutations in codons 183 and 209 of *GNAQ* and *GNA11* genes were investigated by restriction fragment length polymorphism. We identified a heterozygous somatic mutation in codon 209 of *GNA11*. No alterations of *GNAQ*, chromosome 3, 6p or 8q were identified in the patient whose tissue was studied with molecular genetics. Somatic mutations in *GNA11* are unique for uveal melanoma and have not been identified in other types of melanomas. This is the first report of this mutation in optic nerve sheath dural melanoma. It suggests that dural melanomas may have a similar cellular origin to uveal melanomas. The biologic behavior of two additional optic nerve dural melanomas with metastasis to the liver and death at 22 and 36 months supports the commonality between primary uveal and primary dural melanomas suggested by the newly described *GNA11* somatic mutation.

1231F

The clinical and genetic phenotypes of PMS2 HNPCC/Lynch syndrome families in Ireland. *A. Magee[1], V. McConnell[1], M. Loughrey[2], G. McCluggage[2], D. Allen[3], A. Green[4], C.M.J. Tops[5], R. Charlton[6].* 1) NI Regional Genetics Service, Belfast City Hospital Trust, Belfast BT9 7AB Northern Ireland, UK; 2) Institute of Pathology, Royal Victoria Hospital, Belfast Trust, BT12 6BA, Northern Ireland, UK; 3) Department of Pathology, Belfast City Hospital Trust, Belfast BT9 7AB Northern Ireland, UK; 4) National Centre for Medical Genetics, Our Lady's Children's Hospital, Crumlin, Dublin 12, Ireland; 5) Department of Clinical Genetics, LDGA, Leiden University Medical Centre, Leiden, Netherlands; 6) Yorkshire Regional DNA Laboratory, St James's University Hospital, Leeds LS9 7TS, UK.

Of the four mismatch repair (MMR) genes linked to HNPCC/Lynch syndrome, PMS2 has the lowest frequency, being reported in <5% of families. MMR immunohistochemistry (MMRIHC) helps identify cases where molecular testing is likely to identify a germline mutation. Eight probands with isolated loss of staining for PMS2 were identified. Six have confirmed germline PMS2 abnormalities; in one case no abnormality was identified. Molecular testing is underway in the eighth case. Five families were ascertained through a proband with colorectal cancer, the age at diagnosis ranging from 34 to 70. Two probands had endometrial cancer at ages 49 and 55. One had synchronous endometrial and ovarian cancers at age 38. Two families meet the Amsterdam criteria and five others fulfil the revised Bethesda criteria. The remaining pedigree has an isolated case of endometrial cancer at age 49 with no other HNPCC-associated cancers. Four probands have the same exon 2 mutation, c.137G>T(p.S46I), suggesting a possible founder mutation. One has an exon 9-10 deletion. The proband with synchronous endometrial and ovarian tumours has an exon 9 mutation, c.956C>T (p.P319L) plus a variant in exon 11, c.1211C>G (p.P404R). The tumour spectrum reported in these families includes:- melanoma; transitional carcinoma of the kidney and bladder; Merkel cell carcinoma; Hodgkins lymphoma; haemophagocytic lymphohistiocytosis (HLH); gastric, breast, bile duct and pancreatic carcinoma. Where possible, MMRIHC has been used to clarify which tumours were linked to PMS2. The Merkel cell tumour had originally been reported by the family as male breast cancer; MMRIHC showed normal staining. Carrier testing has excluded the case of HLH. Our data expands the genotype/phenotype correlation for PMS2 mutations.

1232F

Copy number and low frequency somatic mutation detection using multiplexed digital PCR. *D.R. Link[1], Q. Zhong[1], S. Bhattacharya[1], S. Kotsopoulos[1], J. Olson[1], V. Taly[2], A.D. Griffiths[2], J.W. Larson[1].* 1) RainDance Technologies, Lexington, MA; 2) Institut de Science et d'Ingenierie Supramoleculaires (ISIS), Strasbourg, France.

The ability to multiplex quantitative polymerase chain reactions (qPCR) is important for many clinically relevant research assays. However, current qPCR multiplexing capacity is typically limited to 4-fold by the spectral overlap of the fluorophores and the assay development process often requires lengthy testing to build standard calibration curves. Single molecule digital PCR (dPCR) in small, 5 picoliter volumes offers an attractive alternative to qPCR that is both more flexible and more precise. Based on a novel multiplexing approach for dPCR in picoliter droplets, we take advantage of the very high numbers of reactions possible within droplets (more than 10 million from 50 microliters of starting template), as well as the high probability that amplification of a single target DNA molecule will initiate within each droplet. By varying the concentration of different fluorogenic probes of the same color and having a narrow size distribution of droplets, it is possible to identify different probes on the basis of fluorescence intensity. Here we will report highly sensitive and absolute quantitative capabilities of this approach to analyzing copy number variation using multiplexed assays as high as ten-plex or more and demonstrate accurate detection of rare DNA mutations in a background of wild type DNA.

1233F

Next-gen sequencing of single human cells for detection of copy number variations and mutations. *J. Langmore[1], E. Kamberov[1], T. Tesmer[1], L. Patel[2], K. Pienta[2].* 1) Rubicon Genomics, Inc, Ann Arbor, MI 48108; 2) Comprehensive Cancer Center, University of Michigan Medical School, Ann Arbor, MI 48109.

Next-Generation sequencing of single cells must be accurate, reproducible, rapid, and inexpensive for use in research and diagnostics. This is difficult because most methods of single-cell amplification produce stochastic and systematic bias in sequence representation and large amounts of extraneous DNA--making single-cell analysis problematic. Under specific conditions stochastic variation and background can be eliminated, leaving only reproducible bias. Using a modified PicoPlex NGS prep kit (Rubicon Genomics), individual flow-sorted cloned cancer and normal cells were amplified and prepared for NGS using indexed adaptors. Each cell was prepared in a four-step, single-tube process with no intermediate purifications followed by pooling cells before size separation. The elapsed time between cell collection and the start of cluster formation was <4 hours. Accuracy and reproducibility of the copy-number and mutation results were validated comparing replicate single cell samples to unamplified DNA using both NGS and PCR. Multiplexing was validated by pooling 4, 8, and 16 cells in single lanes.

The quality of single-cell sequencing on the Illumina GAIIx and HiSeq were evaluated. The GAII gave about 30M reads per lane of which 98-99% were high-quality in read 1 and 91-97% in read 2, with 80-98% mapping to the human genome. Only 0.5% of P-E reads mapped inconsistently due to inversion and 1.5% due to distance. There was very little evidence of chimeric, bacterial, or other spurious sequences. The HiSeq can be used to accurately call amplification or loss of 10kb regions of single cells, whereas variations of about 100kb were determined from 8 indexed single cells.

For patient cancer samples this strategy enables initial screening of many cells to indentify and characterize cell lineage. Individual specific cells can be characterized at higher resolution using additional NGS, microarray and PCR analysis. Multiplexed NGS of single-cells has relevance to characterization of tumor cells (e.g., circulating tumor cells and disseminated tumor cells for cancer research, blastomeres for pre-implantation genetic screening and diagnostics, and stem cell populations to test for heterogeneity).

1234F

Context-dependent estimates of substitution rates in human, chimpanzee and gorilla indicate acceleration in the human lineage. *N. Rustagi[1], I. Gorlov[2], SE. Plon[3,4], M. Kimmel[1], W. Amos[5].* 1) Statistics, Rice University , Houston , TX; 2) The University of Texas MD Anderson Cancer Center, Houston, Texas; 3) Genome Sequencing Center,Houston,Texas; 4) Texas Children's Cancer Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas; 5) Department of Zoology, University of Cambridge, Cambridge, UK.

Although it is often assumed that mutations accumulate randomly and in a strictly clock-like fashion increasing numbers of exceptions are coming to light. In terms of rate, a notable example is the hominid slowdown, which is widely reported but has yet to be quantified in the detail afforded by complete genome datasets. In terms of randomness, in addition to the well-known examples of transitions being commoner than transversions and the high mutability of CpG motifs, the DNA of many species deviates strongly from random in the frequencies of the 16 possible dinucleotide pairs. By implication, sequence context impacts on which mutations occur and how likely they are. To explore these issues in detail, we use a form of relative rate test using the exon and intron sequences of Human (H), Chimpanzee (C) and Gorilla (G), with Orangutan (O) as the out-group. Context was analyzed by considering each base in terms of its immediately flanking bases, giving 64 possible combinations (4 bases x 16 flanking dinucleotides). Relative mutation rates were determined using three way alignments of HCO, HGO, and CGO, generated using the Galaxy (http://galaxy.psu.edu/) program, using only alignments >100 bases in length. To reduce the influence of repeated sequences and poorer alignments, each candidate triplet is considered for analysis with probability 0.5 and only triplets where the flanking bases are identical in all three species are used to estimate context-sensitive substitution rates. A regression-based technique was developed to reconcile the substitution frequencies from the pairwise comparisons. Further, the estimated substitution rates were corrected to yield an ultrametric (balanced) species tree. We conclude that (1) the overall substitution rate in Humans significantly exceeds those in both Chimpanzee and Gorilla and (2) all mutation rates are strongly context-dependent, the extent varying between bases and between the three species. For example, the mutation rate of `A' in `CAT' is approximately fourfold greater than of `A' in `GAA'. We discuss the impact these findings have on our understanding of great ape evolution, including the evolution of disease-causing missense mutations. Supported by CPRIT grant RP101089 to NR, SEP and MK.

Differential expression profile of microRNA in medulloblastoma. *D.R. Lucon[1], C.S. Rocha[1], C.M. Morelli[1], D.P. Cavalcanti[1], S.S. Aguiar[2], S.R. Brandalise[2], J.A. Yunes[2].* 1) Departamento de Genética Médica - FCM, UNICAMP, Campinas, Brazil; 2) Centro Infantil Boldrini, Campinas, Brazil.

Background: Medulloblastoma is one of the most common pediatric cancers, likely originating from abnormal development of cerebellar progenitor neurons. The molecular mechanism contributing with medulloblastoma is poorly understood. MicroRNA has been shown to play an important role in development of the central nervous system. We report a series of microRNAs differentially expressed in medulloblastoma in comparison to normal fetal cerebellum and depict putative target genes. Methods: Five surgical specimens were obtained from patients with medulloblastoma and three normal cerebellum tissues were obtained from fetal autopsy. Total RNA was extracted by Trizol according to manufacturer's instructions, with an additional overnight precipitation step at -20°C with isopropanol. Five hundred micrograms of RNA were labeled with the 3DNA FlashTag Biotin HSR (Genisphere) and hybridized to GeneChip miRNA Arrays (Affymetrix). Data was acquired using a GeneChip Scanner 3000 7G (Affymetrix). The data processing was done in R environment (www.r-project.org) and the packages Affy and RankProd from Bioconductor were used for microRNA expression profile analysis. MicroRNAs were considered differentially expressed when the statistical significance was $p \leq 0.01$. The prediction of potential targets of selected microRNAs was done using the miRGen Targets and miR-Ontology Database softwares. Results: A total of 102 microRNAs were differentially expressed in medulloblastoma. Of these, 60 were upregulated and 42 downregulated. The miR-138, miR-184, miR-219-2-3p and miR-206 were among upregulated microRNAs while miR-199a-3p, miR-199b-3p, and miR-21 among downregulated ones. Target genes of these microRNAs include PTEN (miRs-138 and 21), OTX2 (miRs-138, 184 and 206), PAFAH1B1 (miRs-21, 138, 206 and 219-2-3p) and NOVA1 (miRs-199a-3p, 199b-3p, 21, 138 and 184) which are known to be involved in transcription regulation, cell differentiation, neuronal migration and nervous system development. Conclusion: This is the first time that miR-184, miR-219-2-3p, miR-199a-3p and miR-199b-3p were described in medulloblastoma. Interestingly, miR-21 was previously reported as upregulated in medulloblastoma in comparison to adult cerebellum, while we found it downregulated in comparison to fetal cerebellum. The result of our study hopes to shed some light into the molecular mechanisms of medulloblastoma.

1236F

Role of common genetic variants in pre-micro RNA in susceptibility and prognosis of Esophageal Cancer. *M. Umar[1], R. Upadhyay[1], S. Kumar[2], U.C. Ghoshal[3], B. Mittal[1].* 1) Department of Genetics, Sanjay Gandhi Post Grad Inst of Med Sc(SGPGIMS), Lucknow, India; 2) Department of Radiotherapy, Sanjay Gandhi Post Grad Inst of Med Sc(SGPGIMS), Lucknow, India; 3) Department of Gastroenterology, Sanjay Gandhi Post Grad Inst of Med Sc(SGPGIMS), Lucknow, India.

Introduction: MicroRNAs (miRNAs) are 21-23 nucleotide non-coding RNAs that regulate expression of about one third human genes at the posttranscriptional level through mRNA degradation or translation repression. miRNAs can act as oncogenes or tumor suppressor genes and known to be deregulated in several cancers. Differential expression of several miRNAs in Esophageal cancer (EC) and association of unique miRNA signatures with EC and its clinical phenotypes suggest critical role of miRNAs in cancer. Genetic variants in miRNAs have been also shown to affect progression, diagnosis, and therapeutics response of various malignancies; however their role in EC is controversial. Therefore, we aimed to evaluate role of common genetic variants in cancer related pre-miRNAs (affecting maturation/expression of respective miRNA) in susceptibility/survival outcome of EC patients in northern Indian population. Methods: In hospital based case control study, we genotyped four common polymorphisms in pre-miRNA: mir-196a-2 C>T (rs11614913), mir-146a G>C (rs2910164), mir-499 T>C (rs3746444) and mir-423 C>A (rs6505162) in 309 incident EC cases (including 153 followed-up cases) and 309 controls using PCR/PCR RFLP based methods. Results: Although, none of pre-miRNA genetic variants were associated with EC or its clinical phenotypes (histopathology, tumor location or lymph node metastasis) independently, combined effect of risk genotypes of four pre-miRNA polymorphisms associated with increased risk of EC in dose response manner: OR = 1.0, 1.5, 1.6 for 0-1, 2-3, 4 risk genotype (Ptrend = 0.008). Specifically, patients with⁄ 2 risk genotypes of pre-miRNA polymorphisms had 1.5 fold higher risk of EC compared to patients with 0-1 unfavorable genotype (OR = 1.56, 95% CI = 1.13-2.14, P = 0.007). Kaplan Meier and Cox Regression analysis showed no effect of pre-miRNA genetic variants on survival outcome of EC patients. Furthermore, no significant interaction of pre-miRNA polymorphisms with environmental risk factors was noticed. Conclusion: Combined risk genotypes of four common polymorphisms in pre-miRNAs seem to be associated with increased risk of EC, however no prognostic implication of these pre-miRNA genetic variants in EC was observed. Acknowledgment: Financial support from Council of Scientific and Industrial Research (CSIR), Department of Biotechnology (DBT), Department of Science and Technology (DST) and Indian Council of Medical Research (ICMR), Government of India.

1237F

The role of somatic mtDNA mutations in cancer. *E. Chen-Quin[1], M. Fowler[1], Y. Xie[2].* 1) Biology and Physics, Kennesaw State University, Kennesaw, GA; 2) Computer Sciences and Information Systems, Kennesaw State University, Kennesaw, GA.

Mutations in nuclear encoded mitochondrial genes Succinate Dehydrogenase (SDH-B, C, and D) and Fumarate Hydratase (FH) cause hereditary cancers of the head and neck and implicate a role for mitochondrial dysfunction in tumor formation. Likewise, somatic mutations from the mitochondrial chromosome (mtDNA) are found in 65% of tumors; but whether they play a carcinogenic role or are only a side effect remains unclear. Relative to the nuclear genome, the 10x faster mutation rate of mtDNA renders association of specific mutations at too low of power to link any one lesion with cancer. Current technology also does not allow transfection of individual mtDNA mutations for in vivo or in vitro testing of its role in cancer. It remains upon new computational methods to clarify the tumorigenic role of mtDNA mutations. BCI simulation shows CytB to have somatic cancer missense changes in positions of unusually high conservation (Stafford and Chen-Quin 2010), suggesting that tumors select for mutations in highly functional residues. It also shows CO1 to only mutate in positions of low conservation, suggesting tumor growth requires CO1 function. Using our BCI simulation method, new results from a meta-analysis of 350+ published mtDNA tumor sequences shows cancer mutations in ND6 to occur preferentially in amino acid positions of high conservation. These positions also coincide with observed cancer mutations from other species. We also present identification of COMS (combinations of two or more mutations found in two or more independent tumors; Zhidkov 2009) from a large dataset. Zhidkov 2009 identified recurring cancer mtDNA mutation combinations (COMS) in a limited data set, noting that somatic cancer mutations significantly coincide with ancient haplogroup-defining polymorphisms rather than with younger population polymorphisms. The overlap between somatic cancer mutations and ancient polymorphisms was posited as due to similar selective forces at the tumor and population level. To determine whether similar mutation COMS occur in tumor data from other laboratories, we analyze a mutation data set three times the size of the original analysis (411 tumors, 27 articles). From the additional data, we report COMS related, but not identical to, those in Zhidkov 2009. These other COMS also frequently identify somatic cancer mutations that coincide with ancient population polymorphisms.

1238F

MUTYH mutation spectrum in Brazil: first report of a large deletion in a MAP patient. *G.T. Torrezan[1], F.C.C. Silva[1], A.C. Krepischi[2], E.M.M. Santos[2], B.M. Rossi[2], D.M. Carraro[1].* 1) Genomic and Molecular Biology Laboratory, CIPE, A. C. Camargo Hospital, São Paulo, Brazil; 2) CIPE, A. C. Camargo Hospital, São Paulo, Brazil.

MUTYH-associated Polipose (MAP) is a hereditary colorectal cancer predisposing syndrome caused by biallelic mutations in MUTYH gene with a clinical phenotype that can occasionally resembles Familial Adenomatous Polyposis or Lynch syndrome (LS). We sequenced the entire coding region of MUTYH gene in 7 unrelated probands affected by polyposis and negative for mutations in APC gene. In addition, 51 LS patients non-carriers of germline mutations in the mismatch repair genes MLH1, MSH2, MSH6 and PMS2, were screened for the hotspot MUTYH mutations p.Tyr179Cys and p.Gly396Asp and for the presence of a 4.2 Kb MUTYH deletion identified in this study. Direct DNA sequencing of all exons and long range PCR were performed in polyposis patients, whereas regular PCR and allele specific PCR (AS-PCR) followed by RFLP were performed in LS patients. The biallelic nature of the mutations was confirmed by AS-PCR. From 7 polyposis patients, one was negative for mutations, one presented the p.Gly396Asp variant in a monoallelic state and 5 exhibited biallelic mutations as follows: 3 with the p.Tyr179Cys allele and a pathogenic mutation in the other allele (one deletion, one duplication and one splice site mutation); one homozygote for the p.Arg241Trp mutation and one homozygote for a >4.2 Kb deletion encompassing exons 4-16. For the later, deletion breakpoints were refined to base pair level through aCGH analysis followed by sequencing. The identified breakpoints were located within intron 3 and 146 bp after the 3' end of the gene (c.348+33_*64+146del4285), with the presence on an AluJr element adjacent to the distal breakpoint. For the LS patients, none of them presented this large deletion or the p.Tyr179Cys variant, while one carried the p.Gly396Asp mutation. This patient exhibit in the other allele a polymorphic AluY insertion in intron 15, which has been described to increase the levels of 8-oxyG:A in DNA and is associated with type 2 diabetes mellitus. However, since this insertion has not been studied in the context of colorectal cancer, segregation studies would be important to verify its role in the etiology of this disease. In silico analysis of the MUTYH locus revealed a high Alu density that may predispose this region to other Alu-mediated rearrangements and deletions. In conclusion, we have identified the first large deletion in MUTYH gene and shown that investigation of this sort of mutation may be important to identify causative mutations in MAP patients.

Analytical Resolution of p53 Alteration in the Clinical Context. *Y.G. Yue, S. Kadam, J.T. Brandt, I. Wulur, T.R. Holzer, A.D. Fulford, J. Ting, T.D. Barber, C. Reinhard.* Translational Science - Hum Gent, Eli Lilly and Company, Indianapolis, IN.

Accurate measurement of genetic variation in the p53 gene (TP53) is critical in predicting patient outcome and developing tailored therapeutics. A commonly-used measurement of p53 function relies on detection of nuclear accumulation of the p53 protein by means of immunohistochemistry (IHC). Most missense mutations are known to cause nuclear p53 protein accumulation and IHC results have been associated with clinical outcome in several cancer types. However, the concordance between IHC and mutation assays varies considerably among different studies, even within the same cancer type. The disconnect between DNA alteration and nuclear protein accumulation leaves an uncertainty in the true frequency of p53 alterations in cancer, and limits the utility of p53 status in clinical studies. In this study, we sought to provide resolution of p53 functionality measurement by comparing IHC with DNA-level alterations in 48 NSCLC clinical samples. Based on IHC data from FFPE samples, 29/48 (60.4%) were found positive in p53 alteration. TP53 sequencing, using the corresponding FF samples, identified a higher rate of mutation, 32/48 (66.7%). Compared with published data, we observed an unusually high level (10/48 or 20.8%) of truncating mutations (nonsense, frame-shift, and splice site mutations) that accounted for 31.34% of all mutations found in this study. As expected, 20/22 (90.9%) of tumors carrying missense mutations were IHC-positive, confirming the link between structural mutation and p53 nuclear accumulation. In contrast, 9/10 (90%) of truncating mutations were found in IHC-negative tumors. While this is consistent with the literature, the high frequency of truncating mutations explained the relatively low concordance rate between IHC and mutation, and highlights an inherent shortcoming of IHC. Including 8 IHC-positive tumors with no detectable p53 mutation, the frequency of p53 alteration in NSCLC reached 40/48 (83.3%), much higher than any reports to date. In summary, our findings suggest that overall p53 mutation frequency might be underreported and that altered p53 functionality could be more prevalent in lung cancer.

1240F

Dermatofibrosarcoma protuberans in neurofibromatosis type 1 (NF1). *D. Viskochil[1], L. Randall[2].* 1) Dept Pediatrics, Div Med Gen, Univ Utah, Salt Lake City, UT; 2) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Neurofibromatosis type 1 (NF1) is associated with malignant peripheral nerve sheath tumors (MPNST); however, it is also associated with multiple other types of sarcomas. We present an individual with NF1 who had dermatofibrosarcoma protuberans. The patient was followed for a clinical diagnosis of NF1, and was noted to have left sphenoid wing dysplasia. A fullness over his left temple was noted at 4 years of age, and it enlarged over a few months as a firm mass with only mild tenderness to deep palpation. Given an increase in size with mild tenderness, it was resected under the premise that it was a plexiform neurofibroma. Pathology demonstrated a dermatofibrosarcoma protuberans mixed with giant cell fibroblastoma. The mass was well-cicumscribed but pathology review determined the margins were microscopically positive. He underwent wide surgical excision and has been followed conservatively since age 6 years, without recurrence. Dermatofibrosarcoma protuberans is a rare pediatric malignancy that if detected in early stages and treated with wide surgical excision has a good prognosis. There has not been a published report of this tumor in an individual with NF1. This case also had elements of mixed giant cell fibroblastoma, which has been reported in two other non-NF1 patients and the tumors both had a t(17;22)(q22;q13). These tumors overexpress platelet-derived growth factor receptors A and B (PDGFRA and PDGFRB), and may be ammenable to imatinib treatment rather than radiation therapy in the event of recurrence.

Improved sequencing workflow for characterizing melanoma mutations. *S.-C. Hung[1], S. Berosik[1], S. Schneider[1], P. Ma[1], S. Vemula[2], R. Terrill[2], S. Mirza[2], M. Wenz[1].* 1) Life Technologies, 850 Lincoln Centre Dr., Foster City, CA 94404; 2) University of California, San Francisco, Dept of Dermatopathology, 2340 Sutter Street N-461, San Francisco, CA 94143.

Melanoma is an aggressive skin cancer with increasing incidence worldwide; it is a malignant tumor arising from pigment producing melanocytes in the skin, eye, or mucosal surfaces. Based on histopathological and molecular studies, melanoma can be sub-classified into various categories. Melanoma arising from non-chronically sun damaged (non-CSD) skin shows frequent mutations in the *BRAF* gene and no mutations in the *KIT* gene. In contrast, 20% of melanoma on CSD skin have mutations in the *KIT* gene and infrequently harbor mutations in the *BRAF* gene; whereas in two other categories, acral and mucosal melanomas, 10 to 40% of cancers have been shown to have *KIT* mutations or amplifications of this genomic region. To enable the molecular classification of melanoma in research samples, we have employed an improved capillary electrophoresis Sanger sequencing workflow. The sequencing-based mutation detection workflow described here improved the resolution of sequencing data at the 5' end of all amplicons investigated in the *BRAF*, *NRAS* and *KIT* genes. The modified chemistry used in the workflow enhanced the resolution at tandem mixed base positions in the *BRAF* gene. A combined PCR reaction purification and cycle sequencing step enabled a rapid turn-around time and improved the rate of detection for accurate data and information regarding the metastatic melanoma DNA research samples. Further, the workflow described here occurs in the same sample well from PCR amplification to cycle sequencing reaction purification thereby eliminating the transfer of research samples required in standard sequencing workflows and the possibility of transfer errors. As a result of workflow enhancements, the amount of hands-on time was reduced as were consumable costs, and the number of pipetting steps. Taken together, the sequencing-based mutation detection workflow described here simplifies, increases throughput by 40%, and improves accuracy for the identification of melanoma genetic variants.

1242F

Molecular analysis of possible polymorphism risk factors of CDKN1A gene in sporadic colorectal cancer. *n. zali, m. montazer haghigh, r. fatemi, m. vahedi, m. zali.* Shaheed Beheshti University, Research Center for Gastroenterology and Liver Dis, tehran, IS., tehran, Iran.

Background: Colorectal cancer is the third most commonly diagnosed cancer in both men and women. Progressive loss of cell cycle control is an important feature on the colorectal cancer. p21 (CDKN1A/CIP1/WAF1), one of the cyclin-dependent kinase inhibitors, plays a key role in regulating the cell cycle. The aim of this study was to investigate associations of the CDKN1A gene polymorphism (rs1801270) with risk of colorectal cancer (CRC) in an Iranian population. Methods: The study subjects were 57 cases of colorectal cancer and 65 controls. Genomic DNA was extracted using standard salting out method. Genotypes were determined using the polymerase chain reaction and restriction fragment length polymorphism (PCR-RFLP) method. Results: Statistical analysis of results indicated that the genotype frequencies of polymorphisms CDKN1A gene in patients and healthy controls are AA (3.1%), AC (9.4%) and CC (87.5%) for control subjects and AA (5.3%), AC (10.5%) and CC (84.2%) for CRC cases respectively. We found no significant difference between studied polymorphism, between healthy control individuals and colorectal cancer patients (P= 0.817). After stratification of genotyping result we found no statistically significant difference between case and control groups (P=863). Conclusion: to our knowledge this is the first study on association of rs1801270 polymorphism with CRC risk in Iranian population. Our findings indicated that there is no association between selected single nucleotide polymorphism in p21 gene and risk of colorectal cancer.

Prostate Cancer Proteomics: Using antibody-based high-throughput plasma profiling for the discovery of new prostate cancer biomarkers. *R. Karlsson[1], U. Igel[2], H. Grönberg[1], W. Isaacs[3], M. Uhlén[2], J. Schwenk[2], F. Wiklund[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska institutet, Stockholm, Sweden; 2) Science for Life Laboratory, Department of Proteomics, School of Biotechnology, KTH Royal Institute of Technology, Stockholm, Sweden; 3) Department of Urology, Johns Hopkins Medical Institutions, Baltimore, Maryland, USA.

Introduction: Prostate cancer (PC) is the most common male cancer in Europe and North America. Twin and family studies support a strong genetic component of the disease, and genome-wide association studies (GWAS) have so far produced more than 30 robust disease-marker associations. A major problem in the diagnosis and treatment of PC is the difficulty in separating cancers of an aggressive subtype, for which immediate and powerful treatment is necessary, from indolent forms, for which the treatment itself may do more harm than good. The main PC biomarker in clinical use today is serum level of prostate-specific antigen (PSA), a protein produced in prostate tissue. PC severity correlates with serum PSA, but the low sensitivity and specificity of the marker lead to many false positive and false negative results. In an attempt to find new biomarkers useful for PC diagnosis and prognosis, we have screened plasma levels of a selection of 80 proteins for associations with aggressive PC in a case-control sample. The proteins were selected based on either differential mRNA expression in tumor tissue (Isaacs, unpublished data), or GWAS associated markers in or near their genes. **Material and methods:** Plasma samples from 368 men (135 controls, 160 localized PC, 73 aggressive PC) were selected from a repository established as part of the large-scale, population-based case-control study Cancer of the Prostate in Sweden (CAPS). Plasma was derived from blood samples taken before any cancer treatment. Protein levels were measured in a multiplex antibody-based suspension bead array. Antibodies were first coupled to color-coded microspheres, which were then added to diluted plasma samples. The antibodies were allowed to hybridize with their specific antigens, and bead-specific biotin fluorescence was then measured in a flow cytometry instrument (Luminex) for all 80 proteins in a single reaction. **Results:** In a preliminary analysis of plasma protein levels and aggressive PC no single protein was significantly associated after correcting for multiple testing. Several of the strongest protein-PC associations were however considered interesting and will be analyzed further. A more thorough analysis of the data will focus on building multivariate models to increase discriminatory power. Correlations with clinical covariates such as Gleason score and TNM stage will also be presented in addition to the analysis of binary disease status already performed.

Novel target genes of ETV6 in childhood pre-B acute lymphoblastic leukemia. *B. Neveu[1,2], M. Malouf[1,2], S. Langlois[1], D. Sinnett[1,3].* 1) Division of Hemato-Oncology, Research Center Sainte-Justine University Health Center, Montreal, Canada; 2) Department of Biochemistry, Faculty of Medecine, University of Montreal, Montreal, Canada; 3) Department of Pediatrics, Faculty of Medecine, University of Montreal, Montreal, Canada.

Acute lymphoblastic leukemia (ALL) is the most frequent pediatric cancer. A vast array of genetic aberrations have been described in this disease, of which the most frequent is the t(12;21), observed in 25% of pre-B ALL cases. This translocation involves the ETV6 and AML1 genes on chromosomes 12p13 and 21q22, respectively. The resulting ETV6-AML1 fusion chimera cannot induce leukemia alone, suggesting that additional mutations are required for transformation to occur. The expression of the non-rearranged allele of ETV6 is deleted in 75% of t(12;21) positive ALL patients, which indicates that the complete inactivation of ETV6 is a key event in childhood leukemogenesis. Because ETV6 is a transcriptional repressor (member of the ETS family) it is of great interest to identify ETV6 transcriptional targets to understand how overexpression of these targets (due to ETV6 depletion) could impact ALL onset and progression. Few ETV6 targets are currently known. Using genome-wide expression data, we identified 17 genes whose expression is upregulated in the absence of ETV6. Ten of them were validated by qRT-PCR experiments in childhood ALL patients. To determine whether these genes are direct targets of ETV6, we subcloned the corresponding promoter regions in a gene reporter system and transfected three human cell lines, including Jurkat lymphocyte cells. Using this system, the activity of the ELK3, TERF2, CBFA2T3, RAG1, TCFL5, DPYSL2, FAM134B, RASA4 and SERINC5 promoters was downregulated following overexpression of ETV6 (co-transfection experiments). Chromatin immunoprecipitation (ChIP) assays confirmed the presence of ETV6 on these gene promoters. We then highlighted the importance of the Pointed and ETS domains on ETV6-mediated transcriptional repression by using truncated versions of the ETV6 protein. Interestingly, for certain promoters, the presence of a functional ETS domain was not required for repression, suggesting that ETV6 may regulate transcription without direct DNA binding. We conclude that ETV6 can regulate transcriptional repression through different mechanisms, either by direct DNA binding or possibly through its recruitment via other ETS-transcription factors.

Detection and prioritisation of prostate cancer risk-associated genetic variants in the *KLK4* gene for functional analysis. *F. Lose[1], J. Batra[2], S. Srinivasan[2], S. Chambers[3,4], R.A. Gardiner[5], J. Aitken[4,6], J.A. Clements[2], A.B. Spurdle[1], Australian Prostate Cancer BioResource.* 1) Molecular Cancer Epidemiology, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 2) Australian Prostate Cancer Research Centre-Queensland, Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Queensland, Australia; 3) School of Psychology, Griffith University, Brisbane, Queensland, Australia; 4) Viertel Centre for Cancer Research, Cancer Council Queensland, Brisbane, Queensland, Australia; 5) University of Queensland Centre for Clinical Research, Royal Brisbane Hospital, Brisbane, Queensland, Australia; 6) Griffith Health Institute, Griffith University, Brisbane, Queensland, Australia.

Approximately 40% of prostate cancer is estimated to have a genetic component, and to date over 30 single nucleotide polymorphisms (SNPs) have been identified by genome-wide association studies (GWAS) that influence prostate cancer risk. Interestingly, one of the SNPs detected by a prostate cancer GWAS is located downstream of the *KLK3* gene. Thus, our premise is that genetic markers associated with the *KLK3*/*PSA* gene and other *KLK* family members will prove useful predictive markers for prostate cancer and its progression, rather than, or in addition to, serum tests. Investigation of public SNP databases reveal hundreds of validated genetic variants in the *KLK* genes, the majority of which were not covered by the commonly used GWAS chips. We aimed to comprehensively investigate all validated SNPs in the *KLK* genes for an association with prostate cancer susceptibility and prognostic features, and then to investigate the functional significance of associated SNPs. This study focuses on *KLK4*, which has been shown to be upregulated in prostate cancer and bone metastasis, and several SNPs upstream of *KLK4* were marginally statistically significantly associated with prostate cancer risk in the Cancer Genetic Markers of Susceptibility (CGEMS) project. A total of 70 SNPs in the *KLK4* gene (±10kb) were successfully genotyped in our Queensland, Australia prostate cancer-control sample set of approximately 1,300 prostate cancer cases and 1,300 male controls. Logistic regression analyses showed 7 *KLK4* SNPs to be associated with a decreased risk of prostate cancer ($P<0.05$), none of which are represented on commonly used GWAS chips, either directly or by a surrogate SNP ($r^2 > 0.8$). Four of these SNPs are located in the 3' flanking region of the *KLK4* gene (+0.75-3.5kb) and are in high LD with each other ($r^2 > 0.96$). Bioinformatic analyses predicted 3 of these SNPs to alter transcription factor binding sites relevant to prostate cancer. The remaining three *KLK4* SNPs found to be associated with risk of prostate cancer in our study were independent of each other, with two located upstream of *KLK4* (6.5kb and 8.5kb) and one missense variant 3 nucleotides into exon 2, which alters Serine 22 to an Alanine residue. Although the missense variant is not predicted to have any effect on protein structure or function *in silico*, it may still have important effects on KLK4 stability or splicing. Our results indicate that *KLK4* may be another KLK contributing to prostate cancer susceptibility.

1246F

Integrated molecular profiling of adult and pediatric pilocytic astrocytoma through single nucleotide polymorphism array and gene expression analysis. *M. Shirinian[1,*], A.M. Fontebasso[2,*], D.A. Khuong Quang[2], D.T.W. Jones[3], K. Jacob[1], N. Gerges[1], A. Klekner[4], A. Montpetit[5], A. Nantel[6], S. Albrecht[7], S. Pfister[3], N. Jabado[1,2,8].* 1) Human Genetics, McGill University, Montreal, Canada; 2) Experimental Medicine, McGill Universirty, Montreal, Canada; 3) Division of Molecular Genetics, German Cancer Research Center, Heidelberg, Germany; 4) Department of Neurosurgery, Medical and Health Science Center, University of Debrecen, Debrecen, Hungary,; 5) McGill University and Genome Quebec Innovation Centre,; 6) Biotechnology Research Institute, National Research Council of Canada; 7) Department of Pathology, Montreal Children's Hospital, McGill University Health Centre (MUHC); 8) Department of Hematology & Oncology, Montreal Children's Hospital, McGill University Health Centre (MUHC).

Pilocytic Astrocytoma (PA) is a Grade I Astrocytoma according to the WHO classification and is the most common brain tumor in children. Accounting for 23% of all pediatric brain tumors, PA occurs predominantly in infratentorial regions of the brain in pediatric patients and comprises about 80-85% of all tumors of the cerebellum in children. Recent studies have demonstrated key differences in the gene expression profiles of adult and pediatric glioblastoma multiforme (GBM), but molecular mechanisms important in PA tumorigenesis specific to adult and pediatric patients are largely uncharacterized. As such, we sought to profile key genetic characteristics of adult and pediatric PA tumors utilizing single nucleotide polymorphism (SNP) arrays. In addition, utilizing large-scale microarray-based gene expression profiling of adult and pediatric PA, we have characterized specific molecular mechanisms of putative importance in adult versus pediatric PA tumorigenesis. Upon integration, gene expression profiles can be correlated with genomic alterations that may better profile PA tumors on the basis of patient age, neuroanatomical location and genotype. We have demonstrated, through SNP array analysis, that whole chromosome gain occurs more frequently in adult versus pediatric PA, and that chromosomal gain occurred more frequently in infratentorial brain regions in adult PA patients than pediatric PA patients. Gene expression profiling revealed distinct groups upon unsupervised clustering; namely distinguishing the gene expression profiles of pediatric and adult PA, as well as on a neuroanatomical basis. Such differences in global gene expression may have root in the large-scale genomic changes that distinguish PA with respect to age and brain location. We believe that integrated array-based analyses may allow us to more accurately profile adult and pediatric tumors and design more personalized patient therapy in clinic.

1247F

Identification of functional polymorphisms at the 4q21 locus associated with modification of breast cancer risk in BRCA2 mutation carriers. *Y. Hamdi[1], P. Soucy[1], D. Goldgar[2], B.J Feng[2], G. Reimnitz[1], M. Tranchant[1], T. Pastinen[3], P. Cassart[4], O. Ouimet[4], D. Sinnett[4], C. Verny-Pierre[5], L. Barjhoux[5], D. Stoppa-Lyonnet[5], O. GEMO Study Collaborators[5], O. Sinilnikova[5], J. Simard[1].* 1) Canada Research Chair in Oncogenetics, Department of Molecular Medecine, Faculty of Medecine, Laval University, CHUQ Research Center/CHUL , Ste foy, Quebec, Canada; 2) Department of Dermatology, Health Care, University of Utah, U.S; 3) Department of Human Genetics, McGill University, Montreal, Canada; 4) Division of Hematology-Oncology, Research Center Sainte-Justine University Health center, University of Montreal, Montreal, Canada, H3T 1C5; 5) INSERM U1052, CNRS UMR5286, Université Lyon 1, Cancer Research Center of Lyon, and Unité Mixte de Génétique Constitutionnelle des Cancers Fréquents, Centre Hospitalier Universitaire de Lyon / Centre Léon Bérard, Lyon, France.

Individuals with pathogenic mutations in BRCA1 and BRCA2 genes are known to be at a substantially increased risk of breast cancer throughout their lives. Recent studies have provided evidence of additional genetic risk factors that may considerably modify the risk of developing the disease. Genome Wide Association Studies have shown that a considerable number of these genetic variants reside in the regulatory regions of candidate genes. Also, expression profiling and genome wide mapping studies have shown that strong heritable factors govern differences in gene expression levels within mammalian species. Here we wanted to evaluate the impact of regulatory polymorphisms of candidate genes on their expression levels and assessing their association with breast cancer risk in BRCA1 and BRCA2 mutation carriers. ABRAXAS (FAM175A), located at the 4q21 locus, is a selected candidate gene that encodes for a protein interacting directly with BRCA1 for its recruitment at double-strand DNA breaks. Its promoter region was sequenced in 60 unrelated Caucasian individuals and the functional impact of the identified variants was thereafter assessed using gene reporter assays. Two of these variants were characterized in more details: rs72672798, a rare variant, that significantly decreases the transcriptional activity of this gene and rs530648 that tags major promoter haplotypes. In parallel, we used data from a high density allelic expression analysis of quantitative measurements of allelic expression (AE) to identify SNPs at this locus that are associated with differential AE as previously described. [Pastinen T, Nat Rev Genet. 2010]. rs1494961 is one of the variants shown using this approach to be associated with differential AE. This SNP is located on the same 4q21 locus, in a neighbouring gene, Hel308, a Helicase involved in DNA repair and replication. The two common SNPs, rs1494961 and rs530648, were evaluated for an association with breast cancer risk in approximately 2380 BRCA1 and BRCA2 mutation carriers from the GEMO study (GEnetic MOdifiers of cancer risk in BRCA1/2 mutation carriers). Interestingly, the minor alleles of rs1494961 and rs530648 were significantly associated with a reduced risk of breast cancer (HR, 0.85 and 0.81; P= 0.03 and 0.02 respectively) in BRCA2 but not BRCA1 mutation carriers. We are currently validating these findings by genotyping these two SNPs, as well as other variants at that same locus, in a larger number of BRCA1/2 carriers.

1248F

Genotoxic agents alter the tridimensional nuclear organization of telomeres and the expression profile of shelterin genes. *N. Bastien[1], O. Samassekou[1], D. Lichtensztejn[2], J. Yan[1], S. Mai[2], R. Drouin[1].* 1) Genetics, pediatrics, 3001 12e Avenue, Université de Sherbrooke, Sherbrooke, PQ, j1H 5N4 Canada; 2) Manitoba Institute of Cell Biology, University of Manitoba, 675 McDermot Avenue, Winnipeg, MB, Canada R3E 0V9.

Telomeres are found at chromosome ends. When these ends are not protected by telomeric capping, the telomeres are recognized as double-strand breaks and the consequent recruitment of DNA repair machinery may affect cellular fate. Due to their DNA structure, telomeres are more sensitive to DNA damage, and they might present different outcomes following exposure from different genotoxic agents. For instance, telomeres repair the 8-oxo-7,8-dihydroguanine following hydrogen peroxide treatment whereas they do not remove the cyclobutane pyrimidine dimers after UVB exposure. To study the effects of three DNA-damaging agents on telomere structure, we exposed normal human primary fibroblasts to hydrogen peroxide, gamma radiation, or UVB rays. Parameters of nuclear architecture of telomeres and the expression profile of shelterin genes were assessed just after the exposure to one of the genotoxic agents over a 24-hour period. First, we studied the telomere nuclear architecture by using 3D quantitative fluorescence in situ hybridization. Hydrogen peroxide treatment induced a significant reduction of the number of telomere signals. For gamma irradiation, the nuclear volume was positively correlated to the number of telomere signals and negatively correlated to telomere average intensity. UVB exposure led to a significant increase of telomeric aggregates and disruption of telomere nuclear shape by forming an ellipsoid instead of circular shape. Next, the study of the expression profile of telomere shelterin genes, following exposure of these different DNA damage agents, mainly showed an up regulation of POT1, TERF1 and TERF2IP after hydrogen peroxide treatment. Also, UVB and gamma exposure led to an up regulation of TERF2IP and POT1, respectively. Moreover, we observed an up regulation of ATM, ATR, MRE11, Ku80, p21 following exposure to hydrogen peroxide. In conclusion, certain DNA-damaging events differently alter telomere structure by acting on nuclear telomere architecture and the expression profile of telomere shelterin genes. Furthermore, the shelterin genes might be involved in response and repair of DNA damage. The disruption of telomere structure due to acute insults is another pathway that affects cell homeostasis.

1249F

The Fanconi anemia pathway regulates telomeric recombination and telomere DNA synthesis in ALT-immortalized human cells. *H. Root[1,2], M. Komosa[1], F. Al Azri[1,3], M.S. Meyn[1,2,3,4].* 1) Dept Gen & Genome Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Dept of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 3) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 4) Dept of Paediatrics, University of Toronto, Toronto, ON, Canada.

Fanconi anemia (FA) is an inherited disorder characterized by bone marrow failure, congenital malformations and cancer. FA proteins help maintain genome integrity by playing multiple roles in DNA replication and repair. To understand FA protein function we are studying their involvement in recombination-dependent ALT telomere maintenance. We find that FANCD2, FANCJ, and FA core complex proteins form nuclear foci that colocalize with telomeric foci in ALT-dependent, but not telomerase-positive or primary cells. FANCM, a DNA translocase that recruits the FA core complex to sites of DNA damage and promotes replication fork stability, also frequently colocalizes with telomeric foci in ALT cells. FA proteins colocalize with telomeric DNA primarily within ALT-associated PML bodies (APBs), subnuclear domains that contain high amounts of extrachromosomal telomeric repeat DNA (ECTR). FANCD2 depletion leads to rapid, ALT-specific alterations in telomere homeostasis, including increased telomere dysfunction-induced foci, telomere entanglements, fragile telomeres, and telomere recombination events. FANCD2 depletion leads to marked increases in ECTR DNA synthesis, with FANCD2-depleted cells containing up to 40x more telomeric repeat DNA than the average control cell. Co-depletion of FANCD2 with BLM, but not RAD51, suppresses these telomere phenotypes.

Depletion of FANCJ has the opposite effect of FANCD2 depletion, with FANCJ-depleted cells exhibiting a significant decrease in both the number and intensity of telomeric DNA foci. Co-depletion of FANCJ with FANCD2 partially suppresses amplification of ECTR DNA in FANCD2-depleted cells, suggesting that FANCJ is also required for ECTR DNA synthesis. Interestingly, FANCM depletion also results in increased telomeric DNA synthesis, however this does not appear to be mediated by FANCD2, as FANCD2 continues to localize to telomeric foci in FANCM depleted ALT cells. This suggests that FANCM and FANCD2 may be acting independently to restrain ECTR DNA synthesis. Our results support a model in which FANCD2 and FANCM restrain recombination and/or amplification of telomeric DNA, while BLM and FANCJ DNA helicases promote these processes. We propose that FA proteins do not solely function in a single linear pathway, but rather, work both together and independently to coordinately facilitate genetic recombination and recovery of stalled replication forks.

1250F

Specific TP53 mutations are associated with chromosomal rearrangements, telomere length changes and remodeling of telomere nuclear architecture. *O. Samassekou[1], N. Bastien[1], D. Lichtensztejn[2], J. Yan[1], R. Drouin[1], S. Mai[2].* 1) Dept Med Gen, Sherbrooke Univ (CHUS), Sherbrooke, PQ, Canada; 2) Manitoba Institute of Cell Biology, University of Manitoba, Winnipeg, MB, Canada.

The TP53 mutations are the most common mutations in human cancers and among them the TP53-R175H and TP53-R273H mutations are most frequent. These mutations generally occur during tumor development and are thought to promote genomic instability, with impact on patient's outcome. In order to characterize the effect of specific TP53 mutant on genomic instability, we studied four isogenic lines of LoVo cells, derived from colon carcinoma. The three LoVo cell lines with specific mutation of TP53, TP53-A143V, TP53-R175H and TP53-R273H, and wild-type TP53 were maintained in culture up to twenty population doublings. Using M-FISH, 3D Q-FISH on interphase, and Q-FISH on metaphase chromosomes, we described chromosomal rearrangements, changes in 3D nuclear telomeric architecture and in the length of individual telomeres. We found that LoVo cells expressing mutant TP53-R175H displayed the highest level of chromosomal instability among the LoVo cell lines. This instability was characterized by numerical and structural chromosomal abnormalities. Furthermore, we observed that mutants TP53-R175H and TP53-A143V showed more alterations of their 3D nuclear telomeric architecture than both the mutant TP53-R273H and the wild type. These alterations were mainly characterized by the presence of a substantial number of telomeric aggregates and a change in telomere positions. Telomere length analysis revealed an increase in telomere length in the mutants TP53-R175H and TP53-A143V. Moreover, we noted an association between some chromosomal abnormalities and telomere elongation in the mutant TP53-R175H. Taken together, our results indicate that in the LoVo isogenic cell model, the mutation TP53-R175H is more likely to cause higher levels of genomic instability than the other TP53 mutations. We propose that the type of TP53 mutations associated with the genetic background of a cancer cell is a major determinant of the TP53-dependent genomic instability.

1251F

Mechanisms of maintaining telomere lengths at specific chromosomes in leukemia. *J. Yan[1], J. Lamoureux[1], E. Bouchard[1], J. Herbert[2], H. Li[3], S. Huang[3].* 1) Division of Genetics/Dept Pediatrics, Univ de Sherbrooke, Sherbrooke, PQ, Canada; 2) Banque des Cellules Leucémiques, University of Montreal, Montreal. PQ, Canada; 3) Center for Stem Cell Research and Application, Huazhong University of Science and Technology, Wuhan, Hubei, China.

Leukemia is a neoplasia often characterized by the cellular proliferation of affected cell lineage and specific chromosome abnormalities. As most types of cancers, the telomere lengths in leukemia cells are shorter than normal blood cells. We studied the telomere length on each chromosome in chronic myeloid leukemia (CML) at chronic phase (CP) and acute T lymphoblastic leukemia (T-ALL) using Q-FISH and telomere restriction fragments (TRF). We found there were specific individual telomere elongation profile, or a clonal event, associated with these leukemia samples. The longest telomeres in both leukemia types reached more than 23 Kb, which were correlated specifically with certain chromosome arms as detected by the Q-FISH and the TRF. To understand what mechanism are responsible for the maintenance of the telomere length in these leukemia samples, we examined telomerase activity by real time PCR and a hallmark of alternative lengthening of telomeres (ALT), in terms of extra-chromosome telomeric repeat (ECTR) with 2D gel electrophoresis. Our results showed that the ALT mechanism is involved in these leukemia samples in a higher frequency (~46%) in CML than in T-ALL (12.5%) and the general rate (~15%) that was estimated previously from different types of tumors. Moreover, we found that some of the ALT positive samples were associated with high telomerase activity, suggesting the coexistence of telomerase and ALT maintains for telomere length maintenance. Since activated telomerase was observed in a high rate of T-ALL and CML at the late stage, blastic crisis phase (BP), whereas positive ALT was observed in a high rate in CML at CP, we propose a model that the ALT mechanism might be used at the early stage of leukemogenesis and followed by the telomerase activation to alternately maintain telomere length. This telomere length maintenance model is most likely driven by clonal selection. Therefore, cells of a specific cancer may use different mechanisms to maintain their telomere length depending on disease stage or their mutation status. It is important to take into account in the development of anti telomerase therapeutics that the presence of the ALT mechanism in cancer cells must cause treatment resistance.

1252F

Integrative molecular profiling and regulatory modeling of the Glioblastoma multiforme genome, epigenome, and transcriptome. *S. Li[1], M. Setty[2], P. Zumbo[1], C. Leslie[2], C. Mason[1].* 1) Weill Cornell Medical College, New York, NY; 2) Memorial Sloan-Kettering Cancer Center, New York, NY.

High-throughput, next generation sequencing (NGS) provides rapid and detailed molecular information on nucleic acids from biological samples in a matter of days. RNA-seq is an application of NGS that provides efficient and accurate ways to measure changes in the transcriptome, and it also enables many other types of analysis on the genome that have no yet been utilized in a systematic framework. Here we provide a comprehensive RNA-seq data annotation and analysis package that can integrate data from (T)ranscripts, (E)xons, (A)lleles, (B)ases, poly-(A)denyltation sites, and (G)enes (BEGAT) to annotate the transcriptome information and count reads. After alignment, BEGAT annotates mapped reads with genes, exons and novel transcriptionally active regions (TARs). It will also annotate junction reads that mapped to a database of all possible exon-exon combination. Then, BEGAT annotates reads with poly-A tails by trimmed 3' poly A bases or 5' poly T bases, and identifies the alternative cleavage sites and miRNA targeting site at 3'UTR. Furthermore, all un-mapped reads after every other step will be iteratively trimmed, mapped to the genome again. They will be annotated as fusion genes, which can be identified for novel gene findings with single-end or paired-end data. BEGAT is also capable of aiding in molecular diagnostics and automated tissue source prediction as well. To show our algorithms applicability, we generated miRNA, mRNA, and methylation sequencing data from Glioblastoma multiforme (GBM) patients' tissue, as well as the corresponding cultured tumorspheres (5 tissue/tumorspheres pairs). We used BEGAT to identify specific expression patterns and fusions for the mRNA and miRNA transcriptome between the two primary tumors and their cultured cells. We also demonstrate BEGAT's ability to be integrated with a lasso regression model for delineating the regulators of tumor expression dynamics, which include data on copy number variance, DNA methylation level, and DNase hypersensitive sites (DHS). Together, these tools enable us to build a gene regulatory network for transcription of different GBM types. Further computational analysis will focus on further improving the model of transcriptional regulatory networks to help better classify GBM subtype, and to apply the model to other cancer types from other large-scale sequencing efforts.

1253F

Added value of SNP probes to a CGH chromosomal microarray analysis in clinical diagnostics: experience from a comprehensive high-resolution exon targeted aCGH plus SNP array and pure SNP arrays. *J. Wiszniewska[1,2], S-H.L Kang[1,2], C.A. Bacino[1,2,3], W. Bi[1,2], S. Al Masri[2], P.A. Ward[1,2], C.M. Eng[1,2], C. Shaw[1,2], P. Stankiewicz[1,2], J.R. Lupski[1,2,3], A.L. Beaudet[1,2,3], S.W. Cheung[1,2], A. Patel[1,2].* 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Medical Genetics Laboratories, Baylor College of Medicine, Houston, TX; 3) Dept of Pediatrics, Baylor College of Medicine, Houston, TX.

Chromosomal Microarray Analysis (CMA) is a powerful method widely used for the detection of copy-number variation (CNV) in patients with intellectual disabilities and other clinical abnormalities. A variety of array platforms have been used for the analysis of genomic imbalances, however, only Single Nucleotide Polymorphisms (SNPs) platforms offer the ability to detect copy neutral contiguous regions of absence of heterozygosity (AOH) as in cases of uniparental disomy or consanguinity. Our laboratory tested 603 clinical samples using Illumina Human610-Quad or HumanOmni1-Quad arrays that contain over 610k and 1M SNPs, respectively. We detected clinically significant CNVs in ~10.5% of cases. At least one contiguous region of AOH greater than 5Mb was detected in ~29% of patients including eight cases of uniparental disomy (isodisomy of chromosomes 1, 2, 15, and 18, and segmental isodisomy of chromosomes 11 and 22). Notably, eleven cases had a proportion of AOH that was consistent with matings between first degree relatives. The current resolution of the commercial Illumina arrays does not allow the detection of intragenic deletions or duplications in most disease associated genes. To implement a comprehensive test for both CNVs and AOHs, we have enhanced our custom Agilent high-resolution oligo array with exon coverage of 1714 OMIM genes with 120k SNPs to supplement CNV genomotyping with genotyping data. We tested 581 clinical cases using the combined comprehensive array (CMA HR+SNP) and we detected contiguous regions of AOH greater than 10Mb in ~4.8% of patients, including UPD 9, 14, 15, and 16 as well as two cases consistent with incestuous matings. The higher detection rate of AOH by Illumina array reflects a sampling bias, i.e. many samples were sent for Illumina array analysis to identify regions of AOH in known consanguineous families and assess potential genes/loci responsible for autosomal recessive syndromes. Twenty eight cases with AOH regions detected by comprehensive array were also reflex tested to Illumina SNP array and the results showed high concordance of AOH calls despite the significant difference in the SNP content between the two platforms. Introduction of the CMA HR+SNP array for clinical diagnostics provides an opportunity to benefit from both oligo (exonic resolution) and SNP (chromosome segregation) array technologies enabling optimal genome resolution of potential pathogenic variation and better patient care at lower cost.

1254F

Parental origin of mosaic trisomy 9 or mosaic partial trisomy 9 using SNP microarray analysis. *S.L. Zimmerman, T.A. Smolarek.* Human Gen, Cincinnati Children's Hosp Med, Cincinnati, OH.

Abnormalities of chromosome 9, including unbalanced structural rearrangements and aneuploidy in both mosaic and non-mosaic states are more frequently identified due to the use of single nucleotide polymorphism (SNP) microarray analysis. Common clinical features of mosaic trisomy chromosome 9 anomalies, which are more or less severe depending on the specific region and mosaic state, include skeletal, central nervous system, cardiac and craniofacial abnormalities. Six cases with chromosome 9 aberrations were analyzed using Illumina SNP microarray analysis, standard karyotype, and/or fluorescence in situ hybridization (FISH) analysis. Results from the SNP array analysis identified mosaic abnormalities that were initially missed by standard karyotype analysis. Genotype analysis of child and parental samples was done to determine the parent of origin. Two cases had mosaic partial trisomy 9p, which were maternal in origin. One case had mosaic trisomy 9 with an additional marker chromosome that was derived from chromosome 9 was paternal in origin. Complex inheritance patterns with mitotic recombination events were identified in the three remaining cases. Both of the cases with mosaic trisomy 9 were maternal in origin, while the final case, which was a partial trisomy 9q was shown to be paternal in origin. In summary, of the six cases, 67% (4/6) were maternal in origin while 34% (2/6) were paternal in origin. These results indicate that SNP microarray is a powerful tool to discover low level mosaicism and to provide insight into the mechanisms underlying unusual and complex patterns of inheritance.

Identification of a novel interstitial deletion of chromosome 5 by molecular cytogenetic analysis: a de novo del(5)(q22.3q31.2). *S. Lee[1,4], H. Chae[1,4], M. Kim[1,4], Y. Kim[1,4], I.Y. Park[2], J.C. Shin[2], J. Lee[3], J. Son[4].* 1) Laboratory Medicine, The Catholic University of Korea, Seoul, Korea; 2) Obstetrics and Gynecology, The Catholic University of Korea, Seoul, Korea; 3) Pediatrics, The Catholic University of Korea, Seoul, korea; 4) Catholic Genetic Laboratory Center, The Catholic University of Korea, Seoul, Korea.

We report here on a case with a de novo interstitial deletion of region 5q22.3 to 5q31.2. The prenatal sonogram showed that the fetus had clenched hands and club feet, and the maternal serum marker was normal. The baby was born by cesarean section due to placenta abruption at 35 weeks, 4 days of gestation. The clinical findings in this case included brachycephaly, a high forehead, hypertelorism with prominent eyes, low-set ears, clenched hands, club feet, a prominent coccyx with hair, ambiguous genitalia, inguinal hernia, heart defect and severe failure to thrive. G-banded chromosome analysis revealed interstitial deletion of the long arm of chromosome 5 without delineation. Subsequent high resolution multicolor banding for chromosome 5 and array comparative genomic hybridization analysis defined that a 22.6 Mb interstitial deletion containing about 146 genes was distal to 5q22, with breakpoints at 5q22.3 and 5q31.2. Compared with the previous reports, this case had a more severe phenotype. This case illustrates that molecular techniques might be helpful to accurately confirm the 5q interstitial deletions detected by cytogenetic analysis. Molecular studies need to be performed on these patients to establish the genotype-phenotype correlation and to understand the role and influence of genes in this region of chromosome 5.

1256F

Recurrence of cat-eye syndrome secondary to parental somatic mosaicism. *M. Mathieu[1], G. Morin[1], S. Kanafani[2], K. Braun[3], B. Demeer[1], L. Lichtenberger[1], A. Receveur[2], G. Jedraszak[1], J. Andrieux[4], H. Copin[2].* 1) Clinical Genetic Unit, Amiens University Hospital, Amiens, France; 2) Cytogenetics Laboratory, Amiens University Hospital, Amiens, France; 3) Pediatric Endocrinology, Amiens University Hospital, Amiens, France; 4) Molecular Genetics Laboratory, Jeanne de Flandres Hospital, Lille, France.

Cat-eye syndrome, also named Schmid-Fraccaro syndrome (OMIM N° 115470) is a non exceptional cytogenetic disease occurring in 1 / 50 000 to 1 / 150 000 living birth. The first clinical description was made by Haab in 1878. The cytogenetic anomaly was discovered by Schachenmann in 1965. The name cat-eye syndrome was first suggested by Gerald in 1968. We report on the observation of 2 brothers presenting the association of an anal atresia, preauriculat tags and isolated growth hormone deficiency. On cerebral MRI, they both had an hypoplastic intrasellar anterior pituitary, but an ectopic neurohypophysis. Their ophthalmologic examination showed no iris coloboma but an external palsy named Duane anomaly. Their father was asymptomatic. Their mother presented bilateral preauricular pit. But she had no history of anal atresia or short stature. On blood karyotype, the 2 boys had a supernumerary marker derivative of the chromosome 22 on all the analysed cells. Their father had normal blood karyotype. Their mother presented only on few lymphocytes (5%) the same supernumerary marker.The array-CGH confirmed that the size of this marker was classical of cat-eye syndrome. This observation is original if we consider the recurrence secondary to parental somatic mosaicism, the Duane anomaly and the presence of growth hormone deficiency.

An analysis pipeline for detecting copy number variations with a low false discovery rate in microarray data. *D.-A. Clevert[1,2], A. Mitterecker[1], A. Mayr[1], G. Klambauer[1], M. Tuefferd[3], A. De Bondt[3], W. Talloen[3], H. Göhlmann[3], S. Hochreiter[1].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Department of Nephrology and Internal Intensive Care, Charité University Medicine, Berlin, Germany; 3) Johnson & Johnson Pharmaceutical Research & Development, a Division of Janssen Pharmaceutica, Beerse, Belgium.

Motivation: A low false discovery rate (FDR) at the detection of copy-number aberrations (CNAs) in microarray data ensures sufficient detection power and prevents failures in CNA-disease association studies. A high FDR means many falsely discovered aberrations, which are not associated with the disease, though correction for multiple testing must take them into account. Thus, a high FDR not only decreases the discovery power of studies but also the significance level of the remaining discoveries after correction for multiple testing. **Methods:** We obtain a low FDR at the detection of CNAs in microarray data by a probabilistic latent variable model, called "cn.FARMS". The model is optimized by Bayesian maximum a posteriori approach, where a Laplace prior prefers models, which represent the null hypothesis of observing a constant copy number 2 for all samples. The posterior can only deviate from this prior by strong (deviation from copy number 2 intensities) and consistent signals in the data, which hints at a CNA - the alternative hypothesis. The information gain of the posterior over the prior gives the informative/non-informative (I/NI) call that serves as a filter for CNA candidate regions. I/NI call filtering reduces the FDR, because a region with a large I/NI call is unlikely to be a falsely detected CNA, which would neither have strong nor consistent measurements. It can be shown that the I/NI call filter applied to null hypotheses of the association study is independent of the test statistic which in turn guarantees that a type I error rate control by correction for multiple testing is still possible after filtering. I/NI-calls perform well for the usually rare CNAs that are seen at few samples only, where variance-based filtering approaches fail. **Results:** cn.FARMS clearly outperformed prevalent methods for CNA detection with respect to sensitivity and especially with respect to FDR on different HapMap benchmark data sets. **Availability:** The software cn.FARMS is publicly available as an R package at Bioconductor and at http://www.bioinf.jku.at/software/cnfarms/cnfarms.html.

1258F

Comparison of different reference genes used for qPCR-based CNV quantification. *N. Fang, A. Missel, C. Beckmann, U. Deutsch.* QIAGEN, Hilden, Germany.

Copy Number Variant (CNVs), the change of the DNA copy number in the genome, has been recently shown to be a widely-spread phenomenon that affects about 10-20% of the human genome. The occurrence of the CNVs has been associated with various diseases such as autism, autoimmune disorders, and cancer. The most commonly used molecular biology tools for discovery of CNVs are array and next-generation sequencing (NGS). These two high-throughput methods can discover multiple potential CNVs, which normally need to be validated with an independent method. Once validated, the confirmed CNVs can also be examined in a large number of samples to identify the statistically significant association of the CNV and phenotype. Quantitative PCR (qPCR), with its ease of use, sensitivity, and scalability, is often the method of choice for CNV validation and association studies. Relative quantification principle is used for this application: first, a reference gene, whose copy number is presumed to be constant in different genomes, has to be defined. The copy number of the genes of interest (GOIs) is then calculated based on the Ct difference of GOI and reference gene among different samples. Since the consistent copy number of the reference gene is essential for the qPCR-based CNV quantification, we evaluated the reliability of commonly-used single copy reference genes such as RNaseP, as well as other candidates. Our results suggest that, compared to single copy genes, stable multi-copy regions can serve as a more sensitive and reliable CNV quantification reference. We also demonstrate more reliable CNV quantification with the REST software, which takes different qPCR efficiency into consideration and performs statistical analysis of the qPCR data.

1259F

CNVs detection from targeted sequencing of genes associated with congenital heart defects. *Y. Lai[1], A. Postma[5], T. Rahman[2], J. Laros[1], Y. Ariyurek[1], S. Sperling[3], S. Klaassen[4], J. Goodship[2], P. 't Hoen[1].* 1) Center for Human and Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Institute of Human Genetics, Newcastle University, Central Parkway, Newcastle upon Tyne, UK; 3) Group Cardiovascular Genetics, Department of Vertebrate Genomics, Max Planck Institute for Molecular Genetics, Berlin, Germany; 4) Max Delbrück Center for Molecular Medicine, Berlin, Germany; 5) Heart Failure Research Center, Academic Medical Center Amsterdam, Netherlands.

Copy number variations (CNVs) in the genome are an important source of genetic variability and underlie many disease phenotypes. If a gene residing in a copy number variable region is dosage sensitive, this can affect its gene expression level. For instance when one has only one functional copy of a gene, which may affect the abundance of the protein to support its normal function. Previous studies showed that numerous genes encode transcription factors play an important role in regulating heart formation. We hypothesize that haploinsufficiency of genes related with heart development is the reason for various severity of congenital heart defects. Haploinsufficiency of genes can be due to copy number change of dosage-sensitive genes or unmasking of recessive alleles by single base substitutions or short indels of the functional copy. Here we focus on the aspect of copy-number alterations within the disease cohort. Most current CNVs detection methods are designed for whole genome resequencing data and are able to identify large (>10 kb) or small (10 bp) indels (insertions or deletions). The objective is to discover medium sized deletions from exome sequencing data. Within the EU-sponsored HeartRepair project, we targeted exons of ~400 genes associated with congenital heart defects and sequence the targeted regions to high depth for ~160 patient samples. From this data, we compiled a matrix of reads that can be aligned uniquely to the targeted regions in samples passing minimum coverage criteria (>80% of targeted regions with coverage >20X) and normalized the matrix to the total number of reads on targets. We calculated the coefficient of variation on the depth of coverage for each targeted region to assess variability among samples, assuming that copy number polymorphic regions will show higher dispersion of the coverage across samples. ChrX can be seen as a copy number polymorphism between male and female samples. We used the 119 targeted regions on ChrX as bench mark for calling copy number variable regions and could clearly detect the higher coefficient of variation in the complete data set compared to data sets containing females or males only. 117 copy number polymorphic regions were detected in the 4200 targeted autosomal regions, of which two are overlapping with known CNVs in DGV database. We further assess the validity of the detected copy number polymorphic regions by checking the proportion of unbalanced heterozygous calls.

1260F

Complex genomic aberrations can be the cause of variable phenotypes of 22q11.2 deletion or duplication syndrome. *D. Li, M. Buch, M. Tekin, YS. Fan.* University of Miami, Miller School of Medicine, Miami, FL.

It is well known that the phenotypes of patients with DiGeorge syndrome can be extremely variable from near normal to severe developmental disabilities including congenital heart defects and risk of psychological problems such as schizophrenia. The causes of lack of genotype-phenotype correlation are not well understood. Prior to the clinical use of array CGH, deletion or duplication in the 22q11.2 region was detected by FISH, and therefore changes in the genome other than the 22q11.2 region was barely known. Array CGH studies have made it possible to reveal the imbalances genome-wide, and the findings of copy number changes other than the 22q11.2 microdeletion or duplication may explain the complexity of the genotype-phenotype correlations in these patients. By array CGH, we have detected copy number changes in the 22q11.2 region in 16 (11 deletions; 5 duplications) of 1292 cases referred for intellectual disabilities and/or congenital anomalies. We observed complex genomic imbalances in 2 of the 16 cases. The first case was a baby female of 15 days of age with tetrology of Fallot revealed by ultrasound. Array CGH showed a 2.47 Mb deletion in the 22q11.2 DiGeorge region and a 1.56 Mb deletion in the Xp22.31 region involving multiple genes including the STS gene which causes X-linked recessive ichthyosis when deleted or mutated. The second case was a baby boy of 15 days of age also with an abnormal ultrasound showing complex congenital heart defects. In this baby, array CGH detected multiple pathogenic copy number alterations, including a 2.84Mb duplication in the 22q11.2 DiGeorge region, a 605kb duplication in the 15q13.3 region involving the CHRNA7 gene, as well as a 209 kb deletion in 16p13.2 region involving the A2BP1 gene. Copy number changes of CHRNA are associated with mental retardation, autism and schizophrenia. Deletion of A2BP1 has been reported in patients with mental retardation, autism and seizure. Our observations have provided evidence that complex genomic changes are not rare in DiGeorge patients and they may contribute to the extremely variable phenotypes in this disease. Also, the additional changes such as duplication of CHRNA and deletion of A2BP1 may add additional risk for psychological diseases in the patient. Continuing follow-up and collection of detailed clinical information in these 2 patients may help our understanding on the complicated phenotypes of the DiGeorge or 22q11.2 microdeletion/duplication syndrome.

1261F

A de novo balanced chromosomal translocation disrupting a copy of the hominoid-specific *TBC1D3* gene embedded in a CNV region in a patient with developmental pituitary defects and Attention-Deficit/Hyperactivity Disorder (ADHD). *K. Machini[1], B. Duriez[1], Y. Rakover[2], P. Duquesnoy[1], F. Dastot-Le Moal[1,3], N. Collot[3], S. Amselem[1,3].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM) U.933, Université Pierre et Marie Curie-Paris 6, Paris, France; 2) Pediatric Endocrinology, Haemek Hospital, Afula 18101, Israel; 3) Assistance Publique-Hôpitaux de Paris (AP-HP), Hôpital Armand-Trousseau, Paris, France.

Over the last few years, accumulating data on genome sequences has illustrated the major role of copy number variation (CNV) regions in genome architecture and evolution. Most importantly, such regions are frequently associated with sporadic, Mendelian or complex diseases in humans. However, while deletions, duplications or inversions frequently occur in segmental duplications or CNV regions, no example of chromosomal translocation interrupting these sequences has been reported to date.

In the present study we mapped the breakpoints of a de novo translocation in a region of segmental duplication of chromosome 17. Moreover, we showed that this balanced translocation disrupts one copy of the hominoid-specific gene *TBC1D3*, which is absent in lower species and present in multiple copies in the human genome and has been shown to regulate the highly conserved EGF pathway in humans. The patient presented with anterior pituitary hypoplasia and hormonal deficiencies (GH, TSH and ACTH), a condition known as Combined Pituitary Hormone Deficiency (CPHD). The molecular basis of this disorder has been determined only in a small proportion of patients with the identification of mutations in a limited number of genes, mainly through a candidate-gene approach relying on mouse models. This chromosomal rearrangement did not affect the gene copy number or the transcript level of *TBC1D3* and no chimeric transcripts were detected in the patient's lymphoblastoid cell line. It is, therefore, highly likely that the translocation affects gene expression only in the pituitary and possibly in a specific developmental window.

Besides CPHD, the patient was diagnosed with Attention-Deficit/Hyperactivity Disorder (ADHD). Interestingly, recent studies support a potential role of CNVs in ADHD, and rearrangements in the very same region of chromosome 17 (17q12) have been shown to confer risk of developing autism spectrum disorders.

Overall, our findings illustrate that chromosomal translocations disrupting CNV regions can indeed cause a human disease. Most importantly, this study indicates that hominoid-specific genes, such as *TBC1D3*, are highly likely to play key roles in developmental pathways and, if affected, contribute to human pathology.

1262F

Diagnosis of Skeletal Muscular Atrophy through use of droplet digital PCR. *J. Regan, P. Belgrader, K. Ness, B. Hindson, S. Saxonov.* QuantaLife, Pleasanton, CA.

Skeletal Muscular Atrophy (SMA) is the most common cause of genetically determined neonatal death. One out of every 60 individuals is a carrier for SMA, which affects one in every 1000 births. It is an autosomal recessive disease characterized by progressive motor neuron degeneration. The disease is caused by loss of the SMN1 gene, whereas the severity of the disease, from early infant death to a normal lifespan with mild weakness, is associated with the copy number of SMN2 genes that are able to partially compensate for SMN1 loss. Although qPCR and multiplex ligation dependent probe amplification (MLPA) are traditionally used to diagnosis SMA, neither of these technologies offer sufficient precision to measure SMN1 and SMN2 copy number reliably. For this study, droplet digital PCR (ddPCR) was used to assess SMN1 and SMN2 copy number in over 30 samples from the Coriell repository, including six positive controls. ddPCR was found to measure copy number states for the two SMN genes accurately and reproducibly. In addition, these estimates were verified via a direct SMN1-SMN2 duplex assay which was used to measure the ratio of SMN1 to SMN2.

Complex genetics of radial ray deficiencies: Screening of a cohort of 50 patients. *S. Vergult[1], A.J.M. Hoogeboom[2], E.K. Bijlsma[2], M. Jongmans[3], C. Thiel[4], J. Verheij[5], A. Perez-Aytes[6], H. Van Esch[7], A. Küchler[8], D. Barge-Schaapveld[9], Y. Sznajer[10], G. Mortier[11], B. Menten[1].* 1) Center for Medical Genetics Ghent, Ghent, Belgium; 2) Department of Plastic, Reconstructive and Hand Surgery, Erasmus MC, University Medical Center, Rotterdam, The Netherlands; 3) Department of Human Genetics, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 4) Institute of Human Genetics, University Hospital Erlangen, Erlangen, Germany; 5) Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 6) Dismorfología y Genética Reproductiva, Grupo de Investigación en Perinatología, Instituto de Investigación Sanitaria, Fundación Hospital La Fe, Valencia, Spain; 7) Center for Human Genetics, Leuven, Belgium; 8) Institut für Humangenetik, Universitätsklinikum Essen, Essen, Germany; 9) Department of Clinical Genetics, Academic Medical Centre, UVA, Amsterdam, The Netherlands; 10) Pediatric Clinical Genetics, Hopital Universitaire des Enfants Reine Fabiola, Center for Human Genetics, Université Libre de Bruxelles, Brussels, Belgium; 11) Department for Medical Genetics, Antwerp, Belgium.

Radial ray deficiencies (RRDs) are characterized by unilateral or bilateral absence of varying portions of the radius and thumb. Both isolated and syndromic forms have been described. Although for some of the syndromes the causal genes have been identified e.g. *TBX5* (Holt-Oram Syndrome), the genetics of RRDs remain complex. Given this complexity we searched for genomic aberrations in 50 patients with (non-) syndromic forms of RRDs by means of molecular karyotyping. In >10% an aberration was detected. We identified known aberrations such as the 1q21.1 microduplication and the 16p13.11 microduplication. Next to these, some rare copy number variations were revealed of which two were of high interest: a deletion at chromosome band 7p22.1 and one at chromosome band 10q24.3. The 7p22.1 deletion contains the *RAC1* gene. Conditional knockout mice of *RAC1* exhibit truncated fore- and hindlimbs (Wu *et al.*, 2008), making it an interesting candidate gene for RRDs. Unfortunately, sequencing analysis of *RAC1* in our patient cohort did not reveal any additional causal mutations. Since it cannot be excluded that a recessive allele is unmasked by the 7p22.1 deletion, capture sequencing is being performed for the other allele in this patient. The 10q24.3 deletion contains only one gene, *FBXW4*. This gene is of high interest since in mice insertions in the orthologue dactylin gene give rise to dactylaplasia. In humans duplication of this region is associated with Split Hand Foot Malformation (SHFM3). How these duplications cause SHFM3 is still not known. Since several genes in the vicinity have a role in limb development, it has already been suggested that these duplications may disrupt the interaction between cis-regulatory elements and their target genes, resulting in SHFM. In our patient it could also be possible that the 10q24.3 deletion gives rise to RRDs by deletion of one or more regulatory regions. For this, six CNEs (conserved non-coding elements) were selected. Sequence analysis of these CNEs revealed one mutation in our cohort, which was absent in 96 control samples. Although this substitution was found in a highly conserved region, the phyloP score suggests a rather low impact. Sequence analysis of the exons of *FBXW4* in our cohort did not reveal causal mutations. This is the first microarray study in a larger cohort of patients with RRDs. Some interesting aberrations were detected, which we will further discuss and elaborate on the genotype-phenotype correlation.

1264F

Copy Number Variation Determination with Blood vs. Saliva Sourced DNA. *D.B. Willmot, R. Elumalai.* Genomics, Agilent Technologies, Wilmington , DE.

Array based comparative genomic hybridization is a widely used technology with many clinical and research applications for measuring copy number variation. Aside from tumors, most DNA samples are extracted from blood. The objective of this study is to compare copy number determinations using DNA extracted from blood samples vs. DNA from saliva. Saliva can be collected without a phlebotomist, more safely, and is more acceptable to many - especially children. Newer DNA isolation kits for saliva report yields as high as 55 ug per 1.0 ml collection tube with intactness comparable to blood sourced DNA. Agilent microarrays with one million features were hybridized with DNA from six individuals (blood vs. saliva DNA). Oragene OG-510 kits from DNA Genotek were used followed by a double RNase digestion. Labeling was with Agilent ULS non-enzymatic labeling. The six individuals consisted of two families with the parents and one offspring each. Parent-offspring comparisons provided differential aberrations for tracking the consistency between the DNA sources. Analysis was performed with Agilent Genomic Workbench Lite version 6.5 with differential aberration reports finding relatively minor differences arising by chance or from the DNA sources. We will show graphically and by tabulation that saliva is a viable source of DNA for array based CGH.

1265F

Evolution of Chromosome Abnormality databases from mid70s to the present. *D. Borgaonkar.* LNG,NIA,NIH, Bethesda, MD, Wilmington, DE.

The first edition of Chromosomal Variation in Man was sublitted for publication to the Johns Hopkins Press in December 1974 and was published the following year.The 8th edition was published by John Wiley/Liss in 1997. Online access to the database material has been provided through the website www.wiley.com/borgaonkar since 1998 to date. This work was and remains the most extensive databse of reference material on all kinds of human chromosomal variants, polymorphisms and anomalies. Plans are underway to publish an ebook. This book should be of use to health professionals, family members and others interested in chromosome science and its role in health and disease. Given the effort put in the last 3 1/2 decades in maintaining the database, the parallel advances made in computer technology, and the methodology of studying chromosomes, it would be of interest to seek input from users. We had demonstrated this database at the International Congress in Washington in 1991. However, the wisdom at that time was not to proceed with offering it Online! Howthe world has changed!

1266F

Automating image detection for Molecular Combing: bringing the FSHD test to routine diagnostics laboratories. *P. Walrafen[1], K. Nguyen[2,3], M. Pierret[1], R. Bernard[2,3], C. Thiberville[1], C. Chaix[2,3], E. Renard[1], S. Attarian[2,4], Y. Ghomchi[1], A. Bensimon[1], J. Pouget[2,4], E. Conseiller[1], N. Lévy[2,3].* 1) Genomic Vision, Paris, France; 2) AP-HM, Département de Génétique Médicale - Hôpital d'enfants de la Timone, Marseille, France; 3) Université de la Méditerranée, INSERM UMR_S 910 “Génétique médicale et génomique fonctionnelle”, Marseille, France; 4) AP-HM, Service de Neurologie, centre de référence des maladies neuromusculaires - Hôpital de la Timone, Marseille, France.

Facioscapulohumeral dystrophy (FSHD) is among the most frequent inherited muscular disorders. Clinical symptoms range from mild to severe, the most severe forms involving full-time use of a wheelchair from early adulthood. The transmission is autosomal dominant, but de novo cases are frequent, essentially related to somatic mosaicism in the index case or a healthy / mild symptomatic parent. The current standard for molecular genetic testing involves a combination of several restriction digests, pulsefield gel electrophoresis and Southern blots, a complex and tedious procedure which sometimes suffers from a lack of accuracy. Interpreting the results is indeed made difficult by the genetic characteristics of the disease: testing involves the quantification of a 3.3 kb CNV with copy numbers varying from 1 to 100, pathogenic alleles having 10 repeats or less. The disease-related locus at the chromosome 4q subtelomere shows almost perfect homology with the chr 10q subtelomere. Besides, the pathology is uniquely associated with one of two common haplotypes of chr 4q characterized by kb-scale differences downstream of the repeat array. Finally, rearrangements are relatively frequent, involving either exchanges between chromosomes 4 and 10, deletion of sequences neighboring the repeat array, or more complex rearrangements. We have published a new approach for molecular testing of FSHD based on Molecular Combing. This technology enables single-molecule visualization through fluorescence microscopy of genetic loci at high resolution (~1 kb) over very large regions (several hundreds of kb). Although the results of this initial study clearly showed the advantages of the Molecular Combing test for reliability and ease of interpretation, the comparison with Southern blotting in terms of hands-on time was less favorable, mainly due to operator-performed image analysis. To enable wide use of the test for routine diagnostics in laboratories, we have developed software which automates the analysis step, and considerably reduces operator time. We have also simplified the test design to make the analysis straightforward. We have tested a cohort of patients including prenatal samples, at an increasing rate, which is now compatible with the typical needs of a laboratory performing molecular testing for FSHD. Interestingly, the approach could be extended to other Molecular Combing tests, thus broadening potential applications for this novel diagnostics technology.

1267F

Subtelomeric rearrangements in a cohort of 50 patients with severe mental retardation and dysmorphism diagnosed by fluorescence in situ hybridization and chromosomal microarray analysis. *I. Ben Abdallah Bouhjar[1], H. Elghezal[1], N. Soyah[2], S. Mougou[1], H. Ben Khelifa[1], M. Gribaa[1], D. H'mida[1], A. Saad[1], PRF. Tunisian Network On MR[3].* 1) Cytogenetics and Reproductive Biology Department , Farhat Hached University Teaching Hospital , Tunisia, SOUSSE, Tunisia; 2) Paediatric Department, Farhat Hached University Teaching Hospital, Sousse, Tunisia; 3) Ministry of Higher Education and Research, Tunisia.

About 5-10% of patients with dysmorphisms, severe mental retardation, and normal standard karyotype are affected by subtelomeric chromosome rearrangements. Sequence homology between different chromosomes and variability between homologs make these regions more susceptible to breakage and reunion. We analyzed the telomeric regions of 50 of these patients, selected with strict clinical criteria described by De Vries et al. Fluorescence in situ hybridization, using commercial probes, was performed according to the manufacturer's instructions (TelVysion, Vysis®, Abbott Park, IL). Ten subtelomeric rearrangements were identified (20%). Six had a unique anomaly (del(1)(p36.2), del (2)(q37.2), del(10)(q26.2), dup(10)(q26.2), del (22)(q13.2) and del (6)(p25.2)), there are de novo imbalances. Two subjects had double segmental imbalances inherited from a balanced parent (der(3)t(-3;2)(p26.3;q37.2)mat and der(3)t(X;3) (q27.3;p26.3)mat). For more characterization of rearranged genes and breakpoints, we analyzed by comparative genomic hybridization array the DNA of subjects with subtelomeric anomalies. The 44,000 Agilent oligonucleotides array was used according to the manufacturer's instructions (Agilent Human Genome CGH Microarray Kit 44K, Agilent Technologies®, Santa Clara, CA). This study provides further evidence for the plasticity of subtelomeric regions, which often results in cryptic rearrangements, and recommends stringent criteria for selecting patient candidates to telomere analysis and to establish a precise phenotype genotype correlation and to provide genetic counselling to the parents.

1268F

Human embryonic stem cells and in situ acquisition of chromosomal imbalance: a case of trisomy 20 in the HD90 line carrying a germline VHL mutation. *F. Pellestor[1], F. Becker[2], C. Monzo[2], J. De Vos[2], P. Sarda[1], G. Lefort[1].* 1) Medical and Chromosomal Genetics, Hopital ADV, CHRU Montpellier, Montpellier, France; 2) Research Institute of Biotherapy, Hopital St Eloi, CHRU Montpellier, Montpellier, France.

The occurrence of numerical chromosomal abnormalities is a major problem in cultures of human embryonic stem cells (hESC), since extra or missing chromosomes can compromise cell viability or lead to adaptive advantages in culture. The early detection of these numerical abnormalities is essential to avoid the replacement of normal cell by unbalanced cells in culture. We report the results of classical and molecular cytogenetic analysis performed on the hES cell line HD90, at different passages in long-term culture, and the identification of trisomy 20. The HD90 line was derived from the inner cell mass of a 5 day-old-preimplantation-blastocyst stage embryo harbouring a germline Von Hippel Lindau (VHL) mutation. Cytogenetic analysis was performed using standard methods and R-banding. FISH using both centromeric and painting probes specific for chromosome 20 were used for chromosomal detection on interphase nuclei. R-band karyotyping of HD90 cells was done at passage 26. A minimum of 30 metaphase spreads were analysed and all indicated the presence of trisomy 20. The defect was confirmed by dual colour FISH in a mimimum of 100 interphase cells from passages 12 and 23. No trisomic cells were observed at the earlier passage 6, whereas the trisomy 20 was detected in 17% of the cells at passage 7. This indicates that the chromosomal abnormality was progressively acquired during long-term culture. Chromosomal abnormalities in hESC have previously been reported, especially trisomy 12 and trisomy 17 which appear to give a proliferative growth advantage in hESC cultures. A similar proliferative advantage has been observed in the HD90 line carrying trisomy 20. The presence of the VHL mutation could promote chromosomal instability and aneuploidy, by impairing spindle checkpoint function. The early detection of these cells by cytogenetic analysis is essential, since trisomic cells could replace the normal cell population in a few passages. Although molecular methods such as micro-arrays offer high resolution in terms of detecting genetic changes, karyotyping and interphase FISH are more sensitive methods for identifying small cell populations with clonal chromosomal abnormalities. Consequently, regular chromosomal testing is required to ensure the integrity of embryonic stem cell lines. Supported by the Fondation Pour La Recherche Médicale and the Agence de la Biomédecine.

Spectral Karyotyping for Identification of Constitutional Chromosomal Abnormalities at a National Reference Laboratory. *B.T. Wang, A. Anguiano, S. Wang, F.Z. Boyar, L.W. Mahon, M.M. El Naggar, P.H. Kohn, M.H. Haddadin, V. Sulcova, A. Sbeiti, M. Ayad, T. Sahoo, B.J. White, C.M. Strom.* Cytogenetics Dept, Quest Diagnostics Nichols Inst, San Juan Capistrano, CA.

Spectral karyotyping is a diagnostic tool that allows visualization of chromosomes in different colors using the FISH technology and a spectral imaging system. To assess the value of spectral karyotyping analysis for identifying constitutional supernumerary marker chromosomes or derivative chromosomes at a national reference laboratory, we reviewed the results of 179 consecutive clinical samples (31 prenatal and 148 postnatal) submitted for spectral karyotyping. Over 90% of the cases were requested to identify either supernumerary marker chromosomes or chromosomal exchange material detected by G-banded chromosome analysis. We also reviewed clinical indications of those cases with marker chromosomes in which chromosomal origin was identified by spectral karyotyping. Our results showed that spectral karyotyping identified the chromosomal origin of marker chromosomes or the source of derivative chromosomal material in 158 (88%) of the 179 clinical cases; the identification rate was slightly higher for postnatal (89%) compared to prenatal (84%) cases. Cases in which the origin could not be identified had either a small marker chromosome present at a very low level of mosaicism (<10%), or contained very little euchromatic material. Supplemental FISH analysis confirmed the spectral karyotyping results in all 158 cases. Clinical indications for prenatal cases were mainly for marker identification after amniocentesis. For postnatal cases, the primary indications were developmental delay and multiple congenital anomalies (MCA). The most frequently encountered markers were of chromosome 15 origin for satellited chromosomes, and chromosomes 2 and 16 for non-satellited chromosomes. We were able to obtain pertinent clinical information for 47% (41/88) of cases with an identified marker chromosome. We conclude that spectral karyotyping is sufficiently reliable for use and provides a valuable diagnostic tool for establishing the origin of supernumerary marker chromosomes or derivative chromosomal material that cannot be identified with standard cytogenetic techniques.

The Developmental Genome Anatomy Project (DGAP): Annotating the Genome by Cytogenetic and Sequencing Approaches. *A.M. Lindgren[1], M.E. Talkowski[2,3], C. Hanscom[2], C. Chiang[2], C. Ernst[2,3], S. Ahsan[1], B.B. Currall[1], L. Yuan[1], S. Lachke[4], I. Saadi[4], D.J. Harris[5], R.L. Maas[4], B.J. Quade[1], J.F. Gusella[2,3], C.C. Morton[1].* 1) Depts. of Ob/Gyn and Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Depts. of Genetics and Neurology, Harvard Medical School, Boston, MA; 4) Dept. of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) Children's Hospital Boston, Harvard Medical School, Boston, MA.

The Developmental Genome Anatomy Project (DGAP, dgap.harvard.edu) is a collaborative endeavor to identify genes critical in human development and disease. Balanced chromosomal rearrangements are the biological resource for gene discovery in DGAP as they may indicate the location of disrupted or dysregulated genes that lead to an abnormal phenotype. DGAP analyzes the correlation between genotype and phenotype through FISH-based breakpoint localization, various sequencing methods, candidate gene identification and functional analysis in model organisms. Of 235 cases enrolled to date, breakpoints are FISH mapped in 88 cases, 116 of which are localized to a single clone. Seventy-six breakpoint sequences are determined in 36 cases and 57 disrupted genes identified for which 24 animal models have been evaluated. Notable cases under active investigation include DGAP100 [46,X,t(X;5)(p11.3;q35.2)], a nonverbal 16 year-old female with septo-optic dysplasia, cleft palate, severe myopia, neuromuscular scoliosis, hearing impairment, and a history of seizures. KDM6A, a histone 3 lysine 27 demethylase, is disrupted at Xp11.3, and qRT-PCR reveals ~50% reduction in KDM6A expression compared to control lymphoblast cell lines, suggesting haploinsufficiency of KDM6A is pathogenetic in the phenotype. Zebrafish knockdowns are underway and preliminary analyses show craniofacial anomalies. DGAP120 [46,XY,t(6;11)(q24.3;q21)] is a 12 year-old male with low-to-mid frequency sensorineural hearing loss, intermittent exotropia and craniofacial defects; C6ORF103 is disrupted at 6q24.3. DGAP191 [46,XY,t(5;7)(q14.3;q21.3)], a 3 year-old male, has sensorineural hearing loss, mental retardation, hypotonia and seizures. Although no genes are directly disrupted, the 5q14.3 breakpoint is ~500 kb upstream of MEF2C and the 7q21.3 breakpoint is 2.86 kb upstream of COL1A2. Normal expression of MEF2C and over-expression of COL1A2, as determined by qRT-PCR, suggest dysregulation of COL1A2 as etiologic in the phenotype. Chromosomal rearrangements remain a rich resource for identifying genes and regulatory elements underlying human disease and traits. In conjunction with development of affordable sequencing methods, the study of balanced chromosome rearrangements in phenotypically abnormal individuals is imperative in rapid annotation of the human genome.

1271F

A new case of azoospermic male with 46,XY,t(1;21)(p11;p12) karyotype. *E.O. Ote[1], T. Turunc[2], O. Ozer[1], Z. Yilmaz[1], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Urology, Baskent University Faculty of Medicine, Ankara, Turkey.

Infertile men have an increased prevalence of chromosome abnormalities compared to phenotypically normal newborns. Translocations involving acrocentric chromosomes regardless of the partner chromosome integrate with male meiosis. Here we report a 32 years old azoospermic man with a history of infertility for seven years. The patient consulted the infertility clinic and was evaluated for testicular biopsy. Hormone levels were detected as FSH: 7.5 mIU/ml, LH: 4.3 mIU/ml, total testosterone: 3.11 ng/ml, all in the normal range. The patient was also referred to our department for cytogenetic analysis which resulted in a 46,XY,t(1;21)(p11;p12) karyotype, pedigree analysis, although cytogenetic analysis was not performed, revealed recurrent abortions in mother and sister of the proband suggesting a familial translocation. The patient was informed about the result during genetic counseling. Patients with similar karyotypes were reported previously. The mechanism underlying the relation between translocations involving acrocentric chromosomes and male infertility is not clear yet. However, it has been postulated that interaction between the quadrivalent in pachytene of male meiosis and XY body might be the explanatory mechanism.

Accurate detection of copy number variations in next generation sequencing data by a latent variable model. *G. Klambauer, D.A. Clevert, A. Mayr, K. Schwarzbauer, A. Mitterecker, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Upper Austria, Austria.

The quantitative analysis of next generation sequencing (NGS) data like the detection of copy number variations (CNVs) is still challenging. Current methods detect CNVs as changes of read densities along chromosomes, therefore they are prone to a high false discovery rate (FDR) because of technological or genomic read count variations, even after GC correction. A high FDR means many wrongly detected CNVs that are not associated with the disease considered in a study, though correction for multiple testing must take them into account and thereby decreases the study's discovery power. We propose “Copy Number estimation by a Mixture Of PoissonS” (cn.MOPS) for CNV detection from NGS data, which constructs a model across samples at each genomic position, therefore it is not affected by read count variations along chromosomes. In a Bayesian framework, cn.MOPS decomposes read variations across samples into integer copy numbers and noise by its mixture components and Poisson distributions, respectively. The more the data drives the posterior away from a Dirichlet prior corresponding to copy number two, the more likely the data is caused by a CNV, and, the larger is the informative/non-informative (I/NI) call. cn.MOPS detects a CNV in the DNA of an individual by a region with large I/NI calls. I/NI call based CNV detection gurantees a low FDR because wrong detections are less likely for large I/NI calls. We compare cn.MOPS with the five most popular CNV detection methods for NGS data at three benchmark data sets: (1) artificial, (2) NGS data from a male HapMap individual with implanted CNVs from the X chromosome, and (3) the HapMap phase 2 individuals with known CNVs. At all benchmark data sets cn.MOPS outperformed its five competitors with respect to precision (1-FDR) and recall both at gains and losses.

1273F

Cytogenetic study of couples with infertility and recurrent miscarriage. *O.L.de. Moraes[1], F.C. Vinhaes[1], M.T.O. Cardoso[2], L.F.P. Bravin[2], M. Yoshino[2], M.S. Cordoba[2], S.M.do Couto[2], G. Tenser[2].* 1) Centro Universitário de Brasília, Brasilia, Distrito Federal, Brazil; 2) Núcleo de Genética, Hospital de Apoio de Brasília, Brasilia, Distrito Federal, Brazil.

Infertility is defined as the absence of pregnancy for a year or more in a young, healthy, and sexually active couple, with no use of contraceptive measures. It may result from a variety of factors, including both male and female partner. In approximately 20% of infertile couples the etiology of infertility is not known, despite clinical investigations, and in some cases the origin of infertility may be due to chromosomal or genetic factors. Abnormal karyotypes may explain infertility or recurrent pregnancy loss. When anomalies occur in germline cells, abnormal chromosomes segregate in gametes and may be transmitted to offspring. Balanced translocations (paternal or maternal) may interfere on pairing or disjunction of chromosomes during meiosis, forming unbalanced gametes. Couples who report recurrent miscarriage have a higher risk of being structural chromosome abnormalities carriers, particularly reciprocal translocations and inversions. This study aimed to perform cytogenetic analysis in couples with a history of infertility or recurrent miscarriage. Patients included in this study are from a public hospital in Brasilia, Brazil. Cytogenetic analysis was performed using the method of temporary culture of peripheral lymphocytes described by Moorhead et al., (1960) and the analysis of chromosomal aberrations was performed using the G and C-banding techniques. The 67 patients included in this study, from November 2009 to June 2010, had a history of reproductive problems, and an average age of 34 years old. Among these patients, 65.7% presented general causes of infertility and 34.3% a history of recurrent miscarriage. Cytogenetic study revealed normal karyotype in 88.1% of these patients, and abnormal karyotype in 11.9%, whereas 75% were female patients. Regarding chromosomal abnormalities, four patients (50%) carried a balanced translocation; two patients (25%), derivative chromosomes; one patient (12.5%) presented a balanced translocation and an inversion on chromosome 9, and one patient (12.5%) had sex chromosome mosaicism. The present study demonstrates the importance of cytogenetic analysis in elucidating the infertility and recurrent miscarriage etiology, and enables healthcare professionals to properly conduct genetic counseling, allowing couples to make correct decisions about their reproductive life.

Case reports: A rare chromosomal translocation in woman with recurrent miscarriages. *V. STOIAN[1], D. MIERLA[2], V. RADOI[2,3].* 1) University Bucharest, Faculty of Biology , Bucharest,; 2) Life Memorial Hospital, Bucharest, Romania; 3) Genetic Department, UMF Carol Davila, Bucharest.

Background: Carriers of translocations may have an increased risk of an unbalanced progeny due to imbalances and delays in meiosis. Case: A 38 year old patient was referred to the Genetic Department of Life Memorial Hospital because of her recurrent miscarriages and plurimalformative fetus in history, for genetic counseling. She had three previous pregnancies, each pregnancies ended in abortion. The cytogenetic analysis using GTG banding technique showed that the woman is a carrier of balanced reciprocal translocation involving chromosomes 13 and 16; 46,XX,t(13;16)(q33.3;p12.2), while her husband's karyotype was found to be normal. Therefore, cytogenetic tests are recommended for patients with a history of abortion, especially in women with a higher age to identify chromosomal alterations. Conclusion: To our knowledge, no translocation with such breakpoints t(13;16)(q33.3;p12.2) has been described previously in the women with recurrent miscarriages. Key words: t(13;16), infertility, miscarriage, translocations.

Variant Rett syndrome in a girl with a pericentric X-chromosome inversion leading to overexpression of the MECP2 gene in the absence of gene duplication. *F. Lopes[1], A. Silva-Fernandes[1], S. Moura[1], S. Pereira[1], B. Costa[1], B. Ylstra[2], J. Weiss[3], T. Temudo[1, 4], T. Lourenço[4], J. Vieira[5], P. Maciel[1].* 1) ICVS/3B's, Health Sciences School - University of Minho, Braga, Braga, Portugal; 2) Department of Pathology, VU University Medical Center, Amsterdam, The Netherlands; 3) Department of Clinical Genetics, VU University Medical Centre, Amsterdam, The Netherlands; 4) Unidade de Neuropediatria, Serviço de Pediatria, Hospital Geral de Santo António, Porto, Portugal; 5) Hospital D. Estefânia, Lisbon, Portugal.

Mutation in the MECP2 gene account for up to 80% of the classic Rett syndrome (RTT) phenotype in girls. The genotype of patients without one of these mutations has also been investigated and some cases with gross rearrangements involving the MECP2 gene were found, usually large deletions. In boys, MECP2 duplication is the rare cause of a severe neurologic disease with mental retardation, microcephaly and epilepsy; MECP2 duplication has also been described in a girl with a speech preserved variant of RTT. Overexpression of the normal MeCP2 has also been shown to cause a progressive neurological disorder in a mouse model. We report the case of a girl with the features of variant Rett syndrome in whom we found no mutations in the MECP2 gene by direct sequencing, nor changes in exon dosage (no deletions or duplications) by Robust Dosage PCR. Karyotype analysis, however, revealed a pericentric inversion in the X chromosome (46, X, inv (X)(p22.1q28). This patient had a balanced pattern of X inactivation. Given the location of the breakpoints, we investigated the expression levels of the MECP2 and CDKL5 genes. Intriguingly, she displayed an overexpression of the MECP2 gene at the mRNA level (mean fold change: 2,55±0,38) in comparison to a group of control individuals; the expression of the CDKL5 gene was similar to that of controls (mean fold change: 0,98±0,10). We performed FISH analysis to test the hypothesis that the inversion could have displaced the MECP2 promoter or its 5' regulatory region, separating it from the coding region; however, this was not the case. aCGH analysis using Agilent 180K custom array platform revealed no microdeletions or microduplications in the breakpoint regions that could explain the overexpression of the mRNA. Methylation analysis revealed a hypomethylation of MECP2 gene, which is consistent with the gene overexpression. The X-chromosome inversion detected in the patient leads to hypomethylation of the MECP2 gene and consequent overexpression of this gene. This results in clinical manifestations similar to those of RTT syndrome. We are currently exploring in further detail the mechanisms of MECP2 methylation and expression changes. Independently of the mechanisms, we propose that de-regulation of MECP2 expression may underlie disease in other RTT-like patients who test negative for MECP2 mutations. MECP2 expression may underlie disease in other RTT-like patients who test negative for MECP2 mutations.

Next generation genomic microarrays and custom FISH probes for molecular cytogenetic analysis designed by *ab initio* sequence analysis. *S.N. Dorman[1], B.C. Shirley[2], N.G. Caminsky[1], E.J. Mucaki[1], W.A. Khan[3], L. Guo[4], J.H.M. Knoll[3,4], P.K. Rogan[1,2,4].* 1) Department of Biochemistry, University of Western Ontario, London, Ontario, Canada; 2) Department of Computer Science, University of Western Ontario, London, Ontario, Canada; 3) Department of Pathology, University of Western Ontario, London, Ontario, Canada; 4) Cytognomix Inc.

Array comparative genomic hybridization (aCGH) and fluorescence *in-situ* hybridization (FISH) are recommended as first-line tests for detection of chromosomal abnormalities in patients with congenital disorders and malignancies. Current aCGH platforms exhibit high coefficients of variation and low reproducibility in raw intensities, due to the use of blocking DNA, which is contaminated with single copy sequences. To improve the performance and define the content of FISH probes and microarrays, we have implemented an *ab initio* method (US Pat No 7,734,424) which locates genomic sequence intervals without repeat-masking. Our 44K *ab initio* aCGH microarray has lower coefficients of variation relative to Agilent's 4x44K platform ($p \leq 0.001$). Genotypes have been analyzed for other design parameters including proximity of the closest multicopy sequence, divergence of these repeats and probe length. Array performance metrics are based on Mendelian inheritance of CNVs and probe reproducibility are based on replicate data from YRU and CEU *HapMap* trios. Short single copy (scFISH) probes based on *ab initio* designs improve detection of subtle disease-causing abnormalities for genes not covered or too small to be accurately detected by recombinant BAC probes. The *ab initio* design method includes divergent repetitive elements that increase the length of scFISH probes, especially in intervals that are truncated by conventional repeat-masking. Chromosomal hybridization at high stringency produces the expected metaphase hybridization pattern. scFISH probes have been synthesized for *CDKN2A, TP53, KRAS, ERBB2* and *FLCN*, and validation for *CDKN2A* and *FLCN* probes is complete. A genome-wide set of scFISH probes has been designed, covering approximately 98% of all *ab initio* single copy intervals, and allowing potential production of scFISH probes for all unique genes (ie. 90% of known genes). These scFISH probes characterize chromosomal abnormalities in tumours at a resolution equivalent to Southern blot analysis and can be used to validate small acquired rearrangements seen by aCGH.

1277F

PLACE OF CGH-ARRAY ANALYSIS IN THE INVESTIGATION OF CONSTITUTIONAL CYTOGENETIC ABNORMALITIES: EXAMPLE OF THREE PHENOTYPICALLY RELATED CASES. *H. Hannachi[1], S. Mougou[1], M. Kammoun[1], I. Benabdallah[1], W. Fathallah[1], N. Kahloul[4], N. Gaddour[2], D. H'mida[1], H. El Ghazel[1], D. Sanlaville[3], A. Saad[1].* 1) Cytogenetics Molecular Genetic, CHU Faraht Hached, Sousse, Tunisia; 2) Psychiatric department, Fattouma Bourguiba University Teaching Hospital Monastir- Tunisia; 3) Constitutional cytogenetics department, Lyon- France; 4) Pediatric department Regional Hospital Kairouan- Tunisia.

Array comparative genomic hybridization (CGH-array) has revolutionized the cytogenetic diagnosis of patients with learning disabilities, mental retardation, dysmorphic features and multiple anomalies. We report in this work three patients with common clinical features including in particular, moderate mental retardation, severe delay in language, some autistic features and mild facial dysmorphism. Standard karyotype revealed a derived chromosome 22 in two cases, while the third one showed a normal karyotype. CGH-array investigations revealed a terminal 22q microdeletion of at least 1Mb in size, in all these patients. This loss was checked by Fluorescent In Situ Hybridization (FISH) using three telomeric probes: Totel Vysion MIX3 (tel3p, tel3q and tel22q) from Vysis, MD Digeorge « TUPLE (22q11)/22q13 (SHANK3) from Kreatech and MD Digeorge « TUPLE » (22q11)/22q13(ARSA) from Vysis. The use of FISH technique revealed that only the patients with der(22) showed actually a loss of genetic material. Considering the related phenotypic spectrum of these cases the result of this checking test in the third patient was unexpected and the suspected deletion could have been a technical artifact. In fact, telomeres have always posed a problem at the interpretation stage of results in the CGH-array technology due to their sensitivity to alteration during DNA extraction or marking stages. Our work justifies once again the importance of preliminary standard karyotyping, in spite of its low resolution, and the necessity to check by another independent technique any chromosome aberration detected by CGH-array and suspected as causative.

1278F

A microdeletion in 3p24.2 including a portion of the retinoic acid receptor beta (RARB) gene in a boy with autism spectrum disorder. *X. Li, K. Button, D. Witt.* Dept Genetics, Kaiser Permanente San Jose Medical Ctr, San Jose, CA.

Retinoid (vitamin A and its analogues) signaling is transduced by 2 families of nuclear receptors, retinoic acid receptor (RAR) and retinoid X receptor (RXR), which form RXR/RAR heterodimers. There are 3 retinoic acid receptors, alpha (RARA), beta (RARB), and gamma (RARG). Retinoid signaling is important in morphogenesis of the mammalian brain. Retinoid dysregulation has been implicated in the etiology of schizophrenia and other neuropsychiatric disorders. Here we report a microdeletion in 3p24.2 including a portion of the RARB gene in a boy with autism spectrum disorder. The patient is a 12 year male who resents with symptoms consistent with a diagnosis of Pervasive Developmental Disorder, Not Otherwise Specified (PDD-NOS). He has a history of normal developmental milestones but has always been extremely uncoordinated. He exhibits preoccupation with certain interests and objects. There has been a long history of significant delay in the development of peer relationships and reciprocal social interactions. He demonstrates little insight into typical social and peer relationships. He is high functioning intellectually (above age level in terms of verbal abilities) but his adaptive living skills are significantly delayed. Fragile X test was normal. Array comparative genomic hybridization (CGH) (Agilent/ISCA 8x60K) revealed an interstitial deletion of 967.08 Kb within band 3p24.2 at genomic coordinates chr3:4,543,416-25,510,500. The deleted region of 3p encompasses sequences between the THRB and RARB genes and a portion of the RARB including the 5'UTR and exons 1-2 (UCSC HG Build 18/ Ensembl). Parental array CGH studies showed the same deletion in the father. Father reports he has “dyslexia” and received special education and treatment for ADHD in childhood. There is likely a family history of ADHD in extended relatives. Clinical evaluation of the father has not been performed. Deletions of the RXRA gene at 9q34 have been suggested to be associated with schizophrenia. Studies have shown that retinoids are involved in controlling the function of the dopaminergic mesolimbic pathway and defects in retinoic acid signaling may contribute to autism and schizophrenia.

1279F

Design, validation and clinical routine implementation of custom a-CGH in the diagnosis of patients with psychomotor development delay and/or mild-severe mental retardation. *J. NEVADO[1,2], E. VALLESPIN[1,2], M. PALOMARES[1,2], M.A. MORI[1,2], S. GARCIA-MIÑAUR[1,2], F. SANTOS[1,2], F. GARCIA-SANTIAGO[1,2], E. MANSILLA[1,2], L. FERNANDEZ[1,2], A. DELICADO[1,2], P. LAPUNZINA[1,2].* 1) INGEMM (HULP), Madrid, Spain; 2) CIBERER, Madrid, Spain.

Background: The use of array-CGH in clinical routine is already a common practice in many countries. We report the design, validation and implementation for diagnostic of a custom genome-wide high resolution oligonucleotide aCGH-platform (KaryoArray® v3.0), for the study of patients with psychomotor development delay and/or mild to severe mental retardation. Methods: 1) For validation purposes we blindly tested 120 samples. Genomic imbalances had previously been detected in 62 of the 120 samples by karyotyping, FISH or MLPA. The remaining 50 samples were sexmatched samples from healthy individuals. 2) To implement this tool, a prospective study of 100 strictly selected patients (patients had: karyotype, molecular study of FRAXA and MLPA of subtelomere regions and recurrent-genomic-disorders done previously, with normal results) with psychomotor development delay and/or deficit cognitive were carried out. Results: Design was made selecting 60-mer oligonucleotide features from Agilent's eArray_v4.0 probe library in a custom format of 8x60K (KaryoArray®), covering more than 360 microdeleción/microduplicación syndromes, as well as telomeric/centromeric regions with a resolution from 1 kb in the regions of interest, with an average density of 7 Kb. The average density of the probe coverage is 43Kb. Interestingly within validation process, KaryoArray® reveals new genomic imbalances associated with well-defined disorders, such as trisomies and classical del/dup syndromes, in 9/62 cases. In addition, the implementation process identified at least one causal genomic imbalance responsible for its phenotype in ~30% of patients with psychomotor development delay and/or deficit cognitive. Conclusion: The implementation of KaryoArray® as the first-tier test in patients with unexplained development delay/intellectual disability and multiple congenital anomalies is cost-effective and offers a much higher diagnostic yield than karyotype and/or currently commercial platforms for this selected cohort of patients. In addition, this tool may it reveal that additional genomic imbalances could co-exist in patients with trisomies and classical del/dup syndromes, suggesting that chromosomal microarray analysis may also be also indicated in these individuals. Granted by Redes/FIBHULP08.

1280F

Clinical utility of metaphase FISH and/or chromosome studies following the identification of terminal or subcentromeric deletions identified by chromosomal microarray testing (CMA). *C.J. Packard, J.C. Hodge, N.L. Hoppman-Chaney, E.C. Thorland.* Lab Medicine and Pathology, Mayo Clinic, Rochester, MN.

CMA testing has emerged as a first-tier test for the diagnosis of patients with developmental delay/MR, autism, and multiple congenital anomalies. Current guidelines recommend confirmation of clinically relevant copy number changes (CNCs) by a second method (FISH, MLPA, QPCR, conventional chromosomes, etc.). Based on our confirmatory testing experience, primarily using FISH, our laboratory has never failed to confirm a CNC, calling into question the utility of additional testing purely for confirmatory purposes. However, CMA testing does not provide insight into the chromosomal structure or mechanism underlying an observed CNC. Therefore, additional follow-up testing by either metaphase FISH or conventional chromosome studies has clinical utility when an unbalanced translocation or inversion recombinant is suspected based on the observation of concurrent terminal deletions and duplications. Such rearrangements have significant recurrence risks if inherited from parents who are balanced rearrangement carriers. To address the utility of follow-up metaphase FISH or conventional chromosome studies in cases where terminal or subcentromeric deletions (deletions of array probes directly adjacent to the centromere) are observed, we reviewed the results of ~12,000 patients tested through clinical CMA studies. Of these ~12,000 studies, 137 apparently simple terminal deletions and 11 subcentromeric deletions were identified. Analysis of the follow-up studies performed in these cases demonstrated that 10/137 (7.3%) apparently simple terminal deletions identified by CMA testing were actually more complex chromosomal rearrangements with potentially significant recurrence risks. Of these 10 cases, 5 patients had an unbalanced translocation and 5 patients had a ring chromosome. In addition, 5/11 (45.5%) cases with a subcentromeric deletion demonstrated a more complex chromosomal rearrangement. Subcentromeric deletions of acrocentric chromosomes were more commonly associated with complex rearrangements (4/5 cases) as compared to non-acrocentric chromosomes (1/6 cases). In conclusion, the yield of additional metaphase FISH and/or conventional chromosomes studies to detect a more complex rearrangement justifies routine follow-up when CMA testing identifies terminal or subcentromeric deletions. However, confirmatory tests with methods that do not provide structural information (MLPA, QPCR, etc.) are largely unnecessary.

1281F

Identification of Genomic Copy Number Abnormalities Associated with Childhood Apraxia of Speech (CAS). *G. Raca[1], JJ. Laffin[1,2], GM. Rice[1,2,3], KJ. Jakielski[4], EA. Strand[5], LD. Shriberg[2,3].* 1) UW Cytogenetic Services, State Laboratory of Hygiene, Madison, WI; 2) University of Wisconsin-Madison, WI; 3) Waisman Center, Madison, WI; 4) Augustana College, Rock Island, IL; 5) Department of Neurology, Mayo Clinic, Rochester, MN.

Developmental speech-language disorders are a heterogeneous group of conditions that show high heritability, but very little is known about their genetic causes. We hypothesize that for a subset of patients with Childhood Apraxia of Speech (CAS) copy number abnormalities of speech-related genes could be responsible for the abnormal phenotype. Our study uses high resolution array comparative genomic hybridization (aCGH) analysis to identify novel chromosomal regions and candidate genes associated with CAS. Twenty-three phenotypically well-characterized patients with CAS were tested to date, using custom-designed high density oligonucleotide arrays (Roche NimbleGen Systems Inc., Madison, WI). These arrays provide increased coverage for the known apraxia-associated genomic regions (FOXP2, chromosomal regions 4q35.2, 16q23.2, and others), combined with a median interprobe distance of approximately 6kb for the rest of the genome. aCGH testing of the 23 patients detected one case with a 562-kb deletion of chromosome 16p11.2, with breakpoints at 29,537,669-30,099,8220 (NCBI Build 36.1; hg18). Microdeletions and microduplications of the 16p11.2 region were initially identified in patients with autism and autism related disorders, however, they were later shown to be associated with broad and variable phenotypes. Although non-specific speech and language delay has been described as a common clinical feature of the 16p11.2 deletion, we describe the first case of this deletion in a patient with a confirmed diagnosis of CAS. Evaluation by a speech pathologist may be warranted for all patients with 16p11.2 deletion, to determine if the associated speech delay meets the diagnostic criteria for CAS. Besides the 16p11.2 deletion, likely-pathogenic copy number changes were also observed at several candidate chromosomal regions, including 2p14, 2q24.1, 2q31.2, 5q35.1, 6p11.2p12.1, 12q24.23, 14q23.2 and 16p13.2. Our preliminary studies show that aCGH can detect deletions and duplications associated with CAS, and that genomic copy number abnormalities may play a role in susceptibility to this pediatric motor speech disorder.

1282F

Parallel Detection of Copy Number Variation and Loss of Heterozygosity with CGH Microarrays. *C. Shaw, J. Geoghegan, X. Zhang, E. Rorem, T. Richmond, D. Raterman, R. Selzer.* Roche NimbleGen, Inc, Madison, WI.

High resolution array CGH has been widely used to investigate DNA copy number variation (CNV) associated with complex disorders. Disease association studies have become increasingly focused on copy number variants (CNVs), and several recent reports show links between CNVs and schizophrenia, autism, and cancer, among others. However, many copy neutral events undetected by conventional array CGH, including copy number neutral loss of heterozygosity (LOH) and uniparental disomy (UPD), also contribute to disease phenotypes. Regions of the genome showing (LOH)are usually identified through the analysis of single nucleotide polymorphisms (SNPs). In normal samples, SNPs detected across the genome are randomly heterozygous or homozygous indicating that one copy of each chromosome was contributed by each parent. In contrast,only homozygous SNPs are detected in regions of LOH indicating that these regions were derived from only one parent. Until recently, cytogenetic research needing both high resolution, high quality copy number analysis and LOH detection required two separate array platforms. We use a combination microarray that detects both CNVs using standard CGH probes and LOH regions using probes that respond to common SNPs. Two probes are used to detect each SNP: one probe matches the reference genome and another probe matches a common SNP, similar to our comparative genomic sequencing platform for haploid organisms. Using our patented probe design strategy, the detection of over 700,000 common SNPs (MAF >0.3) were tested to ensure only the best responding probes were added to the array CGH/LOH designs. To accommodate the evolving field of disease association research, we also propose a method by which multiple design files with nested regions of interest and variable probe density can be used to extract only the desired data from a single array. This option allows for reanalysis of retrospective data as additional regions of interest in disease association research emerge, or as increased resolution in existing regions of interest is required. Data demonstrate high resolution and high sensitivity detection of both CNVs and LOH using a standard array CGH workflow. Samples with known regions of UPD were used to assess the performance of this new design with a resolution for detecting LOH at approximately 1 Mb.

Analysis of 24 Cell Lines of Mosaicism by The Affymetrix Genome-Wide Human SNP Array 6.0. *Z. TANG[1,2], N. Gerry[1], D. Berlin[1], A. MacMillan[1], M. Wineburg[1], B. Frederick[1], L. Toji[1], G. Toruner[2], C. Beiswanger[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) Institute of Genomic Medicine, UMDNJ-NJ Medical School, Newark, NJ.

Conventional cytogenetic technique, such as G-banded karyotyping, analyzes chromosomal changes within individual cells. Therefore, it can identify an underlying mosaicism without burden, provided that enough cells are analyzed, especially in low-level mosaicisms. An obvious disadvantage of this technique is that it is time-consuming. Newly developed molecular cytogenetic array-based techniques, e.g. array-based comparative genomic hybridization (aCGH), utilize DNA isolated from various types of specimen to explore the copy number variations (CNVs) throughout the whole genome. The current generation of arrays has a much higher resolution and shorter turnaround time compared to conventional cytogenetic technique, but their application for detection of mosaicism has not been validated. In this study, 24 cell lines of known mosaic status at levels of 6% to 81% as previously detected by G-banded karyotyping were tested by using the Affymetrix Genome-Wide Human SNP Array 6.0 (SNP array). The microarray results were analyzed by using the Chromosomal Analysis Suite (ChAS) software. Our analysis has yielded the following observations. 1. Although this SNP array is not designed for detection of mosaicism, 10 out of 24 cell lines have shown specific patterns of Allele Difference or SmoothSignal, indicating a presence of mosaicism; 2. The SNP array detected all CNVs that had been observed by karyotyping in each cell line; 3. In 6 cell lines, clinically relevant cryptic microdeletions or microduplications were detected by the SNP array only; 4. The SNP array results provided more accurate information about the breakpoints of all CNVs; 5. The SNP array detected one or more loss of heterozygosity larger than 5 Mb in 10 cell lines; 6. The SNP array results provided useful information for further investigation of abnormal chromosomes with additional material of unknown origin. In conclusion, the SNP array is a useful tool for the characterization of CNVs in cell lines, while the application of this technique for detection of mosaicism is still a challenge.

Chromosomal heterochromatic variations involved in reproductive failure. *D. MIERLA[1], V. STOIAN[2].* 1) Life Memorial Hospital, Bucharest , Romania; 2) University Bucharest, Faculty of BiologyBucharest , Romania.

BACKGROUND Cytogenetic heteromorphisms are described as heritable variations at specific chromosomal regions without a proven impact on phenotype. The purpose of this study was to investigate the effects of chromosomal polymorphic variations involved in reproductive failure. We have studied the heterochromatic region polymorphism and pericentric inversions in infertile couple. METHODS During the period from January 2008 to April 2011, 1809 infertile patients who had received in our hospital, were investigate for this retrospective study, and the frequency of chromosomal polymorphic variations was calculated. The control group consists of 1116 fetuses investigated by amniocentesis between January 2009 and April 2011. Chromosomes from cultured peripheral blood lymphocytes and amniotic fluid were analyzed using GiemsaTrypsin-Giemsa (GTG) banding. The results of the two groups were compared. RESULTS Of 1809 infertile people were submitted for cytogenetic investigation 92.53% had normal karyotype and 7.47% showed chromosome polymorphisms, in the control group while the incidence was 94.17%(normal karyotype) and 5.82% (chromosome polymorphisms). CONCLUSIONS Chromosomal polymorphic variations appear to have no adverse effects phenotypic nor clinical, nor of any apparent association with fetal wastag. The statistically significantly higher incidence of heterochromatic variations found in infertile individuals stresses on the need to evaluate their role in infertility and subfertility.

Genome-Wide Analysis of Genomic Stability in Human Induced Pluripotent Stem Cells (iPSCs). *D.S. Berlin[1], M. Bucan[2], R. Allen[1], A. MacMillan[1], N.P. Gerry[1], Z. Tang[1], M.A. Keller[1,3], C. Tarn[1], K. Fecenko-Tacka[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) University of Pennsylvania, Philadelphia, PA; 3) American Red Cross, Philadelphia, PA.

The NIGMS Human Genetic Cell Repository at the Coriell Institute for Medical Research recently began offering human iPSCs to the biomedical research community. These iPSC lines, generated by multiple investigators worldwide, are expanded and characterized at Coriell prior to distribution through our online catalog (www.ccr.coriell.org). Recently, several publications have shown that both embryonic stem cells and human iPSCs are susceptible to genomic instability. We hypothesized that the number of chromosomal aberrations (either gross aberrations detectable by karyotyping, or copy number variations detectable by chromosomal microarray analysis) would increase with increased cell passaging. We evaluated the chromosomal integrity of two human iPSC lines submitted to the NIGMS Repository by testing the lines at three time points representing different cell passage numbers. For each subject, the fibroblast cell line from which the iPSCs were derived was used as a reference. G-banded karyotyping was performed on the parental fibroblasts and in the iPSC lines at 3 time points. Initial analysis of one iPSC line showed a normal 46,XY karotype at early passage, and mosaicism for an additional Y chromosome (47,XYY[6]/46,XY[19]) after 8 additional passages. All cells analyzed after 12 more passages had an extra chromosome Y chromosome and a derivative X chromosome that most likely resulted from a translocation between chromosomes X and 7 (47,der(X)t(X;7)(p22.1;p13),YY). Fluorescence *in situ* hybridization (FISH) is being employed to further investigate the chromosomal stability of these cells. Additionally, fibroblast- and iPSC-derived genomic DNA is being genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0 platform. The genotyping data will be analyzed using a suite of CNV-calling algorithms. We will present chromosomal microarray and karyotyping data as they pertain to assessing iPSC genomic stability in a biobank setting.

1286F

Shorter telomeres on chromosome 1 demonstrated in 11 older individuals with mild cognitive impairment and Down syndrome using linear measurements in microns. *E. Jenkins[1], L. Ye[1], S. Krinsky-McHale[2], W. Zigman[2], N. Schupf[3, 4], W. Silverman[5, 6].* 1) Dept Hum Genetics, NYS Inst Basic Res Dev Disab, Staten Island, NY; 2) Department of Psychology, NYS Inst Basic Res Dev Disab, Staten Island, NY; 3) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 4) Departments of Epidemiology and Psychology, Columbia University, New York; 5) The Department of Behavioral Psychology, Kennedy-Krieger Institute, Baltimore, MD; 6) Department of Psychiatry and Behavioral Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

We have reported previously that people with Down syndrome(DS) and dementia or mild cognitive impairment (MCI) have shorter telomeres (chromosome ends with highly conserved TTAGGG repeats) than their healthy age- and sex-matched peers (Jenkins et al., 2006, 2008a, http://www.ashg.org/cgi-bin/2010/ashg10s), using quantitative light intensity analyses (MetaSystems) of PNA FISH telomere probes. Since our last report, we have studied an additional 11 individuals with MCI/DS who exhibited greater loss of PNA telomere probe signals than their sex- and age-matched peers (Jenkins et al., 2008b). We now have a total of 15 individuals, thereby increasing the strength of evidence that reduced telomere size and signal number are biomarkers for the detection of MCI in older individuals with DS. We have recently identified a “new” measure that allows comparison of telomere length in microns and have found shorter chromosome 1 telomere physical lengths in short-term T lymphocyte cultures from 11/11 individuals with MCI ($p < 10\text{-}6$), versus 11 sex- and age-matched cognitively healthy peers. Importantly, there were no overlaps between telomere lengths from people with MCI versus peer controls with DS using this method of measurement, suggesting that it may be particularly useful for verifying clinical status. We also found that the time needed to measure chromosome 1 telomeres in microns was comparable to, or even slightly less than the other methods that we have been using to quantify telomere length. This indicates that linear length measurement is as practical as other alternatives with the possible exception of interphase measurements that have required significantly less time to find and upload versus whole metaphases. It should be mentioned that it is theoretically possible to use either a fluorescence or bright-field microscope without expensive software to obtain both linear measurements and signal counts. In conclusion, we have now established that shorter as well as “missing” telomeres can be used as a biomarker for MCI in people with DS, and that current techniques providing direct linear measurements of telomere length can be completed as rapidly as alternative measures and may provide better differentiation among individuals varying in dementia status(MCI, dementia or their absence). Background: Chromosomal abnormalities are found in 7.7% to 10% of newborns with eye anomalies associated with other malformations. Introduction of array technologies has revealed that rearrangements below the resolution of standard or high resolution karyotyping are exceedingly common.

Objective: Sixty five patients with unexplained ocular developmental anomalies associated to another congenital malformation and/or mental retardation were analyzed using oligonucleotide array-CGH (Agilent).

Results: In 4 patients, clinically relevant deletions encompassing genes already known to be involved in eye development (*FOXC1* and *OTX2*) were identified. In 4 other patients we found pathogenic deletions not classically associated with abnormal eye morphogenesis: del(17)(p13.3p13.3), del(10)(p14p15.3) and del(16)(p11.2p11.2). We also detected two additional copy number variations of uncertain pathogenicity. Rearranged segments ranged in size from 0.11 to 5.57 Mb.

Conclusion: These results show that array-CGH provides a high diagnostic yield in patients with syndromal ocular developmental anomalies and point to novel chromosomal regions associated with these conditions. Besides their importance for diagnosis and genetic counseling, these data may pave the way to the identification of genes involved in eye development.

1288F

De Novo Intrachromosomal Xp22 Deletion and Xq28 Duplication including HCCS and MECP2 in a Female with Microphthalmia, Glaucoma, Cataracts, Cleft Palate, Seizures and Global Developmental Delay. *I.E. Amarillo[1], B.F. Crandall[2], P.N. Rao[1], F. Quintero-Rivera[1].* 1) Clinical Cytogenetics Lab, Dept of Pathology and Lab Medicine, UCLA, Los Angeles, CA; 2) UCLA Prenatal Diagnosis Center, Los Angeles, CA.

X-chromosome rearrangements are the underlying cause of many human genetic disorders. In females, clinical manifestations of a X-linked disorder are complicated by skewed inactivation of the X-chromosome. Here we report on a 16-year old female followed since birth, due to congenital bilateral microphthalmia, glaucoma, cataract and nystagmus(Peter's anomaly), height and head circumference between 5-10% centile, dysmorphic features with preauricular pits, rolled helices and prominent antihelices, short and broad neck, hypomelanosis of Ito all over the body, except on the face, complex partial seizures, pituitary insufficiency with hypothyroidism and growth hormone deficiency, ventricular tachycardia, and global developmental delay. Standard chromosome studies identified extra chromosomal material of unknown origin at Xp22 leading to a terminal deletion which extended distally, from the STS (Xp22.3) locus to the Xpter. Further characterization by chromosomal microarray analysis not only fine-mapped the deletion breakpoints (12.7 Mb; Xp22.2-p22.33; 109805-12859892 hg18; 49 RefSeq genes) but also identified the unknown material as an extra copy of Xq27.2-q28 region (13.2 Mb; 141297566-154582680 hg18;123 RefSeq genes), as confirmed by metaphase FISH. Parental karyotyping and FISH analyses are normal. X-inactivation studies are ongoing. Patients with Xq28 duplication involving MECP2 , usually present with a Rett syndrome variant phenotype with preserved speech variant , infantile hypotonia, severe mental retardation, progressive spasticity, recurrent respiratory infections, progressive cerebellar degenerative changes and seizures. Patients with Xp deletions involving the STS locus and the telomeric adjacent genes present with short stature and some degree of skeletal abnormalities and learning disability. In addition, HCCS (Xp22.2) associated with micropthalmia with linear skin defects, MLS syndrome, an X-linked dominant trait with male lethality, is also deleted in our patient. To our knowledge, this is the first report of a female patient with concomitant Xp22 microdeletion and Xq28 microduplication. The data presented here highlights not only the importance of metaphase FISH post-microarray results but also improves our understanding of the phenotype of female patients with such chromosomal rearrangements. Finally, these findings provide insights in the genetic counseling of patients with X-linked aberrations.

1289F

Rapid screening of people exposed to ionizing radiation for cytomolecular alteration de novo. *S. Moosavi[1], S. Shabani[1], M. Tondar[1], F. Mojtahedi[1], Z. Ghanbari[1], H. Dargahi[2], F. Heshmati[3].* 1) AST Cytomolecular Diaprognostic Lab, Department of Allied Health, Tehran University of Medical Science (TUMS), Tehran, Iran; 2) Department of Allied Health, Tehran University of Medical Science (TUMS), Tehran, Iran; 3) Department of Laboratory Science, Tehran University of Medical Science (TUMS), Tehran, Iran.

Energy released from ionizing radiation is a source for treat and remove tumors. It also can ironically be the most important etiologic factor in activating proto oncogenes deactivating tumor suppressor gene as well as malfunctioning DNA repair systems leading to quantitative and qualitative aberrations in cell chromosomes. Prompt chromosomal analysis of tissues exposed to radiation is a crucial factor in identifying and prognosing tumor and subsequently in effective treatment and control of tumorigenesis and metastasis. Thus, a rapid cytomolecular screening test with high sensitivity and specificity could be very fruitful to study chromosomal radiosensitivity. 38 PB samples were analyzed at G2 phase using solid-staining chromosomal banding and whole chromosomal painting FISH. Of 38 samples, 14 had 10 % or more various structural aberrations in lymphocytic chromosomes, 8 had 4-8 %, and rest had no structural aberration. We have tested samples with chromosomal breakages by whole chromosomes painting FISH for reconfirmation, but we only obtained numerical information through this technique. Nonetheless, significant relation ($p < 0.05$) existed between duration of radiation exposure and number of aberration in chromosomes. This suggests that longer duration of exposure (>2years) could have profound effect on structure of chromosomes which can be detected efficiently by solid-staining chromosomal banding and whole chromosomal painting FISH.

1290F

Phenylbutyrate therapy for pyruvate dehydrogenase deficiency. *R. Ferriero[1], E. Lamantea[2], B. Lee[3,4], M. Zeviani[2], N. Brunetti-Pierri[1,5].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Besta Neurologic Institute, Milan, Italy; 3) Dept. Molecular and Human Genetics, Baylor College of Medicine, Houston,TX; 4) Howard Hughes Medical Institute, Baylor College of Medicine, Houston,TX; 5) Dept. Pediatrics, Federico II University of Naples, Italy.

Deficiency of pyruvate dehydrogenase complex (PDHC) is the most common disorder leading to lactic acidemia. Phosphorylation of specific serine residues of the E1-alpha subunit of the PDHC by pyruvate dehydrogenase kinase (PDK) inactivates the enzyme, whereas dephosphorylation restores PDHC activity. We recently found that phenylbutyrate prevents phosphorylation of the E1-alpha subunit of the branched-chain ketoacid dehydrogenase complex (BCKDC) and reduces plasma concentrations of neurotoxic branched chain amino acids in patients with maple syrup urine disease (MSUD), due to the deficiency of BCKDC. We hypothesized that, similarly to BCKDC, phenylbutyrate enhances PDHC enzymatic activity by increasing the portion of unphosphorylated enzyme. To test this hypothesis, we treated wild-type human fibroblasts at different concentrations of phenylbutyrate and found that it reduces the levels of phosphorylated E1-alpha as compared to untreated cells. To investigate the effect of phenylbutyrate in vivo, we administered phenylbutyrate to C57B6 wild-type mice and we detected a significant increase in Pdhc enzyme activity and a reduction of phosphorylated E1-alpha subunit in brains and muscles as compared to saline treated mice. Being a drug already approved for human use, phenylbutyrate has great potential for increasing the residual enzymatic activity of PDHC and to improve the clinical phenotype of PDHC deficiency.

1291F

Novel mutations in the GCDH gene. *F. Ghasemi[1], O. Aryani[1], M. Houshmand[1,2].* 1) Special Medical Center, Tehran, Iran; 2) National Institute for Genetic Engineering & Biotechnology, Tehran, Iran.

Glutaric aciduria type I (GA-1) is an autosomal recessive disorder caused by a deficiency of glutaryl-CoA dehydrogenase(GCDH), a mitochondrial enzyme involved in the catabolism pathway of lysine, hydroxylysine and tryptophan. It results in elevation of glutaric acid and related metabolites in blood and urine . Affected patients often present with macrocephaly at birth or shortly after, dystonia, many times resembling seizures at the first episode, with acute basal ganglia injury.The GCDH gene has been mapped to chromosome 19p13. More than 150 GCDH gene mutations have been reported in populations around the world. The aim of this study was the mutational analyses of the GCDH gene in the patients with GA-1. These were carried out on five Iranian unrelated GA-1 patients by PCR and sequencing all 11 exons and the exon/intron borders of the GCDH gene. Homozygote mutations were found in all patients. Two have been reported in the literature previously as follows: c.541G > C (p.E181Q) and c.1205G>A (p.R402Q). Two patients had the first mutation. The other alterations have not been reported before. One was a T to C transition (c.536T>C) in exon 6, causing a leucine at position 179 to be changed to a proline (p.L179P) . Another was leucine substituted by phenylalanine at position 302 (p.L302F) due to a C to T transition (c.904C>T) in exon 8. Both parents of the patients having these novel changes were heterozygote . These two mutations were not found in 50 control subjects. It is thought these novel mutations disrupt the protein structure and were the cause of GA-1.

1292F

Comparison of expression profiles of children born before and after maternal bariatric biliopancreatic diversion surgery. *F. Guenard[1, 2], P. Marceau[3], K. Cianflone[4], Y. Deshaies[4], J.G. Kral[5], M.-C. Vohl[1, 2].* 1) Institute of Nutraceuticals and Functional Foods (INAF), Laval University, Quebec, PQ, Canada; 2) Department of Food Science and Nutrition, Laval University, Quebec, PQ, Canada; 3) Department of Medicine and Laval Hospital Research Center (IUCPQ), Quebec, PQ, Canada; 4) Department of Surgery, Faculty of Medicine, Laval University, Quebec, PQ, Canada; 5) Department of Surgery, State University of New York Downstate Medical Center, Brooklyn, New York, USA.

Obesity is increasing rapidly in children and adolescents worldwide. Parental obesity contributes substantially through genetic and environmental influences. Gestational obesity and diabetes mellitus predispose offspring to lifelong obesity and its comorbidities. We demonstrated that children born after maternal surgical (AMS) weight loss were less obese and exhibited improved cardiometabolic risk profiles compared to their siblings born before maternal surgery (BMS). This study correlates childrens' mRNA expression levels in peripheral blood mononuclear cells (PBMCs) and pathway regulation with their mother's pre- and postoperative status. A cohort of 25 BMS and 21 AMS children and their 20 different mothers was recruited. Fasting plasma glucose, insulin and lipid levels and other phenotypic differences between BMS and AMS children were measured. Expression analysis in PBMCs was conducted using the Illumina HumanHT-12 v4 Expression BeadChip. The FlexArray software and Lumi algorithm were used for expression data analysis and normalization. The SAM algorithm was used to assess differences between AMS children and BMS children. The Ingenuity Pathway Analysis System was used to visualize gene expression and biological pathways to identify potentially altered biological functions. Lower fasting insulin levels were found in AMS compared to BMS children ($p = 0.02$). Whole-genome mRNA expression analysis identified more than 600 transcripts differentially expressed in AMS compared to BMS children ($p \leq 0.05$; fold change: ≥ 1.2 or ≤ 0.83). Pathway analyses revealed that differentially expressed genes were associated with cell development, cell growth and proliferation, cellular function and maintenance, cell-to-cell signaling and interaction, inflammatory response, immune cell trafficking and cell-mediated immune response. Our study demonstrates an impact of maternal weight loss on insulin levels and gene expression profiles, which may partially explain the lower prevalence of obesity and improved cardiometabolic risk profile in children born after maternal weight-loss surgery.

1293F

Accuracy of diagnostic tests in Niemann-Pick type C disease. *R. Hartung, H. Runz, M. Beck, E. Mengel.* Childrens Hospital, University Medical Center Mainz, Mainz, Germany.

Background Niemann-Pick Disease Type C (NPC) is a lysosomal storage disorder caused by an intracellular transport defect. A mutation in one of the 2 genes (NPC1/NPC2) is leading to a progressive accumulation of cholesterols and glycolipids. Clinically patients are suffering from hepatosplenomegaly, supranuclear gaze palsy and neurodegeneration with an onset between 0 and >60 years. Due to the lack of one accurate diagnostic test it is suspected that a large number of un-/misdiagnosed patients is existing. Aim of this study is to evaluate the accuracy of specific tests to find an optimal diagnostic pathway. Methods We analyzed the data of 40 unrelated patients regarding Splenomegaly, Supranuclear gaze palsy, Chitotriosidase, Filipin Staining, Bone marrow biopsy and Genetic mutations in the NPC1 and NPC2 gene by direct sequenzing. Pathological values are: Splenomegaly: >2 Standard deviations Supranuclear gaze palsy: saccadic eye movement or gaze palsy Chitotriosidase: >200 mU/ml (>100 mU/ml with heterozygous mutation in the Chito1-Gene) Filipin Staining (Cholesterolaccumulation in fibroblasts): classic or variant Bone marrow biopsy: Confirmation of Foam cells Genetic mutation: 2 mutations (1 mutation undefinite, cannot be evaluated without clinical symptoms) Results Splenomegaly (35 pat): 34 (97 %) pathological, 1 (3 %) normal Supranuclear gaze palsy (28 pat): 22 (79 %) pathological, 6 (21 %) normal Chitotriosidase (38 pat): 30 (79 %) elevated, 5 (13 %) not significant elevated, 3 (8 %) unevaluable due to a homozygous mutation in the Chito1-Gene Filipin Staining (25 pat): 25 (100 %) pathological; 20 (80 %) classic, 5 (20 %) variant Bone marrow biopsy (15 pat): 14 (93 %) pathological, 1 (7 %) normal Genetic mutation (29 pat): 21 (72 %) pathological (2 mutations), 4 (14 %) undefinite (1 mutation), 4 (14 %) no mutation detected Conclusions Of the different diagnostic tests the Filipin staining showed the best accuracy. All patients had a pathological result. But it should be taken into account that a variant staining can exist in other LSDs or after longer cultivation of fibroblasts. A negative Filipin test excludes NPC. The splenomegaly is to evaluate similar. The bone marrow biopsy shows Foam cells with high accuracy, but due to the invasive nature of the test it was often performed in inconclusive cases. So a selection bias cannot be excluded. The often proposed mutation analysis could give a definite result in 72 % only.

1294F

Mutation screening of two genes involved in intracellular Vitamin B_{12} metabolism genes by high resolution melting analysis (HRMA). *M.L. Illson[1], Q. Huang[2], L. Dempsy Nunez[1], A. Brebner[3], B.M. Gilfix[4], D. Watkins[1], D.S. Rosenblatt[1], C.T. Wittwer[5].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Biomedical Sciences, School of Life Sciences, Xiamen University, Xiamen, Fujian, China; 3) Department of Biology, McGill University, Montreal, Canada; 4) Division of Medical Biochemistry, Royal Victoria Hospital and McGill University, Montreal, Canada; 5) Department of Pathology, University of Utah Medical Center, Salt Lake City, UT USA.

Intracellular vitamin B_{12} (cobalamin) transport and metabolism require the products of at least 10 genes. Some of the inherited diseases involving the cobalamin pathway cannot be distinguished through simple biochemical assays. Time consuming and expensive testing methods such as somatic cell studies and sequencing have traditionally been used for precise diagnosis. HRMA was tested as an alternative screen to identify variants in the cobalamin pathway: *MMACHC*, responsible for the *cblC* disorder and *MUT*, responsible for classic methylmalonic aciduria. A total of 16 coding exons and flanking introns were amplified by PCR (fragments sizes 145-359 bps) and melted in the presence of a saturating dye. Screening of 96 normal DNA samples revealed 6 common polymorphisms, and confirmed that melting curves (max. 4 melting domains) were accurately predicted by uMelt^{SM} and uView^{SM}, (http://www.dna.utah.edu/). A blinded study of 197 whole genome amplified (WGA) patient samples compared HRMA results to sequencing. Melting after PCR identified all heterozygous variants. While homozygotes could be detected in exons containing multiple domains, single domain exons required mixing with known PCR products before re-melting. 241 heterozygous (114 different) and 69 homozygous (48 different) mutations were found. The sensitivity and specificity of variant detection by melting were both >99%. Errors were either clerical or resulted from allele bias secondary to WGA. Unlabeled probes and snapback primers were used to genotype common variants. Batch analysis (many samples, one exon) was easier to interpret than patient-centric analysis (fewer samples, many exons), although both were successful. Having demonstrated the efficacy of HRMA for the recessively inherited genes of the B_{12} pathway, 16 additional coding exons and flanking introns have been optimized for two genes implicated in vitamin B_{12}-responsive methylmalonic aciduria- *MMAA* and *MMAB* (fragments sizes 131-357 bps). Screening of 96 normal DNA samples confirmed melting curve predictions and revealed 5 common polymorphisms. HRMA provides a cost effective, simple and rapid screening method facilitating clinical diagnosis of overlapping phenotypes for genes in the vitamin B_{12} pathway.

1295F

Methylenetetrahydrofolate reductase and methionine synthase reductase deficiency affect behaviour and alter choline metabolism in cerebellum and hippocampus of mice. *N.M. Jadavji[1], L. Deng[1], O. Malysheva[2], M.A. Caudill[2], R. Rozen[1].* 1) Departments of Human Genetics and Paediatrics, McGill University, Montreal, Canada; 2) Division of Nutritional Sciences, Cornell University, Ithaca, NY.

Homocystinuria, an inborn error of homocysteine metabolism, can be caused by mutations in methylenetetrahydrofolate reductase (MTHFR) or methionine synthase reductase (MTRR). MTHFR generates 5-methyltetrahydrofolate, the methyl donor in the remethylation of homocysteine to methionine by methionine synthase. MTRR is involved in maintaining methionine synthase in its active state. Betaine, a metabolite of choline, serves as an alternate methyl donor for homocysteine remethylation, particularly when folate metabolism is disrupted. Since individuals with homocystinuria present with gait and motor abnormalities, mental retardation, seizures, as well as severe developmental delays, we investigated the effects of MTHFR or MTRR deficiency on behaviour and neurobiology of the cerebellum and hippocampus in adult mice. Male mice of 3 genotypes for Mthfr and Mtrr (+/+, +/-, -/-) were tested on motor, anxiety, exploratory and cognitive tasks. Global DNA methylation in cerebellum was measured using thin layer chromatography. Choline acetyltransferase (ChAT) immunoreactive protein and choline metabolites were assessed in cerebellum and hippocampus. Mthfr-/- and Mtrr-/- animals exhibited impaired gait, decreased anxiety, increased exploratory behaviour and impairments in short-term memory. Mthfr-/- and Mtrr-/- mice also had decreased global DNA methylation in cerebellum, and increased protein levels of ChAT in cerebellum and hippocampus. Choline metabolite analysis revealed decreased levels of acetylcholine and betaine in hippocampus of Mthfr-/- and Mtrr-/- animals. Mthfr-/- animals also had decreased levels of betaine in cerebellum and Mtrr-/- animals had decreased levels of choline in cerebellum and hippocampus. Our results suggest that behavioural and biochemical anomalies in these forms of homocystinuria may be due to altered methylation or compensatory disturbances in choline metabolism, and highlight the important role of MTHFR and MTRR in brain development, maturation and normal function. Supported by: Canadian Institutes of Health Research.

1296F

Spatial and temporal characterization of Single Minded 1 (*SIM1*) enhancers. *M.J. Kim[1,2], C. Vaisse[3], N. Ahituv[1,2].* 1) Department of Bioengineering and Therapeutic Sciences, UCSF, San Francisco, CA, USA; 2) Institute for Human Genetics, UCSF, San Francisco, CA, USA; 3) Diabetes Center and Department of Medicine, UCSF, San Francisco, CA, USA.

Obesity leads to an increased risk for a variety of health issues, most notably cardiovascular disease, type 2 diabetes, cancer, arthritis, sleep apnea and liver disease. The Single Minded 1 (*SIM1*) gene is involved in the development of the paraventricular and supraoptic nuclei of the hypothalamus, both regions having essential roles in regulating food intake. In addition, *SIM1* was shown to be important for the long-term regulation of energy homeostasis in adult mice. Rare coding mutations in *SIM1* have been found to be more prevalent in severely obese individuals than in lean controls. In addition, haploinsufficiency of *SIM1* in both humans and mice leads to severe obesity, suggesting that altered expression of *SIM1* by way of regulatory elements, such as enhancers, can also predispose individuals to obesity. To further explore the role of *SIM1* regulatory elements in obesity susceptibility, we have used comparative genomics and an *in vivo* transgenic enhancer assay in zebrafish to identify and characterize noncoding enhancers in the *SIM1* genomic region in a spatial and temporal manner. Of the eighteen tested sequences, three were found to have hypothalamus-specific enhancer activity. Due to the dual role of *SIM1* in hypothalamus development and in adult energy homeostasis, the activity of these three enhancers was annotated from embryonic to adult age. We observed that the tissue-specific enhancer activity of these enhancers changed over time, suggesting that the developmental and physiological expression of *SIM1* may be regulated by different enhancer elements. Combined, these results provide candidate gene regulatory sequences in which nucleotide variation in humans could lead to obesity susceptibility and demonstrate that enhancers can change their spatial activity over time.

Ethylmalonic encephalopathy: case report of a long-surviving patient with a mild course and atypical neurologic presentation. *A. Kwan[1], T.M. Cowan[1], K. Cusmano-Ozog[1], P. Rinaldo[3], V. Tiranti[2], G.E. Enns[1].* 1) Dept Pediatrics, Stanford Univ Med Sch, Stanford, CA; 2) Unit of Molecular Neurogenetics IRCCS Foundation Neurological Institute “C.Besta”, Milano, Italy; 3) Dept Laboratory Medicine and Pathology, Biochemical Genetics Laboratory, Mayo Clinic College of Medicine.

Ethylmalonic encephalopathy (EE) is a rare, recessive metabolic disorder with characteristic biochemical findings, MRI abnormalities and mutations in the ETHE1 gene at 19q13. Typical clinical features include chronic diarrhea, petechiae, orthostatic acrocyanosis and neurologic symptoms which present within the first year of life. The majority of patients have severe developmental delay with death in early childhood in over half of cases reported. We present a patient who is still alive at 27 years. She had chronic diarrhea in childhood. Acrocyanosis was noted at 5 years. Neurologic symptoms did not present until 10-12 years of age with complaints of headaches. At 16, she was noted to have decreased strength in her lower extremities, poor coordination, spasticity, brisks reflexes and a positive Babinski sign. Early gross motor milestones were normal but fine motor skills and language were delayed. IQ was 58 at the age of 7 years. She completed high school in special education. MRIs at 10 and 14 years were normal. Biochemical findings included elevated pyruvate, ethylmalonic acid, glutaric acid, methylsuccinic acid and butyrylglycine in urine organic acids. Acylcarnitine profile showed elevations of C4, C5, C8, and C10. She has a homozygous deletion of the entire ETHE1 gene. We present the oldest living patient with EE and propose that the phenotypic spectrum of EE may be wider than previously described. We recommend that the diagnosis be considered, and mutation analysis performed, in any patient with chronic diarrhea, acrocyanosis, developmental delay and later onset neurologic symptoms, especially if characteristic biochemical findings are present.

1298F

Infantile sialic acid storage disease: Two unrelated Inuit cases homozygous for a common novel *SLC17A5* mutation. *MA. Lines[1], T. Rupar[2], B. Baskin[3], P. Ray[3], D. Grynspan[1], J. Michaud[1], MT. Geraghty[1].* 1) Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Child and Parent Resource Institute, London, Canada; 3) The Hospital for Sick Children, Toronto, Canada.

Infantile Sialic Acid Storage Disease (ISSD) is a clinically severe lysosomal storage disease characterised by accumulation of free sialic acid in multiple tissues. ISSD is allelic with Salla disease, a nonlethal, primarily neurological disorder; the gene for both conditions, *SLC17A5*, encodes an anionic monosaccharide transporter. Salla disease is common in Finland due to the presence of a specific Finnish founder mutation. Other mutations of *SLC17A5* have been described in ISSD patients from a variety of ancestral populations. Here, we describe particulars of two cases of ISSD detected in the Inuit. Both patients presented with nonimmune fetal hydrops and proceeded to follow a severe, rapidly fatal perinatal course despite maximal supportive treatment. Autopsy confirmed a picture of widespread lysosomal storage, with deposition of material negative for Oil-Red-O and Periodic Acid-Schiff stains in multiple tissues from both children. Enzymatic studies showed a marked (tenfold), unexplained, increase in sialidase activity, with lesser elevations in the activities of several other lysosomal enzymes. *SLC17A5* sequencing showed both children, whose parents were unrelated and non-consanguineous, to be homozygous for a novel mutation (c.526-2A>G) situated within the splice acceptor site of exon 4. RT-PCR studies showed skipping of exon 4, predicted to result in a loss of reading frame. As far as we are aware, these constitute the first reported cases of ISSD amongst the Inuit, raising the question of a common founder mutation in this population. Furthermore, if confirmed in further ISSD cases, the marked induction of sialidase activity seen here may prove useful in the clinical diagnosis of this condition.

1299F

Atypical presentations - Fabry disease in a 12 year old female and 55 year old male. *J. MacKenzie[1,4], I. Young[2,4], A. Jin[3,4], J. Garland[3,4], M.T. Geraghty[1,5].* 1) Dept Pediatrics, Kingston General Hosp, Kingston, ON; 2) Dept Pathology, Kingston General Hosp, Kingston, ON; 3) Dept Medicine, Kingston General Hosp, Kingston, ON; 4) Queens University, Kingston, ON; 5) Dept Pediatrics, CHEO, University of Ottawa, ON, Canada.

Fabry disease, due to the deficiency of alpha galactosidase A, results in the accumulation of globotriaosylceramide throughout the body. The clinical presentation includes onset of acroparesthesias, hypohydrosis, angiokeratomas, proteinuria, and abdominal symptoms in childhood or adolescence which progresses to accelerated kidney function decline, cardiac decompensation and neurologic involvement by the third to fifth decade in males. Due to variable X inactivation, females typically have milder disease although some can present with features indistinguishable from males. The average delay in diagnosis is at least 10 years from presentation in spite of patients accessing numerous physicians. First, we report a 12 year old female referred for corneal verticillata found at a routine optometry exam. Although healthy, her activities had been limited by pain in her extremities characterized as intense and burning, exacerbated by heat, cold and intercurrent illness. On examination, angiokeratomas were noted on the right leg and buttock in a linear distribution attributed to trauma 2 years previously. Her mother was asymptomatic except for corneal findings similar to her daughter. Alpha galactosidase A activity was 2 per cent in both and a c.680G>A (p.Arg227Gln) mutation was identified in GLA. Monitoring of renal and cardiac function and MRI have been normal in both over 2 years without enzyme replacement. Second we describe, a 55 yr old male presented to an inherited arrhythmia clinic with left sided hypertrophic cardiomyopathy. He had a brother with the same finding. A cardiomyopathy gene panel revealed a c.729G>C (p.Leu243Phe) change in GLA and 1 per cent residual enzyme activity in the patient. At evaluation, he was on hemodialysis for 3 years, had unexplained acroparasthesias in his hands and feet since 13 years of age, hypohydrosis, and episodes of expressive aphasia. A renal biopsy demonstrated ultrastructural findings diagnostic of Fabry disease. These two cases highlight diverse presentations of Fabry disease and the delay in diagnosis often seen with genetic conditions. This is increasingly relevant with the development of specific therapy. This challenges educators to adopt learning strategies that focus on problem solving and the development of metacognitive learning skills as opposed to recall of distinct rare disorders. By reducing the interval from presentation to intervention, we can reach our ultimate goal of improving health outcomes.

1300F

Transdifferentiation of Patient Fibroblasts for the Study of Tissue Specific Mitochondrial Respiratory Chain Disorders. *M. Menezes[1,2], L. Riley[1], S. Cooper[2,3], D. Thorburn[4], J. Christodoulou[1,2].* 1) Genetic Metabolic Disorders Research Unit, Western Sydney Genetics Program, The Children's Hospital at Westmead , Sydney, NSW, Australia; 2) Discipline of Paediatrics & Child Health, Faculty of Medicine, University of Sydney, Sydney, NSW, Australia; 3) Neuromuscular Research Institute, The Children's Hospital at Westmead, Sydney, NSW, Australia; 4) Mitochondrial Disorders Research Unit, Murdoch Childrens Research Institute, Royal Children's Hospital, Melbourne, Victoria, Australia.

Mitochondrial respiratory chain (RC) disorders are among the most common inborn errors of metabolism with an estimated incidence of 1 in 5000 births. Diagnosis usually relies on detection of altered activities of one or more of the RC complexes. However tissue specific expression of enzymatic defects, where RC enzyme deficiencies can be detected in muscle or liver but do not manifest in fibroblasts, complicates diagnosis. For patients with muscle specific RC defects, transdifferentiation of patient fibroblasts into muscle cells using a MyoD lentiviral vector could improve the accuracy and usefulness of genetic counselling, and potentially facilitate prenatal testing. Previously we identified a novel pathogenic mutation (c.156C>G; p.F52L) in YARS2, in a family with two children affected by myopathy, lactic acidosis and sideroblastic anemia (MLASA). YARS2 encodes mitochondrial tyrosyl tRNA-synthetase. The YARS2 defect, which leads to decreased mitochondrial protein synthesis and RC dysfunction, was a classic example of tissue-specific manifestation of mitochondrial RC dysfunction. We investigated the applicability of MyoD-mediated myogenesis of cultured fibroblasts from two YARS2 mutant RC patients and age-matched controls with normal fibroblast RC enzyme function. Enzymatic analysis of MyoD-derived myotubes revealed a significant reduction in patient complex IV enzyme activity, compared with the non-diseased controls, whereas results in patient fibroblasts were equivocal. Moreover, analysis of the five RC complexes by Western blot demonstrated a distinct reduction in the protein levels of complexes I and IV in patient myotubes compared with the non-diseased samples. We subsequently screened a cohort of patients with a similar phenotype, which led to identification of another three patients with different YARS2 variations. For the additional YARS2 variations, recombinant proteins have been produced and dimerization and aminoacylation activity of YARS2 is being investigated. RC enzyme assays will be performed on MyoD derived myotubes from these additional patients to study whether unmasking can be achieved in other patients. Our study will establish whether in vitro myogenesis of fibroblasts has broad application for diagnosis of mitochondrial RC dysfunction, and provides crucial insight into the basis for tissue-specific manifestation of mitochondrial RC disorders.

1301F

A new patient with the cblD cobalamin disorder presenting with high homocysteine. *J.A.J Raiman[1], I.R Miousse[2], D. Watkins[2], D.S Rosenblatt[2,3].* 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Human Genetics, McGill University, Montreal, Canada; 3) Division of Medical Genetics, McGill University Health Center, Montreal, Canada.

Derivatives of cobalamin (vitamin B12) are essential cofactors for the remethylation of homocysteine to methionine, catalyzed by methionine synthase, and the conversion of methylmalonyl-CoA to succinyl-CoA, catalyzed by methylmalonyl-CoA mutase. A number of inborn errors have been identified that impair conversion of exogenous cobalamin to its metabolically active derivatives, methylcobalamin and adenosylcobalamin. The patient was a 5-year-old girl of East Indian origin with a history of global developmental delay and autistic features. Her parents are first cousins. She initially came to medical attention at 18 months with speech and language delay, and was found to have elevated serum homocysteine and decreased methionine. At five years there was evidence of delay in gross and fine motor skills, autistic features and mental retardation. Serum homocysteine levels were elevated (48mmol/l), methionine 30 mmol/l with normal methylmalonic acid. MRI investigation indicated atrophy of frontal lobes and corpus callosum. Treatment with hydroxocobalamin IM resulted in normalization of biochemical parameters (a reduction of homocystine to 18mmol/l) but was discontinued by the parents after 3 months due to administration difficulties. She was subsequently treated with betaine, resulting in variable homocystine levels between 30-40 mmol/l. Studies of cultured patient fibroblasts showed decreased incorporation of label from methyltetrahydrofolate into cellular macromolecules, indicating decreased function of methionine synthase. Function of methylmalonyl-CoA mutase was normal. Synthesis of methylcobalamin from exogenous cyanocobalamin was decreased, with normal adenosylcobalamin synthesis. Somatic cell complementation identified the disorder in the patient as cblD variant 1. Sequencing of the MMADHC gene resulted in identification of a homozygous missense mutation, c.746A>G (p.Tyr249Cys). This mutation has been reported previously in the heterozygous state in another patient with cblD variant 1. This patient represents only the fourth case of cblD variant 1 to be reported.

1302F

Response to creatine supplementation in 2 boys with X-linked creatine transporter deficiency with residual creatine peak on MR spectroscopy (MRS). *D. Renaud[1], A. Boetticher[2], E. Wirrell[1].* 1) Div Child/Adolescent Neurology, Mayo Clinic, Rochester, MN; 2) Noran Neurological Clinic, Minneapolis, MN.

Background: X-linked creatine transporter (SLC6A8) deficiency presents with developmental delay, seizures and behavioral disturbance in boys due to cerebral creatine deficiency. Oral creatine supplementation generally has not resulted in an improvement in neurological symptoms.

Case reports: The first boy presented at age 12 years with autism, developmental delay and seizures. A hemizygous c.1222_1224del TTC (p.408del) mutation was detected. The second boy presented at age 3 with mild global developmental delay with significant speech impairment. A novel hemizygous c.238 T>C (p.Y80H) variant was found in the SLC6A8 gene. MRS for both boys revealed a significantly decreased but not absent creatine peak. In view of the small residual creatine peak on MRS, treatment with oral creatine monohydrate supplementation was initiated.

Results: Both boys demonstrated an improvement in developmental abilities, particularly speech, on creatine supplementation. In addition, the first boy became seizure-free and had a resolution of abnormal involuntary movements. Despite a clinical response to creatine supplementation in both boys, the size of the MRS peak remained unchanged on serial MRS studies.

Conclusion: Boys with X-linked creatine transporter deficiency with a residual creatine peak on MRS may benefit from supplementation with oral creatine monohydrate.

1303F

Hereditary renal hypouricemia caused by deletion in human urate transporter 1. *I. Sebesta[1,2], B. Stiburkova[2], K. Ichida[3], M. Hosoyadama[4].* 1) Institute of Clinical Biochemistry;; 2) Institute of Inherited Metabolic Disorders,Charles University,First Faculty of Medicine,Prague,Czech Republic; 3) Department of Pathophysiology,Tokyo University of Pharmacy and Life Sciences,Tokyo,Japan; 4) Division of Pharmacotherapeutics, Faculty of Pharmacy,Keio University, Tokyo,Japan.

Introduction: Hereditary renal hypouricemia is an inborn error of renal transport of uric acid. Two types were recently distinguished: a) renal hypouricemia type 1 (OMIM #220150), caused by the defects in the SLC22A12 gene which encodes the human urate transporter 1 (hURAT1) and b) renal hypouricemia type 2 (OMIM #612076), caused by the defects in the SLC2A9 gene, coding GLUT9 transporter. This disorder is characterized by two biochemical markers: hypouricemia (less than 119 μmo/l) and increased fractional excretion of uric acid (more than 10%). Most patients are asymptomatic, but some may form urolithiasis and /or be predisposed to exercise-induced acute renal failure. To date, the cases with mutations in hURAT1 have been reported in East Asia only. Over one hundred cases were identified in Japan and several patients in Korea. Methods: Uric acid was quantified by enzymic method. The analysis of hURAT1 was performed as previously described (Ichida K. et al. J.Am.Soc. Nephrol. 2004;15:164-73). 5-year-old boy with unexplained hypouricemia and urolithiasis was referred to our department for the detailed purine metabolic investigation. At the age of two months ultrasound investigation revealed renal calculi of 5-6 millimeters in size on the right side. Very small calculi was found also in the lower part of the right kidney. Results: Using our diagnostic approach to unexplained hypouricemia we have found repeated hypouricemia (53-108 umol/l) and increased fractional excretion of uric acid (24.5-84.2 %) in this Czech patient. The value of hypoxanhine and xanhine were within normal limits, thus the possible genetic defect of xanthinoxidase was excluded. No other secondary causes of hyperuricosuric hypouricemia such as Wilson diseases, Fanconi syndrome or drug-induced tubulopathy were found. Subsequent mutational analysis revealed novel heterozygous 9bp deletion (1242-1250delGCTGGCAGG) in hURAT1 transporter. Conclusions: First Czech patient with defect in hURAT1 was detected. Our finding shows that this disorder is present also in Caucasian population. Patients with unexplained hypouricemia need detailed purine metabolic investigations. (supported by grant VZMSM0021620806, Czech Republic).

Effects of PPARG, APOE, ACE, LPL, IL-6 and AT1R gene variants on development of metabolic syndrome. *J. Sertic[1,2], J. Lovric[2], T. Bozina[2], N. Bozina[1], B. Jelakovic[3], Z. Reiner[4].* 1) Department of Laboratory Diagnostics, University Hospital Centre Zagreb, Croatia; 2) Department of Medical Chemistry, Biochemistry and Clinical Chemistry, School of Medicine, University of Zagreb, Croatia; 3) Department of Internal Medicine, Division of Nephrology and Arterial Hypertension; University Hospital Centre Zagreb, Croatia; 4) Department of Internal Medicine, Division of Metabolic Diseases; University Hospital Centre, Zagreb, Croatia.

Background: Metabolic syndrome (MS) is a cluster of risk factors including hypertension, abdominal obesity, dyslipidemia and hyperglycemia. The contribution of genetic factors to the development of MS has been widely recognized, but the contribution of genes has not yet been fully clarified. We investigated the possible role of gene polymorphisms of PPARG (Pro12Ala), ApoE (, 2, , 3, , 4), LPL (P+/-), IL-6 (-174G>C), ACE (I/D) and AT1R (1166A>C) in MS. Methods: Genotyping of PPARG, LPL, IL-6, ACE and AT1R was performed by PCR-RFLP and APOE by real-time PCR in a group of 263 patients and 176 controls. Associations of alleles and genotypes with biological and clinical variables were performed using independent t-tests or $\chi 2$ where appropriate and UNPHASED-3.0.10. Results: In comparison to females, males had higher BMI and waist circumference, higher triglycerides and glucose levels and lower HDL. Males had significantly more often high blood pressure. Age accounted for the differences in glucose levels and HDL. In female group associations were found for: LPL and ACE with MS (p=0.04); PPARG and LPL with blood pressure, (p=0.04); LPL with cholesterol and LDL (p=0.01 and p=0.05 respectively). Significant gene interactions observed between: APOE and PPARG, ACE and APOE were associated with BMI (p=0.01 and p=0.05 respectively) ; LPL and PPRG were associated with triglycerides (p=0.03). For males we found associations of: LPL variants with MS (p=0.02), BMI (p=0.002) and waist circumference (p=0.008); PPARG and APOE with BMI (p=0.05); IL-6 with CRP (p=0.02). Significant gene-gene interactions observed between: PPARG and AT1R were associated with blood pressure (p=0.05); PPARG and APOE with triglycerides (p=0.02); PPARG and APOE, PPARG and IL6 (p=0.03), ACE and APOE (p=0.0002) with cholesterol PPARG and LPL (p=0.003) PPARG and IL6 (p=0.06) with HDL; PPARG and IL6 (p=0.01), ACE and APOE (p=0.04), AT1R and ACE (p=0.04) with LDL; PPARG and APOE, LPL and ACE (p=0.01), AT1R and ACE (p=0.06) with CRP. Conclusion: Gene variants of PPARG, APOE, LPL, ACE, AT1R and IL-6 could be susceptibility factors of obesity, lipid status, and glucose intolerance contributing to the development of MS.

1305F

LONG CHAIN ACYL-CoA DEHYDROGENASE DEFICIENCY: A NEW INBORN ERROR of METABOLISM MANIFESTING as CONGENITAL SURFACTANT DEFICIENCY. *J. Vockley[1], K. Suhrie[1], A. Karunanidhi[1], W. Mohsen[1], M. Reyes-Mugica[2].* 1) Pediatrics, Children's Hosp of Pittsburgh of UPMC, Pittsburgh, PA; 2) Department of Pathology Chidren's Hospital of Pittsburgh of UPMC 4401 Penn Ave., Floor B Pittsburgh, PA 15224.

BACKGROUND: The physiologic role of long chain acyl-CoA dehydrogenase (LCAD) has long remained elusive. LCAD is expressed in type II pneumocytes, leading us to hypothesize that a patient with LCAD deficiency would present with congenital surfactant deficiency. OBJECTIVE: Identify a case of LCAD deficiency in patients with a phenotype of congenital surfactant deficiency. DESIGN/METHODS: Term infants with unexplained respiratory distress were evaluated for known causes of congenital surfactant deficiency and confirmed to have a normal genotype. Lung tissue from patient and controls was evaluated using routine light microscopy for histologic evaluation, electron microscopy for lamellar body structure, and detection of LCAD antigen expression by immunostaining and confocal microscopy. Genetic studies were performed. RESULTS: One patient was identified. EM of lung tissue demonstrated eccentric deposits within the lamellar bodies. LCAD antigen was absent in patient lung tissue. Genomic DNA sequencing of patient DNA revealed a homozygous base pair change involving intron 6, causing a splicing error. At six months of age, a liver biopsy demonstrated accumulation of cis-3,4-methylene-heptanoylcarnitine, a likely derivative from an LCAD substrate. CONCLUSIONS: This is the first report of LCAD deficiency. The patient presented with a unique phenotype of congenital surfactant deficiency suggesting that LCAD has a very unique synthetic function rather than a catabolic function as predicted by the other members of the acyl dehydrogenase family of enzymes.

1306F

Multicopy Suppressors Screening in *Saccharomyces cereviseae* Lacking Aspartate-glutamate Carriers. *P. Wongkittichote[1], LT. Jensen[2], S. Tungpradapkul[2], D. Wattanasirichaigoon[3].* 1) Graduate Program in Molecular Medicine, Faculty of Science, Mahidol University, Bangkok, Thailand; 2) Department of Biochemistry, Faculty of Science, Mahidol University, Bangkok, Thailand; 3) Department of Pediatrics, Faculty of Medicine, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Citrin deficiency is an autosomal recessive disorder caused by mutations in *SLC25A13*, which encodes citrin, a member of mitochondrial carrier family. Together with its homologue, aralar, they act as aspartate-glutamate carriers, functioning in the export aspartate from the mitochondrial matrix to the cytosol. Citrin deficiency leads to two phenotypes: neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD, OMIM#605814) and adult-onset type II citrullinemia (CTLN2, OMIM#603471). Currently the only effective treatment of citrin deficiency is liver transplantation. However the limited number of donors as well as the cost and complications of liver transplantation restricts its use as a therapy for citrin deficiency. In order to gain more insight into the pathogenesis of citrin deficiency and to identify new therapeutic targets, we employed the baker's yeast (*Saccharomyces cereviseae*) as a model system to examine defects associated with citrin deficiency. *S. cerevisiae AGC1* is a functional homologue of citrin and yeast lacking *AGC1* (*agc1*Δ) are unable to utilize acetate as a carbon source and the growth of *agc1*Δ yeast on acetate medium can be restored by the introduction of human citrin. In this study we searched for genes that when over-expressed could bypass the growth defect associated with loss of *AGC1*. This multicopy suppressor screen selected for *agc1*Δ transformants with the restored ability to utilize acetate. From approximately 10,000 transformants we identified 24 colonies that were able to utilize acetate as a carbon source, indicating that the genes present on the multi-copy plasmids may be able to compensate for loss of *AGC1*. We are currently working to identify the genes present on these multi-copy suppressors of *agc1*Δ cells. Investigation of how increased expression of the suppressor genes is able to bypass the need for *AGC1* may provide insight into metabolic pathways affected by citrin deficiency in human cells and could possible lead to new avenues of research toward the treatment of citrin deficiency.

1307F

Carnitine Palmitoyltransferase II (CPT II) Deficiency - Clinical phenotypes, Mutations and Polymorphisms. *B.Z. Yang[1], S.A. Greene[1], N. McNeill[1], J.M. Pascual[2], J.H. Ding[1].* 1) Inst Metabolic Disease, Baylor Res Inst, Dallas, TX; 2) UT Southwestern Medical Center.

Carnitine palmitoyltransferase II (CPT II) deficiency, one of the most commonly inherited disorders of fatty acid oxidation defect, is clinically heterogeneous and has three different forms: the neonatal, infantile and adult form. In order to investigate the molecular basis of these three phenotypes, patients with CPT II deficiency have been studied and 82 patients were discovered to have mutation(s) and/or polymorphisms through genetic testing. Genomic DNA was isolated from whole blood or cultured skin fibroblasts. All exons and flanking splice junction of the CPT II gene were amplified from patient`s genomic DNA by using specific intronic primers. The PCR products were purified and bi-directional sequencing of PCR products was performed. Carnitine palmitoyltransferase activities were assayed as palmitoyl L-[methyl- ^{14}C] carnitine formed from L-[methyl- ^{14}C] carnitine and palmitoyl-CoA by using lymphocytes or fibroblasts. A total of thirty different mutations in the CPT II gene have been identified in 82 patients who harbored one or more mutations and/or polymorphisms. Among them, the previously reported common mutation, S113L, was only found in 43 out of 164 of the variant alleles. Three (V245P, R350C, and E645fs) of the 30 mutations were confined only to individual families, whereas the remaining 27 mutations were identified in multiple families. Interestingly, heterozygotes are commonly considered CPT II mutation carriers are expected to remain asymptomatic. However, heterozygotes harboring an additional amino acid-changing polymorphism (in compound heterozygosity) were at risk of developing clinical manifestations when exposed to precipitating factors such as infectious illness, fasting, and/or prolonged exercise. These compound heterozygotes exhibited lower CPT II activity (<40% residual activity) than heterozygotes (>55% residual activity). Our data indicate that CPT II deficiency phenotype correlates closely with residual CPT II activity and that compound heterozygosity represents a disease variant associated with latent onset that manifests upon conditions of increased muscle catabolism.

1308F

Acute Intermittent Porphyria: A Severely Affected Knock-in Mouse that Mimics the Human Homozygous Dominant Phenotype. *M. Yasuda[1], C. Yu[1], J. Zhang[1], S. Clavero[1], W. Edelmann[2], L. Gan[1], J.D. Phillips[3], R.J. Desnick[1].* 1) Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY; 2) Department of Cell Biology, Albert Einstein College of Medicine, Bronx, NY; 3) Hematology, Internal Medicine, University of Utah, Salt Lake City, UT.

Acute Intermittent Porphyria (AIP), the most common acute hepatic porphyria, is an autosomal dominant inborn error of heme biosynthesis due to half-normal hydroxymethylbilane synthase (HMBS) activity. In heterozygous patients, life-threatening acute neurological attacks are triggered by porphyrinogenic drugs, fasting, and hormonal changes that induce heme biosynthesis. In contrast, children with homozygous dominant AIP (HD-AIP) have a severe, early-onset neurologic phenotype, including ataxia and psychomotor retardation. To investigate the nature of their constitutive, severe manifestations, efforts were directed to generate knock-in mice that mimic human HD-AIP. Two mouse lines were generated carrying the HMBS missense mutations R167Q or R173Q, which were identified in human HD-AIP patients. These mutations expressed ~7.5% and ~1.5% of wild-type HMBS activity *in vitro*, respectively. Homozygous R173Q mice were embryonic lethals, while ~65% of the homozygous R167Q mice survived to adulthood and had a normal life span. They had ~5% mean hepatic and erythrocytic HMBS activities, early-onset ataxia, and abnormal motor coordination and locomotion, including impaired rotarod performance, dystonic postures, and action tremors. The mice had constitutively elevated plasma and urinary +- aminolevulinic acid (ALA) and porphobilinogen (PBG) levels (increased ~5 to 7 fold and ~70 to 100 fold, respectively) that were further increased by stimuli that induce heme biosynthesis, including pregnenolone-l6(-carbonitrile and fasting. Liver and brain heme content were ~85% and 50-75% of normal, respectively. Despite their marked neurological phenotype, brain histology was grossly normal. ALA and PBG were markedly elevated in their cerebral spinal fluid (CSF) and central nervous system (CNS) tissues. Of note, the `inducible' AIP mouse model previously generated by Lindberg et al. (Nat Genet 12:195, 1996) did not accumulate porphyrin precursors in their CSF or CNS tissues following phenobarbital induction, despite markedly elevated liver and plasma ALA and PBG levels. These studies suggest that: 1) ALA and PBG do not readily cross the blood brain barrier (BBB) or blood CSF barrier (BCSFB) and 2) the severe neurological phenotype of the HD-AIP children results from the endogenous overproduction of porphyrin precursors in their neuronal tissues and/or neuronal heme deficiency.

1309F

Formation of the multienzyme complex of the de-novo purine synthesis in adenylosuccinate lyase deficiency and AICA-ribosiduria. *M. Zikanova, V. Baresova, V. Skopova, S. Kmoch.* Institute of Inherited Metabolic Disorders, Charles University, First Faculty of Medicine, Prague, Czech Republic.

De-novo purine synthesis (DNPS) requires 10 enzymatic steps to generate inosine monophosphate (IMP), and is catalyzed by 6 enzymes, 3 of which are multifunctional in eukaryotes. Dysfunction of DNPS is represented by genetic defects of individual DNPS enzymes. Two inherited metabolic diseases, adenylosuccinate lyase (ADSL) deficiency and AICA-ribosiduria (aminoimidazolcarboxamide riboside-transformylase/IMP cyclohydrolase (ATIC) deficiency), both leading to severe neurological involvement, are known. In presented study we tested the formation of the multienzyme complex of DNPS - purinosome - in skin fibroblasts obtained from patients with severe and moderate form of ADSL deficiency and with AICA-ribosiduria. We performed immunofluorescence labeling and subsequent analysis of confocal microscopy data of DNPS proteins produced by cells cultured in purine depleted conditions. Firstly the combination of enzymes from the beginning (PPAT) and the end (ATIC) of DNPS was tested, and almost no formation of purinosome was observed in the defect cells. When compared to control fibroblasts, PPAT protein formed clusters but only in reduced rate and ATIC protein remained diffuse in the patient fibroblasts. Secondly we were interested in changes of purinosome formation by the ADSL and ATIC proteins and we observed that the nature of both enzymes remain diffuse in patient cells, suggesting no purinosome formation. Futhermore, when compared to the control fibroblasts, the amount of the produced enzymes was reduced especially in AICA-ribosiduria and the severe form of ADSL deficiency. Finally PPAT and ADSL proteins were colocalized and we observed strong reduction of purinosome formation in patient with severe defect of ADSL, while the reduction was only slight in AICA-ribosiduria and in moderate form of ADSL deficiency. The control fibroblasts formed the complex very strongly in all tested enzyme combinations. We observed correlation between purinosome formation and severity of the disease. It suggest that genetic defects of DNPS affect not only activity and structure of the individual enzyme, but, in the dependency of the relevance of the disease, also the functionality of the DNPS pathway by purinosome complex destabilization. Pathogenic mechanisms leading to neurological involvement are unknown in both diseases, but it is clear that intervention into purinosome formation may represent a new pharmacological target for therapeutic intervention.

1310F

Cell selection in mosaic cell lines from females with Menkes syndrome. *L.B. Møller[1], M. Lenartowicz[2], T.G. Jensen[3].* 1) Department of Applied Human Genetics, Kennedy Center, Gl. Landevej 7, 2600 Glostrup, Denmark; 2) Department of Genetics and Evolution, Institute of Zoology, Jagiellonian University, Ingardena 6, 30-060 Krakow, Poland; 3) Department of Human Genetics, University of Aarhus, Denmark.

Background: Menkes Disease (MD) is a rare X-linked recessive fatal neurodegenerative disorder caused by mutations in the ATP7A gene, and most patients are males. Female carriers are mosaics of wild type and mutant cells due to the random X inactivation, and they are rarely affected. In most of the asymptomatic carriers, the mutant X-chromosomes has been found to be preferential silencing, but preferential silencing of the normal X-chromosome has been observed in affected females. Purpose: The purpose of this study is to test the possibility that the copper status during the foetal development might affect the resultant X-inactivation pattern in the female carrier. Methods: Cell selection was analyzed by exposing mosaic cell cultures obtained from female carriers, to different copper concentrations. The percentage activity of the two different X-chromosomes; the chromosome containing the ATP7A mutation versus the chromosome with normal ATP7A sequence was obtained by investigation of the X-inactivation pattern using the human androgen-receptor gene methylation assay (HUMAR). DNA from an affected male from the same family was included to reveal the allelic AR variant on the mutant X-chromosome. Results: For the first time we demonstrate that cells that express the normal ATP7A gene have a selective growth advantage in media with high copper concentrations, whereas cells that express the mutant ATP7A gene have a selective growth advantage in media with no copper. Conclusions: Giving pregnant heterozygous females supplemental copper in order to favour skewed X-inactivation of the affected X-chromosome in the heterozygous daughters, should be considered.

1311F

Involvement of islet expressed micro RNA regulation in T2D susceptibility risk. *M. van de Bunt[1], K.J. Gaulton[2], I. Moran[3], P.R.V. Johnson[1,4], A.L. Gloyn[1], J. Ferrer[3], M.I. McCarthy[1,2].* 1) Oxford Centre for Diabetes Endocrinology & Metabolism, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Genomic Programming of Beta Cells Laboratory, Institut d'Investigacions Biomèdiques August Pi I Sunyer, Barcelona, Spain; 4) Nuffield Department of Surgery, University of Oxford, Oxford, UK.

Genome-wide association (GWA) studies have identified multiple common variants associated with type 2 diabetes (T2D). Most of these T2D-associated loci map to non-coding regions, and understanding the functional mechanisms through which they influence disease risk has proved challenging. In this study, we aimed to establish whether the transcriptional targets of miRNAs highly-expressed in human pancreatic islets, a critical tissue in T2D pathogenesis, play a role in T2D susceptibility. To establish the miRNA expression profile in human pancreatic islets, we sequenced an islet preparation (purity > 90%) on an Illumina GAII platform. In 17.7 million raw reads, we identified 396 mature miRNAs expressed in islets. Two highly abundant transcripts (mir-143, mir-375) predominated within the islet expression profile, representing 40% of all miRNA aligned reads. It has previously been shown that expression of mir-375 affects glucose-stimulated insulin secretion, whilst mir-30d, also amongst the top 10, has been involved in the regulation of insulin gene expression. To determine if the mRNA targets of the most highly expressed islet miRNAs showed enrichment in T2D association signals, we defined a set of islet miRNA target genes (n=2237) based on prediction using TargetScan for the 29 miRNAs representing 90% of the miRNA reads. We used MAGENTA to determine whether this set of islet miRNA target genes was enriched for variants with significant T2D association in the DIAGRAM GWA meta-analysis (8130 cases / 38,987controls). When compared against 2572 pathway-related gene sets (from GO, KEGG, Ingenuity and Panther), the islet miRNA target set emerged, following false discovery rate correction, as the most significantly enriched set (P= 0.028 for the 5% most significant gene scores). This result was unchanged (p=0.026) when the islet miRNA target gene set (n=1783) was restricted to genes with mRNA-seq expression in human islets. Equivalent analyses using miRNA expression lists from 3 other tissues resulted in no enrichment for T2D GWA signals, providing further evidence that the enrichment has a biological basis. In conclusion, we have established the miRNA profile of human islets and and implicated islet miRNA-regulated transcripts in Type 2 diabetes predisposition.

1312F

A novel mutation in the *MT-ATP8* gene associated with cerebellar atrophy, retinitis pigmentosa, polineuropathy, and hearing loss. *A. Blazquez[1,2], M. Moran[1,2], A. Moreno[1,3], A. Delmiro[1,2], L. Rufian[1,2], H. Rivera[1,2], J. Arenas[1,2], M.A. Martin[1,2].* 1) Mitochondrial diseases laboratory, `12 de Octubre' Hospital. Biomedical Research Institute (i+12), Madrid, Spain; 2) Spanish Biomedical Research Center for Rare Diseases (CIBERER); 3) Neurology Dept, `Morales Messeguer' Hospital, Murcia, Spain.

Background: Mitochondrial respiratory chain (MRC) disorders are caused by mutations in mitochondrial DNA (mtDNA) or nuclear DNA genes. Most of mtDNA disease-causing mutations occur in heteroplasmy. Two structural proteins of ATP synthase (MRC complex V) are encoded by mtDNA (*MT-ATP6* and *MT-ATP8* genes). Common mutations in the *MT-ATP6* gene, particularly, m.8993T>G are associated with MILS (Maternal Inherited Leigh Syndrome) or NARP (Neuropathy, Ataxia, Retinitis Pigmentosa) depending on mutant load. Conversely, only 3 mutations have been reported in the *MT-ATP8* gene so far, associated with cardiomyopathy and neuropathy. Recently, a fatal disorder in a 10 years old child displaying an encephalopathy with leukodystrophy, seizures, and congenital deafness was described. We report on a novel mitochondrial DNA (mtDNA) mutation in the *MT-ATP8* gene associated with NARP and deafness. **Patient**: A 34 year-old female patient was diagnosed at chilhood of ureteral duplication. At the age of 16 she presented with short stature, and severe bilateral hearing loss. Neurological examination showed generalized hyperreflexia and muscle hypotrophy. Brain MRI displayed marked cerebellar atrophy, and white matter symmetric diffuse lesions in thalamus and periventricular area. Electrophysiologic studies revealed a moderate axonal sensitive polyneuropathy. In addition, she currently suffers from migraine and retinitis pigmentosa. **Methods and Results**: Muscle did not show ragged-red or COX negative fibers. MRC complexes activities were normal except for complex V (30% of reduction). Common molecular lesions of mtDNA were discarded by southern blot, real time PCR, and minisequencing. By complete mtDNA sequencing, a change m.8391G>A (p.W9X) in the *MT-ATP8* gene was identified, which was not annotated in a number of mtDNA variation databases. Muscle heteroplasmy was 84% using Bioanalyzer 2100 (Agilent). Mutation was absent in blood from asymptomatic proband's mother, sister and maternal aunt, as well as in muscle DNA from 150 controls. **Conclusions**: Some evidences for the pathogenic role of the novel mtDNA change are: i) diminished complex V activity, ii) heteroplasmy, iii) a non-sense variation, and iv) absence in both controls and SNPs databases. The mutation is thought to be *de novo* as it was not found in 3 asymptomatic maternal relatives. This case contributes to expand the phenotypic variability already observed in the few patients reported with *MT-ATP8* gene mutations.

1313F

Normal urinary methylmalonic acid (MMA) does not rule out *SUCLA2*-related Mitochondrial DNA Depletion Syndrome. *D.C. Buhas[1], D. D'Agostino[1], N. Braverman[2].* 1) Medical Genetics, Montreal Children's Hospital, Montreal, Quebec, Canada; 2) Human Genetics, Montreal Children's Hospital Research Institute, Montreal, Quebec, Canada.

Background: Succinyl CoA synthase is a mitochondrial matrix enzyme that catalyzes the reverse reaction from succinyl-CoA to succinate in the TCA cycle and converts ADP or GDP to ATP or GTP respectively. It is composed of two subunits: (-subunit coded by SUCLG1 and a) -subunit encoded by SUCLA2. Patients with deficient activity of the succinyl-CoA synthase due to SUCLA2 mutations present with severe hypotonia in early infancy, sensorineural hearing loss, Leigh disease, dystonia and progressive muscle weakness with mtDNA depletion in muscle. From 21 patients reported, 16 originate from an inbred Faroe Island community, 3 were Italians and 2 of Muslim origin. Case presentation: An 8 month-old French-Canadian female was evaluated for congenital bilateral sensorineural deafness, severe hypotonia and global developmental delay. Brain MRI showed increased T2 signal intensity in the caudate and lentiform nuclei, internal and external capsules and myelination delay. The plasma lactate was repeatedly increased (6.3, 4.5 and 4mmol/l, normal <2.5) with high alanine (534 umol/l, normal <396). Further evaluation revealed high C3 (2.89 umol/l, normal <0.63) and C4-DC (0.6 umol/l, normal <0.48) on acylcarnitine profile. The urine organic acids showed mild elevations of citric acid cycle intermediates (alpha-ketoglutarate 1004 umol/mmol creatinine, normal <429; fumarate 11 umol/mmol creatinine, normal <10), 3-methylglutaconate (15 umol/mmol creatinine, normal <12), 3-hydroxyisovalerate 226 umol/mmol creatinine (normal <119). There was a mild elevation of methylcitrate (17 umol/mmol creatinine, normal <11) but the MMA was normal: 11 umol/mmol creatinine (normal <15), even in a repeat sample. However, the plasma MMA showed a small increase: 2435 nmol/l (normal <500). The clinical features as well as the high lactate, mild elevation of plasma MMA, acylcarnitines and urinary organic acid profile pointed to a deficiency in Succinyl CoA synthase. The SUCLA2 gene sequencing revealed the common Faroese mutation c.534+1 as well as a new variant c.985A>G, which is predicted by PolyPhen-2 as being deleterious. Treatment with thiamine and riboflavin was started. Conclusions: We report the first North-American patient with SUCLA2 defect. This report underscores also the importance of considering this disorder even if the urinary organic acids do not identify an elevation of MMA but the clinical and the other metabolic investigations are compatible with this diagnosis.

1314F

The use of Next Generation Sequencing for the Development of the Mitochondria Disorder Clinical Assays. *S. Dames[1, 3], T. Wayman[1], J. Stocks[1], J. Durtschi[1], M. Singleton[1], P. Ridge[1], K. Eilbeck[3], R. Mao[1, 2].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT, USA; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT, USA; 3) Department of Biomedical Informatics, University of Utah School of Medicine, Salt Lake City, UT, USA.

Background: Mitochondrial disorders involve mutations in the mitochondrial genome (mtDNA) and human nuclear genes. Since the condition is highly variable and presents with non-specific clinical features, patients with mitochondrial disorders are under-diagnosed. Current clinical tests such as examining lactic acid concentration or oxidative phosphorylation may be ambiguous or falsely negative. Sanger sequencing of the mtDNA and some nuclear genes is available, but is expensive and the sensitivity is low. We have developed a next generation sequencing (NGS) assay that includes both mtDNA and a 128-gene nuclear panel for selected mitochondrial disorders using the Illumina HiSeq 2000. **Methods**: mtDNA is enriched by long range PCR (LRPCR) and the 128-gene panel is enriched using the RainDance 1000 platform (1,304 amplicons). Libraries are constricted with a Beckman SPRI-TE platform, indexed, and 100-base, single-end sequenced. Bioinformatic analysis is performed using multiple alignment and variant detection programs. All clinically associated variants are Sanger-confirmed. **Results**: Analysis of mtDNA NGS has displayed 100% concordance inter/intra between runs based on Sanger verification using clinically associated samples. Preliminary analysis of the 128-gene panel displays very high (~98%) concordance intra/inter run. Differences in concordance between NGS runs for the 128-gene panel are attributed to variant allele frequency outliers. We are in the process of validating selected nonsynonymous and synonymous variants to determine optimal coverage, allele frequency, quality score, and variant calling metrics. **Conclusions**: NGS is a cost-effective and sensitive method for detecting low levels of heteroplasmy in mtDNA. NGS allows for the sequencing of multiple genes that is either technically daunting or cost prohibitive by Sanger sequencing. The reproducibly and sensitivity of the mitochondrial disorder assay is 100% when detecting single nucleotide polymorphisms and short deletion/insertion polymorphisms. Large deletions are difficult to detect using our current sequencing methods. To detect large deletions or insertions, an array-based method is performed concurrently. Critical for all NGS assays will be the development of bioinformatics tools that provide curated information for reported annotations, internal variant databases, and the ability to represent the reported information in a format that is easily reviewed by clinicians and medical directors.

1315F

Succinyl-CoA Ligase Deficiency in the Mouse is a Model for Mitochondrial Disease with mtDNA Depletion. *B.H. Graham[1], T.R. Donti[1], N.K. Hawkins[1], M. Ge[1], K.W. Eldin[2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Dept. Pathology and Immunology, Baylor College of Medicine, Houston, TX, USA.

Over the past few years, mitochondrial DNA (mtDNA) depletion has been implicated in several mitochondrial diseases. Mutations in subunits of Succinyl-CoA Ligase (Synthetase), a component of the citric acid cycle, have been associated with mitochondrial encephalomyopathy and mitochondrial DNA depletion. In humans, mutations in SUCLA2, encoding the ADP-specific beta subunit, and SUCLG1, encoding the alpha subunit, have been identified as causes of mitochondrial disease with mtDNA depletion. The goal of this project is to develop model systems of Sucinyl-CoA Ligase deficiency to study disease pathogenesis and biology of mtDNA maintenance. A gene trap allele of Sucla2 ($Sucla2^{SA}$) geo) has been isolated in mouse embryonic stem (ES) cells and used to generate transgenic animals. $Sucla2^{SA}$) geo homozygotes exhibit recessive lethality with most mutants dying late in gestation (e18.5). Rare stillborn homozygote pups exhibit significantly elevated levels of methylmalonic acid (MMA) and varying degrees of mtDNA depletion. Histological analysis of mutant placenta reveals increased mineralization and mutant embryos are approximately 25% smaller than wild type littermates. Mutant placenta and embryonic brain, heart and muscle show varying degrees of mtDNA depletion (20-60%), while there is no appreciable mtDNA depletion in mutant liver. Mouse embryonic fibroblasts (MEFs) derived from e12.5 embryos show a 50% reduction in mtDNA content after five passages for mutant compared to wild type. The mtDNA depletion in MEFs and mutant tissues is functionally significant as indicated by reduced steady state levels of COXI by western and by respiratory chain deficiencies. Ongoing and future studies include performing complementation experiments in cells to determine the structural requirements of Sucla2 for mtDNA maintenance as well as expression of affinity-tagged Sucla2 in mutant MEFs to identify interacting proteins by pulldown and mass spectrometry. This mouse model of Succinyl-CoA ligase deficiency and mtDNA depletion will provide insights into the pathogenesis of mitochondrial diseases with mtDNA depletion and into the biology of mtDNA maintenance as well as facilitate the exploration of novel therapeutic strategies.

1316F

Relationship of mitochondrial heteroplasmy and variation with childhood obesity in European and African Americans. *S.F.A. Grant[1,2,3], J.T. Glessner[1], J.P. Bradfield[1], J. Zhao[3], J.E. Tirone[4], R.I. Berkowitz[5,6], H. Hakonarson[1,2,3], N. Sondheimer[4].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia Research Institute, Philadelphia, Pennsylvania 19104, USA; 2) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104, USA; 3) Division of Human Genetics, Children's Hospital of Philadelphia Research Institute, Philadelphia, Pennsylvania 19104, USA; 4) Division of Biochemical Genetics, Children's Hospital of Philadelphia Research Institute, Philadelphia, Pennsylvania 19104, USA; 5) Behavioral Health Center and Department of Child and Adolescent Psychiatry, The Children's Hospital of Philadelphia, Philadelphia PA 19104, USA; 6) Center for Weight and Eating Disorders, Department of Psychiatry, University of Pennsylvania, Philadelphia PA 19104, USA.

It has been suggested that the mitochondria genome plays a role in the pathogenesis of obesity. We examined the influence of mitochondrial genotype and heteroplasmy in a large pediatric case-control population. Single nucleotide polymorphism genotyping arrays accurately determine mitochondrial polymorphisms and heteroplasmy. We queried a large existing genome wide genotyped childhood obesity dataset consisting of two different ethnicities: 1,080 European American (EA) cases (BMI$\geq$ 95th percentile) and 2,500 lean controls (BMI<50th percentile) plus 1,479 African American (AA) cases and 1,575 lean controls. Association was not observed between childhood obesity and any of the 138 mitochondrial polymorphisms in either population. We also found no observable differences in gross heteroplasmy between the obese and non-obese groups. Finally, we analyzed the quantitative mitochondrial genotype calls generated, whether they exceeded the heteroplasmy threshold or not. With this more lenient test, we found six positions with a significant difference between EA cases and controls (P<1x10^{-4}). However, when evaluated in the AA data set, no differences were noted at these sites, suggesting that our initial observations were due to chance rather than a meaningful relationship to childhood obesity. It is unlikely that common mitochondrial polymorphisms or heteroplasmy play a role in common childhood obesity.

1317F

Metabolic interventions reduce mitochondrial dysfunction in a neuronal model of MELAS. *V. Procaccio[1,2], V. Desquiret-Dumas[1,2], N. Gueguen[1,2], M. Barth[1], A. Chevrollier[1,2], P. Guardiola[3], S. Hancock[4], D.C. Wallace[4], P. Amati-Bonneau[1,2], D. Henrion[2], D. Bonneau[1,2], P. Reynier[1,2].* 1) Biochemistry and Genetics Dept, Univ Angers, Angers, France; 2) UMR INSERM, U771-CNRS6214, F-49000 Angers, France; 3) Department of Hematology, Angers University Hospital, F-49000, France; 4) Center of Mitochondrial and Epigenomic Medicine; University of Pennsylvania, Philadelphia, PA, USA.

The 3243 A>G variant in the mitochondrial tRNALeu (UUR) gene is one of the most common mitochondrial DNA (mtDNA) mutation. Phenotypic manifestations depend mainly on the ratio of mutant to normal mtDNA copies (heteroplasmy). High percentage of mutant mtDNA is associated with the severe and life-threatening neurological syndrome known as MELAS (Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-like episodes). This mutation primarily affects brain and blood vessels, but the pathophysiology is still poorly understood in neuronal or vascular cells. We have created a series of cybrid cell lines with the nuclear background of a neuroblastoma cell line (SHSY-5Y) and patient fibroblast mitochondria carrying the 3243A>G mutation at different mutant loads (control cells, 70%, 90% and 100% mutant loads). This cellular model should substantially help us to clarify the genetics and pathophysiology of the MELAS disease. We have first investigated the impact on cellular metabolism and mitochondrial respiratory chain in cybrid cells. The introduction of the 3243 A>G mutation in neuronal cells induces a metabolic switch towards glycolysis and severe defects in respiratory chain activity and assembly, highly dependent on the mutant load. As an attempt to compensate the biochemical defects in mutant cells, we used different strategies. Low glucose medium in cultured cells which significantly shifted the 100% mutant towards wildtype reaching 90% mutant and restored respiratory chain complexes assembly and activity. In addition, nitric oxide (NO) metabolism was also significantly altered in mutant neuronal cells, and treatment with arginine, a NO donor, improved significantly complex I activity. Indeed, L-arginine has been proposed as a treatment for MELAS 3243 A>G syndrome patients during the acute stroke phase or long term use. Metabolic interventions such as arginine therapy appear as a promising therapeutic strategy for MELAS patients.

1318F

Renal manifestations in mitochondrial cytopathies : about a series of 55 patients. *M. Rio[1], O. Boyer[2], AS. Lebre[1], P. Niaudet[2], A. Rotig[3], A. Munnich[1].* 1) Departement de Génétique, Hosp Necker-Enfants Malades, Paris, France; 2) Service de Néphrologie Pédiatrique, Hosp Necker-Enfants Malades, Paris, France; 3) INSERM 781, Hosp Necker-Enfants Malades, Paris, France.

Mitochondrial cytopathies are a clinically heterogeneous group of diseases characterized by defect of oxydative phosphorylation (OXPHOS). These disorders can affect several organs or tissues. Renal involvement has been occasionally reported. We report here a series of 55 patients with mitochondrial diseases associated with renal involvement. Age at onset of mitochondrial diseases ranged from birth to 41 years. Renal manifestations were the first sign of the mitochondrial disorder in only three patients. In most cases, renal disease was associated with neurological or multisystemic symptoms. The commonest renal manifestation was a proximal tubulopathy observed in 32/55 patients. Other renal manifestations were nephrotic syndrome and tubulo-interstitial nephropathy. Molecular genetic studies revealed mitochondrial DNA mutations in 5 patients, including 3 point mutations (mt3243A>G, mt13514A>G, mt9185T>C), and 2 large deletions. Mutations in nuclear gene were identified in 15 patients. Among them, four patients had complex III deficiency due to nuclear *BCS1L* mutations and presented with early onset lactic acidosis, tubulopathy, liver involvement, neurological symptoms, and failure to thrive. Five patients with a neonatal multisystemic disorder and tubulopathy showed mtDNA depletion in muscle and *RRM2B* mutation. Two patients had mutations in genes involved in mitochondrial protein translation (*TRMU* and *MRPL3*). Four patients had a primary defect of coenzyme Q10 biosynthesis, related with mutations in *COQ2* and *PDSS2* genes. Finally, 35 patients had variable OXPHOS deficiency with no molecular basis yet identified. In conclusion, renal involvement is an infrequent but possible manifestation of mitochondrial cytopathies and is not associated with a specific OXPHOS deficiency either specific nuclear or mitochondrial mutations being identified in this series of patients.

1319F

Exome-analysis reveals new genes for mitochondrial disorders of early childhood. *A. Suomalainen[1], T. Tyni[1,2], P. Isohanni[1,2], J. Elo[1], P. Ellonen[3], H. Pihko[2], H. Tyynismaa[1].* 1) Molecular Neurology, Biomedicum-Helsinki, University of Helsinki, Helsinki, Finland; 2) Helsinki University Central Hospital, Hospital of Children and Adolescents; 3) Institute of Molecular Medicine Finland, FIMM, Helsinki, Finland.

Mitochondrial dysfunction is the most common cause of inherited metabolic disorders of childhood. The early-onset disorders typically show a severe, progressive disease course and are often fatal. In spite of increasing knowledge on the molecular features of mitochondrial disorders, majority of these children still lack genetic diagnosis. We have collected a wide patient material of early-onset cardiomyopathies and mitochondrial encephalomyopathies. We applied whole-exome sequencing analysis to search for genetic background of these disorders. We utilized an in-house data mining pipeline to analysis of the typically over 60.000 individual single-nucleotide variants in one individual. We applied serial filters to enable identification of changes affecting conserved positions in proteins that are predicted to be targeted to mitochondria. Currently, we have identified mutations in two novel autosomal recessive genes encoding mitochondrial proteins. The first one caused cardiomyopathy in a sibpair; one died before one year of age upon acute progressive cardiac decompensation, induced by respiratory infection, whereas her sister manifested cardiomyopathy before one year of age, but with slower progression, as she is currently a teenager. The second family had two children, both conceived after fertilization treatment, who both developed a progressive mitochondrial encephalopathy soon after birth, leading to their death around one year of age. We showed that the identified defects in the genes, not previously associated with any disease, cause dysfunctional mitochondrial translation, with severe consequences to respiratory chain proteins. Mitochondrial translation defects are emerging as an important cause of both wide-spread and tissue-specific respiratory chain disorders of early childhood.

1320F

Large-scale deletions on 22q13.33 and 12q24.33 detected in patients with mitochondrial disorders. *M. Tesarova[1], A. Vondrackova[1], K. Vesela[1], K. Vinsova[1], V. Stranecky[2], T. Honzik[1], H. Hansikova[1], J. Zeman[1].* 1) Department of Pediatrics and Adolescent Medicine, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic; 2) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University in Prague and General University Hospital in Prague, Prague 2, Czech Republic.

Mitochondrial disorders represent a group of clinically and genetically heterogeneous diseases whose molecular-genetic diagnosis is challenging. The standard diagnostic approach is direct DNA sequencing of candidate genes whose list is steadily growing. Nevertheless, this technique does not enable to detect large heterozygous deletions. To avoid this, gene-specific MLPA analyses or custom oligonucleotide array-based CGH are used. Alternatively, SNP arrays with high marker density may be utilized. The **aim** of this study is to analyze large-scale deletions in group of 15 patients with mitochondrial disorder of unknown etiology. **Methods:** Genome-Wide Human SNP 6.0 array (Affymetrix) was used for genotyping of DNA isolated from leucocytes of patients. Detected deletions were confirmed by TaqMan Copy Number Assays (Applied Biosystems). **Results:** In 20% of patients, large deletions as a cause of the mitochondrial disease were found. In 2 of them, 175-kb, 87-kb resp. heterozygous deletions on 22q13.33 affecting *SCO2* and *TYMP* genes were detected. Missense point mutations in *TYMP*, *SCO2* genes resp. were identified by direct sequencing on the other allele. Patient 1 with MNGIE phenotype inherited c.261G>T in *TYMP* from father and 175-kb deletion from mother. A novel mutation c.667G>A in SCO2 resulting in substitution p.Asp223Asn was found on maternal allele of patient 2 in combination with 87-kb deletion inherited from father. Interestingly, 175-kb deletion on 22q13.33 partially overlaps with two described copy-number variations (CNV; variation_5192 and variation_4139). According to Database of Genomic Variants (Iafrate et al, 2004), these two CNVs spanning *TYMP* and *SCO2* genes occurs with 7% frequency in control samples. In patient 3, homozygous 5-kb deletion on 12q24.33 affecting exon 4 of *PUS1* gene was revealed. Additionally, clinical phenotype of patient 2 and patient 3 did not fully correspond with symptoms usually observed in other *SCO2* and *PUS1* patients resp. **Conclusions:** Genome-Wide Human SNP 6.0 Array allowing detection of deletions larger than 700 bp was successfully used to determine genetic diagnosis in 3 out of 15 patients. Copy-number variations occur frequently in human genome based on the results of whole-genome analyses and they may overlap with many genes associated with clinical phenotypes including mitochondrial disorders. *Supported by research projects MSM0021620806, 1M520 and grants IGA NS 10581-3/ 2009, IGA NS 10561-3/2009, GAUK 28410.*.

1321F

A new mouse model for the R653Q variant of MTHFD1, a trifunctional folate enzyme. *K.E. Christensen[1], L. Deng[1], C. Perugino[1], O.V. Malysheva[2], E. Arning[3], T. Bottiglieri[3], N.I. Krupenko[4], M.A. Caudill[2], R.E. MacKenzie[5], R. Rozen[1].* 1) Depts. of Human Genetics and Pediatrics, McGill University, Montreal, Quebec, Canada; 2) Division of Nutritional Sciences, Cornell University, Ithaca, NY; 3) Baylor Institute of Metabolic Disease, Dallas, TX; 4) Dept. of Biochemistry and Molecular Biology, Medical University of South Carolina, Charleston, SC; 5) Dept. of Biochemistry, McGill University, Montreal, Quebec, Canada.

The MTHFD1 c.1958 G→A (R653Q) polymorphism, an amino acid substitution in the synthetase domain of the trifunctional folate enzyme MTHFD1, has been implicated as a risk factor for common disorders such as birth defects or cancer. MTHFD1 produces folate derivatives for several critical one-carbon transfer reactions including nucleotide synthesis and methylation reactions. We have previously shown that the R653Q mutation destabilizes the synthetase domain and reduces the production of formylTHF by this enzyme. This variant is likely to have its biggest impact in rapidly proliferating tissues, such as developing embryos, because formylTHF is required for the de novo synthesis of purines. To investigate the effect of synthetase deficiency on embryonic development, we have recently generated a new mouse model for synthetase deficiency. In this mouse, a null mutation has been introduced into the synthetase domain of the Mthfd1 gene that inactivates the synthetase leaving the other two activities intact. The Mthfd1 S-/- genotype is embryonic lethal; no Mthfd1 S-/- embryos have been observed beyond gestational day 10.5 and those found were severely delayed and abnormal. The synthetase-deficient (Mthfd1 S+/-) mice are healthy, appear to reproduce normally and should be a good animal model for humans with the MTHFD1 1958AA genotype. Proper expression of the mutant protein has been confirmed by enzyme assay and immunoblot; only synthetase activity differs between the wild type and heterozygous (Mthfd1 S+/-) mice. Preliminary metabolic studies suggest that folate and choline metabolism are disrupted in non-fasted Mthfd1 S+/- males fed standard laboratory chow. The proportion of 10-formylTHF in plasma is decreased ~40% (formylTHF/total folates, p=0.044). The same trend was observed in liver. Additionally, in liver, the amount of glycerophosphocholine, a phosphatidylcholine catabolite that can be used to generate free choline, is reduced ~20% (p=0.053). This observation has implications for cellular methylation as choline becomes an important alternate methyl donor when folate-dependent methylation is compromised. Pilot studies have revealed developmental delays and heart defects in offspring. Experiments are underway to investigate these effects, and to examine the influence of diet on phenotype.

1322F

Loss of the Prader-Willi Syndrome Candidate Gene Magel2 impairs leptin signaling in mice. *R.E. Mercer[1], R. Wevrick[1], W.F. Colmers[2].* 1) Medical Genetics, University of Alberta, Edmonton, Alberta, Canada; 2) Pharmacology, University of Alberta, Edmonton, Alberta, Canada.

Prader-Willi Syndrome (PWS) is the most common genetic cause of severe obesity. People with PWS, who are missing several imprinted genes on chromosome 15 including MAGEL2, have significant alterations in energy homeostasis and body composition associated with hypothalamic dysfunction. MAGEL2 has previously been demonstrated to have very high levels of expression within the hypothalamus, and the known involvement of the hypothalamus in energy homeostasis led us to investigate the leptin system in transgenic mice lacking Magel2, referred to as Magel2-null. Similar to PWS, Magel2-null mice are underweight prior to weaning, but show increased weight gain and increased adiposity as adults. Adult (20-week old) Magel2-null mice fail to respond to an intraperitoneal (IP) injection of leptin (2.5mg/kg) by reducing 24h food intake, in contrast to control mice where a significant reduction in 24h food-intake is seen. This leptin insensitivity precedes the development of obesity, as even 6-week old Magel2-null mice, comparable in weight to controls, also do not respond to IP leptin injection. To study leptin signaling in the hypothalamus of Magel2-null mice, we crossed them to transgenic mice expressing GFP in neurons that express the signaling form of the leptin receptor, and then used patch-clamp recordings in hypothalamic brain slice preparations to study responses of GFP-expressing neurons to the bath application of leptin (100 nM). In the arcuate nucleus (ARC), a region of the hypothalamus possessing first-order leptin-responsive neurons, different populations of neurons are either excited or inhibited by leptin, as seen in de- or hyperpolarizations, respectively, of neuronal membrane potential. While recordings from GFP-expressing neurons from control mice show substantial populations of both cell types, no leptin-excited neurons were found in the ARC of Magel2-null mice, suggesting a critical role for Magel2 in the coupling of the leptin receptor to excitatory neuronal activity. These results reinforce our hypothesis that reduced leptin responsiveness contributes to the energy balance deficits seen in Magel2-null mice. Further, our results suggest a critical role for Magel2 in leptin excited neurons in the ARC, which are mostly pro-opiomelanocortin (POMC) expressing neurons. We plan further investigation of the melanocortin system in these mice.

1323F

Clinicopathological and genetical features of autophagic vacuolar myopathies characterized by autophagic vacuoles with sarcolemmal features (AVSF). *K. Sugie[1,2], H. Komaki[2], T. Kurashige[3], D. Kaneda[4], A. Kimura[5], M. Matsumoto[3], S. Ueno[1], I. Nishino[2].* 1) Department of Neurology, Nara Medical University, Kashihara, Nara, Japan; 2) National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan; 3) Department of Clinical Neuroscience and Therapeutics, Hiroshima University Graduate School, Hiroshima, Japan; 4) Department of Neurology, Osaka Red Cross Hospital, Osaka, Japan; 5) Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan.

Introduction: Danon disease (DD), an X-linked dominant cardiomyopathy and myopathy, is caused by primary LAMP-2 deficiency. X-linked myopathy with excessive autophagy (XMEA) is known to be caused by VMA21 gene mutations. DD, XMEA and related autophagic vacuolar myopathies (AVM) are pathologically characterized by autophagic vacuoles with sarcolemmal features (AVSF). AVSF delineate a group of at least five clinically different myopathies, including DD and XMEA. However, the clinicopathological and genetical features of these AVM are not well established. Patients and Methods: We studied 51 DD patients (27 men and 24 women) from 17 families, 3 XMEA patients, 2 infantile AVM patients, 7 X-linked congenital AVM patients, and 1 adult-onset AVM with multi-organ involvement patient. Clinicopathological and genetical features were based on review of clinical histories and skeletal muscle specimens. Results: All DD patients had LAMP-2 gene mutaions. Myopathy and cardiomyopathy were evident in all DD patients. Hypertrophic cardiomyopathy (HCM) was documented in most men, while dilated cardiomyopathy was more common among women. Cardiomyopathy was the most important prognostic factor and the main cause of death in DD. All XMEA patients had VMA21 gene mutations. XMEA patients showed slowly progressive myopathy and no cardiomyopathy. Both infantile AVM patients had no cardiomyopathy. Only 1 of the 7 patients with congenital AVM had HCM. The adult AVM patient developed HCM with arrhythmias. Pathologically, AVSF in all AVM expressed virtually all sarcolemmal proteins, in addition to acetylcholinesterase, on their vacuolar membranes. Multilayered basal lamina and complement C5b-9 deposition along the vacuolar membranes were present in XMEA, infantile AVM, congenital AVM and adult AVM. These findings suggested that they had a similar pathomechanism. In addition, the locus for infantile AVM and congenital AVM was suggested to be the same region with XMEA. Therefore, these diseases could even be allelic as for each other. Conclusion: These AVM may be primarily due to lysosomal dysfunctions in consideration of both genetically diagnosable DD and XMEA. In addition, because infantile AVM and congenital AVM are pathologically and genetically similar to XMEA, these three diseases could even be allelic as for each other. Furthermore, there will most likely be other diseases in these AVM and the list of these AVM will probably expand rapidly.

Clinical Findings and Molecular Analysis of the GALT gene in Filipino patients with Classical Galactosemia. *C.L.T. Silao[1,2], D.M. Canson[1], K.N. Hernandez[1], S.C. Estrada[1,2].* 1) Inst Human Genetics, Manila, Philippines; 2) Department of Pediatrics, University of the Philippines-Philippine General Hospital, Manila, Philippines.

INTRODUCTION: Galactosemia is caused by enzyme deficiencies involved in galactose metabolism one of which is the deficiency of galactose-1-phosphate uridyltransferase (GALT). This study describes the clinical presentation and the results of the GALT gene analysis of seven (7) unrelated Filipino patients diagnosed with Classical Galactosemia. METHODS: Clinical data were collected from charts of Classical Galactosemia patients who were either referred or were detected via neonatal screening from 1996 to May 2011. DNA from the patients were PCR-amplified and sequenced following standard protocols. RESULTS: All patients presented with elevated galactose metabolites and varying degrees of GALT activity. Those detected by newborn screening had early diagnosis and management thus were spared of the disease complications. Those who did not benefit from a screen, were diagnosed at one month of age. They presented with feeding problems, failure to thrive and liver enlargement. Reversal of the acute complications followed with proper management. All patients are presently doing well and are developmentally at par. The results of the GALT gene analysis will be presented. CONCLUSION: The importance of early detection, immediate institution of the proper management and molecular diagnosis in the medical management and genetic counseling of the patient and their families cannot be overemphasized.

Observations on the Molecular Basis of Sucrase-Isomaltase Deficiency. *Z. Wu, S. Uhrich, C.R. Scott.* Pediatrics, University of Washington, Seattle, WA.

Congenital sucrase-isomaltase deficiency (CSID) is a disorder that affects the ability to digest natural carbohydrates with clinical symptoms of flatulence, diarrhea and malnutrition. CSID is caused by mutations in the sucrase-isomaltase gene, and the condition is inherited in an autosomal recessive pattern. The surcrase-isomaltase gene is 100 kb in size and consists of 1827 amino acids and includes isomaltase and sucrase domains. We have tested thirty-six samples from affected persons worldwide. Twenty-four different mutations were indentified in the sucrase-isomaltase gene. We have identified twenty novel variations: eighteen missense mutations p.W105C, p.Q307X, p.P348L, p.D500E, p.D536V, p.E613X, p.L741P, p.R774G, p.E801X, p.F875S, p.W931R, p.W931X, p.R1124X, p.I1378S, p.Y1417X, p.C1531Y, p.T1606I, p.G1760V; one splicing error IVS10 -2 a→g; and one deletion c.489delT. Analysis of the mutations reveals that: (1) Four mutations were detected more frequently than others with p.G1073D, p.V577G, p.F1745C and p.R1124X having frequencies of 0.28, 0.15, 0.11 and 0.06 respectively; assuming Hardy-Weinberg equilibriums, 84% of affected patients should have one or two of these mutations [p2+2pq]. (2) The frequency of mutations occurring in the sucrase domain was greater than in the isomaltase domain (57% vs. 43%), although the isomaltase domain is larger (1007 amino acids) than the sucrase domain (820 amino acids). For patients suspected of CSID, molecular testing may be a less expensive diagnostic approach than intestinal biopsy and enzyme analysis.

The Heritability of Metabolic Profiles in Preterm Twins. *K.K. Ryckman[1], S.L. Berberich[2], O.A. Shchelochkov[1], S. Copeland[3], J.C. Murray[1].* 1) Dept Pediatrics, University of Iowa, Iowa City, IA; 2) State Hygienic Laboratory, University of Iowa, Iowa City, IA; 3) Health Resources and Services Administration, Rockville, MD.

BACKGROUND: Understanding the genetic and metabolic profiles of neonatal diseases has the potential to impact diagnosis and clinical treatment of neonates. Infants born preterm (<37 weeks) have different genetic and metabolic profiles than term infants; however, the heritability of these metabolic profiles has not been previously characterized, particularly in preterm infants. Measurements taken during routine newborn screening provide a snapshot of the metabolic profile at birth and can be used to determine the heritability. Understanding the genetics factors contributing to the metabolic profiles from newborn screening will aid in the optimization of newborn screening tests and establish associations with metabolic disorders acquired during childhood. OBJECTIVE: To examine metabolic biomarkers in preterm twins at birth and determine the genetic heritability of each measurement. METHODS: This study included 27 monozygotic and 54 dizygotic twin pairs that were born preterm. Measurements of 9 amino acids, 8 acylcarnitines, 17-hydroxprogesterone (17-OHP) and thyroid stimulating hormone (TSH) were obtained from the Iowa Neonatal Metabolic Screening Program for specimens collected between 24 and 72 hours after birth and in infants that had not received a transfusion at the time of specimen collection. Heritability was estimated using multilevel mixed-effects linear regression adjusting for year of sample collection and major change in the assay lot. RESULTS: The highest heritability were found for the essential amino acids including leucine (h^2=0.68), methionine (h^2=0.80) and valine (h^2=0.57). Other groups of metabolites had a wide range of heritability including the non-essential amino acids (h^2=0.16-0.78), short chain (h^2=0.13-0.51), medium chain (h^2=0.15-0.46) and long chain (h^2=0.16-0.24) acylcarnitines. The heritability of TSH (h^2=0.70) was consistent with what is reported in the literature for adult serum TSH and the heritability of 17-OHP was h^2=0.17. CONCLUSIONS: We have identified high heritability for many metabolic factors as measured at birth, particularly essential amino acids and TSH in preterm twins. This implicates that genetic factors regulate variation in metabolites at birth and understanding these factors will help to optimize newborn screening tests as well as in the understanding of metabolic diseases during childhood. Ongoing studies are underway to replicate these findings examining a larger independent cohort of twins.

1327F

Guanidinoacetate methyltransferase (GAMT) deficiency presenting as a late-onset refractory seizure disorder and mental retardation in sibs. *A. Levtova[1], L. Carmant[2], M. Lambert[1], V. Désilets[1].* 1) Medical Genetics, CHU Sainte-Justine, University of Montreal, Montreal, Quebec, Canada; 2) Pediatric neurology, CHU Sainte-Justine, University of Montreal, Montreal, Quebec, Canada.

Introduction: Guanidinoacetate methyltransferase (GAMT) deficiency is a disorder of creatine synthesis resulting in depletion of the brain creatine pool. Case report: We describe two siblings with newly diagnosed guanidinoacetate methyltransferase (GAMT) deficiency. Patient 1, a 6 y.o. girl, had normal milestones until age 2 with subsequent developmental slowing, though without frank regression, particularly affecting language. Her epilepsy began at age 5 with staring, myoclonic and atonic (head nodding) episodes whose frequency escalated over an 8-month period. She then had a tonic-clonic convulsion followed by non-convulsive status. A brain MRI showed delayed myelinisation in the bifrontal and mesiotemporal regions. She has multiple daily seizures despite trials of multiple anticonvulsants; her development is mildly to moderately delayed. Patient 2, a 13 y.o. boy whom we evaluated as part of his sister's investigation, had first presented to the neurology clinic at 10 months with an isolated motor delay; he was then lost to follow-up until the onset of similar complex partial with an atonic component as well as tonic-clonic seizures at age 4. At this point, he had significant global developmental delay. His epilepsy has been refractory to multiple agents; vagus nerve stimulator placement was also not effective. Brain MRI was normal at the ages of 5 and 11. Liquid chromatography/mass spectrometry detection showed low-normal creatine (12 and 22 umol/mmol creatinine in patients 1 and 2, respectively) and high guanidinoacetate (880 and 527 umol/mmol creatinine, respectively). Patient 2's GAMT activity on fibroblasts was undetectable. Brain MRI with spectroscopy for patient 1 and GAMT sequencing for patient 2 are pending. Creatine monohydrate treatment was begun in both children (400 mg/kg/day) and will be escalated as needed. Future steps include dietary arginine restriction and ornithine supplementation. Conclusion: Despite undetectable GAMT activity in Patient 2, these sibs stand apart from most known cases of GAMT deficiency in that their developmental delay has been somewhat milder, but especially in that, in both cases, non-specific developmental delay preceded the onset of epilepsy by several years. As there is evidence that early diagnosis of GAMT deficiency may lead to dramatically improved outcomes, this highlights the importance of measuring urinary creatine and guanidinoacetate in children with nonsyndromic developmental delay.

1328F

The Clinical Spectrum of Pancreatitis in Organic Acidemias. *H. Anderson[1,2], I.S. Fortgang[2], M.S. Petrescu[2], T.C. Narumanchi[1,2], A. Cunningham[1,2].* 1) Hayward Gen Ctr, Tulane Univ Med Ctr, New Orleans, LA; 2) Pediatroc Department, Tulane Univ Med Cntr, New Orleans, LA.

Pancreatitis is a rare complication attributed to organic acidemias. No known pathophysiologic mechanism has been identified and no clear therapeutic recommendations exist. Treatment of pancreatitis involves avoidance of enteral nutrition complicates management of organic acidemias in which avoidance of catabolism is paramount. We describe 3 cases of pancreatitis in patients with organic acidemias illustrating the wide clinical spectrum of pancreatic abnormalities. Cases: Case A was a 12-year old boy with recurrent pancreatitis but no other problems noted who was transferred to tertiary care from an outlying hospital with severe metabolic acidosis and loss of consciousness. He had been fasted for several days for pancreatitis receiving only intravenous dextrose for nutrition. Organic acid analysis revealed significantly elevated propionic acid and 3-OH-propionic acid. He expired of brainstem herniation; his mother, who was pregnant, delivered a healthy male who also has an attenuated form of propionic acidemia (asymptomatic with diagnostic organic acids). Case B is a 6-year old Vietnamese boy with methylmalonic acidemia diagnosed in infancy when he presented with lethargy and metabolic acidosis. He had been managed with protein restriction, metabolic formula, oral carnitine and IM OH-cobalamin without recurrent exacerbations until age 5 years when he presented with intractable abdominal pain and elevated lipase/amylase. Abdominal imaging revealed splenic vein thrombosis and pseudocyst measuring 1.4 cm x 2.8cm. At age 6 years, he had a recurrence of abdominal pain associated with elevated lipase and the pseudocsyt size had doubled to 2cm x 6 cm. Case C is a 5-year old girl with methylmalonic acidemia diagnosed in infancy with severe metabolic acidosis who had yearly severe metabolic exacerbations and presented with abdominal pain and nausea with elevated lipase and amylase but no metabolic exacerbation. Conservative care with gut rest and optimization of parenteral calories (15% dextrose) including amino acids has been successful in abating two episodes of pancreatitis without inducing catabolic crisis. Pancreatitis is a rarely reported complication of many organic acidemias and can be the presenting symptom in mild/attenuated forms. Early detection is important and avoidance of catabolism in management is critical to successful outcomes. Clinical severity and exacerbations do not seem to correlate with incidence of pancreatitis which may be recurrent.

1329F

Identification of novel biochemical abnormalities in organic acidemias through a GC-MS based metabolomics approach. *H. Vernon[1], Y. Sandlers[2], R.I. Kelley[2], D. Valle[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

We applied a GC-MS based metabolomics approach to investigate biochemical abnormalities in energy metabolism in Isovaleric Acidemia (IVA), Methylmalonic Acidemia (MMA) and Propionic Acidemia (PA). We began with a non-targeted GC-MS approach to screen plasma samples from 4 patients with MMA and 4 patients with PKU on diet (as a control population) and identified 95 individual metabolites seen in all 8 individuals. We selected for further study target metabolites that were related to energy metabolism and showed a difference between the MMA and control (PKU) populations. We then studied six Krebs cycle intermediates by GC-MS isotope dilution in plasma samples from 4 patients with IVA, 5 patients with MMA, 6 patients with PA, and 6 control (PKU) patients. We found abnormal profiles of plasma Krebs cycle metabolites in MMA, PA, and IVA patients compared with controls, and cohorts with MMA, PA, and IVA showed individually different profiles. Patients with PA had significantly higher malate (12.9 uM vs. 5.8 uM, P-value 0.0008), fumarate (3.0 vs. 1.5 uM, P-value 7.1E-05), and succinate (8.26 uM vs. 4.56 uM, P-value 0.03) compared to controls, but not 2-ketoglutarate, isocitrate or citrate. Patients with MMA had significantly higher malate (11.0 uM vs. 5.8 uM, P-value 0.05), but not of the other metabolites, however the level of fumarate trended in the same direction as in the PA cohort (3.1 vs 1.5 uM) but did not reach significance because of an outlier in the MMA cohort. Patients with IVA had slightly lower levels of isocitrate compared to controls, but normal levels of the other metabolites. We also used these methods to track metabolic aberrations in a single patient with MMA during different clinical states and found that the level of fumarate appeared to correlate with the severity of illness, with fumarate highest during hospitalization requiring an ICU setting (5.2 uM), moderate when hospitalized in a regular pediatric setting requiring minimal medical intervention (4.0 uM), and lowest when measured twice as an outpatient (3.07 uM and 2.73 uM). Our results indicate that MMA, PA and IVA cause fundamental metabolic disturbances not detected by traditional metabolic testing, which largely focuses on measurements of immediate upstream and downstream metabolites. We propose that a better understanding of the ways by which MMA, PA, and IVA disrupt the Krebs cycle will lead to improved targeted treatments.

1330F

Characterization of surfactant secretion in alveolar type II cells cultured from PEX7 hypomorphic mice: does plasmalogen deficiency lead to surfactant abnormalities? *X. He[1], W. Cui[2], S. Jiralerspong[2], I. Mandeville[2], S. Steinberg[3], A. Moser[3], N. Braverman[1,2].* 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) Montreal Children Hospital Research Institute, Montreal, QC, Canada; 3) Kennedy Krieger Institute, Department of Neurogenetics, Baltimore, MD, USA.

Rhizomelic chondrodysplasia punctata (RCDP) is commonly caused by defects in the peroxisome transporter, PEX7. Clinical features include skeletal dysplasia, cataracts, mental retardation and chronic pulmonary compromise that ultimately causes death. These features result from plasmalogen (PL) deficiency, a specialized class of membrane phospholipids whose functions are largely unknown. Relevantly, PLs are integral components of surfactant, secreted by alveolar type II (ATII) cells. To study RCDP and PLs, we generated Pex7 deficient mouse models, which showed abnormalities in late lung development (see W. Cui et al, abstract on lung abnormalities in the Pex7 mouse model). We hypothesized that ATII cells cultured from the Pex7 hypomorphs produce abnormal surfactant and that this contributes to the chronic lung disease in patients. To test this hypothesis, we will stimulate surfactant secretion in primary ATII cells cultured from these mice using drugs that stimulate the three kinases essential to the surfactant secretion pathway: protein kinase A by terbutaline, protein kinase C by ATP and TPA, and CaMK by ionomycin. We will then evaluate surfactant protein and lipid composition and relative amounts pre and post stimulation. In preliminary experiments, we have characterized the synthesis and secretion of surfactant proteins in ATII cells cultured from wild type neonatal (P7-P10) mouse lungs using fibroblasts as negative controls and A549 human carcinoma lung cells as positive controls. Immunofluorescence assays using antiserum to surfactant proteins A, B, C, and D confirms the intracellular localization of these proteins during synthesis, and immunoblotting shows secretion of these surfactant proteins in cell culture media. In subsequent assays, we will obtain lipid profiles by tandem mass spectrometry to characterize amounts of PLs and other surfactant lipids and then evaluate all of these parameters in our Pex7 deficient mouse models. Finally, we will treat the primary ATII cells with a plasmalogen precursor to determine if we can rescue the abnormalities detected.

1331F

Increased incidence of Zellweger syndrome in French-Canadians of Saguenay-Lac-St-Jean due to a founder mutation in *PEX6*. *S. Levesque[1], C. Morin[2,6], S.-P. Guay[3], J. Villeneuve[2], P. Marquis[5], L. Bouchard[3,7], S. Steinberg[4], K. Dewar[5], N. Braverman[1].* 1) Dept of Medical genetics, Montreal Children`s Hospital, Montreal, QC, Canada; 2) Dept of Pediatrics, Centre Hospitalier de Chicoutimi, Saguenay, QC, Canada; 3) ECOGENE-21, Centre Hospitalier de Chicoutimi, Saguenay, QC, Canada; 4) Dept of Neurogenetics, Kennedy-Krieger Institute, Balimore, MD; 5) Genome Quebec Innovation Center, McGill University, Montreal, QC, Canada; 6) Dept of Pediatrics, Université de Sherbrooke, Sherbrooke, QC, Canada; 7) Dept of Biochemistry, Université de Sherbrooke, Sherbrooke, QC, Canada.

Peroxisome biogenesis disorders show defective peroxisome assembly, division and/or impaired importation of proteins inside the organelle and include Zellweger syndrome (ZS). Patients show dysmorphic features and usually present in the neonatal period with central hypotonia, seizure and multi-organ dysfunction. Neither the clinical presentation nor specialized biochemical assays distinguish between the 12 causative PEX genes. Overall, ZS spectrum has an estimated incidence of 1 in 50,000 births. For decades, clinicians have been suspecting an increased incidence of ZS in French-Canadians of the Saguenay-Lac-St-Jean region (SLSJ), located in the northern-eastern part of province of Quebec. This has remained unproven until now and molecular basis of these ZS cases remained unsolved. Increased incidence related to founder effect has been described for several disorders in SLSJ, including Tyrosinemia type I. Therefore, we hypothesized that if an increased incidence of ZS is indeed present in SLSJ, it is likely due to a founder effect and a low allelic complexity should be expected. We first reviewed the suspected ZS cases diagnosed in SLSJ between 1990 and 2010. During that period, 5 cases of ZS were suspected based on clinical presentation with additional laboratory supportive evidence, either plasma very long chain fatty acid level or liver biopsy. All cases were of French-Canadian descent, presented in the neonatal period with severe hypotonia, and deceased within the first year of life (0.5 months - 6 months). Sanger sequencing was then performed in one patient for known human PEX genes (13), and coding and flanking intronic sequences were analyzed for sequence variations. Among these, a homozygous mutation (c.802_815del) was found in the exon 1 of *PEX6*, which has been previously described in ZS. DNA samples of the 4 remaining patients (if available) and their parents were obtained and PEX6 exon 1 was sequenced. All patients were homozygous for the c.802_815del mutation. Parental heterozygous state was confirmed for all cases. Using these definitive ZS patients, we estimated the incidence in SLSJ to 1 case per 12,191 live births, with calculated carrier frequency of 1 in 55. In conclusion, we showed evidence of founder effect for ZS in the French-Canadian of SLSJ by the identification of a single causal mutation within *PEX6*. To our knowledge, this is the highest reported incidence of ZS worldwide.

1332F

Single nucleotide polymorphisms in the promoter region of ADIPOQ are associated with adiponectin level measured at first trimester in pregnant women. *M-F. Hivert[1], M. Lacroix[1], M. Doyon[1], M-C. Battista[1], P. Perron[1], D. Brisson[2], L. Bouchard[1].* 1) Université de Sherbrooke, Sherbrooke, QC., Canada; 2) Université de Montréal, Montréal, Qc., Canada.

Purpose: Adiponectin is exclusively produced by adipocytes and is suspected to act as an insulin sensitizer. In pregnant women, low circulating adiponectin levels at 1st trimester have been associated with increase risk of developing gestational diabetes mellitus (GDM). Expression of the gene encoding for adiponectin (ADIPOQ) is decrease in adipose tissue of pregnant women developing GDM, suggesting that adiponectin could be involved in insulin resistance pathways leading to GDM. A few genetic variants located in or around ADIPOQ have been associated with adiponectin levels in non-pregnant women, but it is unknown whether those variants are also associated with circulating adiponectin concentration in the pregnant state. Methods: This study includes 2 cohorts of pregnant women recruited in Sherbrooke (n=167) and in Chicoutimi (n =179), Québec, Canada. Women were recruited at 1st trimester and followed over the course of their pregnancy. Anthropometric data were measured with standardized procedures. Blood was collected at 1st trimester to assess adiponectin levels (RIA;Millipore). DNA was extracted from circulating white blood cells; single nucleotide polymorphisms (SNPs) were genotyped on a RT-PCR 7500Fast using TaqMan probes (Applied Biosystems Inc). Regression models were performed using additive genetic models to predict adiponectin level (log-transformed). Results: In Sherbrooke, mean age of the participants was 28.4±4.4 years old, mean BMI at 1st trimester was 25.7±5.9 kg/m^2, and mean adiponectin level was 8.7±6.0 µg/mL. In Chicoutimi, mean age was 28.5±3.9 years old, mean BMI at 1st trimester was 25.4±5.4 kg/m^2 and mean adiponectin level was 13.3±5.1 µg/mL. Three SNPs previously known to be involved in regulatory regions of ADIPOQ were genotyped: rs17300539 and rs822387 in the promoter (both in strong LD), and rs6773957 in the 3'UTR. In the promoter region, presence of the minor allele (A) at rs17300539 was associated with higher level of adiponectin at first trimester (p=0.02 when pooling both cohorts). Similar results were obtained for minor allele at rs822387 (p= 0.02). The SNP located in the 3'UTR was not significantly associated with adiponectin levels. Conclusion: SNPs located in the promoter region of ADIPOQ are associated with adiponectin levels at first trimester in pregnant women from European descent. Future studies will help to determine whether those variants influence adiponectin levels later during pregnancy and development of GDM.

1333F

Significant association of ADRB2 Glu27Gln polymorphism with triglyceride level in Tongans. *I. Naka[1], R. Kimura[2], N. Nishida[3], T. Inaoka[4], Y. Matsumura[5], J. Ohashi[1].* 1) Doctoral Program in Biomedical Sciences, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Ibaraki, Japan; 2) Transdisciplinary Research Organization for Subtropics and Island Studies, University of the Ryukyus, Okinawa, Japan; 3) Research Center for Hepatitis and Immunology, International Medical Center of Japan Konodai Hospital, Ichikawa, Chiba, Japan; 4) Department of Environmental Sociology, Faculty of Agriculture, Saga University, Saga, Japan; 5) Faculty of Health Care, Kiryu University, Gunma, Japan.

To investigate whether the) 2 adrenergic receptor gene (*ADRB2*) polymorphisms play a role in the regulation of lipid mobilization, energy expenditure and glycogen breakdown, the associations of non-synonymous single nucleotide polymorphisms (SNPs) in the coding region of *ADRB2*, Gly16Arg (rs1042713) and Glu27Gln (rs1042714), and in the 5' leader cistron, 5'LC-Arg19Cys (rs1042711), with total-cholesterol, HDL-cholesterol, LDL-cholesterol and triglyceride levels were examined in 142 adult subjects in Tonga. A multiple regression analysis adjusted for age, sex, and body mass index (BMI) revealed that a copy of 27Glu significantly increased serum triglyceride by 0.866 mmol/l (P-value = 0.0379). No other significant associations were observed. Although the detected association of 27Glu with triglyceride level was not highly significant, the present result is consistent with previous studies in various ethnic groups (Ishiyama-Shigemoto et al., 1999; Ehrenborg et al., 2000; Iwamoto et al., 2001; Macho-Azcarate et al., 2002; Isaza et al., 2005; Yoshida et al., 2009). Our results suggest that *ADRB2* Glu27Gln polymorphism is associated with serum triglyceride level independent of BMI in Tongans.

1334F

Genetic polymorphism of -1297 T/C on Interleukin-18 may predispose gallstone patients to cholecystectomy. *H. Yang[1], S. Shih[2,3], T. Chang[1], H. Wang[2,3], K. Hu[2,3], C. Chang[2,3], C. Chang[2,3], C. Hung[2,3], H. Chan[1], M. Lin[1], Y. Lee[1,4,5].* 1) Medical Research, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Internal Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 3) Mackay Medicine, Nursing and Management College, Taipei, Taiwan; 4) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 5) Department of Pediatrics, Taipei Medical University, Taipei, Taiwan.

Individuals with gallstones are often detected in health check by ultrasonography and most of them remain asymptomatic. These asymptomatic ones will tune to symptomatic gallstone disease (GSD) with acute, severe, intermittent abdominal pain, or other complications in 1 to 2% per year. GSD is a complex disease resulting from interaction between genetic and environmental risk factors. During past decades, the incidence and prevalence of GSD have increased in Taiwan. Its overall prevalence was 5% including asymptomatic and symptomatic subjects in a community-based study. IL18 is proinflammatory and able to induce production of INF-. from activated T lymphocytes and natural killer cells and secretion of proinflammatory cytokines. IL18 induces INF-. production in the presence of interleukin-12 but Th2 signaling in an IL4 dependent manner. Genetic mapping of lithogenic susceptible genes also contain immune-related factors including INF-. . The amount of INF-. in the liver correlates with IL18 suggests a critical role of IL18 in Th1 mediated intrahepatic immune responses. Therefore, IL18 may involve in gallstone induced inflammation response by regulating Th1 or Th2 signaling. A number of single nucleotide polymorphisms (SNPs) in the promoter region of IL18 gene are associated with differential levels of gene transcription, protein production, and diseases. For example, -607 C/A and -1297 T/C SNPs can influence transcription factor binding and have an impact on IL18 gene activity in autoimmune diseases. Some of these polymorphisms have been investigated in several autoimmune, inflammatory or metabolic syndromes. The present study was to examine whether specific IL18 gene SNPs, including -1297 T/C and -607 C/A and their haplotypes were associated with GSD.In conclusion, we found an association between IL18 -1297 T/C SNP and cholecystectomy in patients with GSD. Genotype T/T and allele T conferred a risk of cholecystectomy, however, carrier C and haplotype AC rendered protection against this complication. We propose that polymorphisms of IL18 might promote inflammatory response in a gallbladder stones leading to severe inflammatory responses.

A prediction model for gout using genetic polymorphisms of ten loci associated with serum levels of uric acid. *A. Taniguchi[1], W. Urano[1], E. Inoue[1], C. Sekita[1], Y. Koseki[1], N. Ichikawa[1], N. Kamatani[2], H. Yamanaka[1].* 1) Inst Rheumatology, Tokyo Women's Medical Univ, Tokyo, Japan; 2) Laboratory for Statistical Analysis, Center for Genomic Medicine, Institute of Physical and Chemical Research.

Objective: Gout is the most common disorder with inflammatory arthritis. Sustained hyperuricemia introduced crystallization of monosodium urate crystals within joints and eventual development of gouty arthritis. Gout is a multifactorial disease that is caused by the simultaneous action of multiple genetic and environmental factors. Recent genome-wide association studies using Caucasian or Japanese samples have provided evidence that polymorphisms on several genes were associated with serum levels of uric acid and/or the development of gout. In the present study, we validated the associations of these 11 genes using Japanese patients with gout and attempted to construct a prediction model for gout using genetic polymorphisms and environmental factors. Patients and Methods: Subjects were Japanese male patients with gout (n = 153) and male controls (n = 532). The genotypes of 12 polymorphisms on the ten genes, PDZK1, GCKR, ABCG2, LRRC16A, LRP2, SLC2A9, SLC16A9, SLC17A1, SLC22A11, and SLC22A12, were determined using the TaqMan method (Applied Biosystems, Foster city, CA) and allele frequency of each polymorphism was compared between gout patients and controls. Then, each risk allele was allocated weighted score from 0 to 3 according to P value and odds ratio. Genotype score of individual was calculated by summing the weighted scores. A prediction model for gout using C statistics was constructed by incorporating genotype score of the 12 polymorphisms, adjusted for age, body mass index, serum levels of triglyceride, and eGFR. Results: Nine loci showed P value less than 0.05, and 5 of these 9 loci showed significant association by the Bonferroni correction. The minimum genotype score was 7 in gout, and the maximum was 22. The genotype score was significantly higher among patients with gout (16.4±2.3) than those of controls (14.6±2.4) (P<0.0001). The OR of gout increased accordingly across the genotype score. When we compared the OR of gout between the individuals with the lowest score and those with highest score, 27-fold increased risk of developing gout was shown. The C statistic using the weighted genotype score was 0.78, indicating that models including genetic and non-genetic factors may be useful to predict gout. Conclusion: Our data suggest that a model incorporate the weighted genotype scores and environmental factors is useful for prediction of gout in Japanese males.

1336F

Genome wide expression profiling in the Smith-Lemli-Opitz syndrome (SLOS). *R. Steiner[1], J.-B. Roullet[1], C. Wassif[2], F.D. Porter[2], Q. Yang[1], S. Impey[1].* 1) Pediatrics, Oregon Hlth Sci Univ, Portland, OR; 2) Eunice Kennedy Shriver NICHD, Bethesda, MD.

Background: SLOS is caused by inactivating mutations of the DHCR7 gene leading to cholesterol deficiency. It is characterized by a broad phenotypic spectrum typically including congenital malformations and mental retardation. SLOS pathophysiology remains poorly understood and there is no effective treatment. Objectives: to characterize the molecular changes caused by DHCR7 deficiency. Specifically, to obtain baseline gene expression profiles in affected and non-affected cells. Methods: Genome wide expression profiling (RNA-Seq) was performed using skin fibroblasts isolated from a patient with severe SLOS and neural stem cells (NSC) isolated from Dhcr7-/- mice (E18). Results: The SLOS fibroblast gene expression profile showed down regulation of genes involved in mitochondrial function, calcium homeostasis, cytoskeleton, lysosomal function, signaling (caveolin1, Na+/K+ ATPase), folate metabolism and defense against oxidative stress. Genes related to apoptosis, ubiquitination and extracellular matrix synthesis were upregulated. Such expression profile was not observed in Dhcr7-/- NSCs. In these cells, stem-cell marker nestin and cell-replication genes were down-regulated whereas genes implicated in synaptic transmission, signaling, and cell differentiation were upregulated, suggesting abnormal NSC-to-neuron differentiation in vivo. Conclusion: Cell biology is profoundly altered in SLOS. Future studies with cell lines from other patients and from NSC-derived neurons are needed to confirm and expand these findings.

1337F

Surface plasmon resonance - mass spectrometry to identify novel binding partners in intracellular vitamin B_{12} metabolism. *M. Plesa[1,2], M.A. Hancock[3], J.C. Deme[1], D. Watkins[2], D.S. Rosenblatt[2], J.W. Coulton[1].* 1) Microbiology and Immunology, McGill University, Montreal, Quebec, Canada; 2) Department of Human Genetics; 3) Sheldon Biotechnology Centre.

Human MMACHC and MMADHC are soluble proteins involved in the intracellular metabolism of vitamin B_{12}. They are required to generate essential cofactors necessary for activity of two key enzymes: methionine synthase and methylmalonyl CoA mutase. Defects in the genes encoding these proteins result in the *cblC* and *cblD* disorders. Recently, we predicted and validated specific interactions between MMACHC and MMADHC. To identify other potential MMACHC binding partners, we have combined classical fractionation with surface plasmon resonance (SPR) and mass spectrometry (MS). Compared to traditional ligand fishing approaches that include yeast two hybrid and co-immunoprecipitations, SPR-MS offers increased accuracy, sensitivity, and efficiency. Soluble fibroblast lysates were separated by size exclusion chromatography and the individual fractions screened for binding against MMACHC that was immobilized as purified bait on SPR surfaces. Positive hits, species that may be previously unrecognized binding partners, were further fractionated by ion-exchange chromatography and then re-screened for MMACHC-binding activity by SPR. Optimization of the interface between SPR for microrecovery of bound unknowns and MS facilitates identification of novel MMACHC binding partners. Ultimately, we anticipate that SPR-MS directs identification of novel therapeutic candidates for rare, inborn errors of vitamin B_{12} metabolism.

1338F

A Genome Wide Association Study Identifies 31 Genetic Loci Associated with Human Serum Metabolites. *J. Kettunen[1,2], T. Tukiainen[1,3,4,5], A.P. Sarin[1,2], A. Ortega-Alonso[6], E. Over a hundred genetic loci have been associated with metabolic traits such as lipids, glucose and diagnostic biomarkers. In this study, we estimate the heritabilities in 657 twin pairs of circulating levels of 216 metabolic traits identified using serum NMR metabonomic screening techniques. We also test for associations between the metabonomic measurements and 7.7 million genetic markers, directly genotyped or imputed using 1000 genomes reference panel, in 8330 randomly ascertained Finnish individuals from five population cohorts. Our genome wide association analysis reveals 33 independent genomic markers from 31 genetic loci associated with one or more metabolites using a stringent level of statistical significance ($p < 2.31*10^{-10}$). To our knowledge, 15 of the loci have not been associated with metabolic traits before. Our novel findings include association with albumin locus and various lipoprotein measures, four other lipid or lipoprotein associations, an association with citrate ion and nine associations with different amino acids, including six variants associating with amino acids recently linked with risk of developing type 2 diabetes. Using an independent cohort, we find that these 33 variants together explain up to 40% of the genetic variance in an individual metabolic measure. We show that both genetic and phenotypic fine mapping lead to substantial increases in statistical power and bring us in close proximity with the metabolic processes modified by these loci. Thus, our study elucidates novel genetic information and pathways in human metabolism, underpinning genetic influence of metabolic biomarkers informative for cardiovascular disease and diabetes risk assessment.

1339F

Long-term outcome and intervention of urea cycle disorders in Japan. *J. Kido[1], K. Nakamura[1], H. Mitsubuchi[1], T. Ohura[2], M. Takayanagi[3], M. Matsuo[4], M. Yoshino[5], Y. Shigematsu[6], T. Yorifuji[7], M. Kasahara[8], R. Horikawa[9], F. Endo[1].* 1) Department of Pediatrics, Graduate School of Medical Sciences, Kumamoto University, Kumamoto, Japan; 2) Division of Pediatrics, Sendai City Hospital, Sendai, Japan; 3) Division of Emergency and General Medicine, Chiba Children's Hospital, Chiba, Japan; 4) Department of Pediatrics, Kobe University Graduate School of Medicine, Kobe, Japan; 5) Department of Pediatrics and Child Health, Kurume University School of Medicine, Kurume, Japan; 6) School of Nursing, Faculty of Medical Sciences, University of Fukui, Fukui 910-1193, Japan; 7) Division of Pediatric Endocrinology and Metabolism, Osaka City General Hospital, Osaka, Japan; 8) Department of Transplantation Surgery, National Center for Child Health and Development, Tokyo, Japan; 9) Department of Endocrinology and Metabolism, National Center for Child Health and Development, Tokyo, Japan.

Urea cycle disorders (UCDs) are one of the most frequently inherited metabolic diseases in Japan, with an estimated prevalence of 1 per 50,000 live births. Here, we investigated the clinical manifestations and prognosis of 177 patients with UCDs evaluated and treated from January 1999 to March 2009 to study more effective treatment and prognosis in patients. These included 75 cases of neonatal-onset UCDs and 91 cases of late-onset UCDs. The most common disorder in UCDs was ornithine transcarbamylase deficiency (OTCD), which accounted for 116 out of 177 patients. This result is similar to a previous study performed between 1978 and 1995 in Japan: OTCD accounted for about two thirds of the total number of UCD cases. We studied the relationship between prognosis and the peak blood ammonia level at the onset in 151 UCD patients. Compared with a previous survey conducted in Japan, we found that more patients whose peak blood ammonia levels were greater than 360 μmol/l survived without any mental retardation. The 5-year survival rate of patients with OTCD improved to 64% for those with the neonatal-onset type and to 91% for those with the late-onset type. We hypothesize that the increased survival is due to earlier diagnosis and better treatments that are now available in Japan. It is very important to diagnose and treat UCDs, especially OTCD, when the blood ammonia levels in patients are low. The outcome in patients with low blood ammonia levels was better than in patients with high blood ammonia levels.

1340F

Knockdown of upstream stimulatory factor 1 leads to a beneficial metabolic profile in mice. *P-P. Laurila[1,2], J. Soronen[2], E. Kaiharju[2], C. Ehnholm[2], V. Olkkonen[3], M. Jauhiainen[2], L. Peltonen[1,2,4].* 1) Dept of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Public Health Genomics Unit, National Institute for Health and Welfare, Helsinki, Finland; 3) Minerva Research Institute, University of Helsinki, Helsinki, Finland; 4) The Wellcome Trust Sanger Institute, Cambridge, UK.

Metabolic derangements in the body are tightly linked with cardiovascular disease. We have earlier established the association between genetic variants of USF1 with familial combined hyperlipidemia and its component traits, TG and cholesterol in Finnish families. In the current study we have conducted a detailed analysis of the effects of USF1 on metabolic parameters using both in vivo and in vitro models. We generated a congenic strain of Usf1 knockout (-/-) (11 males, 29 females) mice which along with their +/- and +/+ (27 M, 31 F) littermates were fed with Western diet rich in TG and cholesterol for 5 months. The Usf1 -/- mice displayed both elevated cholesterol ($p<0.001$) and phospholipids in their plasma. In human hepatoma cells (HuH7), using USF1 targeting siRNAs, we showed that APOA1 transcription and secretion were elevated in USF1 silenced cells in line with the animal model. USF1 overexpression also inhibited the activity of a 2000 bp APOA1 promoter-linked luciferase ($p<0.05$), raising the possibility of APOA1 being a direct target gene of USF1. The Usf1 -/- mice had lower plasma total and VLDL TG as compared to their +/+ littermates, which is due to increased lipolysis. This was evidenced by -/- mice having higher activity and expression ($p<0.01$) of lipoprotein lipase in the liver, muscle, and adipose tissue which was studied using the Affymetrix microarrays. We observed that despite having increased food consumption and being physically less active than +/+ mice, the Usf1 -/- mice were actually protected from obesity during Western diet and also showed an increased sensitivity to insulin during insulin tolerance test. Expression analysis from their adipose tissue revealed an increased expression of complexes of the mitochondrial respiratory chain ($p<0.001$) which was evidenced by both increased VO2 and VCO2, suggesting a higher overall metabolic rate for the -/- mice. These changes were not observed at an early age, but after 5 months of Western diet. Our study establishes the critical role of USF1 at the crossroads between metabolic and cardiovascular homeostasis. Since the loss-of-function of USF1 caused a favorable blood lipid phenotype and protection from obesity during Western diet, we hypothesize that its knockdown effect in appropriate tissues has favorable cardiovascular and metabolic effects.

1341F

Heterozygous mutation in the X chromosomal NDUFA1 gene in an oligosymptomatic 5-year old girl with complex I deficiency. *O. Bodamer[1], J. Mayr[2], T.B. Haack[3,4], F. Zimmermann[2], H. Prokisch[3,4], C. Rauscher[2], J. Koch[2], W. Sperl[2].* 1) Dept Human Genetics, Univ Miami Miller Sch Medicine, Miami, FL; 2) Dept.Pediatrics, Paracelsus Medical University, Salzburg, Austria; 3) Institute of Human Genetics, Helmholtz Zentrum Munich, Germany; 4) Institute of Human Genetics, Technical University Munich, Germany.

Background: Respiratory chain enzymes consist of multiple subunits encoded either by the mitochondrial or by the nuclear genome. Recently the first X-chromosomal mutations in complex I deficient males have been described. Heterozygous female carriers did not appear to be clinically affected. **Case report:** Here, we report a now 5 year-old girl with age appropriate psychomotor development and essentially normal muscle function. Her past medical history was unremarkable with the exception of recurrent episodes of vomiting and somnolence during episodes of inter-current infections. She is the only child of non-consangineous Caucasian parents. The father suffers from diabetes mellitus type 1 of juvenile onset, the mother is reportedly healthy. Her initial work-up at 11 months of age revealed a moderate lactic acidosis (3-4 mmol/L; norm: < 2.7 mmol/L) and a markedly increased betahydroxybutyrate/acetoacetate (BOH/AA) ratio (7.9; norm: < 2.6) following a 12 hour fast. **Biochemical and genetic investigations:** Biochemical investigation of a muscle biopsy at 15 months of age revealed a deficiency in complex I activity in fresh, unfrozen mitochondria (complex I /citrate synthase activities 0.05; norm: 0.14-0.35). Mutation screening of all structural subunits of complex I identified a heterozygous mutation c.94G>C, p.Gly32Arg in the X-chromosomal NDUFA1 gene. Analysis of the cDNA showed that 72 % of the expressed mRNA was mutated in the muscle biopsy sample. Investigation of the X-inactivation pattern demonstrated that 74 % of the paternally inherited allele was active in the muscle. The mutation was not detectable in either maternal or paternal blood. **Summary and conclusions:** Mutations in X-chromosomal mitochondrial genes pose a particular diagnostic challenge in oligo-symptomatic females. The clinical phenotype may be atypical and sometimes misleading in affected females due to tissue specific X-chromosomal inactivation and expression of proteins. In fact to the best of our knowledge our report is the first of a X-chromosomally inherited respiratory chain defect in a heterozygous female.

1342F

Circulating Collections: Ethics and the Institutional and Social Locations of Resources for Specimen-Based Human Genome Research. *J. Radin[1], J. Brown[2].* 1) History and Sociology of Science, University of Pennsylvania, Philadelphia, PA; 2) Anthropology, University of Pennsylvania, Philadelphia, PA.

This poster identifies the diverse kinds of collections available for genomic research, the similarly diverse ethical concerns that condition their use, and visualizes the paths that these collections trace as they circulate through different institutional contexts.

With the refinement and cost reduction of genomic techniques an increasingly diffuse and diverse array of human biomaterials are now available for analysis. These include ancient materials, those accumulated decades ago, and those being collected today. However, the context of origin of these specimens may mitigate or constrain the use of such materials as they circulate through different institutional locations. Commentators concerned with the appropriate use of human specimens in the context of genomic research often fail to distinguish between samples collected for forensic, biomedical, anthropological, or other purposes. They also frequently overlook the relative age of collections. At the same time, the kinds of questions that contemporary researchers are asking often blend one or more category. For example, biological anthropologists have begun to ask questions about chronic and infectious disease and some in medical genetics have become interested in forensics.

With this poster, we provide a resource for parsing the varied ethical and regulatory requirements that affect human tissues dependent on both the circumstances of their collection and the institutional location of their subsequent genomic interpretation.

1343F

Freedom to directly access to genetic tests on internet: a part of the right to innovation? *E. Rial-Sebbag[1], H. Howard[2], P. Borry[3], A. Cambon-Thomsen[1].* 1) UMR U 1027, Inserm, Université de Toulouse - Université Paul Sabatier -Toulouse III Faculté de médecine. 37 allées Jules Guesde F-31073 Toulouse Cedex 7 France; 2) Institute of Biomedical Ethics, University of Basel, Switzerland; 3) Centre for Biomedical Ethics and Law, University of Leuven, Belgium & Department of Clinical Genetics and Medical Humanities, VU University Medical Centre Amsterdam, The Netherlands.

The ethical, legal and social literature on direct-to-consumer genetic tests (DTC-GT) traditionally emphasizes the protection of individuals against risks, which are often related to the lack of information delivered by the companies selling them. Less has been written regarding the application of the principle of freedom of people in accessing innovations (DTC-GT can be considered as innovations). The right to freedom has been described in several international human rights texts and traditionally applies to rights such as freedom of movement or of expression. Nevertheless freedom is translated in health practice through the implementation of two different principles: autonomy of people to gather information on their health and right to benefit from new innovations. The later is emerging from various social claims (European Charter of Patients' Rights Active Citizenship Network. Rome, November 2002) and is implicitly referred to by European legislations and jurisprudence. This new right would be, on the one hand, limited by States `duties such as the promotion of a high level of protection for health (which implies a control of this new practice), but on the other hand, will have to be built on the current legislation (freedom and autonomy would be used in support of a court decision). Public policies, as well as courts, will have to challenge this new right in the near future. We will then analyse this new claim together with the European legal framework within the context of DTCGT in order to: 1/Assess the possibility of the emergence of a new fundamental right: the right to innovation, 2/ Evaluate the consequences of such a new right, in particular with regards to the construction of a pro-active right while regulation is currently intended to restrict freedom in the name of public health argument.

1344F

A research activity for ethical, legal, and social implications of personal genomics in Japan. *T. Shirai[1], J. Minari[1], A. Nomura[1], K. Kato[1,2,3].* 1) Inst. Res. Humanities, Kyoto University, Kyoto, Japan; 2) Grad. Sch. Biostudies, Kyoto University, Kyoto, Japan; 3) Inst. Integrated Cell-Mat. Sci., Kyoto University, Kyoto, Japan.

In 2010, a large-scale project, “Support for Genome Research” started in Japan. This 5 years' project is funded by the Ministry of Education, Culture, Sports, Science and Technology (MEXT). The aim is to comprehensively support the genome researchers funded by MEXT, and to advance and promote genome research in Japan. The project has 3 support programs; large-scale genome data production program, medical genome science program, and bioinformatics analysis program. These programs perform sequencing and/or data analysis for genome researchers who are selected from among applicants.

Our unit, “Research Unit for the ELSI of Genomics” is a part of the project. The unit's vision is to establish research governance in genome research. Here, “research governance” refers to a mechanism in which scientific research is conducted within the social context based on decision making by researchers and other people from different fields. Under this vision, we cooperate with genome researchers and tackle with ethical, legal, and social implications (ELSIs) of genome research.

The range of their implications has expanded with dramatic developments of genome research, including issues regarding the use of human samples and a new generation sequencer, and other matters about DTC-genetic testing, synthetic biology stem-cell research and public outreach. Among these topics, we are currently focusing on issues associated with personal genome research, since this is the highest priority for one in the medical genome science program of the project.

For this, we have mainly conducted 2 activities. One is preparing and revising a model informed consent document which is used in medical genome science program. This activity contains not only making a document but also making a policy of the program. During this process, we researched and considered various issues such as data sharing, biobanking, return of results, and use of previously collected samples, cooperating with scientists and medical researchers of the program. The other is the creation of a diagram of issues on using the human samples for personal genome researches. For making the diagram, we listed the issues, and categorized them into 5 groups; informed consent, handling of data and samples, IRB, return of results, and working environment of researchers. We also made summarized reports having more detailed information about each issue.

1345F

"My46:" an innovative web-based tool for management of results return from exome and whole genome sequencing studies. *H.K. Tabor[1, 2], A. Hartzler[2], J. Crouch[1], E. Kuwana[2], M.J. McMillin[2, 3], J. Stock[3], J. Yu[2], K.M. Dent[4], N. Anderson[5, 6], J. Swanson[7, 8], M. Bamshad[2, 9].* 1) Ctr Pediatric Bioethics, Seattle Children's Hosp, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Seattle Children's Hospital, Seattle, WA; 4) Department of Pediatrics, University of Utah, Salt Lake City, UT; 5) Department of Biomedical Informatics, University of Washington, Seattle, WA; 6) Institute of Translational Health Sciences, University of Washington, Seattle, WA; 7) National Children's Study Orange County Vanguard Center, Irvine, CA; 8) Department of Pediatrics, University of California, Irvine, CA; 9) Department of Genome Sciences, University of Washington, Seattle, WA.

Exome sequencing (ES) and whole genome sequencing (WGS) are powerful new tools for gene discovery that are rapidly and broadly being applied in human genetics research. ES/WGS have the potential to identify all variants that influence health-related traits, including those of clinical and/or personal utility, thereby challenging existing approaches for return of results. As a feasibility study for the National Children's Study, we are developing a web-based interactive tool that allows research participants to manage return of results from WGS. "My46" has four key modules: 1) a "learn the basics" section about the genome, including an overview of the type of results that might be returned and their potential impact, 2) a tool for selecting preferences for return of results, 3) a platform for reporting results and 4) an instrument for conducting surveys. The educational module is targeted toward participants with limited knowledge of genetics, genomics and/or genetic testing. The preferences tool allows participants to choose which broad categories of results they do or do not want to receive: the disease(s) studied, carrier status for recessive disorders, complex health-related traits, and medication responses. Participants receive available results only for traits in the categories they have selected and can modify their preferences at any time. The results reporting module provides a succinct summary of the utility of each result that can be shared with health care providers. The survey module facilitates the conduct of empirical research, assessing correlations with participant result preferences, impact of results on a psychological and health care utilization outcomes, and participant understanding. Each module can be customized to fit researchers' specific needs and the population being studied. "My46" has several important features for large-scale results management in ES/WGS studies. It provides participants secure access to their individual genetic results to review at their convenience. The design is scalable allowing results to be returned as they become available over time. "My46" also includes a feature that facilitates direct interaction with a genetic counselor via telephone or live streaming video, extending the role of counselors as the amount of genetic information available to research participants increases. These features make "My46" an attractive tool for managing the return of individual research results in ES/WGS studies.

1346F

Genetic research with descendants of Australia's First Peoples. *S. van Holst Pellekaan, A. Wilton.* Biotechnology and Biomolecular Sciences D26, University of New South Wales, Sydney, NSW, Australia.

Over nineteen years, with substantial ongoing consultation and discussion, genetic research has proceeded slowly with a small number of Aboriginal communities in western New South Wales, Australia. Participants are descendants of the Paakintji (Barkindji), Ngiyambaa and associated language groups, whose recent history has followed a familiar pattern of colonization marked by dispossession and sad experience. Initially genetic research was ancestry focused, the results of which augment a rich archaeological heritage, marking cause for celebration of survival and resilience. In the current era of genomic research the opportunity for a health and wellbeing focus with the communities has begun with their ongoing consent, but some issues remain unresolved, constraining the ability to extend into other communities. Poor research practices of the past left a legacy of distrust that obstructs useful dialogue between researchers and Aboriginal Australians. The reasons for distrust are understandable and in the case of genetic research, touch on issues of identity, privacy and the perceived threat to `Aboriginality'. Control over their own research is desirable but is difficult to implement for some projects, especially without adequate funding to provide training or employment. The use of information for community purposes, the sharing of data with other researchers and a perceived distinction between ancestry related and health related genetic research are among the concerns not currently resolved. For example, we are currently unable to share raw data files from a genome wide SNP study with other researchers, limiting the value of published results. The continued resistance to genetic research by many Aboriginal Australian groups has resulted in a paucity of information about the genetic diversity in Australia compared to other studied populations. While the reasons for resistance can be understood, there is a risk that this will lead to increased disadvantage for Aboriginal Australians. Results from genome wide studies in other populations will be used as references to inform future health policies, strategies and treatments, but important information from the Australians will be excluded unless their collaboration in more genetic projects eventuates. There is much still to be learned about how genetic diversity interacts with different environmental and lifestyle conditions.

1347F

Feasibility of informed consent for whole genome sequencing in the National Children's Study: participant understanding and informational needs. *J. Yu[1], H.K. Tabor[1,2], K. Lakes[3,4], P. Flodman[3,4], K. Gutzman[5,6], B. Specker[5,6], J. Swanson[3,4], M.J. Bamshad[1,7].* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Treuman Katz Center for Pediatric Bioethics, Seattle Children's Hospital, Seattle, WA; 3) Department of Pediatrics, University of California, Irvine, CA; 4) National Children's Study Orange County Vanguard Center, Irvine, CA; 5) Ethel Austin Martin Program in Human Nutrition, South Dakota State University, Brookings, SD; 6) National Children's Study South Dakota State University Study Center, Brookings, SD; 7) Department of Genome Sciences, University of Washington, Seattle, WA.

Whole genome sequencing (WGS) and exome sequencing (ES) are transformative new tools for gene discovery in human and medical genetics research. These technologies challenge existing models for informed consent because of the volume of sequence data generated and the number of potentially clinically significant results identified. There are no empirical data on how best to explain to participants during the informed consent process the nature of WGS/ES, the kinds of results that might be identified, the potential benefits and risks of those results, or the potential risks to privacy of sharing WGS/ES data. Therefore, researchers, IRBs, and policy makers have little guidance on how to approach informed consent for WGS/ES research. We developed and tested an informed consent form and protocol for use in a feasibility study for WGS in the National Children's Study, a multisite population-based longitudinal birth cohort study of children and their parents. The informed consent included statements describing WGS, the large volume of data generated by WGS, the identifiability of whole genome data, the indefinite storage of samples and data, and NIH data sharing requirements. It also included an option to be re-contacted about possible future results. A total of 100 parent-child trios are being recruited into the WGS study and will participate in the informed consent process. Parents' subjective and objective understandings of the research protocol are assessed using a modified version of the Quality of Informed Consent (QuIC), a standardized tool for evaluating the effectiveness of the informed consent process. This tool assesses parents' knowledge of information presented in the consent process; their self-perceived understanding of the information presented; and their report of factors that facilitate or impede WGS research participation. We will present the results from the pilot phase of this study and share examples of the language that were used to meet the standards for informed consent. Moreover, the results from this first test of our WGS consent will be useful for the development and implementation of informed consent for other WGS/ES studies.

Evaluating the Status of State-Level Public Health Genetics Activities in the United States: A Decade of Declining Public Health Genetics Leadership. *A.K. Yu, S.M. Au.* Hawaii Department of Health Genetics Program, Honolulu, HI.

In 2010, the Hawai`i Department of Health Genetics Program did a survey to evaluate state-level public health genetics (PHG) activities in the United States. The survey was modeled after a pilot study conducted by the Coalition of State Genetics Coordinators (SGCs) in 2000. Similar in scope, the 2010 SGC survey aimed to collect and disseminate information about state-level PHG activities, with results to be used to help shape future education, policy, research and funding decisions. SGCs from each of the 50 states, the District of Columbia, Puerto Rico, Guam and the US Virgin Islands were identified by phone/email and then invited to participate. As of May 2011, 89% (n=48) of the SGCs had completed the survey. Each survey was done by phone interview with results entered into an online database (SurveyMonkey). Prior to data analysis, each SGC was sent a summary of their responses to review for inaccuracies. Responses were then de-identified and coded into SPSS for analysis. Survey data revealed that SGCs had dissimilar training/education. While 54% of SGCs report having some graduate level genetics education or higher, ~21% of SGCs report having no formal genetics education at all. Comparing the workforces, the number of full-time (≥ 35hrs/wk) SGCs has decreased from 53% to 29% since 2000, with the majority of the part-time SGCs fulfilling other responsibilities, such as newborn bloodspot/hearing screening coordinator. The number of SGCs working <10hrs/wk has also increased from 34% to 52%. As well, 29% of SGCs report having no standalone PHG program. With increased opportunities and ongoing efforts over the past decade to integrate genomics into public health research and practice worldwide, it would be reasonable to hypothesize that the level of PHG activities in the US should be increased. However, the survey data appears to present a contrasting picture. The data affirms the conclusion that the level of support for PHG activities has decreased greatly since 2000 and appears hindered by disappearing state PHG infrastructures. This includes a lack of strong and consistent leadership at the SGC level; a lack of dedicated funding and a lack of resources to ensure appropriate genetics education/training of state PHG staff. We conclude that without an improvement in these areas, the US will encounter a “translational bottleneck”, preventing the successful integration of promising genetic discoveries into public health activities.

Parental Attitudes Towards Participation in a Pediatric Genetic Repository. *S.I. Ziniel[1,2], J.G. Amatruda[3], E.D. Harris[3], C.M. Clinton[3], S.K. Savage[4], N.L. Huntington[1,5], R.C. Green[6,7], I.A. Holm[1,3,8].* 1) Department of Pediatrics, Harvard Medical School, Boston, MA; 2) Clinical Research Program, Children's Hospital Boston, Boston, MA; 3) Division of Genetics and Program in Genomics, Children's Hospital Boston, Boston, MA; 4) Children's Hospital Informatics Program, Children's Hospital Boston, MA; 5) Division of General Pediatrics, Children's Hospital Boston, Boston, MA; 6) Partners Center for Personalized Genetic Medicine, Boston, MA; 7) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 8) The Manton Center for Orphan Disease Research, Children's Hospital Boston, Boston, MA.

Objective: Little is known about factors that influence parental interest in enrolling themselves and their children in a pediatric genetic repository. Children's Hospital Boston (CHB) has initiated a large pediatric genetic repository, The Gene Partnership, in which individual research results will be returned to participants. The goal of this study was to better understand the views of parents of children at CHB towards participation in such a genetic repository. Here we report on factors that influenced parental enrollment in the hypothetical genetic research repository. **Methods:** We designed a survey to assess the interest of parent in enrolling themselves and their children in a hypothetical genetic research repository, and their preferences for return of return of research results on themselves and their children. The survey was mailed to a sample of 6872 parents of patients at CHB. **Results:** Preliminary analysis of data on over 800 respondents showed that 77% of respondents would enroll themselves in the genetic registry and about 75% would enroll at least one of their children. 85% of parents were concordant with their choice to enroll or not enroll themselves and their child. Ninety-eight percent of parents with 2 or more children would make the same choice with regard to participation in a pediatric genetic repository across all of their children. Using logistic regression, parents who were more likely to sign themselves up in a hypothetical genetic registry were older, female, white, of higher income, and had reached a lower education level. They were more likely to have participated in research in the past, have a child with a genetic condition, feel that their participation would contribute to society, and trust that their confidentially would be maintained. Hierarchical logistic regression models showed that the same factors predicted if a parent would enroll their child in a hypothetical genetic registry. Factors that were not important in whether a parent enrolled themselves or their child included prior genetic testing, and anticipated benefits from the research. **Conclusions:** Characteristics of the parents' child did not influence whether or not a parent would enroll their child in a genetic registry. Parents with a positive view of research were overall more likely to participate in research.

1350F

Consistently inconsistent - DTC results of identical twins from three companies and implications for service provision. *K. Barlow-Stewart[1,2], C. Cormick[3].* 1) Ctr for Genetics Education, Sydney, NSW, Australia; 2) Sydney Medical School, University of Sydney, Sydney, NSW, Australia; 3) Public Awareness and Community Engagement, Department of Innovation, Industry, Science and Research, Canberra, ACT, Australia.

With the $1,000 full genome testing imminent, it is useful to examine what has been learned from the experience of direct to consumer (DTC) genetic testing and how consumers and health professionals have reacted to these services. Consumers in Australia have access to DTC genetic testing from several overseas companies, whose laboratories are based in the US (23andMe and Navigenics) and Iceland (DeCODEme). Anecdotal evidence suggests that some consumers who are early adopters of DTC are sending their DNA out of the country to be tested but are then bringing the masses of data generated by these genome wide scans to health professionals including genetics service providers or their primary care providers in Australia for assistance with interpretation and advice, while others prefer to rely on the interpretation provided by the companies alone. Vital to both these approaches is the veracity of the data. Two 50-year-old twin brothers undertook DTC testing with the three companies to allow a comparison not only of the differences in interpretation between the DNA data by the different companies, but how the DNA of two different individuals with near-identical DNA was interpreted by the same company. Through a diary of reactions that was kept before,during and after the testing process, key findings relate to how the data was interpreted by each individual, similarities and differences, and how the inconsistent between company (but within company consistent) results impacted upon levels of trust in genetic testing in general. A key question related to behavioural changes that might be made based on interpretations of data, and how different interpretations affected this. A complimentary study was conducted with clinical geneticists and genetic counsellors in New South Wales (the most populous Australian State) regarding the use of DTC testing over the last two years by current or new patients; possible reasons for its use; relevance and informativeness of the results; and how many primary care providers or other health professionals had sought advice where their patients had had DTC testing. The aim was to gain insight from both the user and clinician end, and examine if there were gaps between how each approached the DTC process and data obtained.

1351F

An overview of the genetic testing offer in Europe. *M. Jovanovic[1], E. Dequeker[2], A. Mondelaers[2], M. Morris[2], J. Cassiman[2], S. Aymé[1].* 1) Orphanet, INSERM SC11, 96 rue Didot, 75014 Paris, France; 2) EuroGentest, Gasthuisberg O&N, Herestraat 49, Box 602, 3000 Leuven, Belgium.

Genetic tests are now offered internationally, through both public and private sector genetic testing services. Physicians prescribing these tests and biologists receiving the samples need to know which tests are available, where they are performed and whether identified laboratories meet quality standards.

To fulfill this need, http://www.orpha.net was launched fourteen years ago to set up a database of medical laboratories in the field of rare diseases. Data was collected in 1 country in 1997, 15 in 2003, 26 in 2006 and 36 in 2011, with resources from the EC DG Public Health. In collaboration with the EuroGentest Network of Excellence, information on quality management has been added to the Orphanet database over the past five years.

Information on genetic testing in Orphanet can be searched by disease name or by gene (symbol or name in English) as well as by laboratory or by professional. The information provided on laboratories includes data on quality management. Information is freely accessible online, and access to all data can be granted upon request. Currently, 1,049 laboratories offering tests for 1,764 genes are registered. The test offer differs greatly from one large country to another: Germany (1,400 genes), France (1,070 genes), Spain (947 genes), Netherlands (763 genes), Italy (753 genes), United-Kingdom (507 genes). The test offer in medium and small-sized countries ranges from 1 to 344 genes.

This situation explains the large cross-border flow of specimens, highlighting the need to provide access to services in other countries when necessary, especially for very rare diseases. According to available data, only testing for Cystic fibrosis is provided by every country. The distribution of this test offer will be presented.

1352F

The UK Genetic Testing Network, its role and achievements. *M. Kroese, J. Westwood, P. Farndon, J. Deller, S. Stenhouse, S. Mohammed, F. Stewart, J. Hoyle, T. Turtiainen, UK Genetic Testing Network.* UK Genetic Testing Network National Specialised Commissioning Team 2nd floor, Southside 105 Victoria Street London SW1E 6QT.

This session describes the UK Genetic Testing Network (UKGTN) organisation and the `Gene Dossier' genetic test evaluation process. A brief review of the UKGTN genetic test evaluation experience and the development of testing criteria will be presented. In addition, examples of UKGTN policy developments and other outputs will be described. The Department of Health (England) supported the establishment of the UKGTN in 2002. A fundamental principle underpinning the UKGTN is that of geographical equity of access for patients and their families who require genetics advice, diagnosis and management via local clinical genetics centres. It advises the National Health Service (NHS) on genetic testing for inherited disorders. It aims to ensure the provision of high quality equitable genetic testing services for all NHS patients across the whole of the UK. This involves evaluating new genetics tests through its Gene Dossier process and making recommendations to commissioners on new NHS clinical genetics services. The UKGTN also provides an advisory role to the Department of Health on national policies relevant to clinical genetics services. The UKGTN covers a range of activities which are summarised below: • Assessing applications from laboratories to become members. All member laboratories must fulfil defined criteria including quality criteria. • Evaluates new tests for scientific validity and clinical utility that member laboratories wish to provide on a national basis and makes recommendations to NHS commissioners. • Inform national policies for clinical genetics services • Provides an information source including the online and open access database of national testing services that member laboratories provide. The UKGTN has completed a significant work programme during 2004-2010 including 269 dossiers evaluated, 203 new genetic tests recommended for NHS provision and 216 testing criteria developed. The testing criteria are a unique feature of the Gene Dossier process, as they identify the key features of the disorder and aim to ensure clinically appropriate genetic testing. From a healthcare purchaser perspective testing criteria provide assurance on the clinically appropriate use of diagnostic resources.

Guidelines for evaluating genetic associations for use in direct-to-consumer personal genetic analysis. *S. Wu, G.M. Benton, J.Y. Tung, A.B. Chowdry, J.L. Mountain, B.T. Naughton.* 23andMe, Inc., Mountain View, CA.

Crowd-sourced, free, and online tools mingle alongside commercial and non-profit ventures now offering genetic testing and analysis to individuals. Groups that offer information about how genetics may influence health and physical traits base their services on the scientific literature, primarily genome-wide association studies (GWAS), but how they evaluate and report on this literature can vary. The standards for evidence used by different groups can range from very permissive to quite stringent, balancing different needs for validity, stability, flexibility, scalability, and relevancy to the state of research. 23andMe has developed and evolved a robust set of guidelines for evaluating genetic associations reported in the literature. These guidelines account for sources of error and bias -- including confirmation bias, multiple hypothesis testing, population stratification, and type I error -- by considering parameters such as sample size, existence of replications, effect size, and correction for multiple hypotheses. In addition, the guidelines address broader issues raised by reporting on research primarily focused on populations of European descent and on associations with different levels of evidence to a diverse consumer audience. We describe lessons learned from several years of evaluating genetic associations in the context of connecting individuals to their genetic information.

1354F

Paternalism vs. Autonomy: Who should be the gatekeeper for genomic testing results? *S. Adam[1], P.H. Birch[1], A. Townsend[2], Z. Lohn[1], F. Rousseau[3], J.M. Friedman[1].* 1) Med Gen, C & WH, University of British Columbia, Vancouver, BC, Canada; 2) Centre for Applied Ethics, University of British Columbia, Vancouver, BC, Canada; 3) Medical Biology, Université Laval, Montreal, PQ, Canada.

Clinical testing with Whole Genome Sequencing (WGS) may uncover unexpected genetic changes with important medical or social implications. No clinical guidelines have been proposed for disclosure/nondisclosure of these incidental findings thus the need for stakeholders to discuss these issues is paramount. The experience and knowledge of genetics professionals and the general public regarding WGS are important, diverse and complementary. We therefore conducted two focus groups, one with 10 genetics professionals (geneticists, genetic counsellors and laboratory personnel), and a second with 10 members of the public (from diverse educational backgrounds, with little knowledge of WGS). Qualitative analysis of the transcripts has yielded important and surprising themes. Genetics professionals focussed on the type of results that might arise and felt that the certainty, complexity, and reliability of the data should all play a role in the disclosure decision. They were keen to find ways to be blind to incidental findings so as to have less to disclose. Much of this related to beneficence and their concerns about the risk of creating the “worried well.” In contrast, the lay group was united in feeling that everything the patient wished to know should be disclosed. They expressed this as an issue of autonomy: “...an element of control that I don't want anybody having other than me.” Not everyone felt that they would want the information but they agreed that it should be personal choice. There was inter-group agreement that pre- and post-test counselling and discussion was critical: Lay individuals discussed the need for educational material but geneticists also considered practical issues such as limited human and financial resources. In addition, both groups identified issues around family members, confidentiality and discrimination as important and possibly problematic. The genetics group appeared willing to use these and other issues such as insurance considerations and the likelihood of patient actionability as reasons to limit the incidental findings communicated to patients. The public on the other hand, perceived this as paternalistic and felt strongly that it was their fundamental right to have access to that information. Our findings suggest that the public values autonomy above all else whereas genetics professionals are concerned that this approach has potential for harm. Wider consultation and study are needed to reconcile this dichotomy.

Are U.S. Doctors Receiving DTC Genetic Tests Results from Their Patients? *V.L. Bonham[1], C. Clark[1], L.A. Cooper[2], W.G. Feero[3,4].* 1) Social and Behavioral Research Branch, NHGRI/NIH, Bethesda, MD; 2) Johns Hopkins University School of Medicine, Department of Medicine, Baltimore, MD; 3) Maine Dartmouth Family Medicine Residency, Augusta, ME; 4) Genomic Healthcare Branch, NHGRI/NIH, Bethesda Maryland.

Background: Since 2005, the number of health-related direct-to-consumer (DTC) genetic tests has increased dramatically. Little is known about how often United States primary care physicians (PCPs) receive DTC genetic test reports and use the results in clinical care. **Methods:** We analyzed data from The Health Professionals' Genetics Education Needs Exploration Survey(HPGENE), a national survey of 787 general internists fielded from April to December 2010 (45% response rate), to examine the frequency with which PCPs received genetic test results in the preceding year, characteristics of PCPs who received these results, the extent to which DTC results were incorporated into clinical care, and the association of physicians' participatory decision-making (PDM) style with receipt of DTC results. **Results:** Of the 787 physicians that responded to the survey 505 were men and 479 were older than 45 years of age. Over half of the PCPs that received DTC test results worked in group or staff model practices (33%) and academic health centers (22%). Nineteen percent of respondents reported receiving DTC genetic test results from at least one patient in the preceding year. A higher proportion of female than male physicians reported seeing patients who presented DTC genetic test reports (24% vs. 16%, $p<0.05$). Physicians who had genetics training in residency (31%) and those who rated their knowledge of genetics as excellent, very good, or good (24%) were more likely to receive test results than physicians who had no training in residency (17%) and those who reported fair or poor knowledge (15 %), both p-values <0.01. Among physicians who received genetic test results, 59% discussed the results with the patients, 46% reviewed and placed the results in the patients' medical records, 14% ordered additional tests, 10% incorporated the results into their treatment plans, and 7% referred the patient to a genetic specialist. Physicians' PDM style score was not associated with their use of patients' DTC test results in clinical care. **Conclusions:** A substantial minority of general internists are receiving patients' DTC genetic test results. Physician gender, practice setting, genetics training during residency, and knowledge of genetics are positively associated with receiving genetic test results. Importantly, physicians are incorporating this data into the medical record and clinical decision making.

1356F

Dutch difficulties with carrier status information: 25 years of health policy. *M.C. Cornel[1,2], S. Jans[1,2], C.G. van El[1,2], P. Lakeman[1], L. Henneman[1,2], G. de Wert[2,3].* 1) Clinical Genetics/EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands; 2) Center for Society and Genomics, Nijmegen, Netherlands; 3) Department of Health, Ethics and Society, Maastricht University, Maastricht, The Netherlands.

Introduction More than two decades ago the Dutch government started asking advice on carrier screening for autosomal recessive disorders, such as hemoglobinopathies (HbP) and cystic fibrosis (CF). So far, carrier screening is not offered in regular Dutch health care, unlike many other countries. The neonatal screening program from 2007 onwards does generate carrier status information for hundreds of families each year, a challenge to physicians not used to this. We investigated the reasons for Dutch reluctance in carrier screening policy. *Methods* We performed a socio-technical analysis (2007) based on previous pilot studies, a Witness seminar (2010), reconstructing recent history with actors involved in these last decades, and surveyed midwives and general practitioners (2010). *Results* Our findings in 2007 showed that technical (im)possibilities and the lack of facilities and services played a role, especially the absence of a preconceptional health care setting and the deficiency of genetic knowledge among health care professionals. The target group of parents-to-be was unaware and no support from government and public health organisations existed. Yet societal acceptability was likely. The witness seminar showed that carrier screening in general never appeared high on the policy agenda. A requested advisory report on HbP screening showed a low prevalence, and indicated fear of stigma and low awareness among the target group as reasons not to implement HbP screening. The advice was followed by the ministry, but debated by professionals who argued both for neonatal screening and carrier screening. The registration of ethnicity in health care (to allow for targeted carrier screening) remained sensitive, more than 50 years after the persecution of ethnic minorities in the Second World War. The involvement of representatives of ethnic minority target groups is very important for further policy making on screening for HbP. Health care workers see the professional standards of their colleagues as relevant: they would not offer carrier testing if their colleagues do not offer it either. Furthermore, they experience the lack of support from health authorities as an obstacle. *The future* Complexities related to carrier status information remain a challenge in Dutch health care. It remains to be seeen whether carrier screening will be considered a valuable complementary strategy in the Netherlands.

Building Genomics Infrastructure in Africa: Ethical and Policy Implications. *E. Peprah, C. Rotimi.* Center for Research on Genomics and Global Health National Human Genome Research Institute, National Institutes of Health Bethesda, MD.

Evidence supporting the potential for genomics to inform the health and history of African people is growing. This growing potential has brought the need for genomics research in Africa to the forefront. As suggested by others, we also believe that genomics has the potential to significantly contribute to the scientific development of the continent if the existing global inequity in the application of genomic science is reduced or eliminated. Encouragingly, several new initiatives are starting to address the gap in genomics research in Africa. These initiatives including the Malaria Genomic Epidemiology Network, the Africa America Diabetes Mellitus Study, the Africa TB Genetics Consortium, Armauer Hansen Research Institute which are characterizing the genetics of infectious and noninfectious disease in African populations. Plant and animal genomics are being investigated at multiple research centers in Africa including the International Livestock Research Institute in Kenya. These ongoing initiatives are funded by several different entities including the Wellcome Trust, Swedish International Development Cooperation Agency, the National Institutes of Health (NIH), World Health Organization (WHO) and non-governmental organizations. In addition, major new genomic initiatives have been funded and are in the process of implementation. These including Human Heredity and Health in Africa co-funded by the NIH and the Wellcome Trust, the Grand Challenges of Canada, the WHO Research Catalyst Platform and the Southern African Human Genome Project Initiative; these initiatives promise to build genomic research capacity in Africa to enable African scientists to become major players in genomic research. As genomics research grows in Africa, there is pressing need to address the local cultural, ethical and legal issues that are likely to be unique to African populations in the design, implementation, analysis and interpretation of results. For example, it has been noted that the existing international policies on sample and data sharing may not necessarily be adequate for developing scientists who are not likely to have the robust research infrastructure. Other issues include how to conduct culturally sensitive community engagements. This presentation will discuss the strategies that have worked and those that have not. It will also offer new insights into some of the issues that have arisen from genomic/genetic studies in African populations.

1358F

Thailand national plan for prevention and care of birth defects. *P. Wasant.* Dept Ped/Div Med Gen, Siriraj Hosp/Mahidol Univ, Bangkok, Thailand.

Introduction: Birth defects are common and important public health problems causing health and economical burden to patients and their families including government long - term budget. Presently, there is no clear - cut public health policy in care and prevention of newborns/children with birth defects in Thailand; while there had been increased awareness in several developed countries for many years. As for developing countries e.g. Philippines and Malaysia already started their Birth defects registry (BDR) and prevention program such as folate supplementation for pregnant women and women of child-bearing age in past couple of years. It is a well-known fact that Birth defects registry is proven and beneficial in setting up government health policies in order to decrease the incidence of birth defects and provide care and prevention for children with birth defects in a holistic manner. **Objectives:** Thailand Task Force on Prevention and care of Birth Defects & Disabilities is working to establish Birth Defects Registry (BDR) to help set up government health policies in order to decrease the incidence of birth defects and provide care and prevention for children with birth defects in a holistic manner. **Materials & Methods:** Thailand Birth Defects Registry (BDR) Working Group had initiated the action plan to develop the BDR including preventive measure and educational program since 2008. The Working Group consist of experts in at least 8 medical schools, had organized the Annual `National Forum on Birth defects and Disabilities' in July 2009, 2010 and 2011; to educate Thai physicians and public health personnels regarding birth defects and disabilities. The Working Group presently, “Thailand Task Force on Prevention and Care of Birth Defects & Disabilities” just received requested funding from Thailand Health Promotion Foundation (ThailHealth) for their goals to accomplish within 3 years (2011-2013). The workshops supported by Thailand Health Promotion Foundation (ThaiHealth) from July to September 2010 successfully produced 1. Strategic mapping 2. Master plan and 3. Care map for 5 chosen common birth defects (Down Syndrome, Neural Tube Defects, Cleft lip/palate, Duchenne Muscular Dystrophy) to start with. **Summary:** The Birth Defects Registry in Thailand is being developed.

1359F

The attitudes and opinions of genetic researchers and clinicians towards the regulation of direct-to-consumer genetic testing. *C.A. Wicklund, S.M. O'Neill, M.G. Hayes, P.M. Kaushik.* Northwestern University, Center for Genetic Medicine, Chicago, IL.

The availability of direct-to-consumer genetic testing has generated much debate in the last few years, in particular the tests available for common complex diseases, which are based on the results of genome-wide association studies. Clinical validity and the regulation of these tests by the FDA and CLIA have been key issues in this debate. To date, no studies have been carried out to assess the attitudes of genetic researchers and clinicians towards the current regulations. In addition, no studies have been performed to determine if there is a sense of concern or responsibility amongst researchers regarding their research data being used to develop these tests. The purpose of this study was to assess genetic researchers' and clinicians' attitudes towards regulation and to determine if concern/responsibility towards the use of their data exists. A survey was developed to assess attitudes towards these two topics and sent electronically to all members of the American Society of Human Genetics (~7000). The overall response rate was 23.3% (n=1631). Of the 1486 respondents who have been involved in research, 23.4% were concerned that their data was being used, 43.2% felt responsible for knowing how their data was being used, and 40.6% would restrict the use of their data if they could. Of the 1517 participants, the majority agreed or strongly agreed (93.6%) that the regulation of DTC genetic tests is important, and 51.9% disagreed or strongly disagreed that current regulations are sufficient. The majority agreed that the DTC genetic testing companies, the government, medical professionals, researchers, and the public should have an input in the development of regulation policies. The majority (67.7%) agreed or strongly agreed that the involvement of a healthcare provider should be required when using DTC genetic tests. Logistic regression analysis showed that clinical experience, involvement in GWAS, and gender were all independent predictors of participants' opinions towards regulation. Individuals without clinical experience, those who have been involved in GWAS, and male participants were less cautious about the regulation of DTC genetic tests. This study suggests that there is concern among some researchers regarding their data being used to develop DTC genetic tests. It also suggests that genetic researchers and clinicians consider current regulations to be insufficient, and would like to have an input in the development of regulation policies.

1360F

***"I'm still going to be me; I'm not going to be anyone else"* Firsthand accounts of predictive genetic testing in adolescents for adult onset conditions.** *C. Mand[1,2,3], L. Gillam[3,4,5], R.E. Duncan[2,3,6,7], M.B. Delatycki[2,3,8].* 1) Department of Medicine, Monash University, Melbourne, VIC, Australia; 2) The Bruce Lefroy Centre for Genetic Health Research, Royal Children's Hospital, Parkville, VIC, Australia; 3) Murdoch Childrens Research Institute, Royal Children's Hospital, Parkville, VIC Australia; 4) Children's Bioethics Centre, Royal Children's Hospital, Parkville, VIC, Australia; 5) Centre for Health and Society, University of Melbourne, Melbourne, VIC, Australia; 6) The Centre for Adolescent Health, Royal Children's Hospital, Parkville, VIC, Australia; 7) Department of Paediatrics, University of Melbourne, VIC, Australia; 8) Clinical Genetics, Austin Health, Melbourne, VIC, Australia.

Background: Technological advances have allowed asymptomatic individuals at risk for genetic disease to undergo predictive testing (PT) to discover if they will develop the condition later in life. PT is routinely offered to adults at risk for adult onset conditions (eg: Huntington disease). More controversial is the PT of minors where no effective treatment or prevention exists. The discourse concerning PT in minors is lively, yet remains largely speculative, with a scarcity of empirical evidence. While sporadic reports of PT in minors and the rise of the `mature minor' doctrine have led to greater flexibility in recommendations, most maintain a general position against testing in minors for conditions without effective medical intervention. Aim: To explore young peoples' experiences of undergoing PT for an adult onset condition, using a qualitative methodology Methods: Interviews with 9 young people who had, as minors, PT for adult onset conditions (3 neurogenetic; 6 familial cancers). Transcripts underwent thematic analysis. Results: A range of harms and benefits were reported in association with the entire PT experience, encompassing the period prior to requesting PT, through the preparative process, receiving a result and the aftermath. Harms were not limited to those who received a gene-positive result. Participants described harms associated with being refused a test as well as with the often protracted predictive testing process. Overall, participants indicated that these harms were significantly outweighed by the benefit they each had derived from PT. Regardless of result, all participants described benefits of PT, and in particular raised the difficulty of living with uncertainty prior to PT, and the relief which greater certainty, in the form of a PT result, brought them. Themes included the impact of living at risk, preconceived ideas about what the result would be, defeated expectations regarding the testing process, and the impact of a PT test. Conclusions: These data add to the breadth and complexity of the discourse concerning PT in minors highlighting factors previously underrepresented in the literature. For the first time, this study gives voice to the adolescents at the centre of the debate, inviting review of whether current guidelines have reached the correct balance. The data highlight the need for further study of outcomes of PT in minors to ensure guidelines are based on empirical evidence and not simply on theoretical analysis.

1361F

Patient's and health care professional's attitude regarding preimplantation genetic diagnosis in cancer genetics. *S. Côté[1,2], B.M. Knoppers[3,4,5], P. Hamet[1,6], C. Bouffard[7].* 1) Centre hospitalier de l'université de Montréal, Département de médecine, Service de médecine génique, Canada; 2) Département des sciences biomédiacles, Faculté de médecine, Université de Montréal, Montréal, Canada; 3) Centre de génomique et politiques, McGill University, Montréal, Canada; 4) Chaire de recherche du Canada en Droit et Médecine, Université McGill, Montréal, Canada; 5) Département de génétique humaine de l'Université McGill, Montréal, Canada; 6) Chaire de recherche du Canada, Génomique Prédictive, Université de Montréal, Montréal, Canada; 7) Service de génétique, Département de Pédiatrie, Faculté de Médecine et des Sciences de la santé de l'Université de Sherbrooke, Canada.

Introduction: An important motivation for patients when considering cancer genetic testing in familial cancer is to learn about children's risk. Despite this fact, there are important gaps regarding information about alternatives in familial planning, such as preimplantation genetic diagnosis (PGD). Method: Review and comparative analysis of the literature. Reviewed18 articles dealing with PGD in cancer genetics (PubMed, Ovid): 12 focused on patient's attitude toward PGD and 3 on health care professionals Results: These studies are not only rare, but their results show important differences. The percentage of patient's acceptability of PGD varies from study to study (90% to 30%). Studies investigating the attitude of health care professionals specialized in medical genetics show a threshold of acceptability around 80% concerning early-onset cancer genetic syndromes. In this study, the health care professionals attitude's toward acceptability drops to 13% when dealing with a late onset cancer genetic syndrome. Others studies, involving obstetrician/gynecologists conclude that the lack of knowledge about PGD is responsible for the rate of referral to genetics clinics. Conclusion: Carriers of mutations in cancer predisposition genes rarely choose PGD, perhaps because they not receive enough information about reproductive options. Current data from the literature is insufficient to clearly identify ethical, organizational and informational problems regarding PGD in familial cancer context.

Report from a patient support group for rare diseases in Japan: our experiences on 3.11 earthquake/tsunami disaster. *A. Nakaoka, J. Koizumi.* SORD (The Supporting Organization for Patients with Rare Diseases), Kyoto, Kyoto, Japan.

A non-profit organization SORD (the Supporting Organization for Patients with Rare Diseases) was launched in 2008 by a woman with rare disease and her supporters. Since only 344 diseases are specified as intractable diseases and funded by the government for research in Japan today, there was a need to establish an environment where rare disease research will be performed more actively. We have been working on 3 major tasks: 1.To support communication between patients and establishment of a patient organization with our social networking service and collect clinical data 2.To collect clinical data from overseas and coordinate the cooperation between Japanese patients and patients overseas 3.To establish a bank for genome information and iPS cells of rare diseases SORD has been connecting patients to patients in Japan, providing clinical information from overseas to them and providing the genome information and iPS cells of Japanese patients to researchers in the world. The Patient-driven iPS Genome Information Bank Project (PRiG Project) was launched in October, 2010. So far iPS cells of 3 cases have been established and the genome analysis completed. Our future plan is to provide the iPS cells and genome information to researchers who are willing to study them. On March 11th, 2011, massive earthquake and tsunami attacked Japan and inflicted damage we have never experienced in Japan before. Although SORD started to provide aid for the devastated patients right after the quake, we found it extremely difficult to reach and provide aid for them. Patients were isolated and left with inadequate care without even being recognized. Most of them have lost connections with support groups or other patients under such disaster. Furthermore the patients' current conditions have not been assessed adequately due to the absence of specialists and the insufficient disaster countermeasure, while they need doctors with high expertise and knowledge and the collaboration of clinicians in various areas. It seems necessary to reorganize the current support system for patients with rare diseases in Japan. Also it is our responsibility to share this tragic experience with other health professionals and patient support organizations worldwide to encourage the discussion about the disaster countermeasure which will not leave the patients alone. We would like to walk forward together with patients and researchers in the world and be there for patients to live a hopeful life.

1363F

Multidisciplinary analysis of emotions in the context of prenatal diagnosis of Down's syndrome and termination of pregnancy: the perspective of couples and health professionals concerned. *A.A. BROUSSIN DUCOS.* Ethique appliquée, Université de Sherbrooke, Sherbrooke, Québec, Canada.

The prenatal diagnosis(PND) is used to estimate the risk and confirm the presence of fetal anomalies. It offers couples the ability to:1- Anticipate the constraints, support necessary, sociocultural representations of the handicaps; 2-Evaluate the future sufferings. In the case of a PND of Down's syndrome(DS), the doctor announces the irreversible nature of the anomaly and associated handicaps. The couples are faced with the options to terminate or not the pregnancy. That's why, those faced with a PND of DS are confronted with negative emotions. If couples choose to abort, they and the Health professionals(HPs) are confronted with the symbolic violence of feticide which lead to psychological distress. PURPOSE:To identify,understand the emotional consequences induced among the couples/HPs concerned by the PND of DS and the termination of pregnancy(TP) in this context METHODE:A Literature review on the : 1-various aspects of the PND of DS; 2-emotions felt by the French, Canadian american couples/HPs concerned, allowed us to developed a conceptual grid analysis RESULTS: This analysis enables us to identify the emotions, their role and consequences on the well-being of couples/HPs concerned. The results can be viewed from various perspectives: A PND of DS and a TP generate various emotions,such as: guilt, shame, anger, hate, regret, fear, anguish, remorse, denial and sadness.An analysis of emotions allows the identification of psychological/physical damages caused by their over-expression Clinical:A categorization grids containing the emotions and the personalities who experience them should help psychologists to identify those who run a significant risk of developing psychological distress Sociopolitical:Acomparative analysis of the emotions experienced by couples/HPs from different countries demonstrates that the emotions,their intensity differ according to societal values and public health organization Ethical:The couples disinvest emotionally the fetus for decision-making. However, the feticide causes the emergence of hidden feelings, generates trauma, casts doubts on the well founded of the TP decision. Those affected grasp the importance to consider the emotions during the decision processes and the importance of the compassion and empathy CONCLUSION:The study of emotions can improve care for those affected by these PND/TP and provide intellectual input/support for the creation of codes of conduct and health policies in the context of PND of DS.

1364F

Diagnostic Misconception Underlies Some Preferences for Return of Genetic Research Results from a DNA Repository. *R. Green[1], S. Ziniel[2], N. Huntington[2], E. Harris[2], S. Savage[2], W. Wolf[2], J. Amatruda[2], I. Holm[2].* 1) Partners Center for Personalized Genetic Medicine, Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Division of Genetics, Children's Hospital Boston and Harvard Medical School, Boston, MA.

Background: "Therapeutic misconception" occurs when research subjects fail to appreciate distinctions between research using study medication and standard clinical treatment. In the controversial area of returning incidental research results to individuals who contribute to DNA repositories, hypothetical surveys consistently reveal that a majority of subjects prefer return of research results. In a survey exploring preferences for return of research results, we hypothesized that respondents who misconceive the personal utility of a DNA repository are more likely to prefer return of research results. **Methods**: Following initial focus groups, a 46 question survey asking about knowledge, attitudes and preferences for return of research results was constructed, refined through additional focus groups and mailed to 6872 parents of children registered as patients at Children's Hospital Boston. Some parents were previously consented to be part of the Gene Partnership (GP) DNA repository. **Results**: Of surveys sent, 941 (13.4%) were returned and used for preliminary analyses. Parents were 41.4 (SD 8.2) years of age, 87.5 % female, 74.4% White, 11.6% African American and 63.7% college graduates. When asked whether participating in a DNA research bank could "directly" help them or their children, 64.8% and 74.7% "Strongly" or "Somewhat" agreed with this misconception, respectively. When asked if they would want to receive genetic research results about themselves and their children, 85.6% responded "Definitely" or "Probably" about themselves and 88.7 % about their children. Persons who misconceived the personal utility of the repository for themselves were 2.3 times (95% CI 1.6,3.3, $p < 0.001$) more likely to prefer receiving genetic research results about themselves. Misconception about the utility of the repository for their children were 2.0 times more likely to prefer receiving results about their children (95% CI 1.4,3.3, $p < 0.001$). These associations were not significantly different between individuals who had been previously consented for GP and those who were not. **Conclusion**: These survey data support and extend impressions from our focus groups that some parents of pediatric patients conflate the research agenda of a DNA repository with hopes that there will be direct medical benefit for themselves or their children. This "diagnostic misconception" may help explain the broad appetite of biobank donors for return of individual genetic research results.

1365F

Genomic Medicine and Health Policy in Mexico: a future perspective in research and application. *P. Oliva-Sanchez, G. Saruwatari, J. Siqueiros, A. Arellano.* ELSI - Ctr, National Inst Genomic Med, Mexico, Mexico.

Objective. To explore the perspectives of Mexican health researchers on genomic medicine (GM) and its consequences in the decision-making process regarding the health policy in Mexico. The research took place at the 2nd National Conference of Genomic Medicine. This Conference was celebrated in Mexico City in October 25 - 27, 2006. Materials and Methods. A grounded theory qualitative research was conducted. Punctual interviews based on four questions were applied to collect data. Results. All researchers that were interviewed agreed on the idea that in developing countries there is no applicability of genomic medicine and that so far, GM is a basic and experimental science. Researchers didn't envision an impact of GM in public health in the near future. For its applicability, the interviewed said that it is necessary to generate a financial policy in order to support research towards defining the contribution of GM to the solution of the public health problems of our country. Some researchers believe that the 3P's of GM (Predictive, Personalized, Preventive) have generated "inflated expectations" according to the real benefits and its impact on public health. Opinions were divided among those who believed that GM is the new `paradigm' of public health and those who thought that GM is just part of a set of tools for public health, along with epidemiology and clinical trials. Discussion. To improve the health conditions of Mexicans, GM must come part of the government programs for human development and social protection. This, under the perspective that it will help to prioritize the National Health Spent. GM must be understood as a new tool in the resolution of the public health problems but we need a realistic view.

NETwork: A New Tool for Education and Empowering Participation in Translational Research. *S. Terry[1], K. Baxter[2], L. Horn[3], A. Krokosky[4], A. Mills[5], J. King[6], P. Terry[7].* 1) President & CEO, Genetic Alliance, Washington DC; 2) Translational Research & Policy Coordinator, Genetic Alliance, Washington DC; 3) Director of the Genetic Alliance BioBank, Genetic Alliance, Washington DC; 4) Assistant Director of Genetics Resources & Services, Washington DC; 5) Translational Research Intern, Genetic Alliance, Washington DC; 6) Biomedical Research Intern, Genetic Alliance, Washington DC; 7) Principal, Scientia Advisors, Cambridge, MA.

Models are important tools for making complex processes understandable. The current drug development model, which depicts drug development as a linear pipeline, grossly oversimplifies a nuanced process and cannot accurately represent the complexities of the real tasks involved. This oversimplification hinders, rather than helps, the translational research enterprise.

A more accurate depiction of the drug development process is needed, and Genetic Alliance has developed a wiring diagram describing the process as a complex system and not the traditional linear pipeline. This provides an alternative structure around which resources, both human and material, can coalesce, for greater participation in translational research. This wiring diagram has been converted into a web-based tool, Navigating the Ecosystem of Translational Research (NETwork). NETwork educates users about the drug development process and indicates key areas where stakeholders, including basic researchers, industry, advocacy leaders, and research participants, can meaningfully engage in translational research.

In creating NETwork, we have organized many tools that currently exist, including peer-reviewed publications, webinars, courses, partnership opportunities and more. The resources that have been included in NETwork come from a variety of organizations, including government organizations, academic institutions and non-profits, including advocacy organizations. We have also created tools as needed to fill gaps in the NETwork.

NETwork was first introduced to the community at the Genetic Alliance Annual Conference (June 2011). A number of organizations and individual stakeholders have also provided feedback on the concept, content, and design of NETwork. NETwork is continually updated to increase the number of available resources, keep the content current and relevant, and reflect feedback received from members of the community. NETwork is a framework for education and collaboration within the drug development process and the translational research enterprise. It is only by working together that we will see advances in translational medicine.

Assessment of a pharmacogenomic marker panel in a population taking multiple medications derived from electronic medical records. *M.T. Oetjens[1], J.C. Denny[2,3], A.R. Baker[1], H.H. Dilks[1], M.A. Basford[4], E. Bowton[4], N.A. Restrepo[1], V.M. Youngblood[1], J.M. Pulley[4], D.M. Roden[2, 4, 5], D.R. Masys[3], M.D. Ritchie[1,6], D.C. Crawford[1,6].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Department of Medicine, Vanderbilt University Nashville, TN; 3) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 4) Office of Personalized Medicine, Vanderbilt University, Nashville, TN; 5) Department of Pharmacology, Vanderbilt University, Nashville, TN; 6) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN.

Inter-individual variability in pharmacokinetics is thought to be a major contributor to variable drug response. Altered sensitivity to multiple drug classes can be expected given the pleiotropic effect of some pharmacogenomic variants. However, important genetic variants in absorption, distribution, metabolism, and excretion (ADME) genes are often rare (minor allele frequency or MAF <5%) or located in difficult-to-assay regions of the genome. We used the Illumina ADME Core Panel, a fixed content panel of 184 pharmacogenomic-related markers in 34 genes, to genotype DNA samples from 320 individuals on five or more classes of medications which have known pharmacogenomic indications (a total of 12 medications) given these individuals might be a potential target for pharmacogenomic panel utilization in a clinical setting. Samples were obtained from BioVU, the Vanderbilt repository linking DNA extracted from discarded blood samples to deidentified electronic medical records. All subjects were European American, 45% were female, and the mean body mass index was 29.7 kg/m2. After removing low quality samples (n=14), the call rates were 100% for the remaining samples. A total of 66 variants were monomorphic, 35 were very rare (MAF<0.0001), and *SLCO1B3* rs7311358 deviated from Hardy Weinberg Equilibrium (p<1x10-5). We abstracted allele frequencies from public repositories (such as the International HapMap Project and PharmGKB) as well as the literature for markers targeted by the ADME Core Panel to compare to this population exhibiting high polypharmacy rates. We tested for differences between allele frequencies in this clinic sample compared with reference sample allele frequencies. Preliminary results suggest that ~30% of ADME targeted markers do not have reference allele frequency data in HapMap or the literature. Out of 130 comparisons that could be made, one variant, *CYP2D6* rs1080985, was significantly different between our sample set and the reference frequencies (Pearson's chi-square; p=5.65x10-7). *CYP2D6* rs1080985 is in the promoter region of the gene, and this variant has been associated with variable response to the anti-Alzheimer drug donepezil. This pilot study suggests that ADME Core Panel performs well on DNA extracted from discarded blood samples from a clinic population. Further research is needed to understand the relationship between *CYP2D6* rs1080985 and the use of multiple medications.

Development of a High-Throughput Microdroplet-based Targeted Next-Generation Sequencing and its application to HLA and ADME gene panel sequencing. *J.A. Brayer, D.R. Link, J. Olson, L. Deming, A. Lennhoff, M. Weart, S. Kellett.* RainDance Technologies, Lexington, MA., Select a Country.

We describe the technical details of a new automation system, called the ThunderStorm, designed to perform PCR amplification of up to 20,000 reactions on each of 96 samples in a single 24-hour run. Samples are combined with PCR primer libraries and single molecule selection of specific regions of the genome is performed in picoliter droplets. To evaluate the performance of the ThunderStorm system, we evaluated a set of 16 HapMap samples against two defined content libraries (RainDance HLASeq™ and ADMESeq™ Extended Research Screening Panels). The HLA panel targets 3.8 MB of the HLA super locus and simultaneously amplifies >240 genes including all of the Class I, II and III cell surface antigen-presenting proteins. The ADME panel targets 241 genes involved with compound pharmacokinetics including CYP2D6, CYP2C19 and ERCC1. We also will discuss the relationship these two panels have in cancer research and immune response. In total 96 samples were processed, 16 samples x 2 libraries x 3 replicates per sample. All 96 samples were processed in a single run in less than 24 hours. The samples were barcoded and subsequently sequenced on an Illumina HiSeq2000. We will describe the uniformity and coverage of the sequence data across often difficult to sequence genes with significant homology. We will also describe the system's performance in detection known and novel variants across the genomic regions of interest.

1369F

Association of CYP2D6 polymorphisms and disease-free survival of Thai Breast cancer patients who received adjuvant tamoxifen. *M. Chamnanphol[1], T. Jantararoungtong[1], S. Santon[1], K. Pechatanan[2], E. Sirachainan[2], T. Sirisinha[2], T. Ativitavas[2], R. Panvichian[2], V. Ratanatharathorn[2], W. Chantratita[3], C. Sukasem[1].* 1) Laboratory for Pharmacogenomics and Personalized Medicine, Department of Pathology, Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 2) Division of Medical Oncology, Department of Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 3) Unit of Virology and Molecular Microbiology, Department of Pathology, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Objective: To investigate the influence of CYP2D6 variant coverage on genotype-phenotype relationships and the disease-free survival (DFS) of Adjuvant tamoxifen efficacy in adjuvant treatment of breast cancer in Ramathibodi hospital.

Methods: We conducted a case-control study. Peripheral blood DNA samples from 24 patients who had disease recurrence during adjuvant tamoxifen treatment, and from 24 patients who had completed 5 years of tamoxifen without recurrence of breast cancer was genotyped using the AmpliChip CYP450 GeneChip®, Roche that facilitates the classification of individuals by test-ing of 33 alleles. Disease free survival and correlation with genotypes were analyzed by Kaplan-Meier method, and log-rank test.

Results: Median follow up time was 5.6 years. Forty-eight patients were evaluated for DFS. The mean age of the subjects was 50 ±11 years. 62.5% of patients had premenopausal status. The phenotypes frequencies of extensive metabolizer (EM) and intermediate metabolizer (IM) were 70.8% and 29.2 %, respectively.The 3 common allelic frequencies were 43.8% (*10), 36.5 (*1) and 10.4% (*2) .All alleles frequencies observed in this study were concordant with previous re-ports in Asian population. No association between CYP2D6 genotypes and DFS was demonstrat-ed. Nevertheless, an exploratory analysis of DFS in postmenopausal patients according to EM (13 of 34 patients) or IM (5 of 14 patients) phenotypes, the result showed statistically significant shorter DFS in IM phenotype patients (HR, 6.85; 95% CI, 1.48 -31.69; P =0.005). Furthermore, we observed statistically significant shorter DFS of homozygous CYP2D6*10 (3 of 10) when compared among heterozygous CYP2D6*10 (7 of 22) and the remaining genotypes (8 of 16) (P=0.005).We found shorter DFS of IM patients (5 of 14) than homozygous EM (7 of 12) and heterozygous EM patients (6 of 22) (P =0.016).

Conclusions: The CYP2D6*10 (reduced alleles) was a common SNP in our subjects. Postmeno-pausal patients with homozygous *10 or IM have shorter DFS. These group of patients may need genotype testing prior to treatment planning .Our findings do not indicate importance of broad CYP2D6 coverage for accurate phenotype prediction and maximum stratification between me-tabolized status.

1370F

Analysis of association between statin medication, genetic variation and prostate cancer outcomes. *R.J. Hamilton[1], S. Alanee[1], J. Vijai[1], D.J. Gallagher[2], I. Ostrovnaya[1], J. Bhatia[1], M.M. Gaudet[3], S. Fine[1], A. Dutra-Clarke[1], J. Przybylo[1], J.M. Rendleman[1], C. Savage[1], S. Lipkin[4], R.J. Klein[1], P.T. Scardino[1], H. Lilja[1], T. Kirchhoff[1], H.I. Scher[1], J.A. Eastham[1], K. Offit[1].* 1) Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Mater University Hospital, Dublin, Ireland; 3) American Cancer Society, Atlanta, GA; 4) Weill Cornell School of Medicine, New York, NY.

BACKGROUND: The relationship between statin use and prostate cancer risk and outcome remains controversial. Genetic variation in cholesterol and statin metabolism pathways appears to modify the effect of statins on cholesterol and their protective association with some cancers. However, no studies to date have examined this pharmacogenetic interaction in the setting of prostate cancer. METHODS: Blood was collected for DNA extraction from 1491 men (775 Ashkenazi Jewish (AJ); 716 non-Jewish (NAJ)) treated for prostate cancer at Memorial Sloan-Kettering Cancer Center. Statin use at the time of diagnosis was recorded. Associations between statin use and biochemical recurrence, castration-resistant metastasis and prostate cancer-specific survival were analyzed using Cox proportional hazards models adjusted for age, year of diagnosis, PSA, Gleason grade, clinical stage, and treatment. Patients were genotyped for 42 single nucleotide polymorphisms (SNPs) in genes implicated in cholesterol synthesis or statin metabolism. We explored if genotype modified the association between statin use and clinical outcomes. RESULTS: In total, 252 (17%) men were taking a statin at diagnosis. Statin users were diagnosed more recently (median year: 2002 vs. 1998, p<0.001), at lower clinical stages (T1:55% vs. 44%, p=0.002), and with lower PSA (6.4 vs. 7.7 ng/mL, p=0.002). After adjusting for baseline features, statin use was associated with a reduced risk of biochemical recurrence (HR 0.67, 95% CI 0.50-0.88, p=0.004), metastases (HR 0.62, 95% CI 0.39- 0.99, p=0.05) and prostate cancer-specific death (HR 0.30, 95% CI 0.12-0.74, p=0.01). For preliminary genetic analyses we only examined interaction with the statin biochemical recurrence association. AJ and NAJ cohorts were analyzed separately. In the AJ cohort 3 SNPs significantly interacted with the statin-recurrence association at p<0.05, but the interaction was driven by a small number of statin users possessing the rare homozygote genotype. In the NAJ cohort, 2 SNPs in genes involved in statin excretion (ABCG2, SLCO1B1) were nominally significant at p=0.03. CONCLUSIONS: In this cohort, statin use was associated with improved outcomes after treatment, however SNPs involved in statin excretion had only weak modifying effects on the association with disease recurrence. Further study is on-going to explore the statin pathway for potential gene-exposure interactions.

1371F

Computational identification of non synonymous SNPs in human cytochrome P450 for prediction of population pk/pd of cyclophosphamide. *R.M. Labib[1], D. Yassin[2], M. Emam[3].* 1) Research, Children's Cancer Hospital, Giza, Egypt; 2) Clinical Pathology, Children's Cancer Hospital, Cairo, Egypt; 3) Faculty of Pharmacy, Beni Sweif University.

Background The potential pharmacogenetic effects of non synonymous single nucleotide polymorphism (nsSNPs) have long been overlooked. These nsSNPs can lead to amino acid changes that may cause altered drug response/toxicity. Cytochromes P450 (CYPs) are the key enzymes for activating and inactivating many drugs; individual expression levels of CYPs may play a crucial role in drug safety and drug efficacy. Genetic polymorphism in CYPs has been studied in different populations, yet studies on middle -eastern variants have not been widely studied. Cyclophosphamide(CPA), a chemotherapeutic agent used in many types of cancer, a prodrug that needs to be activated in vivo by CYPs. Wide inter-individual variations in Clinical response and toxicities to CPA were shown in different clinical studies. The aim of the present study is to search for presence of variants of CYP genes in Egyptian cancer patients, with a particular focus on their effect on population pharmacokinetic/ pharmacodynamic (pk/pd) pattern of CPA. The correlation between presence of such variants and pk/pd of CPA may aid as a potential tool for personalized drug dosing. Materials and Methods Blood samples from pediatric cancer patients were obtained from Children's Cancer Hospital. The pharmacokinetics of CPA was determined using HPLC-UV/Vis. The nsSNPs in all exons of the CYP genes analysed by RFLP and direct DNA sequencing. Population pk/pd will be analyzed using Nonmem® software. Computational tools will be used for the identification, haplotype analysis and prediction of functional effects of nsSNPs. To identify the potential pharmacogenetic effects of nsSNPs within cytochrome enzyme forming genes responsible for CPA activation and metabolism, all nsSNPs within the cytochrome P450 will be identified computationally. This will help in identifying molecular targets for drug treatment, and conducting individualized pharmacotherapy. Python scripts and established bioinformatics tools will be used to determine which of the nsSNPs in cytochrome P450 may result in a pk/pd variation. Results and Conclusion An on-line database and analysis tool will be created. The analysis tool will aid the discovery of the pharmacogenetic effects of these SNPs within genes associated with CPA activation. This prediction tool of nsSNPs in human CYP genes would be useful as a pharmacodiagnostic tool for the study of inter-individual variation in clinical response and drug toxicity.

1372F

Clinical Validation of Fragment Analysis to Genotype the Androgen Receptor VNTRs.. *A.B. Freeman[1], H. Hou[2], L. Shi[2], Q. Shu[2], B. Epps[2], B. Wilkinson[2], L. O'Brien[1].* 1) Eli Lilly and Company, Dept. of Translational Medicine, Indianapolis, IN 46285; 2) SeqWright, Inc., Houston, TX 77054.

The Androgen Receptor gene (AR, Chr X), encodes a transcription factor that is activated by androgens, such as testosterone, to regulate downstream gene expression. The activating domain in AR exon 1 contains a “CAG” and “GGC” variable number of tandem repeats (VNTR) resulting in glutamine (CAG) or glycine (GGC) repeat stretches in the receptor, respectively. Both VNTRs are known to be inversely associated with androgen activity and diseases such as osteoporosis and cancer. Additionally, fragment analysis (FA) genotyping of the CAG and GGC VNTRs in 268 HapMap DNAs showed that they were in linkage disequilibrium (p≤0.05), although having different allelic distributions, in normal African, Asian, and European populations. Therefore, we sought to validate the FA methodology to assess the AR VNTRs as clinical biomarkers in human patients.

Thirty-three (33) HapMap DNAs representing the most frequent CAG and GGC VNTR repeat alleles were blinded, amplified, and genotyped using FA. Clinical accuracy, precision, specificity, and technical variability were assessed for the FA methodology. Twenty (20) HapMap DNAs were subsequently sequenced to confirm the AR VNTR FA genotyping results.

We observed 100% concordance between past and present AR VNTR FA genotyping results in the HapMap samples. Unlike the GGC VNTR, the FA automated genotyping for the CAG VNTR was highly affected by technical variability, but easily corrected by adjusting the allele bin definitions. Ultimately, sequencing confirmed the FA genotyping results in 100% (20/20) and 95% (19/20) of HapMap samples for the CAG and GGC VNTR, respectively.

In one, random HapMap sample, the GGC VNTR FA and sequencing results conflicted, showing 21 and 20 repeats, respectively. Sequencing that sample revealed a “GGT” insertion 5' upstream of the GGC VNTR which mimicked a 21-repeat GGC amplicon size via FA when it actually contained only 20 GGC repeats. Additional genetic variability located within the AR GGC VNTR region with potential clinical relevance, but undetectable via FA, has also been reported (Bogaert, et al., 2009). Based on these results, we concluded that sequencing the AR GGC VNTR region is the most efficient and all-inclusive clinical genotyping methodology, while FA genotyping of the CAG VNTR region is clinically sufficient.

1373F

Phosphodiesterase (PDED4) gene polymorphism - association with the response to short acting bronchodilators in paediatric asthma patients. *M. Labuda[1], S. Laberge[2], J. Brière[1], D. Bérubé[2], P. Beaulieu[1], T. Pastinen[3], M. Krajinovic[1, 2, 4].* 1) Centre des Recherche, Ste_Justine Hospital, Montreal, PQ, Canada; 2) Departement of Paediatrics, University of Montreal; 3) Departments of Human and Medical Genetics, McGill University and Genome Quebec Innovation Centre; 4) Department of Pharmacology, University of Montreal, Montréal, Quebec, Canada.

Short-acting b2-adrenergic receptor agonists are commonly used as bronchodilators for symptom relief in asthmatics. Activated b2-adrenergic receptor leads to increased cAMP level, an essential bronchodilator. In turn, cAMP induces expression of phosphodiesterases (PDE), enzymes promoting cAMP degradation. The aim of this study was to test whether genetic variants in PDE4D gene affect the response to short acting b2-agonists. Bronchodilator responsiveness was assessed by % change in baseline forced expiratory volume in one second (FEV1) after administration of albuterol. FEV1 % change adjusted for baseline FEV1 values was significantly different between genotypes of PDE4D rs1544791 G/A polymorphism (P=0.006) and -1345 C/T (rs1504982) promoter variation (P=0.03) in patients with airway obstruction (n=93). The association remained significant after inclusion of appropriate covariates into multivariate model (p=0.004 and p=0.02, respectively). Our work identifies new genetic variants implicated in modulation of asthma treatment, one of them (rs1544791) previously associated with asthma phenotype.

1374F

Association analysis between *GIRK2* gene polymorphisms and post-operative analgesic requirements after painful cosmetic surgery. *D. Nishizawa[1], K. Fukuda[2], S. Kasai[1], W. Han[1], J. Hasegawa[1], A. Nishi[1], M. Koga[3], T. Arinami[3], M. Hayashida[4], K. Ikeda[1].* 1) Addictive Substances, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Oral Health and Clinical Science, Division of Dental Anesthesiology (Orofacial Pain Center/Suidoubashi Hospital), Tokyo Dental College, Tokyo, Japan; 3) Department of Medical Genetics, Graduate School of Comprehensive Human Sciences, University of Tsukuba, Tsukuba, Japan; 4) Department of Anesthesiology, Juntendo University, Tokyo, Japan.

Purpose: Opioids are commonly used as effective analgesics for the treatment of acute and chronic pain. However, considerable individual differences have been widely observed in sensitivity to opioid analgesics, which can lead to wide variability in the dose of opioid analgesics required to achieve adequate pain control. We focused on a G-protein-activated inwardly rectifying potassium (GIRK) channel subunit, GIRK2, that is an important molecule in opioid signal transmission, and examined genetic polymorphisms associated with opioid sensitivity. **Methods**: Subjects were 248 healthy patients who were scheduled to undergo cosmetic orthognathic surgery for mandibular prognathism at Tokyo Dental College Suidoubashi Hospital and provided informed, written consent for the genetics studies. Postoperative pain was managed with a bolus dose of 20 μg fentanyl on demand using a patient-controlled analgesia (PCA) pump when patients felt pain, with a lockout time set at 10 min. Postoperative PCA fentanyl use during the first 24-h postoperative period was recorded, whereas venous blood (10 ml) of the subjects was sampled for preparation of DNA specimens for genotyping with iScan System and the BeadChip Human1M v1.0 or Human1M-Duo v3 (Illumina K.K.). Association was explored by two-stage analysis between the analgesic requirement and single-nucleotide polymorphisms (SNPs) in the whole exon and intron region as well as 5'- and 3'-flanking regions (~10kbp) of the *GIRK2* gene. **Results**: In the first stage analysis, nine SNPs showed strong association with postoperative PCA fentanyl use (μg/kg) during the first 24-h postoperative period ($p<0.05$) among a total of 122 SNPs selected after the linkage disequilibrium analysis. In the second stage analysis, the association was identified to be significant in the rs2835859 SNP within the intron 3 after correction for multiple tests (combined $p=0.000237$). **Conclusion**: Although the mechanism underlying the difference in opioid sensitivity caused by the SNP needs to be clarified in future studies, the results indicate that this SNP could serve as a marker that predicts analgesic requirements. Our findings will provide valuable information for achieving satisfactory pain control and open new avenues for personalized pain treatment.

Optimizing Efavirenz Treatment by Detection of Pharmacogenetic Markers of CYP2B6 Corrected with Plasma Concentration in HIV-1 Infections. *C. SUKASEM[1], P. PRAPAITHONG[2], E. PASOMSUB[2], C. SRICHUNRUSAMI[1], TR. CRESSEY[3], T. JANTARAROUNGTONG[1], S. SANTHON[1], W. CHANTRATITA[2].* 1) Laboratory for Pharmacogenomics and Personalized Medicine, Department of Pathology, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 2) Unit of Virology and Molecular Microbiology, Department of Pathology, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 3) Program for HIV Prevention and Treatment (PHPT), Department of Medical Technology, Faculty of Associated Medical Sciences, Chiang Mai University, Chiang Mai, Thailand.

AIMS Pharmacogenomic studies are contributing to our understanding of interindividual differences in response to antiretroviral drugs. Recent studies have shown that a polymorphism in the CYP2B6 gene is associated with higher plasma Efavirenz (EFV) concentrations and increased central nervous system (CNS) side effects in Thai HIV-1 infections. METHODS We analyzed the genotypes and the allelic frequencies of CYP2B6 genetic polymorphism that are associated with EFV plasma concentration in a group of Thai HIV-1 infected patient. Extensive genotyping of the 9 single nucleotide polymorphisms (SNPs) of CYP2B6 were performed using the TaqMan real-time PCR assay on blood samples from 52 HIV-1 infected Thai patients who had received an EFV-based regimen. EFV plasma concentrations were measured by HPLC. We also analyzed the genotypes and haplotype structure of CYP2B6. RESULTS Our results showed that plasma EFV concentrations displayed high inter-individual variability amongst subjects with concentrations ranging from 42 to 40,307 ng/μl at 12 hours after initiation of treatment. Four SNPs (rs2279343, rs2279345, rs3745274, rs8192719) were significantly associated with EFV plasma concentration (P=0.0056). The composite CYP2B6 of 6 SNPs (516/3003/21563/18492/785/64) genotypes were significantly associated with EFV concentration. CONCLUSIONS In conclusion, our data indicate that the TTTCGT CYP2B6 haplotype may have value in predicting adverse drug reaction from CNS toxicity to EFV with treatment in Thai patients with HIV-1 infection.

Genetic factors in Bupropion Response and Remission. *A. Tiwari, C. Zai, G. Sajeev, T. Arenovich, D. Mueller, J. Kennedy.* Neuroscience, Centre for Addiction and Mental Health, Toronto, Canada.

There is considerable variability in the rate of response and remission following treatment with antidepressant drugs. Bupropion, a commonly prescribed antidepressant, is a dual norepinephrine and dopamine transporter inhibitor. A total of 532 tagging single nucleotide polymorphisms (SNPs) in 34 candidate genes (monoaminergic pathways and Hypothalamic-pituitary-adrenal axis) were investigated for association with remission and response in patients with major depressive disorder (MDD). These patients were from four GSK funded clinical trials in the USA in which they were treated with bupropion (n=319). Analyses were performed using conditional logistic regression. Gene-wide corrections for multiple testing were carried out. Significant association was observed for remission following treatment with bupropion with a SNP within the serotonin receptor 2A gene (HTR2A, rs2770296, pcorrected=0.02) and marginal evidence for association within the angiotensin converting enzyme gene (ACE, rs8075924, pcorrected= 0.054). Response to bupropion treatment was also significantly associated with a SNP in the dopamine transporter gene (SLC6A3; rs6347, pcorrected= 0.013) and marginally associated with another variant within the vesicular monoamine transporter 2 gene (SLC18A2; rs363225, pcorrected=0.059). These results suggest an important role for HTR2A in remission to bupropion treatment. In accordance with bupropion pharmacology, response may be associated with genetic variation in dopamine and vesicular monoamine transporters.

Correlated Meta-analysis of Genome-Wide Association Studies of Agonist-mediated Native Platelet Aggregation in African Americans. *R. Qayyum[1], D. Becker[1], D. Vaidya[1], L. Yanek[1], N. Faraday[2], R. Mathias[1,3], L. Becker[1].* 1) Medicine, Johns Hopkins School of Medicine, Baltimore, MD., USA; 2) Anesthesiology, Johns Hopkins School of Medicine, Baltimore, MD., USA; 3) Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD, USA.

While genome-wide association studies (GWAS) of dose-specific agonist-mediated platelet aggregation have been reported, results from an agonist-centered GWAS approach that combines the effect of different agonist doses has not been reported. In this study our aim was to identify novel loci that are associated with native platelet aggregation in African Americans (AA) by combining the results from dose-specific GWAS. Platelet-rich plasma (PRP) was isolated from blood samples obtained from AA participants of the GeneSTAR (N=835) cohort. Optical aggregation was used to measure maximal aggregation in PRP after collagen (C) 2, 5, 10 μg/mL, ADP 2, 10 μmol/L, or epinephrine (E) 2, 10 μmol/L. Genotyping was conducted with Illumina 1M arrays. For each dose, linear mixed models adjusting for family structure, population stratification, age, sex, and cardiovascular risk factors were used to test for association between each SNP and phenotype under an additive model. To adjust for correlation between different doses, we pooled dose-specific GWAS results by performing separate meta-analyses with tetrachoric correlation for each agonist. Adequacy of adjustment for correlation between the doses was confirmed by simulation. We sought replication in European Ancestry participants from GeneSTAR (N=1257). We found 48 SNPs associated with aggregation (with ADP=3, C=46, E=1). A previously reported SNP in PEAR1 gene, rs12041331, was associated with all 3 agonists ($p=6.2 \times 10^{-14}$, 9.4×10^{-10}, 1.1×10^{-15} for ADP, C, and E respectively) at GWAS significance and associated at nominal significance with ADP and E in the replication cohort ($p=1.7 \times 10^{-5}$ & 3.4×10^{-5} respectively). Two SNPs in PPARGC1B, rs17797713 & rs10515634, were associated with ADP ($p=5.5 \times 10^{-10}$ & 9.8×10^{-9}) and another SNP in CNTN4, rs13060035, was associated with C ($p=1.1 \times 10^{-9}$); these SNPs were also significant in the replication cohort ($p = 0.01$, 0.03, & 0.04 respectively). Variants in PPARGC1B have been associated with obesity and in CNTN4 with hypertension in previous studies. In this first GWAS of dose-independent, agonist-mediated, native platelet aggregation, we have discovered, and replicated in an independent sample, three regions associated with platelet aggregation in AA. The elucidation of pathophysiological mechanisms of these associations requires further study and may provide insights into platelet biology and the increased risk of thrombosis in obese or hypertensive individuals.

1378F

Mixture regression analysis on antipsychotics induced weight gain: investigation of the role of serotonergic genes. *V. De Luca, B. Nowrouzi, C.C. Zai, J.L. Kennedy.* Neurogenetics, CAMH, Toronto, ON.

Antipsychotics induced weight gain is a complex trait with a relevant underlying genetic basis. HTR1A, HTR1D, HTR2A, HTR3A, HTR4, SLC6A4, TPH1 and TPH2 polymorphisms were genotyped in 139 schizophrenia patients and inserted as covariates in a mixture regression model of antipsychotic-induced weight gain expressed as percentage of weight change. Mixture analysis decompounded the observed distribution of weight gain into a mixture of two normal theoretical distributions. The DENORMIX program found two components with a mean (SD) of 2.61 (3.73) and 8.65 (8.75) comprising respectively 56+/-37; and 44+/-37; of the sample respectively. We obtained a cut-off point at 8% enabling the sample to be divided into two subgroups in order to assess the weight gainers and non-weight gainers. One-hundred-two subjects (73±37;) were included in the non-weight gainer group and 37 (27±37;) were included in the weight-gainer group. None of the studied polymorphisms were associated with non-weight gainer component under recessive or dominant model. The 5HT receptors did not show any significant interaction when pair-wise combinations were considered. These findings do not suggest a role of genes codifying for elements of the serotonergic system in influencing the weight gain in antipsychotic treatment.

1379F

Failure of metformin to reduce diabetes incidence in carriers of the *SLC22A1* Arg61-Leu160 haplotype. *T.I. Pollin[1, 2], J.C. Florez[3,4,5], S-W. Yee[6], K.A. Jablonski[2], J.B. McAteer[3,4], A. Taylor[4], W.C. Knowler[7], K.M. Giacomini[6], A. Shuldiner[1], DPP Research Group.* 1) Div Endocrinol/Diabetes/Nutrit, Univ Maryland, Baltimore, MD; 2) The George Washington University Biostatistics Center, 6110 Executive Blvd, Suite 750, Rockville, MD 20852; 3) Center for Human Genetic Research and Diabetes Research Center (Diabetes Unit), Massachusetts General Hospital, Boston, Massachusetts; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts; 5) Department of Medicine, Harvard Medical School, Boston, Massachusetts; 6) University of California San Francisco, San Francisco, CA; 7) Diabetes Epidemiology and Clinical Research Section, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, Arizona.

In the Diabetes Prevention Program (DPP), a multicenter, multi-ethnic randomized clinical trial conducted in individuals at risk for type 2 diabetes, the insulin-sensitizing drug metformin (MET) reduced diabetes incidence by 31%, and an intensive lifestyle intervention (ILS, consisting of weight loss and dietary modification) by 58% over an average follow-up period of 3.2 years. We evaluated several candidate genes as predictors of metformin response in the DPP. *SLC22A1* encodes the organic cation transporter family member 1 (OCT1), responsible for hepatic metformin uptake. Individual human *SLC22A1* coding variants, including G401S (rs34130495) and R61C (rs12208357) but not F160L (rs683369), were previously shown to alter cellular metformin uptake and metformin pharmacokinetics. In 2,994 DPP participants (990 on metformin), we evaluated the association of all known *SCL22A1* coding variants with overall minor allele frequency (MAF) ⁄ 1% (6 missense, 1 in-frame deletion and 2 silent) with response to metformin and lifestyle interventions using age-, sex- and ethnicity-adjusted Cox proportional hazards. F160L and G401S were significant effect modifiers (SNPxMET interaction *P*-value = 0.01 and 0.05 respectively) of the relationship between metformin and diabetes risk, but not between ILS and diabetes risk (SNPxILS interaction *P*-value = 0.80 and 0.26 respectively). The 7 missense/deletion variants lie in a region of strong LD and comprise 8 haplotypes with frequencies⁄ 1% in the DPP. We identified two metformin-response associated haplotypes/isoforms, distinguishable from the remaining six haplotypes by the genotypes at R61C and F160L and differing from each other at G401S. The combined risk haplotype (HAP), R61-L160, had a frequency in the DPP sample ranging from 0.039 in African Americans to 0.136 in Caucasians. Carriers of at least one copy of R61-L160 (n=583) appeared non-responsive to MET (hazard ratio [HR]=1.13 [0.76-1.68], *P*= 0.55, $P_{METxHAP}$=0.004) but responsive to ILS (HR=0.41 [0.26-0.66], *P*= 0.0002, $P_{ILSxHAP}$=0.87]), whereas noncarriers (n=2,362) exhibited response to both interventions (MET HR=0.61 [0.49-0.75], $P=4x10^{-6}$; ILS HR=0.46 [0.36-0.58], $P=3 \times 10^{-11}$). Pending replication and functional validation, these results suggest that metformin non-responders could be identified preemptively by genotyping these two SNPs, enhancing the ability to personalize effective prevention and/or treatment of type 2 diabetes or other metformin responsive conditions.

1380F

Combining Nested PatchPCR™ and Nextera™ for High-Throughput Targeted Resequencing. *N.C. Caruccio[1], K.T. Varley[2, 3], D.T. Moore[2], R.C. Bachmeyer[2], R.M. Meyers[2, 3].* 1) Epicentre - An Illumina Company, Madison, WI 53713; 2) Kailos Genetics Inc., Huntsville, AL 35806; 3) HudsonAlpha Institute for Biotechnology, Huntsville, AL 35806.

The ability to sequence hundreds to thousands of targeted genomic regions in parallel, across a large number of patient samples is crucial for adopting next-generation sequencing in clinical practice and research settings. While single-locus PCR can be used to amplify genomic regions from many samples, the number of targeted regions is limited. Conversely, hybridization-based capture methods can target many regions, but sample throughput is limited.

To address these limitations, we have combined Nested PatchPCR™ and Nextera™ library construction to enable targeted sequencing across hundreds of genomic regions (of varying sizes) across large numbers of patient samples to more fully utilize Illumina sequencing capacity for clinical re-sequencing.

We have developed a pharmacogenomics panel targeting genetic variants associated with adverse drug reactions. Using Nested PatchPCR™, 480 genomic regions in 39 genes are specifically amplified in a single tube from 250ng of patient genomic DNA. 85 patient samples were processed in parallel in 96-well plates. High-throughput library construction was enabled using Nextera™ technology to prepare Illumina-compatible sequencing libraries containing patient-specific barcodes. The 480 amplified regions from each of 85 patient samples were pooled and sequenced on a single Illumina GAIIx flowcell. We achieved uniform coverage across the targeted amplicons, with an average of 400x read depth (>50X coverage across 85% of amplicons) and 95% of reads aligning to targeted regions.

The CYP2C19*3 polymorphism was detected in six technical replicates of a poor mephenytoin metabolizing patient and not in six technical replicates of a normal patient, validating variant detection using this approach. High coverage depth provides excellent accuracy for SNP identification, but also indicates there is capacity to process more genomic loci or patient samples. We have developed a larger-scale oncology panel combining Nested PatchPCR™ and Nextera™ to sequence 760 genomic regions covering 63 genes that are frequently mutated in cancer and associated with prognosis or response to therapy. The scale and utility of this approach is broadly applicable to re-sequencing candidate genes or regions in large cohorts of individuals.

1381F

Effects of ABCB1 drug transporter genotypes on antiepileptic drug disposition. *N. Božina[1], M. Lovrić[1], S. Hajnšek[2], D. Sporiš[3], Z. Lalić[1], P. Granić[1].* 1) Department of Laboratory Diagnostics, University Hospital Centre Zagreb, Croatia; 2) Department of Neurology, University Hospital Centre Zagreb; 3) Department of Neurology, University Hospital Dubrava, Zagreb.

Background: 25-30 percent of epileptic patients remain resistant to different antiepileptics. ABC transporters which are responsible for drug transport across intestinal, renal and hepatic epithelial membranes and blood-brain barrier represent significant factors of variability in bioavailability of different drugs. The aim of the study was to evaluate the impact of ABCB1 (coding for P-glycoprotein) variants C1236T, G2677T/A, C3435T on antiepileptic drug disposition. We therefore correlated plasma levels of lamotrigine in mono- and polytherapy (carbamazepine, oxcarbazepine, levetiracetame, phenytoin, phenobarbital, topiramate, valproate) with gene variants. Patients and methods: A total of 222 epileptic patients, aged 16-76 years, were stratified into lamotrigine monotherapy group (n=58), a group receiving lamotrigine plus inductors (n=98), and those receiving inhibitors (n=29) or both (n=37). ABCB1 genotyping (C1236T, G2677T/A), C3435T, was performed by Real-time PCR and PCR-RFLP. Therapeutic drug monitoring was performed by HPLC with diode array detector and immunoassay. Results: A statistically significant correlation was confirmed between lamotrigine concentration and additional drugs (p<0.001), type of epilepsy, GGT, ALT, age and weight. Statistical analysis showed correlation between lamotrigine concentrations and ABCB1 C1236T allele (p=0.005), and genotype (p= 0.021) and G2677T/A genotype (p=0.05). Lamotrigine concentrations in subjects who were T allele carriers were significantly decreased. Haplotype analysis showed that 1236T-2677T-3435C carriers had the lowest dose-corrected lamotrigine level (p<0.001), followed by 1236T-2677T-3435C haplotype (p<0.04). Conclusion: The obtained results show that ABCB1 polymorphisms exert an influence on antiepileptic drug pharmacokinetics and may serve as a pharmacogenetic marker of lamotrigine bioavailability.

1382F

Decreased mucosal expression of barrier genes and vitamin D receptor gene in inflammatory bowel disease. *I. Arijs[1,2], J. Van Der Goten[1], K. Machiels[1], L. Van Lommel[2], I. Cleynen[1], G. De Hertogh[3], K. Van Steen[4], G. Van Assche[1], S. Vermeire[1], F. Schuit[2], P. Rutgeerts[1].* 1) Department of Gastroenterology, KU Leuven, Leuven, Belgium; 2) Gene Expression Unit, Department of Molecular Cell Biology, KU Leuven, Leuven, Belgium; 3) Department of Pathology, KU Leuven, Leuven, Belgium; 4) Department of Electrical Engineering and Computer Science (Montefiore Institute), University of Liège, Liège, Belgium.

INTRODUCTION: In inflammatory bowel disease (IBD), the intestinal epithelial barrier function is thought to be impaired, leading to aberrant exposure to changed luminal microbiota causing chronic mucosal inflammation. Kong et al showed that vitamin D receptor (VDR) plays a role in maintaining mucosal barrier integrity. This study investigated colonic expression of *VDR* and of known barrier genes in active IBD patients, and studied the effect of anti-inflammatory therapy with infliximab (IFX) and mucosal healing on colonic expression of these genes. METHODS: The expression of *VDR* gene and genes related to intestinal epithelial barrier function [IBD candidate susceptibility genes, claudins (CLDNs), mucins (MUCs), tight junction proteins (TJPs), E-cadherin (CDH1)] was investigated in colonic mucosa from 43 anti-TNF naïve IBD patients with active colitis (24 ulcerative colitis (UC) and 19 Crohn's disease (CD)) before and 4-6 weeks after their first IFX infusion and in 6 controls. Response to IFX was defined as complete endoscopic and histologic healing. Total RNA isolated from biopsies was used to analyze gene expression via Affymetrix Human Genome U133Plus2.0 Arrays. Quantitative RT-PCR and immunohistochemistry were used to confirm array data. Data was analyzed with Bioconductor and SPSS software. RESULTS: *VDR* gene expression was >1.5-fold significantly (false discovery rate<5%) decreased in active IBD vs controls. IFX therapy slightly increased *VDR* gene expression in healed mucosa in IBD responders. Gene expression levels of *ABCB1*, *CDH1*, *CFTR*, *CLDN3*, *CLDN8*, *CLDN23*, *CXADR*, *MUC20*, *OCLN*, *SLC22A4*, *SLC22A5*, *TJP1* and *TJP3* were all >1.5-fold significantly decreased in active UC and/or CD vs controls. After IFX therapy, gene expression of *ABCB1*, *CXADR*, *SLC22A5* and *TJP1* remained >1.5-fold significantly decreased after complete healing in UC and/or CD. Colonic expression of the decreased barrier genes after IFX and *VDR* gene significantly ($P_{Spearman's\ rho}$<5%) correlated with villin-1 expression, a gut epithelial cell marker, indicating that the decrease is directly related to epithelial damage. Immunohistochemistry of VDR showed partial restoration of epithelial expression in IBD colon with mucosal healing. CONCLUSION: Our data shows that decreased expression of the barrier genes and the *VDR* gene in IBD colon is directly related to mucosal damage, but a persistent barrier defect even after healing may contribute to an increased risk of relapse of mucosal ulceration.

1383F

Evidence for a heritable response to treatment for asthma. *C. Teerlink[1], M. Hegewald[2], L. Cannon-Albright[1,3].* 1) Dept Internal Medicine, Univ UtahSch Med, Salt Lake City, UT; 2) Department of Pulmonary and Critical Care Medicine, University of Utah and LDS Hospital, Salt Lake City, UT; 3) George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, Utah.

Evidence of familial clustering for a phenotype of interest can provide strong motivation to investigate the underlying genetic contribution. However, assessment of heritability to treatment response for a disease that is itself recognized to have a heritable component can be problematic due to the potential for confounding with the underlying disease heritability. We have applied a strategy to consider the heritability of the response to various asthma medications while correcting for the underlying heritability of asthma. The approach uses the Genealogical Index of Familiality (GIF) to compare the familial clustering of the subset of treated cases to the expected familial clustering for all asthma cases. A significant excess relatedness among the subset of cases provides evidence for familial clustering of the subset beyond the expected clustering for all asthma cases; thereby effectively identifying a subset of asthma cases who share a heritable response to medication. We have applied this strategy to clinically relevant treatment response phenotypes for asthma using genealogy records from the Utah Population Database that have been record-linked to over 15 years of electronic prescription drug data at the University of Utah Health Sciences Data Warehouse. Using ICD-9 codes, we identified 5,458 total asthma cases to serve as controls. We then identified various subsets of this cohort that had prescription drug records consistent with one of several treatment responses to serve as cases. To empirically assess significance we calculated the GIF statistic for each subset and then compared the value of the GIF to the distribution of GIFs collected from 1000 random sets of the controls, matched on place of birth, sex and age. Phenotypes of interest included multiple prescriptions for oral corticosteroids (n=196, case GIF=9.0, control GIF=4.6, p = 0.000); any prescription for corticosteroids (n=616, case GIF=9.6, control GIF=4.8, p=0.000); prescriptions only for inhaled beta-agonists (n=1487, case GIF= 7.6, control GIF=4.8, p=0.000); multiple prescriptions for leukotriene modifiers (n=207, case GIF=10.3, control GIF=4.8, p=0.000); and multiple prescriptions for long-acting beta-agonists (n=526, case GIF=7.6, control GIF=4.9, p=0.000). These results show strong evidence for familial clustering for all of the treatment response outcomes for asthma management, and encourage further investigation into underlying genetic factors.

Evaluation of pharmacogenetic markers by exome-sequencing of DNA extracted from saliva samples. *R.M. Iwasiow, M. Tayeb.* DNA Genotek, Inc., Ottawa, ON, Canada.

With increasing popularity and advancements in next generation sequencing resulting in decreasing costs it is enabling the use of these technologies for clinical applications. It is becoming feasible to process large numbers of samples for the purpose of genetic analysis. Sequencing large number of samples requires complex and expensive bioinformatics infrastructure. An alternative which can significantly reduce this burden is the use of targeted enrichment to only sequence areas of interest. Using the Agilent SureSelect Human All Exon Kit to capture regions totaling 38MB = 1.22% of human genomic regions significantly reduces the bioinformatics burden. Both next generation sequencing and target enrichment technologies require the collection of reliable, high quality samples. Previously, we have demonstrated that Oragene®•DNA provides an alternative method to blood samples for collecting large amounts of high quality genomic DNA that is suitable for next generation sequencing applications. Oragene•DNA collection devices are designed for non-invasive collection of saliva samples. The devices contain a stabilizing reagent that ensures the sample is of high quality and allows long term storage at ambient temperature. In this study we investigated DNA extracted from saliva collected using Oragene•DNA and paired-end sequenced on the Illumina Genome Analyzer II after target enrichment using the Agilent SureSelect Human All Exon Kit for the purpose of identifying pharmacogenetic markers for drug metabolism. Using the Agilent SureSelect Human All Exon Kit we observed a mean coverage of 98.48% against the targeted sequences at a mean depth of 77x. Paired-end sequencing of the target enriched sample on the Illumina Genome Analyzer II generated a mean lane yield of 6,352,886 kbases of which 46.1% corresponded to exon sequences. The high depth of coverage and depth of sequencing achieved by using DNA from saliva with the Agilent SureSelect Human All Exon Kit and sequencing using paired-end sequencing on a single lane of the Illumina Genome Analyzer II has allowed us to confidently mine the data for SNPs of interest. As such, here we demonstrate the ability to use saliva as a non-invasive DNA sample to investigate pharmacogenetic markers using next generation sequencing technologies.

Whole exome sequencing study of drug-induced liver injury: the association of rare variants. *Y. Shen[1,7], A. Floratos[1], A. Daly[2], M. Lucena[3], M. Molokhia[4], C. Stephens[3], M. Nelson[5], M. Daly[6], I. Pe'er[1,7].* 1) Center for Computational Biology and Bioinformatics, Columbia University, New York, NY; 2) Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 3) Facultad de Medicina, Hospital Universitario Virgen de la Victoria, Campus Universitario s/n, Málaga, Spain; 4) Department of Primary Care & Public Health Sciences, Kings College, London, United Kingdom; 5) GlaxoSmithKline, Research Triangle Park, North Carolina; 6) Harvard Medical School, Boston, Massachusetts; 7) Department of Computer Science, Columbia University, New York, NY.

Drug-Induced Liver Injury (DILI) is an important cause of drug withdrawal from the market, termination of clinical development, and mortality and mobility in developed countries. Amoxicillin-clavulanate (coamoxiclav) is a widely used antibiotic drug and a leading cause of DILI worldwide. Previous studies (Lucena et al 2011) of coamoxiclav liver toxicity established common HLA alleles as risk factor with large effect in European population. However, the clinical utility is limited by poor positive prediction value. Here we hypothesize that rare variants have significant contribution to the susceptibility of DILI. We performed a whole exome sequencing study to search for the association of rare variants. We searched the association of rare variants using both single variant and gene-based group test, and found suggestive evidence of rare variants association in several interesting genes. We are working towards validation and replication of these findings.

1386F

Pharmacogenomic study of side effects for antidepressant treatment options in STAR*D. *S.L. Clark[1], D.E. Adkins[1], K. Aberg[1], J.M. Hettema[2], J.L. McClay[1], R.P. Souza[3], E.J.C.G. van den Oord[1].* 1) Center for Biomarker Research and Personalized Medicine, Virginia Commonwealth University, Richmond, VA; 2) Department of Psychiatry, Virginia Commonwealth University, Richmond, Va; 3) Laboratory of Neurosciences, Universidade Do Extremo Sul Catarinense, Criciuma, SC, Brazil.

Understanding individual differences in susceptibility to antidepressant therapy side effects is essential to optimize the treatment of depression. Clinical trials have suggested that only 50% of patients with uncomplicated major depressive disorder respond to any single antidepressant (Papakostas & Fava, 2009), with inability to tolerate side effects being the most common reason for discontinuing antidepressant therapy (Bull, Hu et al., 2002; Bull, Hunkeler et al., 2002; Maddox, Levi, & Thompson, 1994; Mitchell, 2006). Studies have consistently indicated that antidepressant response is substantially heritable (Franchini, Serretti, Gasperini, & Smeraldi, 1998; Malhotra, Murphy, & Kennedy, 2004; Oreilly, Bogue, & Singh, 1994; Pare & Mack, 1971), suggesting that pharmacogenomic approaches represent a particularly promising avenue toward individualizing antidepressant treatment. Here we perform genome-wide association studies (GWAS) to search for genetic variation affecting the susceptibility to side effects. The analysis sample consisted of 1,439 depression patients, successfully genotyped for 421K SNPs, from the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study. Outcomes included four indicators of side effects: general side effect burden, sexual side effects, dizziness and vision/hearing related side effects. Our criterion for genome-wide significance was a pre-specified threshold ensuring that, on average, only 10% of the significant findings are false discoveries. Thirty-four SNPs satisfied this criterion. The top finding indicated 10 SNPs in SACM1L (p = 4.98x10-7, q =0.023) and MAGI2 (p = 2.76x10-6, q =0.097) whose minor allele effects mediate the effects of bupropion on sexual side effects. Both SACM1L and MAGI2 potentially alter cellular trafficking which has been shown to be associated with sexual dysfunction. Genome-wide significant findings were also found for SNPs in DTWD1 (p = 2.76x10-7, q =0.069), WDFY4 (p = 1.64x10-7, q =0.069) and CHL1 (p = 2.28x10-6, q =0.080). Possible clinical implications of the findings will be discussed. Although our findings require replication and functional validation, this study demonstrates the potential of GWAS to discover genes and pathways that potentially mediate adverse effects of antidepressant medication.

1387F

Association of COX-2 rs20417 with Stroke Risk, Functional outcome and Aspirin resistance. *A. Munshi[1, 2], V. Sharma[1], S. Kaul[3], A. Jyothy[1].* 1) Molecular Biology, Institute of Genetics and Hospital for Genetic Dis, Hyderabad, India; 2) Department of Botanand Microbiology, King Saud University, Riyadh, Saudi Arabia; 3) Nizams Institute of Medical Sciences, Panjagutta, Hyderabad.

Aspirin is the most commonly used antiplatelet drug for treatment of a serious vascular event, most notably stroke and myocardial infarction. However, despite the demonstrated benefit of aspirin, significant fraction of aspirin-treated patients may be resistant to the antiplatelet effects of the drug. A genetic basis for aspirin resistance has been suggested to exist. Therefore, the present study was taken up to investigate the role of -765 G/C polymorphism (rs 20417) in the Cyclooxygenase-2 (COX-2) gene with aspirin resistance in stroke patients. Four hundred and fifty stroke patients and 440 age and sex matched healthy controls were involved in the study. Baseline clinical data were collected and follow-up telephone interviews were conducted with patients at 3 months post event to determine stroke outcome. Blood sample were collected and genotypes determined. Significant difference was observed in the genotype distribution and allele frequency between patients and controls. CC genotype and C allele associated significantly with stroke (p=0.026 and 0.003). A step wise logistic regression analysis confirmed these findings. Further the COX-2 GC genotype showed a significant association with poor stroke outcome and CC genotype with poor outcome as well as death at 3 months from stroke onset. Therefore the carriers of C allele of COX-2 rs 20417 are more prone to aspirin resistance in comparison with non carriers. Further C allele of COX-2 gene is also an important risk factor for ischemic stroke. However, this is a preliminary study and the results need to be confirmed in a larger cohort.

1388F

The AA Genotype of Tumor Necrosis Factor Induced Protein 2 (TNFAIP2) rs8126 Polymorphism is Associated with Increased Mortality in Septic Shock. *S.A. Thair, J.H. Boyd, T.A. Nakada, J.A. Russell, K.R. Walley.* University of British Columbia Critical Care Research Laboratories, Heart + Lung Institute, St. Paul's Hospital, 1081 Burrard Street, Vancouver, BC, Canada V6Z 1Y6.

One of the central mediators of the pathophysiology of septic shock is the transcription factor nuclear factor 2B (NF-2B). We tested the hypothesis that genetic variation in inflammatory mediators of the NF-2B pathway are associated with increased 28-day mortality in patients who have septic shock. Using microarray to measure gene expression under inflammatory conditions we found that TNFAIP2 transcription is greatly increased in multiple settings. We then tested the hypothesis that single nucleotide polymorphisms (SNPs) of TNFAIP2 are associated with altered clinical outcome of septic shock patients. We performed an Armitage trend test using 28-day mortality on 68 SNPs genotyped in the region of TNFAIP2 +/- 50,000 bp in 530 Caucasian patients of the Vasopressin and Septic Shock Trial (VASST). In vitro studies include IL-6 ELISAs on genotyped lymphoblastoid cell lines after inflammatory stimulus, as well as IL-6 ELISAs on Hela cells after knock down and over expression of TNFAIP2. The initial screening analysis of the 68 SNPs identified rs8126 as highly associated with mortality (uncorrected p= 0.007). Using Cox regression we found that septic shock patients with the GG (homozygous minor) genotype of rs8126 had increased 28-day mortality (VASST relative risk 0.73 (95% CI 0.59-0.82, p=0.0065)). In vitro studies of lymphoblastoid cells with the AA (homozygous minor) genotype of rs8176373 (linkage disequilibrium (LD) with rs8126 >0.8) had lower levels of IL-6 production due to inflammatory stimulus than those of the GG genotype (p=0.03). Furthermore, IL-6 ELISAs of knock down and over expression of TNFAIP2 in Hela cells shows a statistically significant decrease in IL-6 levels when TNFAIP2 is knocked down and conversely, a statistically significant increase in IL-6 when TNFAIP2 is over expressed (p=0.005 and p= 0.00003 respectively). We conclude that the GG genotype of TNFAIP2 rs8126 is associated with increased septic shock mortality, possibly because this allele contributes to decreased TNFAIP2 function and subsequently decreased IL-6 and other pro-inflammatory cytokine production.

Deep Resequencing Identifies Common, Low Frequency and Rare Variants in ADIPOQ Underlying Adiponectin Variation and Provides Insight into its Role in Type 2 Diabetes Susceptibility. *L. Warren[1], L. Li[1], M. Nelson[1], M. Ehm[1], J. Perry[4], C. Palmer[4], T. Frayling[4], V. Mooser[2], J. Whittaker[3], D. Waterworth[2].* 1) Quantitative Sciences, GlaxoSmithKline, Res Triangle Park, NC. USA; 2) Quantitative Sciences, GlaxoSmithKline, Upper Merion, PA, USA; 3) Quantitative Sciences, GlaxoSmithKline, Stevenage, UK; 4) Peninsula College of Medicine and Dentistry University of Exeter, UK.

Resequencing technologies make it possible to investigate the role of genetic variants across the allele frequency spectrum and so dissect the genetic architecture underlying complex trait variation. Here we report a resequencing study of ADIPOQ in 3665 subjects with adiponectin levels from two independent studies. We confirmed previously reported common variant associations and identified multiple novel associations due to low frequency (P=2.2E-17) and very rare amino acid-changing variants (p=0.02). As expected, we found that the effects of common variants were modest, while the less common possessed large effect and the extremely rare variants resulted in extreme phenotypic outliers. This level of insight into the genetic architecture of a gene of medical interest is only possible by large scale resequencing. By analyzing genome-wide genotype and resequence data jointly and via frequentist and bayes variable selection methods, we identified seven independent signals that contribute to adiponectin levels, explaining 6% of the variation. Epidemiological studies have shown an inverse relationship between adiponectin levels and T2D risk, however whether adiponectin is causal or merely a marker of pre-diabetes is not yet known. These SNPs were thus subsequently genotyped in a cohort of 5145 type 2 diabetes (T2D) cases and 6374 controls and tested in a Mendelian randomization framework. None of the SNPs were significantly association with T2D. The lack of association between ADIPOQ SNPs that affect adiponectin levels and T2D suggests that low adiponectin levels do not causally predispose to T2D. This study exemplifies the capability of deep resequencing to elucidate the genetic architecture underlying traits of medical interest. Such knowledge can enhance our understanding of the genetic causes of complex disease and serves to inform drug target discovery and validation.

Cytochrome oxidase subunits: a pharmacogenetics prediction marker of Accutane therapy. *S. ABADPOUR, A. TAVAKOLI TAMEH, S. MATOO, A. YASARI MAZANDARANI, B. SEDAGHATI KHAYAT, N. HATAMNEJADIAN, M. MAHDAVI, A. EBRAHIMI.* Parseh Medical Genetics Counselling Center, Floor 7, No.75, Royan Alley,Keshavarz Bolv. Tehran, Iran; Tel-Fax: +98 21 88966579, 88996889; E-mail: ae35m@yahoo.com.

Accutane is one of the commonly drugs which is used vastly in therapy of skin disorders. Different people taking Accutane often have very different reactions. These variations in response and side effects are caused by many variables, but genetic variation and metabolism-based drug, herbal, and food interactions are among the most common. Most of variations in genes involved in, drug metabolism with a particular emphasis on improving drug safety in skin disorders area focused on CYP gene families. As part of the inborn system for clearing the body of xenobiotics, the cytochrome P450 oxidases (CYPs) are heavily involved in drug metabolism, and genetic variations in CYPs affect large populations. Molecular studies of CYPs subunits polymorphism can help the physicians to predict the drug responses and reduce unexpected side effects of Accutane. Materials and methods To evaluating of common polymorphisms in CYP2C9, CYP2C19 and CYP2D6 we selected about 50 patients which were under treatment for acne. Clinical examinations and genetic counselling were done and then the patients were divided into three groups including positive drug response, negative drug response and control group. The blood samples were collected, DNA was extracted and common polymorphisms were studied by using PCR, ARMS_PCR and RFLP methods. Result The results revealed that polymorphisms of CYP2C9 and CYP2D6 subunits have the most important effect in prediction of Accutane treatment responses in studied group. KEY WORDS: pharmacogenetics, Accutane, CYP2C9, CYP2C19, CYP2D6.

Web-based phenotyping for pharmacogenomics research. *K.E. Barnholt[1], A.K. Kiefer[1], T.K. Acquaye[1], R.B. Altman[2], H.L. McLeod[3], J.A. Johnson[4], C.B. Marsh[5], J.Y. Tung[1], J.L. Mountain[1].* 1) 23andMe, Inc., Mountain View, CA; 2) Department of Bioengineering, Stanford University, Stanford, CA; 3) Division of Pharmacotherapy and Experimental Therapeutics, Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, Gainesville, FL; 5) Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine, Department of Internal Medicine, Ohio State University, Columbus, OH.

Significant barriers to the progress of pharmacogenomics research include the cost and time required to assemble, phenotype and genotype an appropriately-sized cohort. 23andMe's research program uses web-based surveys to gather a broad range of phenotype data from an expanding cohort of genotyped individuals. The primary goal of this study is to develop, assess and implement web-based surveys for the rapid, efficient collection of drug response and toxicity data across three classes of medication: warfarin, proton pump inhibitors (PPIs), and non-steroidal anti-inflammatory drugs (NSAIDs). In the initial phase of this two-part study, we have assessed how well web-based surveys elucidate drug response data by comparing online self-reported data to responses obtained via semi-structured telephone interviews. A set of approximately 120 telephone interviews is currently underway. The second phase will incorporate data from tens of thousands of 23andMe customers to validate known associations between PPIs and the CYP2C19 gene, and between warfarin and NSAIDs and the CYP2C9 gene. The latter phase will also leverage 23andMe's customized genotyping chip to search for novel genetic associations with drug efficacy and toxicity. Our survey objective is to gather high quality data regarding drug name, drug dosage, duration of drug use, side effects, and efficacy while achieving a high completion rate. Telephone interview data from the initial phase have indicated that the greatest challenges center around providing accurate date and dosage information. Based on participant feedback, we have revised the structure and flexibility of surveys to correspond with the type of drug under investigation. For drug classes that encompass a broad range of use patterns, such as NSAIDs, we have implemented a web-based approach with several layers of conditional logic to allow adequate input of the most relevant data. This approach is designed to better meet the needs of responders with both vague and precise recollections of their drug dosage and use duration. These survey revisions are undergoing further assessment. Since web-based surveys can be administered efficiently to millions of individuals, validation of this method of assessing drug response would lead to significant acceleration of pharmacogenomics research. This study is funded in part by NIH grant 1R43HG005807-01.

Warfarin pharmacogenetic algorithms: why the dose of some patients cannot be explained? *M.R. Botton[1], E. Bandinelli[1], L.E.P. Rohde[2], L.C. Amon[3], M.H. Hutz[1].* 1) Department of Genetics, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 2) Cardiology Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil; 3) Internal Medicine Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brazil.

Warfarin is an oral anticoagulant used for prophylaxis of thromboembolic diseases. Its effect varies among patients. Medicines and genetic profile influence the dose/effect of warfarin. Based on these factors, several algorithms to predict warfarin dose have been developed. The algorithms can predict most of patients' dose, but some patients cannot have their doses explained by these models. Moreover, some studies related the presence of some non-synonymous mutations in VKORC1 gene in patients with warfarin resistance. We have developed an algorithm that includes: body weight, age, use of amlodipine, amiodarone, carbamazepine, beta-blocker, diuretics and polymorphisms in CYP2C9, VKORC1, CYP4F2 and F2 genes. This model explains 63.3% of warfarin dose variation, one of the highest coefficients of determination among those described in the literature. However, some patients had a great difference between predicted dose and observed stable warfarin dose. The aim of this study is to investigate the presence of mutations in VKORC1 gene exons in patients with, at least, 30% higher observed doses when compared to predicted doses. A total of 279 patients of European ancestry on warfarin medication were included to elaborate an algorithm, of which, 13 showed, at least, 30% higher observed warfarin doses. Exons 1, 2 and 3 of VKORC1 gene of these patients were sequenced to detect possible mutations. None non-synonymous mutations were found, but some synonymous mutations were detected: one patient with Arg12Arg mutation in exon 1 and one patient with Leu120Leu mutation in exon 3. These results indicate that mutations that cause warfarin resistance are not the same than those that determine higher observed doses than that predicted by algorithms. In addition, these synonymous mutations may interfere in other unknown processes. Genetic variants in introns or in other genes could also be associated with these predictions. Moreover, environmental factors like diet or even other medicines not reported by patients could be related with algorithm prediction errors in some cases. However, due to the differences in variables included in algorithms described in the literature, different models can have different causes of errors and they must be investigated.

1393F

Meta-analysis of warfarin stable dose in Caucasians. *S. Bourgeois[1], N. Eriksson[2], A. Jorgensen[3], C. Nilsson[4], B. Burkley[5], M. Wadelius[6], M. Pirmohamed[4], A. Rane[7], J. Lindh[7], M.J. Rieder[8], J.K. Burmester[9], M.D. Caldwell[9], T. Mushiroda[10], M. Kubo[10], A. Wu[11], D. Roden[12], D. Crawford[12], M. Wagner[13], P. Svensson[4], S. Scott[14], R. Desnick[14], T.E. Klein[15], Y. Nakamura[10], J.A. Johnson[5], P. Deloukas[1], International Warfarin Pharmacogenetics Consortium.* 1) Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) Uppsala Clinical Research Center, Uppsala, Sweden; 3) University of Liverpool, Liverpool, United Kingdom; 4) University Hospital, Malmö, Sweden; 5) University of Florida, Gainesville, USA; 6) Uppsala University, Uppsala, Sweden; 7) Karolinska Institutet, Stockholm, Sweden; 8) University of Washington, Seattle, USA; 9) Marshfield Clinic, Marshfield, USA; 10) RIKEN Center for Genomic Medicine, Yokohama, Japan; 11) University of California, San Francisco, USA; 12) Vanderbilt University, Nashville, USA; 13) University of North Carolina, Chapel Hill, USA; 14) Mount Sinai School of Medicine, New-York, USA; 15) Stanford University, Stanford, USA.

Warfarin is the most widely used oral anticoagulant worldwide, prescribed for thromboembolic disease prophylaxis. Genome-wide association (GWA) studies in Caucasians have identified common variants in VKORC1, CYP2C9, and more recently in CYP4F2 as the main genetic determinants of warfarin stable dose. Models including both known environmental (age, height, weight, amiodarone) and genetic factors explain ~ 49.6% of the observed inter-individual variability in stable dose requirement. In the International Warfarin Pharmacogenetics Consortium we undertook an inverse-variance weighted GWA meta-analysis in 1781 subjects from Europe and North America representing five studies. GWA data sets were imputed against 1000 Genomes and HapMap 3 with Impute v2. We applied study-wise standard QC and genomic control correction. We selected 17 loci (20 SNPs) at p < 10-05 for replication in an independent sample of 2000 Caucasians. Initial analysis in 693 of the replication samples found one SNP to be significant after taking multiple testing in to account. It is a synonymous-coding SNP, rs6042 (p=1.68x10-03, combined p=5.2x10-05), located in the sixth exon of the Factor 7 gene on chromosome 13. Factor 7 is a vitamin K dependent clotting factor whose synthesis in the liver is directly affected by warfarin. The locus harbours two additional biological candidates Factor 10, another clotting factor, and Protein Z, a regulatory factor implicated in the coagulation cascade, both of which are vitamin K dependent. In conclusion, we identified a novel locus influencing warfarin stable dose. A model comprising environmental (age, height, weight, amiodarone), rs9923231 (VKORC1), rs1799853 and rs1057910 (CYP2C9*2 and *3 respectively), rs2108622 (CYP4F2) and rs6042 accounts for 50.3% of warfarin dose variance, thus explaining a further 0.7% of the variance.

Genome-wide mapping for predictors of cutaneous hypersensitivity reactions associated with anti-epileptic drugs. *G. Cavalleri[1], M. McCormack[1], C. Depondt[6], K. Shianna[2], T. Urban[2], N. Walley[2], E. Chaila[3], G. O'Conner[3], C. Catanario[4], D. Kasperavičiūtė[4], R. Radtke[5], S. Sisodiya[4], D. Goldstein[2], N. Delanty[3].* 1) MCT, Royal College Surgeons, Dublin, Ireland; 2) Center for Human Genome Variation, Duke University; 3) Beaumont Hospital, Dublin, Ireland; 4) Department of Clinical and Experimental Epilepsy, Univer- sity College London, Institute of Neurology, Queen Square; 5) The Department of Medicine, Duke University Medical School; 6) the Department of Neurology, Hôpital Erasme, Université Libre de Bruxelles, Brussels.

Ranging from mild to life threatening, adverse drug reactions are a common feature in the pharmacological treatment of epilepsy. We and others recently illustrated the potential of HLA-A*3101 as a predictor for the full spectrum of hypersensitivity reactions associated with the anti-epileptic drug (AED) carbamazepine. HLA-A*3101 therefore joins HLA-B*1502 as a clinically relevant pharmacogenomic test for epilepsy. However, cutaneous hypersensitivity reactions in AED treatment extend beyond carbamazepine and are also well described for phenytoin, lamotrigine and oxcarbazepine. These drugs are structurally related to carbamazepine in that they contain aromatic rings. Here we report on a case-control genome-wide association study conducted using a European-descent cohort of 90 hypersensitivity cases (due to phenytoin, lamotrigine and oxcarbazepine) and 1500 controls. Applying imputation to enrich for variation across the HLA, we i) explore to what extent HLA-A*3101 acts as a predictor for hypersensitivity reactions beyond carbamazepine and ii) report on mapping results for the wider genome. Results to date suggest the predictive ability of HLA-A*3101 in the development of milder hypersensitivity ADRs is, in European-descent patients, specific to carbamazepine.

1395F

Pharmacogenomic investigations on drug metabolizing enzymes GSTT1, GSTM1 and CYP2B6 in breast cancer. *P. Chaturvedi[1], S. Tulsyan[1], G. Agarwal[2], P. Lal[3], B. Mittal[1].* 1) Medical Genetics, SGPGIMS, Lucknow, Uttar Pradesh, India; 2) Endocrine surgery, SGPGIMS, Lucknow, Uttar Pradesh, India; 3) Radiotherapy, SGPGIMS, Lucknow, Uttar Pradesh, India.

Background: Breast cancer remains a major health problem around the world and its incidence continues to increase. Chemotherapeutic drug responses are genetically determined and the relationship between genotype and drug response is of particular diagnostic value, especially in breast cancer. Polymorphisms in genes encoding Phase I and Phase II drug metabolizing enzymes are important tools in predicting clinical outcomes. Rationale: Glutathione S transferase plays an important role in phase II detoxification of chemotherapeutic drugs. The deficiency is highly correlated with the inability to conjugate glutathione with small molecular weight toxicants, hence drug tolerance. In cyclophosphamide based chemotherapy Cytochrome P450 (CYP2B6) mediates the conversion of cyclophosphamide to 4-hydroxycyclophosphamide. Drug toxicity or efficacy is determined by pharmacogenetic variability in these genes which is one of the possible mechanisms underlying drug metabolism. Aim: To screen genetic variations in Phase I drug metabolizing enzyme cytochrome P450 CYP2B6*9 (rs3745274; Q172H) and Phase II enzyme glutathione-S transferase GSTM1, GSTT1 and their role in predicting clinical outcomes and toxicity profiles. Work Plan: Clinical outcome on survival, toxicity and recurrence in 144 breast cancer patients was followed in this pilot study. The patients were genotyped for GSTM1, GSTT1 and CYP2B6 variatns using PCR-RFLP. Chi square and logistic regression was carried out using SPSS ver.17.0. Findings: Total 144 patients were followed for a minimum period of three years and therapeutic failure in terms of recurrence was noticed in 5 patients. Out of 5, in 1 patient both GSTM1 and GSTT1 were absent and it carried heterozygote allele GT for CYP2B*6. Others either lacked GSTM1 or GSTT1 and two of them were heterozygote for CYP2B*6. In 10 patients, dose delay or dose reduction was noticed due to toxicity in terms of grade IV neutropenia/leucopenia. The frequency for GSTT1 null and GSTM1 null was found to be 20.1% and 39.9% respectively in these patients and CYP2B6*9 showed a minor allele frequency of 38.85%. As it is pilot study, a larger sample size may be more efficient in ascertaining the role of these genes in pharmacogenetic assessments.

1396F

Genetic Association Study between Proopiomelanocortin and Melanocortin-4 Receptor Gene Polymorphisms with Antipsychotic Induced Weight Gain. *N. Chowdhury[1], A. Tiwari[1], R. Souza[1], C. Zai[1], S. Shaikh[1], S. Chen[2], F. Liu[2], J. Lieberman[3], H. Meltzer[4], J. Kennedy[1], D. Müller[1].* 1) Neurogenetics, Centre for Addiction & Mental Health, Toronto, Ontario, Canada; 2) Molecular Neuroscience, Department of Neuroscience, Centre for Addiction and Mental Health, University of Toronto, Toronto, ON, Canada; 3) 3. Department of Psychiatry, College of Physicians and Surgeons, Columbia University and the New York State Psychiatric Institute, New York City, NY, USA; 4) 4. Psychiatric Hospital at Vanderbilt University, Nashville, TN, USA.

Introduction Antipsychotic induced weight gain (AIWG) may result in the metabolic syndrome in schizophrenia patients. A recent genome wide association study of AIWG found the highest main peak in the region of the melanocortin 4 receptor (MC4R) gene, at the downstream marker rs489693. The precursor polypeptide proopiomelanocortin (POMC) has a downstream stimulatory effect on MC4R to regulate food intake and energy expenditure in the hypothalamus. Thus, we investigated the potential role of MC4R and POMC variants with antipsychotic induced weight gain Methods Four MC4R SNPs (rs2229616, rs17782313, rs11872992, rs8087522) and two POMC SNPs (rs1042571, rs6715352) were genotyped in 237 patients who underwent treatment for chronic schizophrenia and were evaluated for AIWG for up to 14 weeks. We compared weight change (%) across genotypic groups using analysis of variance and covariance for three SNPs (r2／ 0.8).Variants were genotyped using ABI TaqMan assays. In the case of a positive association, we investigated in silico and in vitro for functional relevance of the SNP. Results The rs2229616 SNP was monomorphic in our population and thus excluded from analyses. No significant genotypic or allelic associations were found between the MC4R rs11872992, rs17782313 or rs8087522 polymorphisms or the POMC rs1042571 and rs6713532 polymorphisms and weight gain (p > 0.05). However, a subsequent analysis showed that patients of European ancestry who were carriers of the MC4R rs8087522 A-allele (AG+AA) on clozapine gained significantly more weight than non-carriers (p=0.027). Electrophoretic mobility shift assay suggested that the presence of the A-allele may create a transcription factor-binding site. Conclusions In this study, we observed that the rs8087522 SNP of the MC4R gene may be associated with AIWG in schizophrenia patients of European origin. This SNP is present in the promoter, alters transcription factor binding and therefore may affect MC4R expression. This observation warrants replication in an independent sample and for exploration of MC4R and POMC interaction analyses.

1397F

Pharmacogenetic determinants of statin-induced reductions in C-reactive protein. *A.Y. Chu[1], F. Guilianini[1], J. MacFadyen[1], B.J. Barratt[2], F. Nyberg[3], D.I. Chasman[1], P.M Ridker[1].* 1) Preventive Medicine, Brigham and Women's Hospital, Boston, MA; 2) AstraZeneca Research and Development, Adderley Park, United Kingdom; 3) AstraZeneca Research and Development, Mölndal, Sweden.

In clinical trials, reduction in plasma levels of both C-reactive protein (CRP) and LDL-C on statin therapy is associated with decreases in cardiovascular events. However, whether mechanisms of statin-induced CRP reduction differ from statin-induced LDL-C reduction is unknown. Using genome wide data from the Illumina Omni 1M platform on 3,386 individuals of European ancestry randomly allocated to rosuvastatin 20 mg daily in the JUPITER (Justification for the Use of Statins in Primary Prevention) trial, we performed an association study to identify genetic determinants of rosuvastatin-induced CRP response, and compared the results to known pharmacogenetic determinants of LDL-C response previously described in this cohort (manuscript submitted). Similar to other statin trials, both CRP and LDL-C levels were reduced by ~50% after 12 months of therapy. There was no correlation, however, between statin induced LDL-C reduction and statin induced CRP reduction (Spearman's rho=0.05). No associations were detected at a genome wide level ($p<5x10^{-8}$) for rosuvastatin-induced CRP change. None of the SNPs in three genes previously shown on a genomewide basis to be associated with rosuvastatin-induced LDL-C reduction in the JUPITER population (*ABCG2*, *LPA*, and *APOE*) were associated with rosuvastatin-induced changes in CRP. However, among 20 candidate SNPs selected based on prior evidence from genetic analyses of baseline CRP levels (Dehghan, 2011), rosuvastatin-induced changes in CRP were most strongly associated with rs2794520 in *CRP* (mean -3.7% [se 2.0] CRP change per minor allele, $p=6.4x10^{-4}$), and with rs2847281 in *PTPN2* (mean 3.6% [se 1.9] CRP change per minor allele, $p=7.4x10^{-4}$), and remained significant after correction for multiple testing. By contrast, neither the *CRP* nor *PTPN2* variants were associated with LDL-C reduction; sensitivity analyses including LDL-C change as a covariate in regression analyses minimally influenced the association between *CRP* and *PTPN2* with CRP change. In summary, within the JUPITER trial, the major pharmacogenetic determinants of rosuvastatin-induced CRP reduction differ from and are largely independent of the major pharmacogenetic determinants of rosuvastatin-induced LDL-C reduction. This supports the hypothesis that different pathways may mediate the anti-inflammatory and lipid-lowering properties of statin therapy.

Genome wide association analysis of rheumatoid arthritis patients treated with anti-TNF medication. *M. Coenen[1], M. Umicevic Mirkov[1], J. Wessels[2], S. Vermeulen[9, 1], E. Toonen[1], A. Lee[3], R. Makkinje[1], W. Kievit[4, 8], H. Scheffer[1], T. Jansen[5, 8], E. Dutmer[6, 8], T. Radstake[4], M. van de Laar[7, 8], P. Barrera[4], P. van Riel[4, 8], H. Guchelaar[2], P. Gregersen[3], B. Franke[1].* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Department of Clinical Pharmacy & Toxicology, Leiden University Medical Center, Leiden, The Netherlands; 3) The Feinstein Institute for Medical Research, Manhasset, New York, USA; 4) Department of Rheumatology, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands,; 5) Department of Rheumatology, Medical Centre Leeuwarden, Leeuwarden, The Netherlands; 6) Department of Rheumatology, Gelderse Vallei Hospital, Ede, The Netherlands; 7) Department of Rheumatology, University Twente & Medisch Spectrum Twente, Enschede, The Netherlands; 8) Dutch Rheumatoid Arthritis Monitoring registry; 9) Department of Epidemiology, Biostatistics and HTA, Radboud University Nijmegen Medical Centre, The Netherlands.

Background Treatment strategies blocking tumour necrosis factor (anti-TNF) have proven very successful in patients with rheumatoid arthritis (RA). However, a relevant subset of patients does not respond for reasons that are unknown. Although there is some indication that genetic variants may influence the response to TNF blockers, there are currently no means of identifying these patients prior to treatment start. **Objective** We aimed at identifying genetic factors predicting anti-TNF treatment outcome in patient with RA using a genome-wide association approach. **Methods** We selected patients with RA treated with antibodies directed against TNF from the Dutch Rheumatoid Arthritis Monitoring (DREAM) registry and the database of Apotheekzorg, which facilitates the Dutch distribution of adalimumab. Disease activity scores (DAS) 28 at baseline and after 14 weeks were available of 872 patients. Single nucleotide polymorphisms (SNPs) were genotyped using the Illumina HumanHap550-Duo BeadChip or the Human660W-Quad. Association analysis using the DAS28 change as outcome was performed using the whole genome association analysis toolset in PLINK. DAS28 at baseline and use of methotrexate were included as covariates. **Results** 516168 SNPs passed quality control. No findings passed the threshold for genome-wide significance ($p\text{-value} \leq 5x10^{-8}$). Eight SNPs showed suggestive association with DAS28 change with a $p\text{-value}<10^{-6}$. Seven of these were located in genes (*ALK, NKAIN3, CETP, CICP10, L3MBTL3, PBX3, RPL18P1*). The top associated gene *ALK* ($p=8.11x10^{-7}$) is involved in apoptosis, one of the working mechanisms of anti-TNF. Pathway analysis, including all SNPs with a p-value $<10^{-4}$, was performed using Ingenuity. This resulted in the identification of four gene networks of which two could be linked to apoptosis. The second largest network linked thirteen of the associated genes to TNF and its downstream signaling pathway. Replication of the top 50 associated SNPs in ~1500 RA patients treated with anti-TNF is ongoing. **Conclusions** The GWA approach is a potent tool for the identification of new candidate biomarkers predicting anti-TNF response. Suggestive findings will be replicated in larger, independent patient cohorts to prove whether the identified SNPs are associated with treatment outcome.

1399F

A Comparison of the Power and False-Positive Rate Protection When Analyzing Pharmacogenetic Data in Clinical Trials Using LOCF and MMRM. *B. Fijal, F. Zhao, C. Mallinckrodt.* Global Statistical Sciences, Eli Lilly, Indianapolis, IN.

Introduction: Within clinical trials, efficacy measurements are typically repeated on subjects throughout the trial. However, subjects frequently drop out of trials for various reasons, such as lack of efficacy, before the trial ends. Two statistical approaches that can be used to compensate for subject dropout are last observation carried forward (LOCF) and mixed models repeated measures (MMRM). The goal of our simulation study was to compare the performance of these two approaches. Methods: The simulation study was set up to mimic neuropsychiatric trials. Three dropout scenarios were examined: 1) all subjects completed the trial, 2) subjects' dropout was not related to the observed efficacy data, or 3) subjects' dropout was related to the observed efficacy data which, in some of the scenarios examined, could be impacted by a gene. The gene was assumed to 1) be bi-allelic, 2) have a minor allele frequency of 30%, and 3) behave in an additive manner. The sample size was 100 unless otherwise indicated. In both the LOCF and MMRM analyses, genotype was analyzed as a continuous variable. The accuracy of the estimate of the impact of the gene was measured by the slope (i.e., the improvement in response for each copy of the “good” responder allele a subject had). Results: When all subjects completed the trial or left the trial for reasons unrelated to the observed efficacy data, both LOCF and MMRM were comparable in terms of power and in controlling the false-positive rate. When dropout was related to the observed efficacy endpoint, MMRM provided adequate false-positive rate control while LOCF inflated the false-positive rate, and, in the scenarios examined here, the inflation increased as the sample size increased. When the gene had an impact on efficacy and it resulted in differential dropout between the genetic groups, MMRM provided an unbiased estimate of the genetic effect while LOCF, in the scenarios examined here, underestimated the impact of the gene. Additionally, MMRM provided better power to detect the genetic effect. Conclusions: Our research provided evidence that, in many situations, MMRM outperforms LOCF analysis by providing adequate false-positive control and unbiased estimates of genetic effects.

Characterization of the CYP2C19*alleles by using different genotyping and sequencing platforms. *G. Ghaffari, M. Rodriguez, S. Rodriguez, C.Y. Hung, L. Brenton, M. Tekin, M. Morra.* CMGDL, Department of Human Genetics, University of Miami Miller School of Medicine, 1501 NW 10th avenue, BRB-415 (M-860), Miami FL, 33136.

Individuals respond differently to drugs and this depends, at least in part, on individual variation in genes associated with drug metabolism, transport, and their receptors. The cytochrome P450 enzyme CYP2C19 is an important drug-metabolizing enzyme involved with the metabolism of many therapeutic agents, including antidepressants, antiulcers, anticonvulsants, antidiabetic, and antiplatelets drugs such as clopidogrel. To date, more than 38 CYP2C19 SNPs have been reported which are associated with CYP2C19 increased, decreased, or abolished enzyme function, leading to classify individuals into ultra rapid, extensive and poor metabolizers. Different methodologies both PCR- and array-based have been so far used to determine the CYP2C19 gene variation. In our laboratory we have performed studies by using the Illumina's BeadExpress Vera Code ADME Core panel (San Diego, CA) and a GeneMark Dx eSensor XT-8 platform (Carlsbad, CA), targeting the CYP2C19 gene. The Vera Code ADME Core panel covers the CYP2C19*2, *3, *4, *5, *6, *7, *8, *12, *17 and the eSensor XT-8 platform covers the *2, *3, *4, *5, *6, *7, *8, *9, *10, *13, *17 alleles. We have tested multiple DNA samples derived from different collections such as the Coriell Institute (Camden, NJ), ParagonDx samples (Decisive Diagnostics, Jackson, WY) and clinical samples kindly provided by diagnostics laboratories. Results accuracy was determined by cross-matching our data obtained with different platform against the results from other laboratories. Samples reported to carry a *10 or *2 allele have been further subjected to molecular characterization by capillary sequencing of the CYP2C19 gene. Data publicly available at NCBI dbSNP were also used in case that a specific genotypic allele was not available by other means. Our results highlight difficulties in demonstrating accuracy for ultra rare alleles. Also, our work indicates the relevance of using a multi-platform testing approach, in particular capillary gene sequencing as an important tool to be used in confirming uncertain genotypes.

1401F

Impact of HLA-B*1502 Testing for Carbamazepine on Medical Practice. *S.K. Grantham[1,2], S. Katsanis[1].* 1) Duke University Institute for Genome Sciences and Policy, Duke University, Durham, NC; 2) North Carolina State University, Raleigh, NC.

Carbamazepine (Tegretol®) is considered to be a first-line pharmaceutical treatment for epilepsy. Carbamazepine can trigger the potentially fatal skin reactions Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN) among those who possess the HLA-B*1502 variant, the risk of which is approximately 1-6:10,000 in those of European descent. The risk is 10 times greater in individuals of Asian ancestry. In December 2007, the FDA directed carbamazepine manufacturers to update package inserts, resulting in a black box warning stating, “studies in patients of Chinese ancestry have found a strong association between the risk of developing SJS/TEN and the presence of HLA-B*1502,” and further asserting, “patients testing positive for the allele should not be treated with Tegretol unless the benefit clearly outweighs the risk.” Assuming adherence to the warning, we postulated two outcomes of this labeling change: a) an increase in pharmacogenetic testing for carbamazepine; or b) a decrease in prescription of carbamazepine. With 200,000 new diagnoses of epilepsy made per year in the U.S., and over 10 million U.S. individuals self-reporting as “Asian,” the market for testing for HLA-B*1502 is expected to be significant. We approached 149 U.S. laboratories designated by the American Society for Histocompatability and Immunogenetics as HLA DNA laboratories for information on testing volume. Of the 149 laboratories, 17 offer HLA-B*1502 testing for carbamazepine. Of the 8 consenting laboratories, the 6 responding to our survey reported negligible requests for HLA-B*1502 testing in comparison with total testing volume and total pharmacogenetic testing volume. Three laboratories reported never receiving requisitions for HLA-B*1502 testing, 2 laboratories reported 0-2 requisitions per month, and 1 laboratory reported 3-19 requests per month. These figures are significantly lower than expected if carbamazepine testing were integrated into routine care for newly diagnosed Asian patients. Our findings demonstrate that the FDA recommendation for pharmacogenetic testing in Asian patients has either been ignored or patients of Asian descent are prescribed medications other than carbamazepine. We suggest that updating the labeling of carbamazepine with pharmacogenetic recommendations dramatically decreased the prescription of this first-line pharmaceutical treatment, highlighting the direct impact that FDA recommendations can have on medical practices.

Pharmacogenomic variation and implications in African populations, using existing data. *K. Kalideen, R.S. Ramesar.* University of Cape Town , Cape Town , Western Province, South Africa.

Pharmacogenomics, the study of genetic variation and influence on an individual's response to xenobiotic agents, is capable of immediate translation from the bench to the bedside. A constituent of adequate health relies on the optimal prescribing and utilisation of medication for the effective management and treatment of a plethora of diseases. However, a significant proportion of individuals treated with standard doses of a specific medication have differential responses such as adverse drug reactions, no response or a partial response. Efficacy and effectiveness of said medication is of immense importance in Africa, as National health systems do not have the resources to supplement their treatment regimens with alternate and additional pharmaceuticals. It is therefore necessary to investigate methods to optimize existing treatment. Aim: (1) Use existing data to investigate pharmacogenetic variants in African populations compared to their Caucasian counterparts, (2) Create a diversity map of African populations, based on their pharmacogenetic profiles and (3) Investigate the implications of these variants in South African populations in terms of the Burden of Disease and Essential Drugs List in South Africa. Methods: Pharmacogenetic relevant genes were identified and the allelic frequencies of variants within these genes were mined using existing databases (HapMap 3, African Affymetrix SNP6.0 database, 1000 Genomes). Statistical analysis (Fishers Exact test, df = 1, $p>0.05$) was performed for each variant in a population (in comparison to the Caucasian population). The significant variants were then classified and comparedto the South African Burden of Disease and Essential Drugs List. Population genetic analyses (Arelquin 3.3 and Phylip) were performed to estimate the distance between the populations. Results and Discussion: A total of 84 variants in pharmacogenes were significantly different between African populations and the reference Caucasian population. Furthermore, the genetic structure of certain genes differed within the different African populations. In terms of clinical utility, the significant variants in this study, have an impact on the treatment recommended in the South African Essential Drugs List; therefore providing impetus on future research in this area.

1403F

Targeted resequencing and haplotyping of a large panel of ADME genes. *F. Kaper, B. Klotzle, J. Chen, M. Bibikova, M. Ronaghi, J.B. Fan.* Illumina, Inc., San Diego, CA.

Individual response to environmental factors, chemicals and drugs can vary significantly and is frequently associated with polymorphisms in genes involved in absorption, distribution, metabolism and excretion (ADME). In order to predict drug response and drug toxicity in an individual, it is important to determine the genotype of these genes. We have therefore selected a consensus panel of 329 ADME genes, and designed probes to capture all exons in a targeted pull-down assay, followed by sequencing on an Illumina® Genome Analyzer IIx. The targeted region encompasses 1Mb, allowing for multiplexing of 15 samples within one assay, while achieving 30X coverage on one of the 8 lanes of the Genome Analyzer IIx. Optimizations to the pull-down assay and probe design resulted in coverage of 99.7% of the 329 genes. Coverage was quite uniform, with 70% of the genes within 2-fold of average coverage, and 96% within 5-fold of average coverage. In addition, a method was developed to obtain the haplotypes of each gene. This information is clinically relevant as the phenotype may vary depending on whether multiple polymorphisms are located on the same chromosomal copy or on different copies. Genomic DNA was distributed into multiple aliquots, each receiving less than a haploid copy number. The DNA was subsequently amplified using a multiple displacement amplification (MDA) protocol, followed by Infinium® genotyping on an Illumina® 300K HumanCytoSNP-12 BeadChip. In parallel, MDA-amplified DNA was used for next generation sequencing library preparation with targeted pull-down of the ADME genes, as described above. In an initial pilot experiment, we show that all heterozygote alleles were resolved into homozygotes. Per aliquot, approximately 10-20% of the expected ADME genes were detected by sequencing. Furthermore, we were able to determine and confirm the haplotype of the daughter of a father/mother/daughter family trio.

1404F

Pharmacogenetics and cycling: the interactive effects of the ADRB2 A46G SNP and salbutamol on cycling performance. *S. Koch[1], M.J. MacInnis[1], B.C. Sporer[2,3], J.L. Rupert[1], M.S. Koehle[1,4].* 1) School of Human Kinetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Faculty of Medicine, University of British Columbia, Vancouver, Canada; 3) Canadian Sport Centre Pacific, Vancouver, Canada; 4) Division of Sport Medicine, University of British Columbia, Vancouver, Canada.

Polymorphisms of the adrenergic) 2-receptor gene (ADRB2) are associated with key components of cardiorespiratory function during exercise. Specifically, the G-allele of the A46G SNP (Arg16Gly; rs1042713) results in a substitution of a glycine for an arginine at amino acid 16, which is associated with increased bronchodilation, heart rate, and cardiac output. Asthmatic and non-asthmatic individuals with the G-allele have a greater increase in forced expiratory volume in one second (FEV1) after the inhalation of a short-acting) 2-agonist such as salbutamol (SAL). It is unclear if the influence of the G-allele on change in FEV1 after the inhalation of SAL affects performance in highly trained athletes. **PURPOSE**: 1. To determine if common variants of the adrenergic) 2-receptor influence percent change in FEV1 after the inhalation of SAL in male cyclists. 2. To assess the influence of the A46G SNP on 10-km time trial performance in cyclists after inhaling SAL. **METHODS**: The A46G SNP of the ADRB2 gene was genotyped in 36 unrelated competitive male cyclists aged 19 - 40 years (AA: 4; AG: 14; GG: 17). Athletes performed two simulated 10-km time trial rides on a cycle ergometer 60 min after the inhalation of either 400 µg of SAL or placebo. Medication administration was double-blinded and randomly assigned. The change in FEV1 was assessed immediately before and 30 min after inhalation. Performance was assessed by the time needed to complete the ride. Mixed between-within subject ANOVAs were conducted to assess differences between percent change in FEV1 and cycling performance after the inhalation of SAL or placebo based on an individual's A46G SNP. **RESULTS**: The percent change in FEV1 after the inhalation of SAL was significantly greater than placebo, $F(1,33) = 4.4$, $p = 0.043$, / $p^2 = 0.118$). This was independent of A46G genotype, $F(2,33) = 0.26$, $p = 0.77$, / $p^2 = 0.016$. Furthermore, there was no interaction effect between the A46G SNP and the time needed to complete a time trial after the inhalation of SAL or placebo, $F(2,32) = 0.68$, $p = 0.51$, / $p^2 = 0.01$. No main effect was found between the SAL and the placebo condition, $F(1,32) = 1.4$, $p = 0.71$, / $p^2 = 0.004$). **CONCLUSION**: In competitive male cyclists, FEV1 is improved after the inhalation of SAL (400 µg) regardless of genotype at the ADRB2 A46G SNP. In addition, the A46G SNP did not influence a 10-km time trial performance after the inhalation of SAL in male cyclists.

1405F

Pharmacogenetics of childhood acute lymphoblastic leukemia - asparaginase pathway. *M. Krajinovic[1,2,3], V. Gagné[1], J. Rousseau[1], M. Labuda[1], C. Cyrielle Beaubois[1], D. Sinnett[1,2], C. Laverdière[1,2], A. Moghrabi[1,2], S.E. Sallan[4,5], J.L. Kutok[6], D. Neuberg4[4], L.B. Silverman[4,5].* 1) Research Center, CHU Sainte-Justine, Montreal, QC, Canada; 2) Department of Pediatrics, University of Montreal; 3) Department of Pharmacology, University of Montreal; 4) Department of Pediatric Oncology, Bostatistics and Computational Biology, Dana-Farber Cancer Institute, Boston, MA; 5) Division of Hematology/Oncology, Children's Hospital, Boston, MA; 6) Department of Pathology, Brigham and Women's Hospital, Boston, MA.

Several groups including ours conducted pharmacogenetic studies in acute lymphoblastic leukemia (ALL) and identified variations in several genes that may contribute to variability in treatment responses. This presentation gives a short overview of the present knowledge in ALL pharmacogenetics and presents in more details our recent results on the polymorphisms of asparaginase pathway in ALL. Asparaginase is a standard and critical component in the therapy of childhood ALL .Several enzymes are essential for antileukemic effect of asparaginase such as asparagine synthetase (ASNS), the basic region leucine zipper transcription factors ATF5 and arginosuccinate synthase 1 (ASS1). They have been shown to display variable expression between leukemia cells that are resistant and sensitive to aspraginase. Fourteen polymorphisms in regulatory and coding regions of these genes were investigated for an association with ALL outcome in 336 children diagnosed with ALL and CHU Sainte Justine (discovery cohort). Lower event free survival (EFS) was associated with ATF5T1562C, tandem repeat ASNS polymorphism and derived haplotype, as well as with ASS1 G1343T and G34T substitutions ($p \leq 0.03$). Associations were limited to patients who received E.coli asparaginase. Variations that sustained correction for multiple testing (ATF5T1562C, $p=0.005$, ASNS tandem repeat and related haplotype, $p \leq 0.01$) were subsequently analyzed in replication cohort (Dana Farber Cancer Institute, Boston). The E.coli dependent association of ATF5 T1562 allele with reduced EFS was confirmed ($p=0.01$). Given significant association of ATF5 C1562T (located in 5'UTR) in the test and replication cohort, further analyses focused on the functional assessment of C1562T and remaining polymorphisms in the promoter and 5'UTR of the gene. Gene reporter assay showed that the haplotype tagged by the T1562 had higher promoter activity ($p \leq 0.01$). Remaining regulatory polymorphisms appeared also to affect ATF5 function; two additional high-activity haplotypes were identified ($p \leq 0.02$) and further corroborated by quantitative mRNA analysis in lymphoblastoid cell lines. ATF5- regulated increase in ASNS expression in a response to more efficacious E.coli induced asparagine depletion might explain observed results. The study will further increase the knowledge how to use host genetic variations to tailor therapy of antileukemia drugs.

Whole Exome Sequencing and Antidepressant Treatment Outcome. *G. Laje, N. Akula, F.J. McMahon.* Human Genetics Branch, Intramural Research Program, NIMH, NIH, USDHHS, Bethesda, MD.

Background: Genome-wide association studies of antidepressant treatment cohorts have not identified common genetic variants that have a large and reproducible impact on treatment outcome. It is possible that rare genetic variants may offer additional insight into the etiology of this complex phenotype. We undertook a whole exome sequencing experiment in individuals selected from the Sequenced Treatment Alternatives to Relieve Depression study (STAR*D).

Methods: In this pilot study we employed an extreme trait strategy to detect genetic variants that may be enriched at the extremes of the antidepressant response distribution. European-ancestry individuals who failed to respond to several treatment s were compared to individuals who experienced a sustained remission of symptoms after typical treatment. Individuals were matched on gender, anxious depression status, treatment adherence, drug and alcohol abuse, and genetic ancestry, determined by a large set of common SNPs. DNA samples were processed with the Agilent SureSelect Human All Exon 50MB kit and sequenced on a SOLiD platform with⁄ 10X coverage. Functional relationships among implicated genes were analyzed with DAVID.

Results: At this time, we only report single nucleotide variants (SNVs). SNVs were initially called using CLC Bio software and an in-house pipeline using BFAST, PICARD and GATK. SNVs with < 4X coverage were excluded from our analysis. Each individual had about 90,000 SNVs. Transition/transversion ratio was 3.04 for known and 2.03 for novel SNVs, and there was >99.9% agreement among common SNPs genotyped on the Illumina OmniExpress Array. There were no overall differences between the groups in the number of known SNVs. However, novel SNVs predicted to be damaging by SIFT were increased in the sustained remitters ($p<0.05$). Genes with damaging SNVs observed in at least 3 out of 4 treatment-resistant cases but no remitters were enriched for rhodopsin-like G protein-coupled receptors (Benjamini $p=0.008$).

Conclusions: The detection of rare variants through high throughput sequencing may provide new insight into the etiology of treatment-resistant depression.

1407F

Association of the *CES1* G143E Polymorphism with Platelet Aggregation and Cardiovascular Outcomes in Patients on Clopidogrel Therapy. *J.P. Lewis[1], K. Ryan[1], Q. Gibson[1], J.R. O'Connell[1], R.B. Horenstein[1], B.D. Mitchell[1], K. Tanner[1], R. Pakzy[1], U.S. Tantry[2], K.P. Bliden[2], P.A. Gurbel[2], A.R. Shuldiner[1].* 1) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 2) Sinai Center for Thrombosis Research, Sinai Hospital of Baltimore, Baltimore, MD.

Anti-platelet therapy with clopidogrel prevents recurrent cardiovascular events in patients with coronary artery disease undergoing percutaneous coronary intervention (PCI). However, inter-individual variation in response to clopidogrel is widely recognized and has been attributed, in part, to genetic factors. The gene for carboxylesterase-1 (*CES1*), the primary enzyme responsible for metabolism of clopidogrel into inactive metabolites, is highly polymorphic. A relatively uncommon variant causing a glycine to glutamic acid substitution at position 143 (G143E; rs71647871) has recently been identified and shown to encode a protein with decreased CES1 activity. We measured *ex-vivo* platelet aggregation before and after clopidogrel administration in 565 healthy Amish individuals from the Pharmacogenomics of Antiplatelet Intervention (PAPI) study and evaluated the impact of the *CES1* G143E variant on clopidogrel response. The decreased function 143E allele was significantly associated with greater clopidogrel response (P = 0.003); this allele had no effect on baseline measures of ADP-stimulated platelet aggregation (P = 0.27). These findings were extended by examining the relationship between *CES1* G143E genotype and ADP-stimulated platelet aggregation as well as cardiovascular outcomes in 227 patients undergoing PCI at Sinai Hospital in Baltimore. Similar to the PAPI study, there was a considerable difference in post-clopidogrel maximal ADP-stimulated platelet aggregation between *CES1* 143GG homozygotes and 143E carriers (36.7% vs. 15.7% respectively, P = 0.07). Patients who carried the *CES1* E-allele (n = 3) tended to be less likely to experience a cardiovascular event or death compared to 143GG homozygotes (n = 224) at 1 year of follow-up (0.0% vs. 13.7% respectively). Taken together, the *CES1* G143E polymorphism may be an important determinant of clopidogrel response - improved cardiovascular outcomes and/or increased bleeding events - although further evaluations in larger populations are warranted.

1408F

Influence of NR1I3 nuclear receptor gene polymorphisms on the lipid-lowering efficacy and safety of statin therapy. *L.O. Lima[1,2], M.H. Hutz[1], C.R. Van der Sand[3], L.C. Van der Sand[3], M.E.W. Ferreira[3], R.C. Pires[3], S. Almeida[2, 4], M. Fiegenbaum[2,4,5].* 1) Departamento de Genética, Universidade Federal do Rio Grande do Sul, Porto Alegre, RS, Brazil; 2) Laboratório de Biologia Molecular, Universidade Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, RS, Brazil; 3) Centro de Diagnóstico Cardiológico - CDC, Porto Alegre, RS, Brazil; 4) Departamento de Ciências Básicas da Saúde, Universidade Federal de Ciências da Saúde de Porto Alegre, Porto Alegre, RS, Brazil; 5) Laboratório de Biologia Molecular, Centro Universitário Metodista do IPA, Porto Alegre, RS, Brazil.

HMG-CoA reductase inhibitors (statins) are the most effective and prescribed drug for dyslipidemia treatment and are generally well tolerated. Nevertheless, interindividual variability has been seen in relation to lipid-lowering efficacy and adverse effects occurrence. Constitutive androstane receptor (CAR) is a transcription factor involved in xenobiotic metabolism pathways by regulating the expression of drug-metabolizing enzymes (phase I and II) and transporters, and statins have been described as target of xenobiotic response mediated by this receptor. The aim of the present study was to investigate the association of genetic variants in the CAR gene, NR1I3, with lipid-lowering efficacy and safety of statin therapy. The sample consisted of 240 Brazilian hypercholesterolemic patients of European descent on simvastatin or atorvastatin therapy. For efficacy analyses these patients had their lipid and lipoprotein concentrations measured at baseline and after approximately 6 months (5.97 ± 2.44 months) of treatment. The safety analyses were carried out by genotype and allele frequencies comparisons between 98 patients who remained on the same dose for more than a year (37.70 ± 23.12 months) without presenting adverse drug reactions (non-ADR group) and 30 patients who developed adverse drug reactions (myalgia/ elevation of creatinine kinase/ alteration of hepatic function; ADR group). The polymorphisms were genotyped by TaqMan 5' allelic discrimination assays. When a recessive model was tested the NR1I3 rs2501873 polymorphism was associated with statin efficacy. G allele carriers showed a greater LDL-C reduction than A/A homozygotes (-37.63 ± 16.79% versus -29.82 ± 21.66%; P=0.026). The NR1I3 rs2307424 polymorphism was associated with side effects. All 30 individuals that presented an adverse reaction were carriers of a C allele (T/T versus C carriers; P=0.0066). The total absence of T/T homozygotes observed in the ADR group suggest that this genotype might confer a protection against statin ADRs. To our knowledge, this is the first study describing the possible influence of NR1I3 rs2307424 and rs2501873 polymorphisms on statin pharmacogenetics; therefore additional studies in independent and larger samples are warranted to confirm these results.

1409F

Common and rare variants in the POMC pathway markedly influence antipsychotic drug-induced weight gain: Discovery GWAS and subsequent replication data. *A.K. Malhotra[1,2], C. U. Correll[1,2], N. I. Chowdhury[3], D. J. Müller[3], P. K. Gregersen[2], A. T. Lee[2], A. K. Tiwari[3], J. M. Kane[1,2], J. A. Lieberman[4], H. Y. Meltzer[5], T. Lencz[1,2], J. L. Kennedy[3].* 1) The Zucker Hillside Hospital, Glen Oaks, NY; 2) The Feinstein Institute for Medical Research, Manhasset, NY; 3) Centre for Addiction and Mental Health, Toronto, CA; 4) New York Psychiatric Institute/Columbia University, New York, NY; 5) Vanderbilt University Medical Center, Nashville, TN.

Introduction: Weight gain and related metabolic abnormalities are a significant side effect associated with antipsychotic drug treatment. Treatment studies comprised of chronic patients may underestimate the severity of this side effect, as prior treatments may have caused weight gain and obscure the true weight liability of the current drug treatment. In a recent study (Correll et al. 2009, JAMA), we showed that pediatric patients without prior exposure to antipsychotic medications experienced marked weight gain at 12 weeks of treatment with each of the study drugs; the weight gain was far greater than reported for previously treated patients and the weight change was highly variable. Therefore, we have completed the first genome-wide association study of antipsychotic induced weight gain in previously untreated patients, **Methods:** We comprehensively characterized a discovery cohort of antipsychotic-naïve pediatric patients undergoing initial clinical treatment with the second generation antipsychotic drugs. Subjects were confirmed to be receiving antipsychotic drug by plasma blood levels, and were weighed at baseline, 4, 8 and 12 weeks of treatment. DNA was collected via blood sample and genotyping conducted with the Illumina 1M OmniQuad platform. Regression analysis of weight at 12 weeks of treatment versus baseline was conducted using both additive and recessive models. Subsequently, we assessed two additional cohorts of subjects treated with second generation agents and genotyped SNPs implicated in the discovery cohort, as well as conducted a rare variant analysis of our discovery cohort focused on missense SNPs. **Results:** QTL analysis revealed a region of the genome near the melanocortin 4 receptor gene (MC4R) that significantly associated with antipsychotic induced weight gain. SNPs in this region were also associated with weight gain in the two additional cohorts, with the same allele relationships and effect sizes observed across all three cohorts. Rare variant analysis also revealed a relationship between an amino acid substitution in the PCSK1 gene, also located in the proopiomelanocortin (POMC) pathway, and significant weight gain. **Conclusions:** Our data provide convergent evidence that genes in the POMC pathway are associated with antipsychotic-induced weight gain. These results have implications for gene x environment studies, as well as potential clinical impact for patients beginning antipsychotic drug treatment.

1410F

Multi-ethnic Cytochrome-P450 Copy Number Profiling Identifies Mechanism of Copy Number Variation Formation and Novel Pharmacogenetic Alleles. *S. Martis[1], H. Mei[1], R. Vijzelaar[2], L. Edelmann[1], R.J. Desnick[1], S.A. Scott[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) MRC Holland, Willem Schoutenstraat 6, Amsterdam, The Netherlands.

The polymorphic cytochrome-P450 (CYP450) system is a superfamily of over 50 hemoproteins involved in drug metabolism and bioactivation. Inherited genetic variation among CYP450 genes contributes to disease susceptibility and interindividual differences in drug response. Copy number variants (CNV) can influence CYP450 activity, particularly for CYP2D6; however, little is known about the role of CNVs in other CYP450 family members. To determine if other CYP450 genes have common deletion or duplication alleles, multiplex ligation-dependent probe amplification (MLPA) that interrogated CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5 was performed on over 100 DNA samples each from healthy African-American, Asian, Caucasian, Hispanic, and Ashkenazi Jewish (AJ) individuals. Among the CYP450 genes studied, CNVs were identified in CYP2A6, CYP2B6, CYP2D6, and CYP2E1. The total deletion/duplication allele frequencies for these four genes among African-Americans, Asians, Caucasians, Hispanics, and AJs were 20%, 10%, 8.7%, 32%, and 18%, respectively, and all detected CNVs were confirmed by quantitative TaqMan copy number assays. To determine the breakpoint regions of these alleles, a high resolution oligonucleotide microarray (average probe spacing of ~270 bp) was designed that interrogated 32 core pharmacogenetic genes, including all those analyzed by MLPA, and array-based comparative genomic hybridization (aCGH) was performed on 46 selected samples. aCGH analyses localized the CYP2A6 CNV breakpoints to a cluster of neighboring repetitive Alu and LINE elements present in two directly orientated low copy repeats (LCRs; >90% similarity) resulting in full gene deletion and duplication. Interestingly, the CYP2B6 CNV breakpoint occurred in an intron 4 Alu region and in another directly orientated LCR (>90% similarity) that encompassed the CYP2B7P1 pseudogene, resulting in the CYP2B6*29 partial deletion allele and the reciprocal, and novel, CYP2B6-CYP2B7P1 duplication fusion allele (designated CYP2B6*30). CYP2E1 CNV breakpoints were also localized to two directly orientated LCRs (>98% similarity); however, only CYP2E1 full gene duplication was detected in the studied populations (designated CYP2E1x2). These data identify two novel CYP450 CNV alleles and indicate that common CYP450 CNV formation is likely mediated by nonallelic homologous recombination resulting in both full gene and gene-fusion copy number imbalances.

Genetic variability associated with antiretroviral therapy-related adverse effects in HIV-infected individuals. *V.S. Mattevi[1,2,3], A.S. Gasparotto[2], J.R. Trinca[2], M.L. Kayser[3], R.K. Lazzaretti[4], R. Kuhmmer[4], S. de Almeida[1,2], J.P. Ribeiro[4], E. Sprinz[4].* 1) Health Basic Sciences, UFCSPA, Porto Alegre, RS, Brazil; 2) Health Sciences Graduate Program, UFCSPA, Porto Alegre, RS, Brazil; 3) Pathology Graduate Program, UFCSPA, Porto Alegre, RS, Brazil; 4) Hospital de Clínicas de Porto Alegre, Porto Alegre, RS, Brazil.

A significant improvement in the survival of human immunodeficiency virus (HIV)-infected patients has been observed since the introduction of highly active antiretroviral therapy (HAART). However, the development of adverse events may compromise adherence to HAART. Lipodystrophy (LD) stands out among the most important HAART-related adverse effects, being characterized by abnormal body fat redistribution, dyslipidemia, insulin resistance and metabolic syndrome. We investigated the association of selected polymorphisms in candidate genes involved in the pharmacokinetics and pharmacodynamics of HAART and the occurrence of the aforementioned adverse effects in HIV-infected individuals. Patients on HAART (n = 614) for, at least, one year, were recruited in three reference treatment services from the south of Brazil. Twenty-one polymorphisms in 15 candidate genes were genotyped through real-time polymerase chain reaction (PCR) using the TaqMan® methodology or conventional PCR-based methods. Poisson regression models with robust variance were used to assess the predictor variables for the development of categorical outcomes. Mean biochemical and anthropometric phenotypes related to adverse effects were adjusted for covariables and compared among genotypes through general linear models. The polymorphisms analyzed were located in the following candidate genes: SREBF1 (rs2297508), TNF (rs361525), PPARG (rs1801282), APOB (rs17240441 and rs693), UCP1 (rs1800592), UCP2 (+3474 45bp ins/del), UCP3 (rs1800849), ESR1 (rs2234693, rs1801132, rs7757956, rs2813544), ESR2 (rs3020450, rs7154455, rs4986938), CYP3A4 (rs2740574), CYP3A5 (rs776746), CYP2B6 (rs3745274), CYP2C19 (rs4244285), MDR1 (rs1045642), MRP4 (rs3742106). CYP3A4 and CYP3A5 variants were significantly associated with the LD phenotype, while the SREBF1 single nucleotide polymorphism (SNP) was associated with the lipohypertrophy subtype in euro-descendants, and one ESR2 SNP (rs3020450) was associated with lipoatrophy. Regarding the LD-related phenotypes, the TNF variant was associated with glucose levels and metabolic syndrome, while the two APOB variants were associated with lipid levels, and one ESR1 SNP (rs2813544) was associated with body mass index and subcutaneous fat in the female gender only. In conclusion, lipoatrophy and lipohypertrophy seem to be different entities from the genetics point of view. Our findings suggest that pharmacogenomics can give a better insight to the understanding of LD etiology.

Pharmacogenetic predictors of maintenance dose of Coumarinic oral-anticoagulants in patients with thromboembolic disorders in North Indian population. *B. Mittal[1], S.S. Rathore[1], S.K. Agarwal[2], S. Pande[2], S.K. Singh[3], T. Mittal[1].* 1) Dept Med Gen, Sanjay Gandhi Med Inst, Lucknow, UP, India; 2) Dept CVTS, Sanjay Gandhi Med Inst, Lucknow, UP, India; 3) Dept CTVS, CSMMU, Lucknow, India.

Coumarinic oral-anticoagulants (COAs) are the most commonly prescribed treatment option for thromboembolic events. However, their use requires close monitoring because of narrow therapeutic range and large inter-individual variations in drug response. Pharmacogenetic advancements in recent times have confirmed the role of genetic polymorphisms in VKORC1 and CYP2C9 in the dose requirements for COAs. The genotypic frequencies of VKORC1-1639 G>A, CYP2C9*2 and CYP2C9*3 polymorphisms in Indians are quite different from the HapMap populations. Therefore, we aimed at determining the relationship between these polymorphisms and weight normalised maintenance daily doses of oral anticoagulants for therapeutically stable INR in North Indians. We enrolled 206 patients taking acenocoumarol after heart valve replacement surgery (who had attained stable INR range between 2 and 3.5) and genotyped three polymorphisms. Mean daily maintenance drug doses were calculated for each genotype for the three polymorphisms under study. The patients with VKORC1 -1639 wild type (GG), heterozygous (GA) and variant (AA) genotypes showed a gradually decreasing requirement of mean daily maintenance drug dose (0.062±.023 mg/kg, 0.047±.023 mg/kg and .024±.010 mg/kg respectively). Patients with CYP2C9*1 (wild type) genotype needed higher mean daily maintenance drug dose (0.056±.023 mg/kg) than CYP2C9*2 and CYP2C9*3 carriers (0.049±0.019 mg/kg and 0.047±0.020 mg/kg respectively). These results are in accordance with the fact that promoter polymorphism affects the expression of VKORC enzyme and exonic polymorphisms influence the activity of the CYP2C9 enzyme. Based on these findings, we have developed a population specific pharmacogenetic dosing algorithm, including the clinical as well as genetic factors, by stepwise linear regression and found it to be more accurate in predicting doses than the published algorithms. Pharmacogenetic analysis of drug disposition genes in Azorean healthy population. *L. Mota-Vieira[1,2], S. Bulhoes[1,2], C. C. Branco[1,2], A. M. Vicente[2,3], R. Cabral[1,2], T. Pereirinha[1].* 1) Molecular Genetics & Pathology Unit of the Hospital of Divino Espirito Santo of Ponta Delgada, EPE - Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 3) INSA, Lisbon, Portugal.

Inter-individual and -ethnic variability of drug disposition genes can cause unexpected outcomes such as adverse reactions and toxicity. Therefore, the knowledge of pharmacologically relevant allele, genotype and/or haplotype distribution within specific populations is important for pharmacogenetics. Here, we evaluate in Azoreans, an admixed population, 17 polymorphisms in genes coding for 5 drug metabolizing enzymes (CYP2C19, CYP2D6, NAT2, TPMT and UGT1A1) and 1 transporter (ABCB1). Genotyping of 170 blood donors was performed by Taqman real-time PCR and fragment analysis by capillary electrophoresis. For CYP2C19, the metabolizing enzyme of clopidrogel activation and proton pump inhibitors, we found a lower incidence of poor metabolizers (1.2%). Concerning CYP2D6, an enzyme involved in about 25% of drugs biotransformation (eg. tamoxifen), the data showed 2 groups: carriers of at least 1 loss-of-function allele (11.2%), where, individuals are at risk for decreased tamoxifen response (postmenopausal early breast cancer treatment); and carriers of 2 functional alleles (30.6%), including gene duplication, which are likely to respond to tamoxifen. These results validate the need to genotype individuals before treatment. Regarding the NAT2, an enzyme involved in drug acetylation, 64.1% have slow acetylator phenotype, thus these individuals have increased risk for adverse effects if treated with isoniazid and hydralazine. The genotyping of TPMT, an enzyme of thiopurines metabolism used as anti-neoplasic or immunosuppressive drugs, identified 2 groups that require thiopurine pharmacogenetic based dosing prior treatment: high toxicity (4.7%), having 2 nonfunctional alleles; and moderate toxicity (2.4%) with 1 nonfunctional allele. The UGT1A1 analysis revealed that Azoreans have a high frequency of *28/*28 genotype (10.6%), resulting in reduced enzymatic activity and increased toxicity of irinotecan, a drug used to treat colorectal cancer. Finally, 25.3% of Azoreans are homozygous for 3435T (ABCB1), leading to a reduced expression and function of P-glycoprotein. Individuals with this genotype have been correlated with decreased bioavailability of digoxin, a P-gp substrate. Currently, we are analyzing haplotype and linkage disequilibrium of other pharmacogenes, in order to deeper understand the clinical impact of relevant pharmacogenetic information in Azorean population. A pharmacogenomic screen of common variation in candidate genes reveals moderators of antipsychotic-induced weight gain in the RUPP Autism samples. *E.L. Nurmi, S.L. Spilman, J.T. McCracken, The RUPP Autism Network.* Department of Psychiatry, University of California at Los Angeles, Los Angeles, CA.

Objective: Weight gain is a common adverse event resulting from antipsychotic exposure that carries significant morbidity and treatment complication. In order to dissect pharmacogenomic influences on antipsychotic-induced weight gain, we queried common variation and functional elements in key neurotransmitter receptor (DRD1, 2, 4, 5, ADRA2A, HTR2C, HRH1) and energy balance (FTO, MC4R, leptin, CNR1, FAAH) genes for association with weight gain in the two NIMH RUPP Risperidone RCT childhood autism samples. **Methods:** Gene variants were examined for association with weight gain during the first 8 weeks of similar risperidone exposure per protocol in a sample of 225 autistic children from the RUPP (2002) and RUPP-PI (2009) Risperidone studies. **Results:** Two independent gene variants in adrenergic receptor ADRA2A ($p<0.0001$ and $p=0.0002$) and single SNPs in dopamine D1, D2, and D4 ($p<0.0001$) as well as D5 ($p=0.0007$) receptor genes were associated with greater weight gain. While no individual SNPs in the serotonin receptor HTR2C reached significance, a protective haplotype explained 16.6% of the variance in weight gain in boys. A functional promoter variant and a synonymous SNP in the cannabinoid receptor 1 (CNR1) gene conferred independent risks for weight gain ($p<0.0001$) consistent with published results in adults. There was no evidence for association with a reported functional variant in the endocannabinoid metabolic enzyme FAAH. One leptin gene variant reached significance ($p=0.0001$) in our dataset. An additional leptin marker, BMI-associated SNPs in FTO and melanocortin 4 receptor (MC4R), and markers in histamine receptor HRH1 (the common target of antipsychotics with the greatest weight gain burden) showed only trends toward association. All reported results remained significant after correcting for multiple comparisons. **Conclusions:** These data support a greater genetic contribution of monoamine receptor and energy balance candidates to antipsychotic-related weight gain in children than prior adult studies suggest. Effects are robust enough to be detected after only 8 weeks of exposure. The variance explained by individual SNPs is modest, highlighting multifactorial contributions that likely include other unexamined factors, gene variants, and gene-gene and gene-environment interactions. Pharmacogenomics holds considerable promise in explaining individual variability in treatment effects and may help guide clinical intervention and drug development.

HLA-A*3101 **allele as a genetic risk factor for carbamazepine-induced cutaneous adverse drug reactions in Japanese population.** *T. Ozeki[1], T. Mushiroda[1], A. Yowang[1], A. Takahashi[2], M. Kubo[3], Y. Shirakata[4], Z. Ikezawa[5], M. Iijima[6], T. Shiohara[7], K. Hashimoto[4], N. Kamatani[1], Y. Nakamura[1,8].* 1) Research Group for Pharmacogenomics, RIKEN Center for Genomic Medicine, Yokohama, Kanagawa, Japan; 2) Research Group for Medical Informatics, RIKEN Center for Genomic Medicine, Yokohama, Kanagawa, Japan; 3) Research Group for Genotyping, RIKEN Center for Genomic Medicine, Yokohama, Kanagawa, Japan; 4) Department of Dermatology, Ehime University Graduate School of Medicine, Ehime, Japan; 5) Department of Dermatology, Yokohama City University Graduate School of Medicine, Kanagawa, Japan; 6) Department of Dermatology, Showa University School of Medicine, Tokyo, Japan; 7) Department of Dermatology, Kyorin University School of Medicine, Tokyo, Japan; 8) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

An anticonvulsant, carbamazepine (CBZ), is known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). To identify a gene(s) susceptible to CBZ-induced cADRs, we conducted a genome-wide association study (GWAS) in 53 subjects with the CBZ-induced cADRs including SJS, TEN and DIHS, and 882 subjects of a general population in Japanese. Among the SNPs analyzed in the GWAS, 12 SNPs showed significant association with CBZ-induced cADRs, and rs1633021 showed the smallest *P*-value for association with CBZ-induced cADRs ($P = 1.18 \times 10^{-13}$). These SNPs were located within a 430-kb linkage disequilibrium (LD) block on chromosome 6p21.33 including the *HLA-A* locus. Thus, we genotyped the individual *HLA-A* alleles in 61 cases and 376 patients who showed no cADRs by administration of CBZ (CBZ-tolerant controls) and found that *HLA-A*3101* was present in 60.7%; (37/61) of the patients with CBZ-induced cADRs, but in only 12.5%; (47/376) of the CBZ-tolerant controls (odds ratio (OR) = 10.8, 95% confidence interval (CI) = 5.9-19.6, $P = 3.64 \times 10^{-15}$). To validate the significant associations of *HLA-A*3101*, we performed a replication study using an independent Japanese case-control cohort which consisted of 16 CBZ-induced cADR cases and 44 CBZ-tolerant controls. The association of HLA-A*3101 was replicated in the second cohort ($P = 1.53 \times 10^{-2}$, OR = 9.5, 95% CI of 1.5-24.5; combined-analysis $P = 1.09 \times 10^{-16}$, OR = 9.5, 95% CI of 5.6-16.3), implying that this allele has the 58.4% sensitivity and 87.1% specificity when we apply *HLA-A*3101* as a risk predictor for CBZ-induced cADRs. We further analyzed the association of *HLA-A*3101* according to the type of cADR using the combined cohorts. *HLA-A*3101* showed significant associations with DIHS ($P = 2.06 \times 10^{-9}$, OR = 9.5, 95% CI of 4.6-19.5) and SJS/TEN ($P = 2.35 \times 10^{-4}$, OR = 33.9, 95% CI of 3.9-295.6) as well as other cADRs ($P = 4.74 \times 10^{-8}$, OR = 8.0, 95% CI of 3.9-16.6), respectively. Although DIHS is clinically distinguished from SJS and TEN, our data presented here have indicated that they share a common genetic factor as well as a common pathophysiological mechanism. Our findings should provide useful information for making a decision of individualized medication of anticonvulsants.

Effect of PON1 Q192R genetic polymorphism on cardiovascular events in the CURE trial. *G. Pare[1, 2], S. Ross[1, 2], S. Mehta[1, 2], S. Yusuf[1, 2], S. Anand[1, 2], K. Fox[3], J.W. Eikelboom[1, 2].* 1) McMaster University, Hamilton, ON, Canada; 2) Population Health Research Institute, Hamilton, ON, Canada; 3) 4. Edinburgh University, Edinburgh, Scotland, UK.

A recent report suggested that carriers of the Q allele of the PON1 Q192R polymorphism had decreased biotransformation of clopidogrel into its active metabolite and decreased efficacy of clopidogrel in preventing cardiovascular events. Furthermore, PON1 has been reported to have a central role in the antioxidant function of HDL and the Q192R polymorphism has been previously associated with cardiovascular risk in patients not treated with clopidogrel. Patients from the CURE randomized trial that demonstrated benefits of clopidogrel versus placebo in preventing CV events in acute coronary syndromes (ACS) were genotyped for the PON1 Q192R polymorphism. Clopidogrel compared to placebo significantly reduced the primary efficacy outcome, irrespective of PON1 Q192R genotype (P=0.07 for heterogeneity). No association was observed between the Q192R polymorphism and cardiovascular events in the overall sample (HR= 1.09 per allele; 95%CI 0.95-1.24; p=0.23). However, an association was observed between the Q allele and increased cardiovascular events in the placebo group (HR=1.23 per allele; 95%CI 1.03-1.47; p=0.03), but not in the clopidogrel group (HR= 0.93 per allele; 95%CI 0.76-1.13; p=0.46). In conclusion, our study shows that PON1 Q192R genotype do not modify the efficacy and safety of clopidogrel in ACS patients. Further studies will be needed to confirm or refute the association of the Q allele with adverse cardiovascular events independently of clopidogrel in secondary prevention patients.

MDR1 variation is associated with adverse drug reactions of methylphenidate in Korean children and adolescents with ADHD. *HS. Park[1], SW. Kim[1], SH. Lee[1], KH. Kim[1], MG. Lee[1,2], HJ. Hong[3], KH. Yook[4], JH. Lee[1,2,5].* 1) Department of Pharmacology, Brain Korea 21 Project for Medical Science, College of Medicine, Yonsei University, Seoul, Korea; 2) Research Center for Human Natural Defense System, College of Medicine, Yonsei University, Seoul, Korea; 3) Department of Neuropsychiatry, College of Medicine, Hallym University, Anyang, Korea; 4) Department of Psychiatry, School of Medicine, CHA University, Seoungnam, Korea; 5) Corresponding Author.

Methylphenidate (MPH) is the drug of choice for treatment of patients with attention-deficit hyperactivity disorder (ADHD). MPH is a substrate of multidrug resistant protein 1 (MDR1, ABCB1, p-gp), which plays an important role in the clearance of psychotropic drugs and their metabolites from brain tissues. Therefore, genetic variations in the MDR1 gene may affect individual drug responses to MPH. In this study, we analyzed the adverse drug reactions (ADRs) of MPH in 134 Korean ADHD patients who completed a 4-week trial of osmotic-release oral system-MPH. The adverse effects of MPH were evaluated using the Barkley Stimulant Side Effects Rating Scale. From the association study between MDR1 polymorphisms and adverse effects of MPH, one nonsynonymous polymorphism showed a strong association with MPH-related adverse effects (P=0.008). Logistic regression analysis with multiple clinical variables indicated that this variation is an independent determinant of adverse effects attributed to MPH. In a functional study using adenosine triphosphatase assays, the variation markedly reduced MPH transport across the cell membrane. This study is the first to demonstrate that the single nucleotide polymorphism in the MDR1 gene is associated with ADRs to MPH.

1418F

Genetic determinants of the busulfan pharmacokinetics. *M.A. Rezgui[1,4], M. Ansari[1,5], Y. Théoret[1,2,4], M. Duval[1,3], M.F. Vachon[1], H. Bittencourt[1,3], M. Krajinovic[1,2,3,4].* 1) Charles-Bruneau Cancer Center, CHU Sainte-Justine Research Center, Montreal, QC; 2) Clinical Pharmacology unit, CHU Sainte-Justine, Montréal, QC; 3) Department of Pediatrics, Faculty of medicine, University of Montreal, Montreal, QC; 4) Department of Pharmacology, Faculty of medicine, University of Montreal, Montreal, QC; 5) Department of Pediatrics, Geneva University Hospital.

Busulfan (BU) is a key compound in conditioning myeloablative regimens for children undergoing hematopoietic stem cell transplantation (HSCT). There are wide interindividual differences in BU pharmacokinetics, which increase the risk of veno-occlusive disease, graft rejection and disease relapse. As BU is mainly metabolized by glutathione S-transferase (GST), it is possible that functional polymorphisms in GST genes may contribute to the variability in BU pharmacokinetics. Our recent pilot study interrogating the polymorphisms in GST gene and pharmacokinetics after the first dose of intravenous BU showed a significant association between GSTM1 null genotype and higher drug exposure. In order to replicate and validate obtained pharmacogenetic finding we carried out a prospective study which included~70 children who underwent HSCT at the CHU Sainte-Justine, Montreal. Blood samples were collected immediately before the first BU administration and at 15, 30, 60, 120, 180 and 240 min after drug administration. Plasma BU was determined using a modified high-performance liquid chromatography assay. All patients had individualized dosing based on pharmacokinetics after the first dose of intravenous BU. The genotypes in GSTA1 (C-69T, A-513G, G-631T, C-1142G), GSTM1 (deletion) and GSTP1 gene (A1578G, C2293T) were obtained by PCR followed by allele specific oligonucleotide hybridization or gel electrophoresis. Genotypes were dichotomized according to the presence or absence of minor allele or presence or absence of GSTM1 deletion (GSTM1 null genotype vs. non-null genotype). The distribution of pharmacokinetic parameters (AUC, Cmax, Css and clearance) obtained after the first BU dose was compared for patients with or without the given genotype using Student t-test. Results seem to successfully replicate those obtained in retrospective study. GSTM1-null individuals had higher drug exposure (P(Cmax)=0.03; P(AUC)=0.05; P(Css)=0.04) and lower clearance (P(CL)=0.05). No association was found between BU exposure and major GSTA1 or GSTP1 gene variants. GSTM1 polymorphism seems to modify BU pharmacokinetics after intravenous drug administration, as shown in two independent patients cohorts opening the possibility to tailor first Bu dose according to patient genetics.

1419F

Polymorphisms in DNA Repair Genes, chemotherapy and survival in Bladder Cancer. *A. Russo[1,5], S. Guarrera[1], F. Ricceri[1,5], C. Sacerdote[1,3], S. Polidoro[1], R. Critelli[1,5], A. Allione[1], P. Gontero[2], P. Destefanis[7], G. Cucchiarale[4], P. Vineis[1,6], G. Matullo[1,5].* 1) Human Genetics Foundation, Turin, Turin, Italy; 2) Urologia 1, S. Giovanni Battista Hospital, Turin, Italy; 3) Epidemiology of Cancer Unit, S. Giovanni Battista Hospital, Turin, Italy; 4) Unità operativa di Urologia, Clinica Cellini, Turin, Italy; 5) Department of Genetics, Biology and Biochemistry, University of Turin, Italy; 6) Imperial College, London, UK; 7) Urologia 2, S. Giovanni Battista Hospital, Turin, Italy.

Bladder cancer (BC) survival is highly influenced by environmental and susceptibility genetic factors. Evidence of the important role played by DNA repair systems in the survival after cancer therapy has been reported. We conducted a hospital-based case-control study. Cases are incident BC patients, males, aged 40 to 75 years. We followed up BC patients for death and recurrences. In the cohort of BC patients, we genotyped 36 Single Nucleotide Polymorphisms (SNPs) in 10 DNA repair genes to assess the relationship between DNA repair genes SNPs and survival after treatment in BC patients. We analyzed survival on BC patients using a Cox proportional-hazards regression statistics for codominant and per-allele models, adjusted for age, stage and grading and stratified by therapy (chemotherapy vs no or other therapies). Chemotherapy group include patients treated with systemic and local chemotherapy with different therapeutic plans (Carboplatinum doublets, Gencitabin, Epirubicin, etc). We identified 456 BC patients which were followed-up for mortality (median follow-up 62 months). In multivariate analysis both stage and grade predicted the outcome in a statistically significant way. The variant alleles of two SNPs in XRCC1 gene (rs2854509 and rs3213255) were associated to a significant lower risk of death whereas one SNP in ERCC2 gene (rs171140) showed a significant higher risk of death compared to the wild type only in the group treated with chemotherapy. Haplotype analyses confirmed the results. Our findings suggest that DNA damage levels induced by chemotherapy may be modulated by individual DNA repair activity, resulting in a different response to chemotherapy and, consequentially, in different survival rates.

1420F

Multi-ethnic Distribution of Clinically Relevant CYP2C Genotypes and Haplotypes. *S.A. Scott[1], I. Peter[1], J.S. Hulot[2], R. Kornreich[1], R.J. Desnick[1], S. Martis[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Cardiovascular Research Center, Mount Sinai School of Medicine, New York, NY.

The human cytochrome P450-2C (CYP2C) enzyme family, encoded by CYP2C19, CYP2C9 and CYP2C8 at 10q23.33, is responsible for the metabolism of ~25% of clinically used drugs. Although many CYP2C variant alleles have been identified, their frequencies in many populations remain unknown. Moreover, linkage disequilibrium (LD) between the common CYP2C19*17 and *2 gain- and loss-of-function alleles, respectively, and other known functional CYP2C variants has not been adequately studied in different ethnicities. Thus, to determine the haplotype structure of the CYP2C locus, 35 functional CYP2C19, CYP2C9, and CYP2C8 variant alleles were genotyped in up to 250 DNA samples each from healthy African-American (AA), Asian, Caucasian, Hispanic, and Ashkenazi Jewish (AJ) individuals. Allele and genotype frequencies, determined for each variant, differed significantly between racial and ethnic groups. Previously understudied variant alleles were detected at low frequencies (e.g. CYP2C19*6, *9, *13, *15; CYP2C8*13, *14) and the recently identified CYP2C19*4B allele, defined by c.-806C>T (*17) and c.1A>G (*4) in cis, was confirmed by cloning and sequencing in the Caucasian (0.4%), Hispanic (0.4%), and AJ (2.0%) populations. This allele was found on a haplotype with wild-type CYP2C9 and CYP2C8 (i.e. 2C19*4B-2C9*1-2C8*1). In total, 15 different CYP2C haplotypes with frequencies greater than 1% were inferred using 13 informative alleles and the two most common variant haplotypes were 2C19*2-2C9*1-2C8*1 (12-27%) and 2C19*17-2C9*1-2C8*1 (5-17%). Importantly, a 2C19*17-2C9*1-2C8*2 haplotype was also identified among AAs (7.8%), Hispanics (2.9%) and AJs (1.0%), indicating that CYP2C19*17 does not always tag a CYP2C haplotype that encodes efficient CYP2C-substrate metabolism as previously suggested. Moreover, a haplotype containing two CYP2C loss-of-function alleles (2C19*1-2C9*2-2C8*3) was identified in all populations except AAs. Unique ethnic-specific haplotypes were also detected, including 2C19*3-2C9*1-2C8*1 among Asians, and 2C19*2-2C9*1-2C8*4 and 2C19*17-2C9*1-2C8*4 among AJs. These data highlight that, despite largely acting as independent loci, CYP2C19*17 and *2 can also be found in LD with other CYP2C loss-of-function alleles that significantly modify the metabolizer phenotypes. These results have important implications for pharmacogenetic association studies involving the CYP2C locus and are clinically relevant when administering CYP2C-substrate medications.

Preclinical evaluation of relapse-predisposing variations in DHFR and TS genes. *B. Sharif-Askari[1,3], F. Fontaine[1], E. Haddad[1], D. Sinnett[1,2], M. Krajinovic[1,2,3].* 1) Research Center, Centre Hospitalier Universitaire Sainte-Justine, Montreal, QC; 2) Department of Pediatrics, University of Montreal, Montreal, QC; 3) Department of Pharmacology, University of Montreal, Montreal, QC.

Acute lymphoblastic leukemia (ALL) is the most frequent malignancy of childhood. It is the principal cause of cancer-related mortality in children due to a persistent group of patients who does not respond to standard anti-cancer treatment. Dihydrofolate reductase (DHFR) and tymidylate syntase (TS) are major targets of methotrexate (MTX), a crucial component of ALL treatment. Our pharmacogenetic study interrogating association between genetic variations of MTX action pathway and ALL outcome indicated a higher risk of relapse in patients who are homozygous for triple repeat (3R) allele of TS gene and/or have *1b haplotype defined by particular allelic combination of polymorphisms in the promoter of DHFR gene. Both variations were associated with an increase in respective gene expression, suggesting that lower sensitivity to MTX associated with these variations might be a cause of higher risk of relapse. To verify this and examine if any increase in MTX dose may overcome genotype-associated MTX resistance (and provide thus basis for individually tailored therapy), we recently initiated preclinical study which uses appropriate in vitro and animal models (NSG immuno-compromised mice injected with patients lymphoblasts) to address above questions. The preliminary results of this study will be presented. We are using lymphoblastoid CEPH cell lines to correlate in vitro sensitivity to MTX with relapse-predisposing genotypes in DFHR and TS genes. DNA from 94 lymphoblastoid cell lines was extracted for genotyping and cell viability test in response to MTX challenge was performed for each of them. Results indicate that 57 cell lines (60.6%) are sensitive to MTX, (with IC 50 ranging from 0.1to10 μM) and 22 (23.4%) are resistant to treatment with MTX (IC50 more than 100 μM), whereas remaining had intermediate phenotype. In the next step we will compare sensitivity status of each cell line with the results of TS 3R3R and DHFR *1b genotyping currently performed in cell lines. NSG mice injected with patient's leukemia cells, showed the expansion of leukemia cells, about four weeks after receiving patient's cells, MTX treated group showed significant reduction of leukemia cells compared to PBS control group, one week after treatment with MTX. We are currently proceeding with NSG mice experiments including patients having either TS or DHFR relapse predisposing genotypes.

1422F

Transcription factor protein levels correlate with chemotherapeutic susceptibility in lymphoblastoid cell lines. *A.L. Stark[1], R.J. Hause, Jr.[2], L. Gorsic[3], N. Antao[3], K.P. White[1,4,5], R.B. Jones[4,5], M.E. Dolan[3].* 1) Dept Human Gen, Univ Chicago, Chicago, IL; 2) Committee on Genetics, Genomics, and System Biology, Univ Chicago, Chicago, IL; 3) Section of Hematology/Oncology, Department of Medicine, Univ Chicago, Chicago, IL; 4) Ben May Department of Cancer Research, Univ Chicago, Chicago, IL; 5) Institute for Genomics and Systems Biology, Univ Chicago, Chicago, IL.

A substantial number of cancer patients undergo ineffective chemotherapy while enduring toxic side effects. Pharmacogenomics aims to develop predictive markers for patients at greatest risk of experiencing chemotherapeutic related toxicities and/or nonresponse to avoid this predicament. Our lab has developed models that employ HapMap lymphoblastoid cell lines (LCLs) to identify chemotherapeutic susceptibility genetic variants by evaluating performing GWAS with HapMap SNPs and chemotherapeutic-induced cytotoxicity. These LCLs have also been used to study correlations between mRNA expression and drug susceptibility. To expand our model into the proteome, we used newly developed micro-western arrays and reverse phase lysate arrays to assay protein levels for over 400 transcription factors and core signaling proteins in 68 unrelated Yoruba derived LCLs. Protein levels were quantified from three different thaws for each cell line providing a robust baseline measurement. We then correlated each protein level against 13 different phenotypes from 8 chemotherapeutic agents (etoposide, daunorubicin, cisplatin, carboplatin, cytarabine, capecitabine, pemetrexed, and paclitaxel). We identified 17 protein-drug relationships with an r^2 greater than 0.10 ($p<0.007$, $q<0.20$). Among these top relationships, only one quarter would have been identified through mRNA correlation with chemotherapeutic induced cytotoxicity ($p<0.05$). The highest correlation between protein level and cisplatin- and carboplatin- induced cytotoxicity was TUB with an r^2 correlation of 0.13 for both phenotypes. TUB protein levels showed no significant ($p<0.01$) correlation with any other drug phenotype. TULP1, TUB's binding partner was also significantly correlated with carboplatin-induced cytotoxicity ($r^2=0.09$). We also detected two different isoforms of STAT3 that are highly correlated with drug-induced apoptosis for cisplatin, cytarabine, and paclitaxel. In addition, we performed genomewide association studies and identified SNPs that associate with drug phenotypes that also predict protein level. We identified 42 SNPs that were associated with drug phenotype and protein level at $p<0.0001$. To our knowledge, these protein levels represent the largest dataset of its type. This allows pharmacogenomic discovery work to move from the transcriptome to the proteome. A better understanding of the variation in the proteome can aid in the discovery of genetic predictors of chemotherapy toxicity and response.

Genealogical analysis of intolerance to statins in the Saguenay-Lac-Saint-Jean population. *M. Tremblay[1], T. Bouhali[2], D. Gaudet[2], D. Brisson[2].* 1) Université du Québec à Chicoutimi, 555 boul. de l'Université, Chicoutimi, Qc, Canada, G7H 2B1; 2) ECOGENE-21 (Université de Montréal), Centre hospitalier affilié universitaire régional (CAUR) de Chicoutimi, 305 Rue St-Vallier, Chicoutimi, Qc, Canada, G7H 5H6.

Purpose: Statins are the most widely prescribed class of cholesterol-lowering drugs worldwide. Familial hypercholesterolemia (FH) patients are among those receiving the highest daily doses. Although well tolerated, statins can be associated with muscular and non-muscular side effects that affect compliance to drug treatment. Type of statins, age, gender and daily dose are factors associated with muscular side effects. Moreover, family aggregation of intolerance to statins is frequently observed, suggesting the involvement of gene factor transmission. The objective of the present study was to measure and compare various genealogical parameters that could shed some light on the origins and diffusion of intolerance to statins using FH as a model. **Data and methods**: Analysis was performed on a total of 224 genealogies from 112 FH subjects carrying either the D15kb (n=28) or W66G (n=84) mutations and 112 non-FH controls. For each mutation, carriers were split into two equal groups according to their tolerance to statins. Genealogical material was obtained from the BALSAC population register. Number of ancestors, geographical origins and genetic contribution of founders, identification of common and specific ancestors, inbreeding coefficients and kinship coefficients amongst and between subjects and controls were calculated using the S-Plus based GENLIB software package. **Results**: For both mutations, repeated occurrences of the same ancestors are more frequent among the carriers' genealogies than among the controls', but no important difference was observed between tolerant and non-tolerant subjects. Kinship coefficients are also significantly higher among carriers than among controls, with no difference according to tolerance to statins. However, inbreeding coefficients are slightly lower among intolerant subjects, which suggests different patterns of demographic behavior among their ancestors. Although analysis of common and specific ancestors helped to identify the founders who most probably introduced each mutation in the SLSJ population, no distinction could be made between tolerant and intolerant subjects. These findings suggest that if family aggregation of intolerance to statins is influenced by genetic factors, these are far from being the unique modulators. **Funding**: This study was supported by the ECOGENE-21 project (CIHR TEAM grant # CTP-82941) and by the Social Sciences and Humanities Research Council of Canada (grant # 410-2009-2292).

Genetic variation database of anticancer pharmacogenomic biomarkers using cross species sequence analysis. *L. Wang, J. Liu, D. Chen.* School of Medicine, University of California, Irvine, Irvine, CA.

Interindividual variability in the response to pharmacologic agents is well documented. Genetic differences is one significant component contributing to such variability. With the rapidly advancement in cancer treatment using targeted therapy, several biomarkers are known to be associated with drug response variability. Genetic variations in these biomarkers are known to cause either pharmacokinetic effect variability or pharmacodynamic effect variability. These biomarkers includes TPMT, UGT1A1, EGFR, KRAS, ABL, KIT, ERBB2 and Estrogen receptor. It is estimated these biomarkers contribute a significant portion of pharmacologic variability. Our goal is to design a comprehensive database containing all the genes in the associated biochemical pathways of these known biomarker causing cancer drug variable responses. Together, over 470 genes are found by multiple query approach. In addition, corresponding orthologous gene from 13 mammalian genomes that completely sequences are identified. We then conducted sequence comparisons at both the DNA and protein level of each of the 470 human genes with it's corresponding orthologous gene sequence. Nucleotide positions that are conserved across species and, if mutated would likely result in functional changes are identified. Our attempt is to build a database which enable targeted mutational analysis on nucleotide acid position that is most likely contributing to drug response variability currently not explained by the known drug biomarkers.

Pharmacogenomics Knowledge Base (PharmGKB): Personal genome annotation. *M. Whirl-Carrillo[1], L. Gong[1], M. Gong[1], J.M. Hebert[1], F. Liu[1], E.M. McDonagh[1], K. Sangkuhl[1], C.F. Thorn[1], R. Whaley[1], M. Woon[1], R.B. Altman[1,2], T.E. Klein[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Bioengineering, Stanford University, Stanford, CA.

The Pharmacogenomics Knowledge Base (PharmGKB: http://www.pharmgkb.org) is an online resource devoted to pharmacogenomic knowledge acquisition and clinical applications of this knowledge. One potential application is personal genome annotation. In the age of Direct-to-Consumer genomics, genome-wide genotyping is readily available and the number of people in possession of their own genomic information is growing. Customers typically purchase these products because they are interested in phenotypes associated with their genotypes and DTC companies often provide some interpretation services for their customers. PharmGKB is well-positioned to use its specialized pharmacogenomics knowledge to annotate DTC genotypes and next-generation genome sequences. PharmGKB has previously used its manually curated database of drug-genetic variant associations to annotate a sequenced human genome (Lancet, 2010 May 1;375(9275):1525-35). Over 1600 variant annotations from PharmGKB were screened for quality of evidence and an MD determined the clinical relevance of the annotations. This process was entirely manual and required a substantial amount of personnel resources. Recently, PharmGKB systematically revisited its drug-variant associations and streamlined its genome annotation process. We updated all drug-variant annotations with more specific information and statistics such as study size, ethnicity and association p-value. We aggregated annotations from multiple literature sources for each drug-variant combination and created one “clinical annotation” for each combination based on ethnicity. We created a text summary for each possible genotype and assigned an evidence score based on standardized criteria to each clinical annotation. Finally, we implemented an automated pipeline to take an uploaded file of genotypes defined by dbSNP rs IDs and generate a report of personalized clinical annotations. We analyzed 23andMe genotyping results from four unrelated individuals using this system. We were able to quickly and automatically assign pharmacogenomic interpretations based on each individual's genotype. This system can be used routinely for pharmacogenomic genome annotation.

Association of CYP3A4 and CYP2C19 genotypes with treatment-related acid peptic disease. *LE. Wong-Ley[1,2], MA. Aguilar-Rodríguez[2], A. Flores García[2], P. Aguiar García[2], M. Pérez-Nuño[2], A. Puentes[1], E. Higareda-Almaraz[3].* 1) Dept Gen, SSN, Tepic, Mexico; 2) Dept Gen, UAN, Tepic, Mexico; 3) Dept Gen, IMSS, Tepic, Mexico.

The usage of omeprazol as a medical treatment for acid peptic disease and its main complication, ulcer disease, it is effective because it modifies the acid/pepsin homeostasis and it plays a very important role at the beginning and progression of the ulcers, the main cause of mobility in our country for about four decades Some differences have been reported in the response to the treatment with omeprazol related with ethnic origin and there are differences in the frequencies of the polymorphisms that are studied, that are why we considered a probable association between this polymorphisms and the response to the treatment. The objective the present study is to know the participation of CYP3A4 and CYP2C19 genes in the variation of omeprazol dose in Mexican population. They were included in the study 73 patients that were receiving omeprazol as part of the acid peptic disease treatment. All patients signed an informed consent and a questionnaire was answered. DNA was obtained from lymphocytes and followed the identification by PCR and enzymatic digestion of *1B of CYP3A4 and *2 of CYP2C19 variants. At of Student test was applied to determine doses differences between genotype groups. The genotype and allelic frequencies compared from the two referred polymorphisms between sensible and resistant groups without estimating differences that can refer to association among them and the clinical response to the treatment with omeprazol. When making the analysis of the polymorphisms of CYP3A4 and CYP2C19, between the reference group and patients with omeprazol treatment, we did not find significant statistical differences between the genotype and allelic frequencies. The genotype and allelic frequencies of the *1B of CYP3A4 and *2 of CYP2C19 polymorphisms in the patients with acid peptic disease in the reference population, are similar to the ones of the general population. As well as the distribution of the CYP3A4*1B and CYP2C19*2 polymorphisms, the reference population agreed with the predictions of the Hardy-Weinberg Law. No main variables play an important role in the dosing of omeprazol in the studied population.

1428F

Molecular study of SLC19A1 sequence variations in Iranian patients affected with psoriasis. *A. YASARI MAZANDARANI, S. MATOO, A. TAVAKOLI TAMEH, M. MAHDAVI, B. SEDAGHATI KHAYAT, N. HATAMNEJADIAN, SH. ABADPOUR, A. EBRAHIMI*. Dr. Ahmad Ebrahimi Molecular Genetics , PhD Parseh Medical Genetics Counselling Center, Floor 7, No.75, Royan Alley,Keshavarz Bolv. Tehran, Iran Tel-Fax: +98 21 88966579,88996889 E-mail: ae35m@yahoo.com.

Introduction: Psoriasis is a chronic autoimmune skin disease with polygenic inheritance with five main types including; Plaque, Guttate, Inverse, Pustular and Erythrodermic. Methotrexate (MTX) is a first-line systemic therapy for psoriasis. The use of MTX is limited by individual variability in response. It is transported into the cell via the solute carrier family 19, member1 (SLC19A1). This evidence suggests that SLC19A1 genetic variations may affect the response to mtx in psoriasis patients. Material and method: To assess if SLC19A1single nucleotide polymorphisms in order to evaluate treatment outcomes in patients with psoriasis we clinically screened affected patients and selected 100 patients with psoriasis who had been treated with methotrexate. Results: All coding regions were amplified using intronic primers and the PCR product was analyzed by direct sequencing We detect some sequence variations which show significant difference between case control groups. Also we detect some sequence variations were suspected as a new mutation that needs to be analyzed by protein assay methods. Key words: Psoriasis, SLC19A1, PCR, Sequencing.

CYP2C9*8 and Warfarin Dose Requirements in African-Americans. *C. King[1], C. Eby[1,2], P. Lenzini[1], R. Porche-Sorbet[2], E. Do[1], G. Moskowitz[1], P. Ridker[3], S. Scott[4], R. Desnick[4], B. Gage[1].* 1) Department of Internal Medicine, Washington Univeristy School of Medicine, St Louis, Missouri; 2) Department of Pathology & Immunology, Washington Univeristy School of Medicine, St Louis, Missouri; 3) Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; 4) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, New York.

Introduction: Warfarin initiation is associated with a high rate of adverse events, especially in African-American populations. While CYP2C9*2 and *3 and VKORC1 -1639 G>A single-nucleotide polymorphisms (SNPs) affect with warfarin dosing, they explain less than 8% of the variation in warfarin dose requirements in African-Americans. The goal of our study was to quantify the contribution of additional SNPs to warfarin dosing in African-Americans. **Methods:** We genotyped CYP2C9*8 (rs7900194), CYP2C9*11 (rs28371685), and VKORC1 D36Y (rs61742245) in 213 African-American patients whose therapeutic warfarin dose was known. For each SNP, we performed a regression of the residual dosing error from a validated pharmacogenetic dosing algorithm (i.e. ln(observed therapeutic dose - pharmacogenetic predicted therapeutic dose) onto the number of variant alleles. **Results:** CYP2C9*8 was a significant (p= 0.0008) predictor of residual dosing error and was associated with a 22.9% reduction in warfarin dose (95% CI: 10.5%-33.7%) per A allele. Among the 206 patients with complete information, 2 were homozygous for the *8 allele, both of whom had an elevated INR (> 4.0) within the first week of starting warfarin therapy. Thirteen percent (N = 26) were heterozygous. Patients with the CYP2C9*11 variant (N = 7) averaged a 10.6% lower therapeutic dose than predicted, but this reduction was not significant (P = 0.49) possibly due to the low frequency of the SNP. VKORC1 D36Y was not present in our population. **Conclusions:** CYP2C9*8 is a significant predictor of warfarin dose in African-American patients. Including CYP2C9*8 in a panel of SNPs may improve warfarin dosing accuracy in African-Americans and reduce the risk of bleeding during warfarin initiation.

Association of -354GG genotype of the *GGH* gene and bone marrow toxicity in rheumatoid arthritis patients treated with methotrexate. *L. Lukovic[1], B. Jekic[1], T. Damnjanovic[1], V. Milic[2], V. Bunjevacki[1], N. Maksimovic[1], J. Milasin[3], I. Novakovic[1], B. Popovic[3], N. Damjanov[2], G. Radunovic[2], N. Pejnovic[2], M. Krajinovic[4].* 1) Institute of Human Genetics, Faculty of Medicine, University of Belgrade, 26, Visegradska Str., 11000 Belgrade, Serbia; 2) Institute of Rheumatology, Faculty of Medicine, University of Belgrade, 69, Resavska Str., 11000 Belgrade, Serbia; 3) 3Institute of Biology and Human Genetics, Faculty of Dentistry, University of Belgrade, 1, Dr Subotica Str., 11000 Belgrade, Serbia; 4) Centre de Recherche, CHU Sainte-Justine, 3175 Chemin de la Côte-Ste-Catherine, Montréal, QC, H3T 1C5 Canada.

Due to its great interpatients variability in efficacy and toxicity in the therapy of rheumatoid arthritis (RA), methotrexate (MTX) is an attractive target for pharmacogenetic testings. In a group of 184 RA patients treated with MTX we have investigated whether 5 polymorphisms in 3 genes involved in MTX action [gamma-glutamyl hydrolase (GGH), cyclin D1 (CCND1) and thymidylate synthase (TYMS)] modulate MTX efficacy and/or have impact on drug adverse effects. The efficacy of MTX therapy has been estimated through the disease activity score in 28 joints (DAS28) based on EULAR criteria and relative DAS28 values (rDAS28). Among 184 RA patients 89 (48.4%) were classified as responders (good/moderate response)and 95(51.6%)as non-responders (poor response) according to EULAR criteria. rDAS28 values ranged from -0.02 to 0.80 (mean value 0.32±0.18). Fifty three (28.8%) patients experienced adverse drug events (ADEs) (hepatotoxicity, vomitus, cough and bone marrow toxicity). Genotypes of the selected polymorphisms in *GGH* gene (-354G>T and 452C>T) and *CCND1* (870 A>G) were obtained by PCR-RFLP. Genotypes of the 2R/3R tandem repeat polymorphism in the *TYMS* gene were analyzed by PCR and gele electrophoresis, whereas the SNP in the second repeat of 3R allele was detected by PCR-RFLP method. Obtained genotypes were then investigated for an association with the efficacy and toxicity of MTX. No significant associations of analyzed genetic variants with MTX efficacy and overall toxicity were demonstrated. Interestingly, when analysis were performed according to the type of ADE, an association was found between *GGH* -354G>T polymorphism and bone marrow toxicity (p=0.01). All patients with bone marrow toxicity were homozygous for -354G allele of the *GGH* gene (p=0.003, when individuals with GG genotype were compared to the carriers of T allele). Our data indicate strong association between MTX bone marrow toxicity and -354GG genotype of the *GGH* gene.

1431F

Impact of genetic polymorphism of xenobiotics detoxification on bronchial asthma phenotypic features in children. *Y. Alimova[1], L. Jelenina[1], A. Galustyan[1], A. Glotov[2].* 1) Saint-Petersburg State Pediatric Medical Academy, Saint-Petersburg, Russian Federation; 2) Research Institute of Obstetric and Gynecology under the RAMN, Saint-Petersburg, Russian Federation.

Bronchial asthma(BA)formation is genetically influenced by both “main” genes and “candidate” genes. The goal of this research is to study peculiarities of bronchial asthma genotypes in children depending on provoking factors and on polymorphism of “candidate” genes, namely genes I and II of xenobiotics detoxification phase. Research methods: Bronchial asthma was diagnosed in 81 children. The multiform variants of genes CYP2D6, CYP2C19,CYP2C9,CYP1A1 and GSTT1,GSTM were studied with the help of the PCR method in the prenatal diagnostics laboratory.Results In order to assess the contribution of several polymorphous genes to BA clinical course, it is possible to use the scoring system where each sign is coded with points (A.Glotov, 2009). The points were counted in the following way: “wild type” homozygotes were labeled as number 1, heterozygotes had number 2, and “mutant allele homozygotes were labeled as number 3. Then the points were summarized for genotypes of xenobiotics intoxication system for each patient, with different phenotypic variants of BA. On the grounds of clinical features, two phenotypes of bronchial asthma were found in children. The first phenotype (37 children) was bronchial asthma in combination with allergic rhinitis and atopic dermatitis (atopic march-AM); the second phenotype (44 children) was found in children who only had respiratory tract lesions (atopic bronchial asthma-ABA). Results 1.For ABA patients, the average count for “adverse alleles” was 3.4 points. 2.For children with BA in the atopic march structure, the average count for “adverse alleles” was 4.2 points, which is reliably higher than the count in the first group (p=0.005). 3.In the ABA group, 35%; of the children had a combination of more than four “adverse alleles”, whereas the number of child patients in the atopic march BA group was twice as high (65%;,p<0.05). 4.65%; of the patients with ABA had less than three “adverse alleles”. The number of child patients in the atopic march BA group was twice as low (35%;;, p<0.05). Conclusion: The research has established a higher frequency of gene defects in the xenobiotics detoxification system in patients with atopic march compared to patients with ABA. The phase I and phase II genetic defects of the xenobiotics detoxification system found in this research are likely to stipulate phenotypic differences in clinical presentation of BA; besides, they are an aggravating factor in the clinical course of the disease.

1432F

Polymorphisms in IL4R Gene are Associated with Asthma Exacerbation. *L. Huang, B. Koshy, M. Mosteller, W. Anderson.* GSK, Durham, NC.

Asthma is a heterogeneous disease with variable signs and symptoms among patients. Asthma exacerbations are defined as acute episodic events that require urgent action on the part of the patient and physician to prevent a serious outcome, such as hospitalization, intubation for respiratory failure or death from asthma. Although a number of clinical and environmental factors have been associated with recurrent asthma exacerbations, currently there is no way of accurately predicting those at risk of having a serious asthma exacerbation. This study sought to identify genetic marker(s) that are associated with asthma exacerbations and define a subgroup of asthmatics with increased risk for asthma exacerbation. Fifty-one genetic polymorphisms in 18 candidate genes were evaluated in asthmatics who participated in Phase IV clinical trials ADA109055/ADA109057 (clinicaltrials.gov No.: NCT00452699/NCT00452348) or SFA103153 (NCT00102765) and provided consent for pharmacogenetic analysis. Majority of asthmatics in ADA109055/ADA109057 studies are whites while SFA103153 is a study of asthmatic subjects of African descent. Association analyses between each of the markers and asthma exacerbation presence/absence status were performed within each of studies. A meta-analysis was applied to estimate and assess the genetic effect across studies. Based on the meta-analysis results, several coding variants from interleukin-4 receptor (IL4R) were identified as being associated with asthma exacerbation, including rs1805011 (E400A; P=0.0016), rs1801275 (Q576R; P=0.0021), rs2234898 (L414L; P= 0.0028), rs2234900 (L433L; P=0.0041) and rs1805015 (S503P; P=0.0047). All five SNPs were in strong LD, which may represent a single underlying association. Allele frequencies showed significant differences between whites and African American, such that the minor alleles for E400A and Q576R in whites were more frequent alleles in the African American. The C allele at E400A is a protective allele for asthma exacerbation, with odds ratio equal to 0.52 in ADA109055/ADA109057 studies and 0.53 in SFA103153 study when using an additive model. Genetic admixture measures were analyzed to better understand the differences in genetic association across different study/race groups. These findings add to our understanding of the genetics of asthma exacerbation and contribute information that may lead to the identification of a subgroup of asthmatics with increased risk for asthma exacerbation.

Molecular mechanisms underlying glucocorticoid response eQTLs. *F. Luca[1], J.C. Maranville[1], A.L. Richards[1], D.B. Witonsky[1], M. Stephens[1,2], A. Di Rienzo[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

Despite the functional relevance of eQTLs, there is a general lack of understanding of the molecular mechanisms by which they affect gene expression levels. Intervention experiments informed by data on the molecular biology of the altered pathway represent an ideal setting to dissect the molecular mechanisms underlying eQTLs that interact with treatment condition (gene-by-environment interactions). Because glucocorticoids (GCs) are steroid hormones that mediate the response to stress and are also widely used as pharmacological agents, GC treatment is an intervention of clear biomedical and evolutionary interest. In a recent study, we have identified cis eQTLs that interact with GC treatment in lymphoblastoid cell lines (LCLs). Using a novel Bayesian approach, we discriminated between genetic variants that affect gene expression equally or differently in the presence/absence of GCs. GC action is largely mediated by the GC receptor (GR), which interacts with other transcription factors to regulate gene expression of direct targets. By leveraging the molecular biology of the response to GC, we attempt to characterize the molecular mechanisms of these distinct classes of interaction eQTLs. To this end, we performed ChIP-seq experiments for the GR and its interacting transcription factor NF2B in Yoruba (YRI) LCLs treated with GC or with vehicle control. We identified 5,668 GR binding regions (FDR<15%). A large fraction of differentially expressed genes are direct GR targets (42% of them have a GR binding site within 100Kb). We also identified 558 and 657 NF2B binding sites (in the absence and presence of Dex, respectively, FDR<15%). To identify functional polymorphisms within each interaction eQTL, we used the 1000 Genomes data to perform cis-eQTL mapping in the same 58 YRI individuals previously analyzed. By overlying the eQTL mapping on the ChIP-seq data, we showed that genetic variants that affect gene expression only in the presence of GC (GC-only eQTLs) are 2.6-fold more likely to occur in GR binding sites, than genetic variants that affect gene expression only in the absence of GC (Control-only eQTLs) (p=0.04). We also observed an opposite trend, with Control-only eQTLs being 1.5-fold more likely to occur near NF2B binding sites. Overall, our results indicate that the different classes of eQTLs correspond to distinct molecular mechanisms of regulation of gene expression by the GR and its interacting transcription factors.

1434F

Hindlimb Skeletal Muscle Function and Femoral Strength in +/*G610C* Mice With and Without Impact Exercise. *S.M. Carleton[1], B.A. Gentry[2], J.A. Ferreira[3], D.J. Salamango[1], A.M. Williams[1], A.D. Kettle[4], M.G. McCray[1], M. Brown[3], C.L. Phillips[1].* 1) Biochemistry, University of Missouri, Columbia, MO; 2) Veterinary Pathobiology, University of Missouri, Columbia, MO; 3) Biomedical Sciences and Physical Therapy Program, University of Missouri, Columbia, MO; 4) Biological Sciences, University of Missouri, Columbia, MO.

Osteogenesis imperfecta (OI) is a genetically and clinically heterogeneous disease characterized by impaired biomechanical properties of type I collagen-containing tissues such as bone. Greater than 85% of OI-causing mutations are in one of the two type I procollagen genes, pro(1(I) or pro(2(I). Recently, 64 individuals were identified who all carry the same glycine to cysteine substitution at position 610 of the (2(I) chain, causing mild OI type I/IV with reduced bone mineral density (BMD) and an increased number of fractures compared to non-affected family members. Heterozygote *G610C OI* mice (+/*G610C*) model this population in both genotype and phenotype, exhibiting reduced BMD and femoral biomechanical strength. OI type I children are reported to have significantly reduced exercise capacity and muscle force as compared to their healthy peers. It is unclear if the muscle weakness is due to reduced physical activity and/or an inherent muscle pathology. Bone is inherently mechanosensitive and the largest physiological loads bones typically experience are from muscles, with bone strength directly proportional to muscle mass. Physically active children accrue 10-40% more bone than inactive children and the lack of physical activity in OI children during the critical pubertal growth spurt may result in even poorer bone health as adults. Therefore, we sought to determine if +/*G610C* mice have 1) a muscle pathology, 2) altered activity levels, and 3) the ability to participate in and respond to weight-bearing treadmill exercise. +/*G610C* mice did not exhibit a gross muscle pathology (histomorphometric evaluation and contractile generating force analyses) or altered activity levels (open field monitors). +/*G610C* mice were able to participate in and complete an eight week treadmill regimen (10 m/min, 30 min/day, 5 days/week). Interestingly, male and female +/*G610C* femora responded differently to treadmill exercise, with +/*G610C* and wildtype exhibiting similar responses to this exercise regimen, though neither gender showed remarkable gains in bone strength. However, the relatively weak intensity and short duration of the exercise protocol may be insufficient to elicit significant changes in bone strength. These results indicate that despite an impaired musculoskeletal system therapeutic inclusion of moderate impact exercise may be beneficial to human patients with mild OI.

INTRODUCTION. Due articular cartilage has a poor regeneration capacity, numerous cell-based approaches to therapy are currently being explored. Following stimulation with growth factors adipose-derived mesenchymal stem cells (MSCs) have the capacity to differentiate into connective tissues such as cartilage. Although MSCs are potentially useful as alternative cell source to chondrocytes, methods to effectively stimulate proliferation and subsequent chondrogenic differentiation of MSCs are needed to further development of tissue engineering approaches for cartilage repair or regeneration for the treatment of joint injury or osteoarthritis. In this study, the chondrogenesis of adipose-derived MSCs *in vitro* following genetic modification with adenoviral vectors encoding chondrogenic growth factors was investigated. METHODS. Adenoviral vectors carrying the cDNAs for human TGF-B1, IGF-1, FGF-2 and SOX9 were constructed. MSCs were isolated from adipose tissue of young adult Ovis aries. Confluent monolayer cultures of MSCs were individually infected with 100 MOIs of each recombinant adenovirus (Ad.IGF-1, Ad.TGF-B1, Ad.FGF-2 and Ad.SOX9), or in combination (Ad.IGF-1/Ad.TGF-B1, Ad.IGF-1/Ad.FGF2, Ad.IGF-1/Ad.TGF-B1/Ad.SOX9 and Ad.IGF-1/Ad.FGF2/Ad.SOX9), and cultured for 3, 7, 14, 21 and 28 days. Total RNA was isolated, and retrotranscribed to cDNA. Quantitative RT-PCR was used to evaluate the expression of cartilage-specific genes at each time. The evaluation of matrix proteoglycan, and collagen was done using toluidine blue, safranine-O and Fast green dyes. RESULTS. Levels of transgene expression were initially high at day 3, and declined thereafter. We found that co-expression of IGF-1 and TGF-B1, resulted in higher expression levels of aggrecan, proteoglycan, cartilage-matrix, biglycan, II and X collagen, and induced chondrogenesis of MSCs as evidenced by stronger staining for proteoglycans and collagen type II and X, better than either individual or combined transgene. CONCLUSIONS. Our findings indicate that gene-induced chondrogenesis of MSCs using multiple genes that act synergistically may enable the use of adenoviral mediated-gene transfer *in vivo* for the development of cell-based therapies for cartilage repair.

Hypophosphatasia (HPP): Affected infants and children benefit significantly from ENB-0040 treatment despite high allelic variability. *C. Greenberg[1], M.P. Whyte[2], E. Mornet[3], J.C. Hyland[4], L. Ala-Kokko[4], S. Mumm[2], A. Mhanni[1], K. Madson[2], N.C. Kreher[5], H. Landy[5].* 1) Dept Pediatrics & Child Hlth, Children's Hospital, Winnipeg, MB, Canada; 2) Shriner's Hospital for Children, Center for Metabolic Bone Disease and Molecular Research, St. Louis, MO, USA; 3) Laboratoire SESEP, Centre Hospitalier de Versailles, France; 4) Connective Tissue Gene Tests, Allentown, PA, USA; 5) Enobia Pharma, Cambridge, MA, USA.

HPP is the heritable disorder featuring impaired skeletal mineralization due to inactivating mutations within the gene that encodes the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP). HPP is transmitted in an AR or AD pattern; AR HPP is generally more severe. More than 240 mutations in TNSALP have been reported (SESEP laboratory, http: www.sesep.uvsq.fr/03_hypo_mutations.php). We present genotypes and corresponding responses to therapy of infants and children receiving ENB-0040, an investigational, subcutaneous, bone-targeted enzyme replacement therapy. Methods: Mutation analysis of TNSALP was performed by PCR amplification of exons 1 — 12 and their flanking intronic regions. PCR products were sequenced using dye terminator methodology and migrated onto a capillary electrophoresis system. Mutations were confirmed by sequencing two independent PCR products and, if possible, inheritance and allelism were checked by sequencing parental DNA. Using a bioinformatic tool combining site-directed mutagenesis and predictive tools Polyphen, SIFT, and Pmut, a severity score was assigned to each mutation. Scores ranged from 0.4 -1.08 (benign — most severe); <0.75 is “moderate,” and >0.75 “severe”. Results: Of 31 patients, 26 were compound heterozygotes, 3 homozygotes (2 with known perinatal lethal “Mennonite” mutation), 1 AD, and 1 had no identifiable mutation in the coding regions of TNSALP. Using severity scores, most infants had 2 “severe” mutations whereas children were primarily compound heterozygotes for 1 “severe” and 1 “moderate” allele. Missense mutations represented the majority of defects; 4 were small deletions. Common mutations were c.571G>A (n=11), c. 1001G>A (n=7), and c.881A>C (n=5); 7 mutations have not been described (c.875_888delCAGGGGAinsT, c.997+3A>G, c.1881_1182delCT, c.252G>C, c.1010A>G, c.1077C>G, c.658G>A). Patients have received ENB-0040 for／ 6 months; 6 for nearly 2 years. All, including the 2 with the lethal Mennonite genotype, have improvements in the radiographic appearance of rickets, respiratory status, and/or functional status (Greenberg et al and Whyte et al, ASHG 2010). Conclusions: We confirm that high allelic heterogeneity in TNSALP underlies the remarkable clinical heterogeneity of HPP, and add 7 new mutations to the many reported. Whatever the genotype and clinical phenotype identified, all infants and children treated with ENB-0040 have experienced significant clinical improvement.

Parental Myostatin Status Affects Femoral Polar Moment of Area and Biomechanical Strength in Four Month Old Wildtype Male and Female Offspring. *C.L. Phillips[1], S.M. Carleton[1], M. Brown[2].* 1) Dept Biochem/Child Hlth, Univ Missouri, Columbia, MO; 2) Biomedical Sciences and Physical Therapy Program, Unic Missouri, Columbia, MO.

Osteogenesis imperfecta (OI) is a heritable connective tissue disorder in which mutations in type I procollagen genes result in bone deformity and fragility. The OI model mice (*oim/oim*) are homozygous for a null mutation in the COL1A2 gene of type I collagen and have significantly reduced bone biomechanical integrity and bone mineral density as well as altered bone mineral composition. Heterozygous mice (+/*oim*) have a phenotype intermediate to homozygous (*oim/oim*) and wildtype (wt) mice. Bone is inherently mechanosensitive, responding and adapting to its mechanical environment. Bone formation occurs in response to high mechanical loads, often changing its geometry to strengthen the skeleton. The largest physiological loads bones typically experience are from muscles with bone strength directly proportional to muscle mass. Myostatin (*mstn*) is a member of the transforming growth factor-) (TGF-)) superfamily and is a negative regulator of skeletal muscle growth. When the myostatin protein is missing the result is uncontrolled muscle growth with a concomitant increase in bone strength. Myostatin deficient mice (+/*mstn*) have been shown to have increased muscle mass and bone strength compared to wt mice. We hypothesized that a reduction in the amount of myostatin protein would potentially ameliorate the bone phenotype of heterozygous *oim* (+/*oim*) mice. A pilot study demonstrated the reduction in bone strength seen in male and female +/*oim* animals was partially rescued when those mice were also heterozygote for myostatin deficiency (+/*mstn*). However, a parental effect of myostatin deficiency was also seen. At four months of age, femora from wt male and female offspring had increased polar moment of area while wt female offspring had increased torsional loading to failure when both parents were +/*mstn* as compared to wt male and female offspring of +/*oim* parents. The tensile strength of the bone material was not significantly different in femora from either wt male or female offspring regardless of parental genotype, suggesting a potential geometric adaptation influencing bone integrity. Taken together, these data indicate that absence of parental myostatin influences bone parameters in the wt offspring and these changes appear persistent through adulthood.

Enzyme replacement therapy for children with hypophosphatasia (HPP): Dual-energy x-ray absorptiometry (DXA) improvement after 6 months of treatment with ENB-0040. *M.P. Whyte[1,2], F. Zhang[1], K.L. Madson[1], D. Wenkert[1], C.R. Greenberg[3], W.H. McAlister[4], A.L. Reeves[1], K.E. Mack[1], A.G. Yakimoski[3], A. Mhanni[3], A.M. Skrinar[5], H. Landy[5].* 1) Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO, United States, 63131; 2) Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, United States, 63110; 3) Department Pediatrics and Child Health, University of Manitoba, Winnipeg, Manitoba, Canada, R3T 2N2; 4) Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO, United States, 63110; 5) Enobia Pharma, Montreal, Quebec, Canada, H1W 4A4.

Background: HPP is the inborn-error-of-metabolism caused by inactivating mutation(s) within the gene that encodes the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP). Severity ranges from stillbirth due to profound skeletal hypomineralization to adult fractures from osteomalacia. There is no established medical treatment. ENB-0040 is a bone-targeted, recombinant, TNSALP protein being studied in HPP. **Objective**: Assess changes in bone mineral density (BMD) after 6 months of ENB-0040 delivered subcutaneously (SC) in children with rickets from HPP. **Design/Methods**: This was a 6-mo, multi-center, open-label, historical control study of 13 children (ages 5-12 yr) given ENB-0040 (2 or 3 mg/kg SC 3X weekly). Controls were 16 children with HPP of similar age and clinical characteristics whose DXA data (20 mo interval) were retrieved from a natural history database. Hologic QDR4500A lumbar spine (L_1-L_4) and total hip BMD were assessed for all patients. BMD Z-scores were calculated based upon patient chronologic age (CA), and with equations to correct for stature using height-age (HA). BMD Z-score changes were expressed per mo for both groups to correct for the different DXA intervals. **Results**: DXA data were analyzed for 11 patients (one had withdrawn for elective surgery and another had started growth hormone). The baseline CA spine and hip z-scores for the ENB-0040 treated group ranged from -3.8 to +0.1 and from -4.8 to -2.2, respectively. The historical control CA baseline spine z-score range was -3.3 to -0.2 and hip -3.7 to -0.6. With treatment, the average 6 mo increase in CA spine BMD z-score was 0.74 and HA 0.86 compared to the control 20 mo CA change of 0.12 and HA 0.20. Similarly, the treatment 6 mo CA hip BMD z-score change was 1.41 and HA 1.55 compared to 20 mo control CA change of -0.09 and HA -0.24. Although the ENB-0040 six mo response was impressive, we also normalized the treatment and control data to a per mo interval for assessing statistical significance. The spine z-score change/mo for treatment vs control CA was 0.13 vs 0.0124 (p=0.0054), and for HA 0.16 vs 0.0179 (p=0.0044). The hip z-score change/mo for ENB-0040 vs control CA was 0.26 vs -0.0042 (p=0.0024) and for HA 0.28 vs -0.0038 (p=0.0014). **Conclusion**: Six months of ENB-0040 enzyme replacement therapy in children with HPP resulted in substantial increases in spine and hip BMD z-scores, whether adjusted for age or height, consistent with healing of their skeletal disease.

1439F

Studies on recombinant adeno-associated virus vector co-expressing hVEGF165 and hBMP-7 genes combined with BMSCs promoting steroid-induced avascular necrosis of the femoral head repair. *C. Zhang[1], K. Wang[1], M. Li[2], X. Dang[1], Z. Shi[1].* 1) Department of Orthopedic Surgery, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an 710004, China; 2) Department of Ultrasound, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an 710004, China.

Therapy for steroid-induced avascular necrosis of the femoral head (SANFH) diseases remains a considerable clinical challenge despite advances in surgical techniques. Vascular endothelial growth factor (VEGF)and bone morphogenetic protein(BMP)play important roles in angiogenesis and osteogenesis. Combining these two factors may be a promising therapeutic strategy for SANFH. To establish a more efficient gene transfer method, we investigated the therapeutic potential of adeno-associated virus (AAV)-mediated expression of VEGF and BMP (rAAV-hVEGF$_{165}$-internal ribosome entry site (IRES)-hBMP-7). Rabbit bone marrow-derived mesenchymal stem cells (BMSCs) were isolated and purified by density gradient centrifugation combined with attachment culture methods. The best MOI of BMSCs transfected with rAAV was detected by fluorescent cell counting, and cell viability was determined by MTT assay. Expression of the genes of interest was detected by GFP gene expression, RT-PCR assay and ELISA assay. The biological activities of VEGF and BMP were detected by angiogenic and osteogenic assays. After receiving an established inductive protocol for inducing SANFH rabbit's model, BMSCs modified with rAAV-hVEGF$_{165}$- IRES-hBMP-7 virus were injected into cavitas medullaris by core decompression operation. Before and after injection, MRI was performed on proximal femur for osteonecrosis detection. 12 weeks post injection, the reconstructions of bone tissue were detected by X ray and micro-CT and the reconstruction of vascular was detected by bone scintigraphy assessment. We detected that the best MOI of BMSCs transfected with rAAV was 5×10^4 v.g./cell. By comparing the cell growth curves, there was no significant difference of cell viability when rAAV vectors transfection. Expressions of the GFP, VEGF$_{165}$, and BMP7 genes were detected 1 day post-transfection, peaked 14 days post-transfection and sustained over one month. Recombinant adeno-associated viral vectors co-expressing the hVEGF165 and hBMP7 genes showed efficient gene expression ability. VEGF and BMP proteins secreted from BMSCs transfected with rAAV-hVEGF$_{165}$-IRES-hBMP7 enhanced angiogenesis and osteogenesis and have efficient biological activity in vitro. In vivo, rAAV-hVEGF$_{165}$-IRES-hBMP7 combined with BMSCs efficiently reconstructed bone formation and enhanced neovascularlaration. All these indicated that rAAV-hVEGF$_{165}$-IRES-hBMP7 virus vector may be a new therapeutic technique for the treatment of SANFH.

Enriched rearing improves behavioral responses of an animal model for CNV-based autism-like traits. *M. Heney[1], C. Spencer[1], W. Gu[1], R. Paylor[1], J. Lupski[1,2,3].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Department of Pediatrics, Baylor College Med, Houston, TX; 3) Texas Children's Hospital, Houston, TX.

Autism and autism spectrum disorder (ASD) are common neuropsychiatric conditions diagnosed by the presence of specific behavioural characteristics, including impairment in social interactions and communication, and stereotypic or inflexible behaviour. Many mouse models for the disorder have been generated by knocking-out candidate genes, however, these genes are only causative for a very small portion of autism. In contrast, chromosomal abnormalities are thought to account for 10-20% of autism cases. In particular, many microdeletion/ microduplication syndromes are associated with specific autistic-like, abnormal behavioural phenotypes. Potocki-Lupski syndrome (PTLS; MIM #610883) is associated with a microduplication on chromosome 17p11.2, and it is characterized by neurobehavioral and congenital abnormalities as well as developmental delay. Previous studies characterizing the cognitive and behavioural phenotypes of PTLS patients determined that ~70-90% of the patients studied tested positive for autism or ASD. We previously generated a mouse model for PTLS (Dp(11)17/+) that harbors a duplication of a ~2 Mb region syntenic to the human PTLS region. Utilizing this mouse model, behavioral phenotypes were studied with a battery of experiments that have been established for the study of core and associated autistic-like phenotypes, including tests for social abnormalities, ultrasonic vocalizations, perseverative and stereotypic behaviors, anxiety, learning & memory deficits, and motor defects. Alterations were identified in both core and associated ASD-like traits. In addition, we have shown that rearing mice in an enriched environment altered and rescued some of the neurobehavioral phenotypes identified, suggesting a role for gene-environment interaction in the determination of phenotypic severity. The mouse model described here parallels both phenotypic and genotypic (CNV) aspects of autism in humans, making it an interesting model for the study of CNV-based autism and ASD.

Substrate reduction therapy in patients with Juvenile-Onset Batten disease due to CLN1 mutations using Cysteamine Bitartrate: A pilot study. *M. Velinov[1], M. Gavin[2], G.Y. Wen[3].* 1) Human Genetics, NYS Institute for Basic Research in Developmental Disabilities, Staten island, NY; 2) George Jervis Clinic,NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY; 3) Developmental Neurobiology, NYS Institute for Basic Research in Developmental Disabilities, Staten Island, NY.

Neuronal Ceroid Lipofuscinoses (NCL) are a group of inherited neurodegenerative storage disorders. Mutations of at least 10 different genes are responsible for the various NCL forms. Mutations in the gene CLN1 typically result in severe, infantile-onset form of NCL. CLN1 encodes the enzyme palmitoyl protein thioesterase (PPT) that participate in the lysosomal degradation of acetylated proteins. Cysteamine bitartrate (Cystagon), a lysosomotropic agent used in the treatment of cystinosis, has been previously shown to reduce the storage material in PPT deficient cells. We report the results of a 7 year, open label substrate-reduction therapy trial using Cystagon in four patients with atypical, juvenile-onset NCL due to milder CLN1 mutations. Cystagon was given in gradually increasing doses with the goal to achieve and maintain a dose of 40-50 mg per kg body weight when possible. Five untreated patients with the same CLN1 mutations, three of whom were participants' siblings were included as controls. Parental questionnaire along with physician evaluations were used to monitor the disease course during the treatment. In addition, patients' peripheral lymphocytes were studied for lysosomal storage inclusions using electron microscopy. The Cystagon treatment resulted in substantial decrease in the storage material in peripheral lymphocytes. This storage reduction paralleled the Cystagon dose. No severe side effects of the treatment were noted except for allergic rash in one of the patient that required dose reduction. A minor slowing of the disease progression compared to the controls was observed in three out of the four treated patients. The parents of two of the treated patients reported improvements in some of the disease symptoms after the start of treatment. In conclusion, we observed significant storage reduction and possible minor slowing of the disease progression in the treated patients. We conclude that the amount of storage material associated with PTT deficiency does not directly parallel the disease severity and progression. The Cystagone therapy was not successful in reversing the disease course but resulted in some minor slowing of the progression of the disease and a slight improvement of symptoms in some of the patients. It is possible that better outcomes may be achieved if the Cystagone treatment is started earlier in the disease course, and/or if it is applied in combination with other therapeutic agents.

***Peewee*, a Novel Mutant Allele of Natriuretic Peptide Receptor 2 with Skeletal Dysplasia and Female Infertility.** *K.A. Geister, M.L. Brinkmeier, S.A. Camper.* University of Michigan, Ann Arbor, MI 48109-5618 USA.

Skeletal dysplasias are an important contributor to short stature, occurring 1/5000 births. Half of the known subtypes can be explained by mutations in about 140 genes. There are no current treatments other than controversial leg lengthening surgeries. Mouse models of human skeletal dysplasias provide a tool for understanding the mechanisms of disease pathology and for exploring therapies. The *peewee* mouse is a novel spontaneous mutant allele of *Npr2*, the gene that encodes natriuretic peptide receptor 2 (NPR2), and serves as a model for a human form of skeletal dysplasia known as Acromesomelic Dysplasia Maroteaux Type (AMDM). Both the human and mouse forms of this condition are autosomal recessive. *Peewee* mutants exhibit severe disproportionate growth insufficiency and reduction in the hypertrophic zone of the epiphyseal growth plate. NPR2 is a guanylyl cyclase that is activated by C-type natriuretic peptide (CNP) to regulate the MEK/ERK axis of the MAP kinase signaling pathway in chondrocytes. NPR2 activation inhibits fibroblast growth factor signaling by inhibiting activation of MEK1/2 by inhibiting the action of RAF1, resulting in balanced regulation of bone growth. We treated fetal tibiae from normal and *peewee* mutants with U0126, a MEK1/2 inhibitor, in culture and rescued the deficiency in bone growth. Additionally, *Npr2* knock-out mutants have reduced levels of circulating IGF-1, which implicates the growth hormone axis as a contributor to the growth defect present in *peewee* mutants. We are currently assessing the role of *Npr2* in regulating the growth hormone axis, and are considering this pathway as a potential avenue for therapeutic intervention. *Peewee* females are infertile. *Npr2* is expressed in multiple tissues of the hypothalamic-pituitary-gonadal axis, including the brain, pituitary, uterus, and ovary. *Npr2* is necessary for maintenance of meiotic arrest in oocytes, which explains the infertility of *peewee* females. We are exploring the role of NPR2 in other parts of the hypothalamic-pituitary-gonadal axis. In summary, we present a mouse model of human skeletal dysplasia that is responsive to pharmacotherapy in culture.

1443F

The Soluble Myostatin Inhibitor Act2b(fc) Prevents Only Certain Forms of Acquired Muscle Atrophy. *E.M. MacDonald[1], S.J. Lee[2], R.D. Cohn[1,3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Molecular Biology and Genetics, Johns Hopkins University, Baltimore, MD; 3) Departments of Pediatrics and Neurology, Johns Hopkins University, Baltimore, MD.

Myostatin is member of the TGF) signaling family that acts as a natural negative regulator of skeletal muscle mass via binding to the Act2b receptor on the cell surface of the myofibers. It has been shown that administration of a soluble form of the Act2b receptor causes hypertrophy of skeletal muscle in normal adult mice. Given the dramatic effect on muscle growth, inhibition of the myostatin signaling cascade has been explored as a therapeutic option for various inherited forms of skeletal muscle disorders. Here, we investigated whether administration of the soluble Act2b receptor is beneficial for combating acquired forms of muscle atrophy in models of hindlimb immobilization, denervation and steroid-induced myopathy. Each set of experiments lasted for three weeks and consisted of three groups of mice; controls, atrophy with placebo, and atrophy treated with soluble Act2b receptor. In both the immobilization and steroid myopathy models, administration of the soluble Act2b receptor prevented skeletal muscle atrophy based on muscle mass measurements (p-value = 4.1x10-3 and 1x10-7 respectively). Indeed, skeletal muscle from the Act2b treated group was either the same size or hypertrophic when compared to muscles from the control group (p-value = 0.883 and 1.2x10-4). In contrast to these first two models, the denervation model showed no difference between the skeletal muscle from the soluble Act2b receptor and placebo treated groups (p-value = 0.998). Skeletal muscle from both the soluble Act2b receptor and placebo treated mice were significantly smaller than the control mice (p-value = 2.7x10-7 and 1.4x10-10). Together, our data demonstrate that the soluble Act2b receptor provides a promising therapeutic avenue for preventing skeletal muscle atrophy in immobilization and steroid-induced myopathy. However, our data also indicates that when the muscle is denervated, administration of the soluble Act2b receptor does not protect against muscle atrophy development. This suggests that an intact nerve-skeletal muscle conduction system is essential for the inhibition to be effective in preserving skeletal muscle mass. Ongoing studies will explore the interaction between electrical stimulation of the muscle and the cellular signaling pathways associated with myostatin inhibition.

1444F

Characterization of a polyalanine antibody for the diagnosis of oculopharyngeal muscular dystrophy and other polyalanine related diseases. *S.J. Stochmanski[1], F. Blondeau[2], P.A. Dion[1], P.S. McPherson[2], G.A. Rouleau[1].* 1) Centre of Excellence in Neuroscience of the Université de Montréal (CENUM), CHUM Research Centre, Montréal, QC, Canada; 2) Dept. of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montréal, QC, Canada.

Nine severe human diseases have so far been associated with expansions of polyalanine (polyala) tracts. Among them, oculopharyngeal muscular dystrophy (OPMD) is a late onset autosomal dominant disorder characterized by the presence of intranuclear inclusions (INI) in skeletal muscle fibers. We previously have identified the OPMD causative mutation as a small expansion of a GCG repeat encoding for polyala in the *PABPN1* gene. Wild-type *PABPN1* has a $(GCG)_6$ repeat that encodes for the first six alanine residues within a stretch of ten alanines whereas patients with OPMD have modestly expanded and stable alleles (GCG_{8-13}), the same being true for the other polyala diseases. Data from OPMD suggest that polyala-induced toxicity is very sensitive to the dosage and length of the alanine repeat.

Here we report the characterization of a polyclonal antibody that selectively recognizes alanine expansions of 10 or more in the protein PABPN1 implicated in OPMD. To produce the antibody, an antigen containing a 19-mer peptide comprising 18 alanine residues followed by one glycine residue was generated. Two rabbits were immunized with the fusion protein and the resulting serum (final bleed after 3 boost injections) was affinity purified.

This antibody will serve to pinpoint and characterize the sub-cellular localization of proteins containing these polymers, as well as be used to screen other “orphan” neurodegenerative or developmental diseases for the presence of expanded alanine tracts, which may help uncover new polyala diseases.

1445F

Ex vivo adenoviral-mediated gene therapy: Phosphatase inhibitors improve gene transduction. *M. Samson[1, 2], A-M. Bessette[1, 2], M. Drouin[1], M-P. Cayer[1], D. Jung[1, 2].* 1) Research and development, Hema-quebec, Quebec, Canada; 2) Department of Microbiology and Biochemistry, Laval University, Quebec, Canada.

Intravenous immunoglobulin (IVIG) contains the pooled immunoglobulin G (IgG) from the plasma of approximately a thousand or more blood donors. From year to year, several studies are reporting new utilizations of IVIG and this is resulting in a continuous increase in their utilization, raising the possibility of product shortages and increasing costs. In order to exploit terminally differentiated normal B lymphocytes for the production of IVIg in vitro, we have undertaken to determine genes involved in the control of proliferation and differentiation of human peripheral blood B lymphocytes. However, the functional characterization of these genes is limited by the failure to efficiently introduce genes in B lymphocytes and haematopoietic progenitor cells. Adenoviral vectors (Ad) are an attractive alternative since they can efficiently transduce both proliferating and quiescent cells and achieve transgene expression within hours post-infection. Moreover, Ad do not integrate their genome within the host cell chromosomes, thus leaving the genome of the host cell intact. However, we have demonstrated that primary B cells were poorly transduced with Ad5/F35, a chimeric vector that utilizes the ubiquitous CD46 molecule as receptor. We have previously showed that treatment of primary human B lymphocytes with phosphatase inhibitors prior to adenoviral infection increases substantially transduction efficiency. Phophastase inhibitors are well-known for their effects on endocytosis and intracellular trafficking, especially those that are specific for PP1 and PP2A. Adenoviral transduction efficiency is unaffected by inhibition of PP1 by tautomycin, whereas inhibition of PP2A with cantharidic acid or both PP1 and PP2A with okadaic acid substantially increases transduction efficiency. In order to better understand the effects of PP2A inhibitor on the transduction efficiency of adenoviral vectors, we followed a CY3 labeled Ad5/F35 in normal human peripheral blood B lymphocytes treated with cantharidic acid, throughout endocytosis. We show that specific PP2A inhibitor, cantharidic acid, alters intracellular trafficking of Ad5/F35.

Derivation of Insulin Producing Cells from Mesenchymal Stem Cells. *S. Talebi[1], A. Aleyasin[1], M. Soleimani[2].* 1) medical genetic, natinal institute of genetic engineering and biote, tehran, tehran, Iran; 2) medical department, tarbiat modares university.

The Pancreatic cells transplantation is a promising approach for treatment of type1 diabetes that caused by insulin deficiency; however, lack of suitable donors limits the application. Differentiated mesenchymal stem cells (MSCs) can be therapeutic source for the cure of type 1 diabetes. The aim of current experiment is to explore the possibility of derivation of insulin producing cells from bone marrow MSCs by overexpression of pdx1. In this study rat MSCs were isolated and identified by flow cytometry. Then, MSCs were transduced by lentiviruses harboring pdx1. The appropriate expression of exogenous pdx1 was confirmed in level of mRNA and protein using RT-PCR and immunofluorescent analyses. In addition to ectopic expression of pdx1, differentiating medium containing nicotinamid and betamercaptoethanol used to efficient differentiation of MSCs into beta cells. Then, the expression of islet specific markers was investigated by quantitative RT-PCR. The immunoflurescent showed a nuclear localization of pdx1. Pdx1-expressing MSCs transcribed specific pancreatic endocrine markers such as endogenous Pdx1, Ngn3, Glucagon and insulin regardless to using Nico/betaME, but the quantitative RT-PCR showed a high increase in all markers except insulin, in Nico/betaME treated cells compared to non-treated cells. The beta cells derived from MSCs also expressed glucokinase and Glut2 indicating these cells have the glucose sensing ability. In contrast, treated MSCs didn't express P48; it implies these cells have been committed to endocrine linage. Also, Pdx1+ MSCs were transplanted into diabetic rats, euglycemia can be obtained within one week. In conclusion, MSCs as an available resource can have impacted in cell based gene therapy of type1 diabetes.

1447F

Randomized, Placebo-Controlled, Cross-Over Trial of Simvastatin in Smith-Lemli-Opitz Syndrome. *C.A. Wassif[1], S.K. Conley[1], H. Goodwin[1], S.E. Sparks[2], E. Tierney[3], F.D. Porter[1].* 1) Section on Molecular Dysmorphology, Program in Developmental Endocrinology and Genetics, Eunice Kennedy Shiver National Institute of Child Health and Human Development,NIH, DHSS. Bethesda, MD; 2) Clinical Genetics, Dept. of Pediatrics Levine Children's Hospital at Carolinas Medical Center PO Box 32861, Charlotte, NC; 3) Department of Psychiatry, Kennedy Krieger Institute, Baltimore, MD,.

Smith-Lemli-Opitz syndrome (SLOS) is a malformation syndrome with behavioral and cognitive impairment caused by mutation of the 7-dehydrocholesterol reductase gene (*DHCR7*). Mutations of DHCR7 result in impaired cholesterol synthesis and accumulation of dehydrocholesterol (DHC). Treatment of SLOS involves dietary cholesterol supplementation. However, cholesterol supplementation fails to normalize DHC levels, and does not treat the central nervous system (CNS)manifestations as cholesterol does not cross the blood-brain-barrier (BBB). Simvastatin inhibits the rate limiting step in cholesterol synthesis, the conversion of HMGCoA to mevalonate. Simvastatin also induces expression of SREBP2 regulated genes including DHCR7. We hypothesized that increased expression of hypomorphic DHCR7 alleles would improve cholesterol synthesis in SLOS. In vitro and in vivo preclinical studies and a small case series showing a paradoxical increase in cholesterol were consistent with this hypothesis. Because simvastatin crosses the BBB, we also postulated that it would improve sterol biochemistry in the brain and thus impact behavior. To test the safety and efficacy of simvastatin in SLOS we performed a placebo-controlled, cross-over trial in SLOS patients with significant (>10% normal) residual DHCR7 activity. Each phase was 12 months and patients were continued on dietary cholesterol supplementation (150 mg/kg/d). We enrolled 23 patients and 18 patients completed both phases of the study. The primary outcome measure was improvement of the serum DHC/cholesterol ratio. Secondary outcome measures were improvement of the cerebral spinal fluid (CSF) DHC/cholesterol ratio and the irritability subscale of the Aberrant Behavioral Checklist (ABC). We did not replicate the finding of a paradoxical increase in cholesterol levels. The average serum cholesterol level showed a mild decrease from 132 to 113 mg/dl ($p<0.01$). However, in serum we observed a significant reduction ($p<0.001$) in DHC and a significant improvement ($p<0.005$) in the total DHC/cholesterol ratio. CSF cholesterol values remained constant but there was a trend ($p=0.06$) toward an improved DHC/cholesterol ratio. No significant changes in behavior were detected by the ABC. These data suggest that simvastatin can be used to alter sterol levels in SLOS; however, an increased response in the CNS may be needed to impact behavior.

1448F

Treating inflammatory aspects of Gaucher disease: Do different ERT choices matter? *O. Goker-Alpan, S. Kasmani, A. Farwah, T. Taber, O. Alpan.* Lysosomal Disorders Research and Treatment Unit, Center for Clinical Trials, Springfield, VA.

The standard of care for Gaucher disease (GD), the inherited deficiency lysosomal enzyme glucocerebrosidase is enzyme replacement therapy (ERT). Imiglucerase is highly effective in reversing the visceral and hematologic manifestations. However, GD is still regarded an inflammatory condition, as the response to therapy is variable. Velaglucerase has a specific activity comparable to imiglucerase, but different patterns of glycosylation, displaying high-mannose type glycans. In this study, we followed the therapeutic response among patients with type 1 GD, who switched to or initially treated with velaglucerase by following macrophage activation (chitotriosidase) and inflammatory markers Methods and subjects: 6 (5F:1M) patients with type 1 GD were treated with commercial velaglucerase alpha for an average duration of one year. Switch patients were kept at the same dose, whereas naïve patients received 60 IU/kg EOW. All four splenectomized patients, among whom two were naïve, had significant disease-load, and inflammatory aspects of disease, such as systemic inflammation with increased ESR, inflammatory bowel disease, skeletal and pulmonary involvement. Results: Chitotriosidase levels while on imiglucerease were between 54 to1100, and the levels in naïve patients were 737 and 7366 nmoles/hr/ml. At the end of one year on velaglucerase alpha, the decrease in chitotriosidase ranged 15 to 90 %, in all but one. The levels did not correlate with organ volumes. In one patient, persistently increased ESR levels were normalized. Conclusions: Chitotriosidase is a marker of activation of the macrophage alternate pathway of the immune system, and the decrease may reflect better internalization into human macrophages. For GD1, there is now a choice for ERT, which should be individualized to each patient.

Treatment with galsulfase results in improved endurance in a MPS VI patient with history of bone marrow transplantation in early childhood. *K. Kim[1,2], B. Burton[1,2].* 1) Division of Genetics, Children's Memorial Hospital, Chicago, IL; 2) Department of Pediatrics, Northwestern University, Feinberg School of Medicine, Chicago, IL.

We report our experience with weekly galsulfase treatment in a 16 year old boy with mucopolysaccharidosis type VI who had previously undergone bone marrow transplantation (BMT) from an unrelated donor at 26 months of age. He had complete engraftment of donor cells with minimal post-transplantation complications. Despite successful BMT, he developed multiple complications associated with MPS, including short stature, bilateral genu valgum, degenerative hip disease, carpal tunnel syndrome, corneal clouding, cervical cord compression, mitral and aortic valve disease, and mild restrictive airway disease. At his initial evaluation at our center in 2009, measurement of arylsulfatase B enzyme activity in leukocytes was normal at 111.1 nmoles/mg/hr (normal:40 - 150). Urine glycosaminoglycan (GAG) level was normal at 54.5 mg GAG/g creat (normal:0 - 60). At the patient's one year follow up visit, he complained of decreased endurance and expressed interest in a trial of galsulfase treatment. We discussed the potential risks associated with galsulfase treatment and unknown benefit of ERT for BMT patients with normal leukocyte enzyme activity and urine GAG level. The patient elected to proceed and began weekly infusions of galsulfase at the recommended dose of 1 mg/kg. Pulmonary function tests and 6 minute walk tests were obtained prior to start of ERT and again after 7 months of galsulfase treatment. After 7 months of treatment, there were no significant changes on physical examination. PFT's showed worsening of the restrictive airway disease. Despite this, the patient had an increase in the distance walked in 6 minutes of 450 feet. His mother also reported a decrease in respiratory infections and congestion since initiating ERT. The patient remains on weekly home based infusions of galsulfase. No infusion related reactions have been observed. Urine GAG levels remain normal at 12.63 ug GAG/mg creat at start of ERT and 16.69 ug GAG/mg creat after 7 months of treatment (normal:0 - 48.68). The benefits of galsulfase infusions in MPS VI patients with prior BMT/HSCT remain unclear. Given our patient's experience, the possibility remains that successfully transplanted patients could derive additional benefit from ERT. Long-term follow up and study of additional treated patients is needed before any definite conclusions can be drawn.

Galsulfase enzyme replacement therapy improves urine GAG excretion and clinical course in Maroteaux-Lamy syndrome (MPS type VI) after donor-engrafted bone marrow transplant. *M.L. Raff.* Genomics Institute, MultiCare Health System, Tacoma, WA.

Maroteaux-Lamy syndrome, mucopolysaccharidosis type VI, is an autosomal recessive lysosomal storage disorder (LSD) due to deficient arylsulfatase B activity. Therapies include hematopoietic stem cell transplantation (HSCT) and enzyme replacement therapy (ERT) with intravenous recombinant enzyme, galsulfase. ERT with recombinant galsulfase was approved in the US in 2005 after its efficacy and safety were demonstrated in clinical trials. This paper describes a young girl with a rapidly progressing form of Maroteaux-Lamy syndrome who received HSCT at age 23 months, prior to the availability of galsulfase ERT. She presented prior to one year of age with pectus carinatum, mild motor delay, and short stature. Urine dermatan sulfate was elevated and WBC arylsulfatase B was greatly reduced. She had an HLA-matched related donor bone marrow transplant with successful engraftment. 100 days post-transplant, her urine GAGs were moderately elevated at 86-125 μg/mg creatinine (normal range < 60). Galsulfase ERT was initiated 2 years post-bone marrow transplant. After > 1 year of weekly galsulfase ERT, urine GAGs decreased to 56-75 μg/mg creatinine. Growth velocity remained reduced after both transplant and after ERT initiation, but physical endurance and subjective quality of life improved at and > 1 year post-ERT initiation. This suggests that ERT therapy may provide therapeutic benefit even after bone marrow/HSCT in patients with MPS disorders.

Lithium chloride protects against the toxicity caused by oculopharyngeal muscular dystrophy. *A. Abu-Baker, R. Gaudet, J. Laganiere, P. Dion, G. Rouleau.* Faculty of Medicine, University of Montreal, Montreal, Quebec, Canada.

Oculopharyngeal muscular dystrophy (OPMD) is an adult-onset disorder characterized by progressive eyelid drooping, swallowing difficulties and proximal limb weakness. OPMD is caused by a small expansion of a short polyalanine tract in the poly (A) binding protein nuclear 1 protein (PABPN1). No medical treatment is available for OPMD. Here, we demonstrate for the first time that lithium chloride (LiCL) can protect against the toxicity caused by mutant PABPN1 protein in our established OPMD cell models. The enhancement of cell survival after LiCl treatment was measured at different days post treatment using live cell imaging and FACS methods. We also show that these protective effects can be partly accounted for by LiCl acting through the Wnt/beta-catenin pathway, as elevated level of beta-catenin protein was detected. Our results suggest that LiCl should be considered as a new therapeutic intervention for OPMD.

Balloon delivery of helper-dependent adenoviral vector results in sustained FIX expression in rhesus macaques. *N. Brunetti-Pierri[1,2], A. Liou[3], P. Patel[3], D. Palmer[4], N. Grove[4], M. Finegold[5], A. Beaudet[4], C. Mullins[3], P. Ng[4].* 1) Telethon Institute of Genetics and Medicine, Naples, Italy; 2) Dept. Pediatrics, Federico II University of Naples, Italy; 3) Dept. Cardiology, Baylor College of Medicine, Houston, TX; 4) Dept. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 5) Dept. Pathology, Baylor College of Medicine, Houston, TX.

Hemophilia B is an excellent candidate for gene therapy because low levels (< 1%) of factor IX (FIX) result in clinically significant improvement of the bleeding diathesis. Helper-dependent adenoviral (HDAd) vectors hold tremendous potential because they mediate long-term transgene expression without chronic toxicity. To determine the potential for HDAd-mediated hemophilia B gene therapy, we administered an HDAd expressing the human FIX (hFIX) into rhesus macaques, pre-treated with recombinant hFIX, through a balloon occlusion catheter-based delivery method designed to achieve high efficiency of hepatocyte transduction by clinically relevant vector doses. In this approach a balloon catheter is percutaneously positioned in the inferior vena cava to occlude hepatic venous outflow and various doses of an HDAd expressing hFIX under the control of a liver-specific promoter were injected directly into the liver via a hepatic artery catheter. Animals injected with 1x10e12 and 1x10e11 vp/kg exhibited therapeutic levels of hFIX (>5% of normal FIX activity) long-term for at least 1.5-2 years. Sub-therapeutic levels corresponding to ~0.1-0.5% were achieved in the animals injected with 3x10e10 vp/kg and 1x10e10 vp/kg. Therefore, the minimum therapeutic dose appears to be between 3x10e10 vp/kg and 1x10e11 vp/kg. HDAd administration at all doses tested resulted in negligible hepatotoxicity. The development of neutralizing anti-hFIX antibodies was observed in two out of the six rhesus macaques which received the lowest vector doses of 3x10e10 vp/kg and 1x10e10 vp/kg. In one animal inhibitor antibodies were detected at low titer after infusions of recombinant FIX protein and prior to vector injection. In conclusion, these results support a potential clinical trial for hemophilia B gene therapy with HDAd vectors.

1453F

Cysteine quantity correction in CADASIL using antisense mediated exon-skipping. *J.G. Dauwerse[1,2], S.A.J Lesnik Oberstein[1], D.J.M Peters[2], M.H. Breuning[1], G.J.B van Ommen[2], A.M. Aartsma-Rus[2].* 1) Department of Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is the most prevalent type of hereditary vascular dementia and is recognized as an important cause of stroke and dementia in the young. CADASIL is caused by characteristic missense mutations of the *NOTCH3* gene which lead to an uneven number of cysteine residues in the protein's ectodomain. This causes misfolding of the protein which leads to aggregation of NOTCH3 at the surface of vascular smooth muscle cells, a key factor in CADASIL pathophysiology We are currently testing a novel application for antisense-mediated protein modulation, named `cysteine quantity correction', as a treatment strategy for CADASIL. In this approach we use antisense mediated exon-skipping to intervene in protein synthesis at the pre-mRNA level. By inducing the skipping of specific exons, we re-establish an even number of cysteine residues in the NOTCH3 protein's ectodomain. Our hypothesis is that by this modulation the protein maintains function, but loses toxicity. With this approach, we can target ca. 70% of CADASIL related mutations using the same set of antisense oligonucleotides. Technically, we are able to induce the desired exon-skipping in our CADASIL cell models as shown by RT-PCR and sequencing analysis. Currently, we are evaluating whether the induced cysteine quantity correction reduces CADASIL associated NOTCH3 accumulation *in vitro*, using Western blot and immunocytofluorescence. Our hypothesis and preliminary, but promising, *in vitro* results will be presented.

1454F

Systemic administration of AAV9 gene therapy rescues a Menkes disease mouse model. *A. Donsante, M. Haddad, S. Kaler.* Unit on Human Copper Metabolism,NICHD, NIH, Bethesda, MD.

Menkes disease is a lethal infantile neurodegenerative disorder of copper metabolism caused by mutations in a P-type ATPase, ATP7A. Currently, treatments for this devastating disorder of copper metabolism are limited. Therefore, exploring the utilization of gene transfer for this disorder is well justified. In an animal model that recapitulates the Menkes disease phenotype, the *mottled-brindled* (*mo-br*) mouse, we previously reported promising improvement of several parameters, as well as a substantial increase in life span, using combination brain-directed AAV5 gene transfer plus copper. Systemic viral therapy in Menkes disease would enable less invasive delivery and may provide substantial improvement of the non-neurological components of this disorder including renal, pulmonary, and musculoskeletal effects. To refine prospects for clinical translation of gene therapy for this disorder, we evaluated transduction efficiency and preliminary therapeutic effectiveness of AAV serotype 9, which has a unique capacity to cross the blood-brain barrier, and thus may be administered systemically. We treated mo-br mice with $5x10^{11}$ viral particles of AAV9 carrying a human ATP7A cDNA delivered by intraperitoneal injection on day 2 of life and 50 ng copper chloride to the lateral ventricles on day 3 (similar to our previous study). Over 70% of treated *mo-br* mice survived to weaning and median life span doubled. Western blot analysis indicated high ATP7A transgene expression in skeletal and cardiac muscle. AAV9-ATP7A transduction of liver, kidney, heart, lung, intestine, cerebral cortex and choroid plexus was confirmed by quantitative PCR. Measurements of plasma catecholamines at 28 days of age suggested normal neurochemical ratios, consistent with corrected deficiency of dopamine-) -hydroxylase activity, a copper-dependent enzyme. Our findings provide the first definitive evidence that systemic administration of AAV9 gene therapy may have clinical utility for treatment of Menkes disease.

Adeno-associated Viral Vector 2/8 (AAV2/8) Rescues Retinal Degeneration in a Mouse Model of Retinitis Pigmentosa. *K.J. Wert[1,2,3], S.H. Tsang[1,3,4].* 1) Department of Ophthalmology, Columbia University Medical Center, New York, NY; 2) Institute of Human Nutrition, Columbia University Medical Center, New York, NY; 3) Bernard & Shirlee Brown Glaucoma Laboratory, Columbia University Medical Center, New York, NY; 4) Department of Pathology and Cell Biology, College of Physicians & Surgeons, Columbia University, New York, NY.

BACKGROUND: Approximately 36,000 cases of simplex and familial retinitis pigmentosa (RP) worldwide are caused by mutant phosphodiesterase (PDE6). In spite of this high prevalence, the interplay between defective PDE metabolism and RP pathogenesis remains poorly understood. There is, however, a mouse model for this form of RP: *Pde6(* ^{nmf363}*/Pde6(* ^{nmf363}. In this model, defects in the PDE6(subunit results in the loss of photoreceptors and visual function. We hypothesize that an AAV2/8 vector delivery that increases PDE6(production will improve retinal function and survival. **METHODS:** We tested an AAV2/8 vector for PDE6(driven by an opsin promoter: *Opsin::PDE6(* AAV2/8. We injected one microliter subretinally into the right eye of *Pde6(* ^{nmf363}*/Pde6(* ^{nmf363} mice at P5 and the left eye was injected subretinally with one microliter of saline or *CMV::EGFP* AAV2/8 and used as a control. The number and morphology of photoreceptor cells of the *Opsin::PDE6(* AAV2/8 injected eyes were compared to control eyes. Electroretinograms (ERGs) were performed weekly beginning at P28 to assess global retinal function in transduced and control eyes, using an Espion simulator. **RESULTS:** The *Opsin::Pde6(* AAV2/8 vector increased survival of photoreceptor cells and retinal function in the *Pde6(* ^{nmf363}*/Pde6(* ^{nmf363} mutants. At P36, the mutant retinae transduced with *CMV::EGFP* AAV2/8 exhibited only a single row of photoreceptor cells. In contrast, *Opsin::PDE6(* AAV2/8 transduced eyes showed an increase in the number of photoreceptor cells. ERGs performed weekly beginning at P28 showed higher b-wave amplitudes in *Opsin::PDE6(* AAV2/8 injected eyes compared to control eyes throughout the study period. **CONCLUSIONS:** Increased photoreceptor survival and function in a phosphodiesterase mouse model of RP can be induced by an AAV2/8 mediated increase in the PDE6(enzyme. This strategy tested in mice shows that increasing PDE6(production through gene therapy may be a novel approach for treating patients with RP occasioned by PDE6 deficiency.

Antisense RNA/Ethylene-bridged nucleic acid chimera induces exon 45 skipping in cultured myocytes from DMD patients with 6 different deletion mutations. *M. Yagi[1], T. Lee[1], H. Awano[1], Y. Takeshima[1], M. Matsuo[2].* 1) Dept Pediatrics, Kobe Univ Graduate Sch Med, Hyogo, Japan; 2) Dept Medical Rehabilitation, Kobe Gakuin Univ, Hyogo, Japan.

Duchenne muscular dystrophy (DMD) is the most common muscle wasting disease, with patients succumbing in their twenties and caused by mutations in the *dystrophin* gene. Antisense oligonucleotides that induce exon skipping is now attracting much attention to express internally deleted-dystrophin in DMD [1]. In our previous study, we identified antisense RNA/2'-*O*, 4'-*C*-ethylene-bridged nucleic acid (ENA) chimera (AO85) that could induce exon 45 skipping efficiently. The skipping of exon 45 would theoretically be applicable to 9 % of DMD patients [2]. Here, we investigated efficiencies of exon 45 skipping and dystrophin expression in DMD patient-derived myocytes carrying different types of deletion mutations. We examined the ability of AO85 to induce exon 45 skipping and dystrophin expression in ten DMD myocytes carrying six different deletion mutations, as follows: exon 44, 46-47, 46-48, 46-49, 46-51, or 46-53. In each case, the exon 45 skipping was induced by AO85 as expected, however, the skipping efficiency was different from patients to patients. In myocytes with exon 46-48, 46-49, 46-51, or 46-53 deletion more than 50% of the dystrophin mRNA showed exon 45 skipping, while less than 20% in myocytes carrying exon 44 or 46-47 deletion. Western blot analysis showed clear visible signal for dystrophin in three myocytes with exon 44, 46-49, or 46-51 deletion. It was remarkable that myocytes from one DMD patient with exon 44 deletion showed low exon 45 skipping efficiency but expressed dystrophin detectable by the Western blotting. It needs further study to clarify the mechanism that provides discrepancy between exon skipping and dystrophin expression. Results of our in vitro study indicated that exon 45 skipping with AO85 is applicable to the DMD treatment. <Reference> 1.Takeshima et al. Statement of purpose: To measure changes in plasma biomarkers, chitotriosidase and CCL18, in patients with type 1Gaucher Disease (GD1) transitioned from imiglucerase to velaglucerase alfa in a phase II/III trial and its extension. Methods: In trial TKT034, GD1 patients aged ⁄ 2 years and clinically stable on imiglucerase switched to velaglucerase alfa for 12 months (same U/kg [15-60] every other week as prior imiglucerase treatment), after which they could continue in the ongoing extension HGT-GCB-044. Results: All 38/40 treated patients completing TKT034 enrolled in HGT-GCB-044. At TKT034 baseline, 47% were male, the median age was 35 years (range 9-71; 24% <18), 8% were splenectomized, and the prior range for imiglucerase exposure was 22-192 months (median 65). The median (range) CCL18 level was 325 ng/mL (49-1582) and for chitotriosidase activity was 3363 nmol/mL/h (108-30785). One patient was chitotriosidase deficient and was excluded from the analysis of chitotriosidase. After 24 months' velaglucerase alfa, the mean (95% CI) change in CCL18 level was -50.9% (-55.5, -46.3) and for chitotriosidase activity -34.5% (-42.2, -26.9), while hemoglobin concentration, platelet count, liver and splenic volumes remained within prespecified clinically significant bounds of stability. Conclusions: GD1 patients switching from long-term imiglucerase maintained key clinical parameters through 2 years of velaglucerase alfa while biomarkers of glucosylceramide burden improved. Further studies with active control groups that remained on imiglucerase are recommended to determine whether the normalization of biomarkers is similar and clinically significant between patients who switch to velaglucerase alfa versus patients who do not.

1458F

Abnormal autophagy in mucopolysaccharidosis VII can be rescued by enzyme replacement therapy. *R. Datta[1], J. Grubb[2], A. Waheed[2], J. Ryerse[3], W. Sly[2].* 1) Department of Biological Sciences, Indian Institute of Science Education and Research-Kolkata, Mohanpur campus, West Bengal, INDIA; 2) Edward A. Doisy department of Biochemistry and Molecular Biology, Saint Louis University School of Medicine, 1100 South Grand Blvd. Saint Louis, MO 63104, USA; 3) Department of Pathology, Saint Louis University School of Medicine, 1100 South Grand Blvd. Saint Louis, MO 63104, USA.

Mucopolysaccharidosis VII (MPSVII) is an autosomal recessive lysosomal storage disorder caused by the deficiency of) -glucuronidase () -GUS), a lysosomal enzyme required for degradation of glycosaminoglycans (GAGs). Accumulation of undegraded or partially degraded GAGs in the lysosomes results in cellular and multiple organ dysfunctions leading to premature death in most cases. To better understand the pathogenesis of this disease we used MPSVII patient's fibroblasts and mouse model () -GUS knockout) to study the status of autophagy, a vesicular transport system by which cellular debris are targeted to the lysosome for degradation and reuse. We report here that in MPSVII patient's fibroblasts as well as in the brain of MPSVII mice there is an abnormal accumulation of autophagosomes as evidenced by the elevated LC3II levels. Electron microscopic evaluation of the MPSVII mice brain sections also showed increased abundance of autophagosomes. Co-localization studies with LC3II positive vesicles and a neuronal marker suggest that the autophagosomes primarily accumulate in the neurons. Our data also show massive increase in the levels of polyubiquitinated proteins (autophagic cargo) in the MPSVII fibroblasts as compared to the normal fibroblasts, suggesting impaired clearance of autophagosomes rather than increased formation. Nutrient acquisition through induction of autophagy is a well established mechanism of survival during starvation. That MPSVII fibroblasts are highly sensitive to serum starvation confirms that autophagy is indeed defective in this disease. Treatment of MPSVII fibroblasts with purified) -GUS (8000 units/ml for 72 hrs) completely reversed the autophagy defect. More importantly, intraperitoneal injection of the MPSVII mice with periodate modified) -GUS (2mg/kg, bi-weekly) not only restored normalcy in terms of brain pathology but also significantly reduced the LC3II levels in the brain. Taken together our data establishes MPSVII as an autophagy disorder and suggests that abnormal autophagy can be a useful biomarker for testing the efficacy of treatment of MPSVII patients.

1459F

The Pharmacological Chaperone AT2220 Increases the Muscle Uptake of Recombinant Human Acid (-Glucosidase Resulting in Greater Glycogen Reduction in a Mouse Model of Pompe Disease. *J. Feng, R. Soska, L. Pellegrino, M. Frascella, Y. Lun, J. Flanagan, D. Guillen, D. Lockhart, K. Valenzano, R. Khanna.* Amicus Therapeutics, 6 Cedar Brook Drive, Cranbury, NJ. 08512.

Pompe disease is an inherited metabolic disorder caused by a deficiency in acid (-glucosidase (GAA) activity, which impairs lysosomal glycogen catabolism and results in progressive skeletal muscle weakness, reduced cardiac function, and respiratory insufficiency. Recombinant human GAA (rhGAA; Myozyme®, Genzyme Corp.) given as a bi-weekly infusion is an approved enzyme replacement therapy (ERT) for Pompe disease. While somewhat effective, rhGAA has a short circulating half-life, low tissue uptake, and can elicit immune responses that adversely affect tolerability and efficacy. AT2220 (1-deoxynojirimycin-HCl) is a small molecule pharmacological chaperone that binds endogenous GAA in cells and tissues, resulting in increased lysosomal GAA levels and activity. We hypothesized that AT2220 might also interact with exogenous rhGAA to improve its pharmacological properties. In human plasma, AT2220 co-incubation increased the stability and prevented denaturation of rhGAA at neutral pH and 37°C for up to 24 hours. In cultured rat myoblasts, AT2220 co-incubation also increased the cellular uptake of rhGAA by more than 3-fold. In rats, a single intravenous bolus administration of rhGAA 30 minutes after a single oral administration of AT2220 resulted in a dose-dependent increase of up to 2-fold in the circulating half life of rhGAA, indicating that AT2220 can bind and stabilize rhGAA in vivo. A similar effect of AT2220 was seen on the circulating half-life when rhGAA was administered by 1-hour infusion. In GAA KO mice, oral administration of AT2220 resulted in up to 2.5-fold greater tissue uptake and glycogen reduction compared to administration of rhGAA alone. Collectively, these results indicate that AT2220 increases the stability of rhGAA, increase enzyme activity and substrate turnover in muscle when administered orally prior to rhGAA IV dosing. Based on these findings, a Phase 2a study with AT2220 co-administration with rhGAA has been initiated.

Oral Migalastat HCL (AT1001/GR181314A) is an Investigational Therapy Evaluated in Females with Fabry Disease. *P. Fernhoff[1], R. Giugliani[2], K. Nicholls[3], D.P. Germain[4], S. Waldek[5], D.G. Bichet[6], V. Sniukiene[7], P. Boudes[7].* 1) Div Med Gen/Dept Human Gen, Emory Univ Sch Med, Decatur, GA. 30033 United States; 2) Department of Genetics, UFRGS Director,WHO CC Develop Med Genet Serv Lat America Medical Genetics Service Hospital de Clínicas de Porto Alegre Rua Ramiro Barcelos 2350 90035-903 - Porto Alegre - RS - Brazil; 3) Department of Nephrology The Royal Melbourne Hospital Parkville, Victoria 3050; 4) Department of Medical Genetics, Hôpital Raymond Poincaré, University of Versailles, Saint Quentin en Yvelines, Garches, France; 5) Willink Biochemical Genetics Unit Genetic Medicine, 6th Floor, Pod 1, St Mary's Hospital, Oxford Road, Manchester, M13 9WL; 6) Department of Medicine Université de Montréal Hôpital du Sacré-Coeur de Montréal 5400 Blvd. Gouin Ouest Centre de Recherches Montreal, Quebec H4J 1C5 Canada; 7) Amicus Therapeutics 6 Cedar Brook Drive Cranbury, New Jersey 08512.

Background: Fabry disease (FD) is an X-linked lysosomal storage disorder characterized by deficiency of alpha-galactosidase A ((- Gal A) with accumulation of globotriaosylceramide (GL-3) in tissues and body fluids, leading to progressive, multi-organ dysfunction. Heterozygote females develop signs and symptoms generally later than men and may require treatment. Objective: A phase II study to evaluate safety and tolerability of migalastat, an orally administrated pharmacological chaperone, in symptomatic FD females. Methods: Migalastat was administered at 50, 100 or 250 mg once every other day for 48 weeks. Results: Nine females (36 to 62 years old) with baseline leukocyte (- Gal A activity ranging from 15% to 114 % of normal were enrolled. Five of nine had GLA mutations characterized as responsive to migalastat using an in vitro assay. Medical history and baseline findings were significant: five females had left ventricular hypertrophy, five had Stage 2 chronic kidney disease and two experienced transient ischemic attack prior to treatment. Seven of nine had elevated urine GL-3 (uGL-3). Kidney biopsy demonstrated GL-3 inclusions in multiple cell types predominantly in podocytes. On treatment all females (N=5) with responsive GLA mutations demonstrated an increase in leukocyte (-Gal A with mean increase at Week 48 of 61% and mean decline in uGL-3 of 46 %; four of them had a decline in interstitial capillary GL-3 (mean 56%). Migalastat was generally safe and well- tolerated. All subjects completed treatment; no treatment-related serious adverse events and no treatment-limiting toxicities were identified. Conclusion: Data suggest that migalastat is safe and tolerable investigational therapy with emerging evidence of efficacy in symptomatic FD females with amenable GLA mutations.

Improvements in Skeletal Manifestations in Gaucher Disease Type 1 Patients After 3 Years of Treatment with Oral Eliglustat During a Phase 2 Trial. *R.S. Kamath[1], E. Lukina[2], N. Watman[3], M. Dragosky[4], M. Iastrebner[4], G. Pastores[5], E. Avila Arreguin[6], M. Phillips[7], H. Rosenbaum[8], E. Sysoeva[2], R. Aguzzi[9], A.C. Puga[9], M.J. Peterschmitt[9], D.I. Rosenthal[1].* 1) Massachusetts General Hospital, Boston, MA; 2) National Research Center for Haematology, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) Instituto Argentino de Diagnostico y Tratamiento, Buenos Aires, Argentina; 5) New York University, New York, USA;; 6) Instituto Mexicano del Seguro Social, Hospital de Especialidades, Col. La Raza, Mexico; 7) Sha'are Zedek Medical Center, Jerusalem, Israel; 8) Rambam Medical Center, Haifa, Israel; 9) Genzyme Corporation, Cambridge, MA, USA.

Background: In Gaucher disease type 1 (GD1), the deficiency of lysosomal acid) -glucosidase leads to the accumulation of glucosylceramide. Skeletal complications are a major cause of morbidity and include bone marrow infiltration, osteopenia/osteoporosis, lytic lesions, fractures, avascular necrosis and bone pain. Eliglustat, a novel, oral inhibitor of glucosylceramide synthase, is under investigation for the treatment of GD1. **Aim:** Report skeletal changes after 3 years of eliglustat therapy. **Methods:** Phase 2 study entry criteria required that patients be untreated, have no new pathologic bone involvement or bone crises within the preceding 12 months, and not be using bisphosphonates. Changes from baseline were reported for centrally reviewed skeletal x-rays, dual-energy x-ray absorptiometry (DXA) and MRI assessments. **Results:** Of 26 enrolled patients, 19 completed 3 years of treatment. In 15 patients with evaluable DXA results at baseline and 1, 2 and 3 years, mean lumbar spine BMD increased by 0.6±0.69 Z-score (baseline -1.28) with greatest increases in osteoporotic patients. Mean femur BMD (T- and Z-score) remained normal through 3 years. Femur dark marrow on MRI reflecting bone marrow infiltration by Gaucher cells was reduced (56%, 10/18) or stable (44%, 8/18) in 18 patients with findings at baseline. No bone crises or reductions in mobility occurred. On baseline radiographs, no patients had fractures, 8/19 (42%) had femoral lytic lesions and 7/19 (37%) had bone infarcts. After 3 years, the lumbar spine and femurs showed no new lytic lesions, bone infarcts, fractures or areas of osteonecrosis and no worsening of pre-existing lytic lesions or bone infarcts; 1 patient had worsening of asymptomatic osteonecrosis after 1 year that was noted retrospectively at baseline. Eliglustat was well-tolerated. Most adverse events (AEs) were mild and unrelated to treatment; the most common were viral infections (6 pts); urinary and upper respiratory tract infections (4 pts each); and headache, increased blood pressure, abdominal pain, diarrhea (3 pts each). Eight drug-related AEs, all mild, occurred in 6 patients. **Conclusions:** During 3 years of eliglustat treatment, radiologic monitoring showed improvement or stabilization of GD1 bony manifestations with no noted safety-related trends. Results suggest that eliglustat may be a promising treatment for skeletal complications of GD1. Ongoing Phase 3 studies will provide more information on the bone effects of eliglustat.

The Pharmacological Chaperone AT1001 Increases the Tissue Uptake of Agalsidase Alfa Resulting in Greater Substrate Reduction in a Mouse Model of Fabry Disease. *L. Pellegrino, J. Feng, M. Frascella, R. Soska, J.J. Flanagan, D. Guillen, D.J. Lockhart, K.J. Valenzano, R. Khanna.* Amicus Therapeutics, Cranbury, NJ.

Fabry disease is an X-linked lysosomal storage disorder caused by mutations in the gene that encodes (-galactosidase A ((-Gal A), and is characterized by pathological accumulation of globotriaosylceramide (GL-3). Regular infusion of recombinant human (-Gal A (rh(-Gal A), termed enzyme replacement therapy (ERT), is the primary treatment for Fabry disease. However, rh(-Gal A has low physical stability (especially at neutral pH and body temperature), a short circulating half-life, and variable access and uptake across different tissues. The iminosugar AT1001 (GR181413A, deoxygalactonojirimycin; migalastat hydrochloride) is a pharmacological chaperone that selectively binds endogenous (-Gal A (wild-type and mutant forms), increasing physical stability, lysosomal trafficking, and total cellular activity. We hypothesized that AT1001 might also improve the pharmacological properties of exogenous rh(-Gal A. Hence, in this study we investigated the effects of AT1001 on agalsidase alfa (Replagal™, Shire Human Genetic Therapies, Inc.) in vitro and in vivo. Binding of AT1001 increased the physical stability of agalsidase alfa, preventing denaturation and loss of activity at neutral pH and 37°. In rats, oral administration of AT1001 in combination with intravenous administration of agalsidase alfa dose-dependently increased the circulating half-life of the enzyme by up to 3-fold. In GLA knockout mice, AT1001 co-administration increased the uptake of agalsidase alfa into skin, heart, and kidney up to 4-fold more than seen following administration of agalsidase alfa alone; these higher levels were also sustained for longer periods of time. In addition, AT1001 co-administration resulted in up to 20% greater GL-3 reduction in tissues compared to administration of agalsidase alfa alone. Collectively, these results indicate that AT1001 increases the stability of rh(-Gal A, translating to greater enzyme activity and substrate turnover in situ when administered orally prior to rh(-Gal A dosing. Based on these findings, a Phase 2a study of AT1001 in combination with agalsidase alfa has been initiated.

Eliglustat, an Investigational Oral Therapy for Gaucher Disease Type 1 (GD1): Phase 2 Results after 3 Years. *M.J. Peterschmitt[1], E. Lukina[2], N. Watman[3], M. Dragosky[4], M. Iastrebner[4], G. Pastores[5], E. Avila Arreguin[6], M. Phillips[7], H. Rosenbaum[8], E. Sysoeva[2], R. Aguzzi[1], L.H. Ross[1], A.C. Puga[1].* 1) Genzyme Corporation, Cambridge, MA, USA; 2) National Research Center for Haematology, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) Instituto Argentino de Diagnostico y Tratamiento, Buenos Aires, Argentina; 5) New York University, New York, USA; 6) Instituto Mexicano del Seguro Social Hospital de Especialidades, Col. La Raza, Mexico; 7) Sha'are Zedek Medical Center, Jerusalem, Israel; 8) Rambam Medical Center, Haifa, Israel.

Background: Gaucher disease type 1 (GD1) is an inherited lysosomal storage disorder caused by deficient activity of acid) -glucosidase. This enzymatic deficiency leads to accumulation of undegraded glucosylceramide primarily in tissue macrophages and results in multisystemic manifestations, including thrombocytopenia, anemia, hepatosplenomegaly and skeletal complications. Eliglustat, a novel, potent and specific inhibitor of glucosylceramide synthase, is under development as an oral substrate reduction therapy (SRT) for GD1. **Aim**: To report long-term efficacy and safety results of eliglustat. **Methods**: This ongoing, open-label, uncontrolled, multicenter Phase 2 clinical trial enrolled 26 adults with GD1 not on treatment for the previous 12 months, who had splenomegaly with thrombocytopenia and/or anemia. Efficacy outcomes included changes from baseline in hemoglobin, platelets, spleen and liver volumes and bone mineral density (mean±SD); biomarker levels (median); and achievement of therapeutic goals for anemia, thrombocytopenia, splenomegaly and hepatomegaly (Pastores *Semin Hematol* 2004). **Results**: Nineteen patients completed 3 years of treatment; 7 patients discontinued the trial. After 3 years, hemoglobin increased by 2.6±1.39 g/dL (11.3±1.63 to 13.8±1.37); platelets increased by 91±65.9% (70,000±21,700 to 126,800±40,500/mm^3); and spleen and liver volumes (multiples of normal, MN) decreased by 61±12.2% (16.8±9.5 to 6.2±3.6 MN) and 29±15.8% (1.7±0.5 to 1.2±0.3 MN), respectively. Most patients met long-term therapeutic goals for hemoglobin (100%), spleen volume (100%), liver volume (89%) and platelets (63%); all patients met⁄3 therapeutic goals at 3 years. Plasma GL-1 and GM3 levels normalized; median chitotriosidase and CCL-18 decreased by 80% and 73%, respectively. Mean lumbar spine BMD increased by 0.6 Z-score (-1.3±1.0 to -1.7±1.1). Eliglustat was well tolerated. Most adverse events (AEs) were mild and unrelated to treatment. The most common AEs were viral infections (6 pts); urinary and upper respiratory tract infections (4 pts each); and headache, increased blood pressure, abdominal pain and diarrhea (3 pts each). Eight drug-related AEs, all mild, occurred in 6 patients. **Conclusions**: Eliglustat has shown promising efficacy and safety, with clinically meaningful hematologic, visceral, and bone improvements. Most patients met long-term therapeutic goals by 3 years. Eliglustat has been well tolerated. Three international Phase 3 studies are ongoing.

1464F

Continued improvement in a forty year old man with mucopolysaccharidosis type II after four years of enzyme replacement therapy. *F.J. Stewart[1], M. McCloskey[2], J.E. Wraith[3].* 1) Dept Medical Genetics, Belfast City Hosp, Belfast, United Kingdom; 2) Altnagelvin Hospital, Londonderry, UK; 3) Willink biochemical Genetics Unit, St Mary's Hospital, Manchester, UK.

Our patient was diagnosed with Mucopolysaccharidosis (MPS) Type II Hunter disease at the age of 12 years. MPS II is caused by a deficiency of iduronate sulphatase which is one of the lysosomal enzymes. Developmental outcome ranges from severe learning disability to normal intelligence as is seen in our patient. Our patient had short stature, characteristic facial features, joint contractures and marked hepatosplenomegaly. He developed worsening respiratory problems and his FEV1 dropped from 0.98 to 0.42 (17.6% predicted). At age 28 he was started on overnight CPAP as he had episodes of sleep apnoea with overnight O2 saturations falling to 61%. He started on idursulfase (Elaprase ®) with a weekly dose of 0.5mg/kg in June 2007 at the age of 36. He was gradually able to reduce his CPAP and within a year this was discontinued. His sats improved to 99% in room air. Overnight oximetry was normal. FEV1 improved to 0.71 (30% predicted).His hepatosplenomegaly has reduced and his waist is four inches smaller. He has much more energy and was able to cook Christmas dinner unaided. He was also able to travel to Vancouver which previously would have been unthinkable. His joint contractures are also improving slightly giving him better hand function. He has now been on treatment for 4 years and his respiratory function has not deteriorated. He remains off his CPAP. Overall his quality of life has continued to improve. Our patient is one of the older patietns with MPS II to have received enzyme replacement therapy. His case demonstrates that treatment of an older MPS II individual may lead to a significant improvement in their clinical condition and quality of life and that treatment should not be discounted on the grounds of age.

1465F

Quantitative evaluation of bones in murine MPS VII after replacement therapy using chemically modified enzyme. *S. Tomatsu[1], DJ. Rowan[1], JH. Grubb[3], B. Haupt[2], AM. Montaño[1], WS. Sly[3].* 1) Dept Pediatrics, Saint Louis Univ Doisy Res Ctr, St Louis, MO; 2) Edward A. Doisy Department of Biochemistry and Molecular Biology, Saint Louis University, St. Louis, Missouri; 3) Department of Pathology, Saint Louis University, St. Louis, Missouri.

Mucopolysaccharidosis (MPS) type VII is a lysosomal storage disease caused by deficiency of the lysosomal enzyme)-glucuronidase (GUS), which is involved in degradation of glycosaminoglycans (GAGs). GAG storage in the tissue of patients with MPS VII causes a wide spectrum of clinical manifestations that affect the central nervous system (CNS), bone, and viscera. Enzyme replacement therapy (ERT), effectively clears GAG storage in the viscera. However, clearance of storage material in CNS has been limited by the blood brain barrier. Nonetheless, recent studies showed that a chemically modified form of GUS (PerT-GUS) escaped clearance by mannose 6-phosphate and mannose receptors leading to its prolonged circulation and reduced CNS storage more effectively than native GUS. Although clearance of storage in bone is somewhat limited by the avascularity of the growth plate, prior work showed clinical and pathological improvement of skeletal disease in MPS VII mice treated from birth with weekly IV injections of native GUS. To evaluate the effectiveness of PerT-GUS in reducing the skeletal pathology, we treated MPS VII mice from birth with PerT-GUS and used micro-CT, X-rays and quantitative histopathological analysis for assessment of bones. Micro-CT and X-rays demonstrated marked improvements in bone lesions of legs, ribs, and spine of treated mice. Quantitative histopathological assay also showed moderate improvements in GAG storage and morphology of articular and epiphyseal chondrocytes. These findings indicate that PerT-GUS therapy from birth may significantly reduce disability caused by bone dysplasia in MPS VII in addition to addressing CNS storage.

1466F

Cell-based evaluation of small molecules for treatment of Pompe disease. *W. Westbroek[1], A.M. Gustafson[1], J.J. Marugan[2], J. Xiao[2], W. Zheng[2], A. Velayati[1], E. Goldin[1], E. Sidransky[1].* 1) Medical Genetics Branch/NHGRI/NIH. Bl35, 35Convent Drive, Bethesda, MD 20892; 2) NIH Chemical Genomics Center/NIH. 9800 Medical Center Drive, Rockville, MD 20850.

Glycogen storage disease II or Pompe disease is an autosomal recessive lysosomal storage disorder (LSD) caused by dysfunction of the lysosomal enzyme acid alpha-glucosidase (GAA). Mutations in GAA impair the breakdown of glycogen, causing storage of the substrate in enlarged lysosomes. Cardiac and skeletal muscles are severely affected, causing impaired breathing and mobility. More than 100 distinct disease-causing mutations in GAA have been identified, some of which retain enzymatic activity in vitro, but are not trafficked to the lysosome. Instead the misfolded GAA stays in the endoplasmic reticulum (ER) and eventually undergoes proteosome-mediated breakdown. Enzyme replacement therapy with Myozyme®, the only current treatment for Pompe disease, improves clinical outcome, but the treatment remains expensive, inconvenient and does not reverse all disease manifestations. It was postulated that small molecules which aid in protein folding, ER trafficking, and translocation of enzymes to lysosomes could provide an alternate therapeutic strategy. We identified several promising non-inhibitory compounds for GAA from a chemical compound library by performing distinct in vitro assays. For further biological evaluation of these GAA compounds, we developed an in vivo cell-based immune-fluorescence cytochemistry assay to assess chaperone capacity. Translocation of GAA to the lysosomes in Pompe cells was evaluated by measuring the extent of co-localization between GAA and Cathepsin-D, a lysosomal marker, using laser scanning confocal microscopy. Using a GAA-specific antibody, control fibroblasts showed specific GAA staining in the lysosomes, while fibroblasts from patients with Pompe disease lacked this signal with immune-fluorescence cytochemistry. However, after six days of treatment of Pompe fibroblasts by adding the GAA activator to the growth medium, the expression level and translocation of GAA to lysosomes was comparable to control cells. Such activators are particularly desirable chaperones, since enzyme function remains intact. These promising small molecules, identified using an in vivo cell-based assay, merit further evaluation as a potential new therapy for Pompe disease.

1467F

Current treatment and outcome of infantile cobalamin C disease. *N. Carrillo-Carrasco[1], J. Sloan[1], I. Manoli[1], N. Hauser[1], A. Gropman[5], C. O'Shea[3], R.D. Graf[3], W.M. Zein[2], P. Tanpaiboon[5], S.M. Paul[3], J. Snow[3], C. Wagner[6], S.H. Mudd[4], B.P. Brooks[2], C.P. Venditti[1].* 1) National Human Genome Research Institute, NIH, USA; 2) National Eye Institute, NIH, USA; 3) Clinical Research Center, NIH, USA; 4) National Mental Health Institute, NIH, USA; 5) Children's National Medical Center, USA; 6) Vanderbilt University Medical Center, USA.

Background: Cobalamin C disease (cblC), thought to be the most common inborn error of intracellular vitamin B12 metabolism, is caused by mutations in MMACHC and results in impaired synthesis of adenosyl- and methylcobalamin. Manifestations of this multisystemic disorder include impaired growth, neurologic and ophthalmologic abnormalities, and decreased lifespan. **Methods**: We evaluated 22 patients with infantile cblC disease (age range, 2 to 27 years) through NIH study 04-HG-0127 (clinicaltrials.gov: NCT00078078) to define their outcomes under current management strategies. **Results**: The median age of detection of patients diagnosed clinically was 2.6 months (range 0.6-24 months, n=16), compared to 0.3 months (n=3) by newborn screening. Common presentations included failure to thrive, encephalopathy, poor eye contact and nystagmus. All patients were treated after diagnosis, with considerable clinical improvement. We found that management was highly variable among patients. Protein restriction, although controversial, was seen in 41% of patients, with a median intake of 70% of their RDA. All patients had long-term complications despite treatment. Head circumference was the growth parameter most affected (median z-score -0.97; range -0.5 to -3.4). Seizures were reported in 55% and included refractory (14%; n=3), controlled (9%; n=2) and past history of seizures (32%; n=7); resolution coincided with lowering tHcy levels (n=4). The mean Vineland-II Adaptive Behavior Composite score was over 3 SD below normal (n=14, 52.9±18.87), but earlier age of initiation of treatment correlated with improved neurocognitive outcome (n=13, R=-0.755, p=0.003). Patients had progressive visual loss with a mean acuity of 20/500 (range 20/50 to 5/400). Fundoscopy revealed the characteristic findings of maculopathy, pigmentary retinopathy and/or optic pallor. Mean plasma MMA was 20 μM (range: 0.49-151 μM), tHcy 70.8 μM (22-134 μM) and methionine 19.5 μM (4-53 μM). Most patients had trough plasma vitamin B12 levels below 1,000,000 pg/ml, a level noted to be therapeutic in other studies. **Conclusion**: We performed a single center study to define the outcome of infantile cblC. Early diagnosis and treatment seem to improve neurocognitive outcome, but not the progression of eye disease. Current treatment strategies are variable and commonly suboptimal. This study also provides baseline information to evaluate the efficacy of newborn screening and novel therapeutic interventions.

1468F

Long-term effectiveness of helper-dependent adenoviral gene therapy in an hypomorphic mouse model of argininosuccinic aciduria. *P. Campeau[1], O. Shchelochkov[2], K. Guse[1], S.C. Sreenath Nagamani[1], Y. Chen[1], J. Zhang[1], M.H. Premkumar[3], T. Bertin[1], D. Palmer[1], N. Brunetti-Pierri[4], J. Marini[3], Q. Sun[1], W. O'Brien[1], N.S. Bryan[5], A. Erez[1], B.H. Lee[1,6].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Division of Medical Genetics, Department of Pediatrics, University of Iowa Children's Hospital; 3) Department of Pediatrics, Baylor College of Medicine; 4) Telethon Institute of Genetics and Medicine, Napoli, Italy; 5) Institute of Molecular Medicine, UT Health Science Center; 6) Howard Hughes Medical Institute, Houston, TX.

Argininosuccinic aciduria (ASA) is an inborn error of the ureagenesis caused by mutations in the gene encoding argininosuccinate lyase (ASL). The enzyme is a homotetramer expressed in the liver where it participates in the detoxification of ammonia by converting argininosuccinate to arginine which is then converted to urea for excretion. Patients can present clinically with encephalopathy, seizures or lethargy caused by elevated plasma ammonia and are diagnosed biochemicaly by having increased citrulline and elevated ASA in their blood. Current treatments for ASA are limited to arginine supplementation, nitrogen scavenging medications and liver transplantation in rare cases. We have generated a hypomorphic model of argininosuccinic aciduria by inserting a neomycin resistance cassette in the mouse *Asl* locus. *Asl* hypomorphic mice die within the first month of life from multi-organ failure. In an attempt to rescue the mice, we delivered a helper-dependent adenovirus encoding *Asl* under a liver-specific promoter at 4 weeks of life. The gene therapy group showed dramatic improvement in their growth with normalization of Asl expression in the liver by 2 weeks which allowed survival past the critical period of weaning. Most mice survived more than 10 months, showing a correction of their blood and tissue amino acid levels. Gene therapy also corrected the citrulline flux in these mice providing additional evidence for functional correction of Asl. At 10 months of age, the mice displayed normal motor coordination and balance on the rota-rod test, and normal learning and memory on the cued and contextual fear conditioning test in spite of lower levels of Asl in the liver. These data highlight the age related different requirement for ASL in the neonatal versus long term adult correction and importantly demonstrate the potential of gene therapy for argininosuccinic aciduria.

1469F

A New Pharmacologic Approach for Cystinuria. *A. Sahota[1], M. Yang[1], S. Shikhel[1], M.R. Lewis[2], M.D. Ward[3], D.S. Goldfarb[4], J.A. Tischfield[1].* 1) Dept Gen, Rutgers Univ, Piscataway, NJ; 2) Faculty Med, Imperial Coll, London, UK; 3) Dept Chem, New York Univ, NY, NY; 4) NYU Langone Med Ctr, NY, NY.

Background: Slc3a1 knockout mice excrete cystine in the urine, but males from age 3 months also have cystine stones in the bladder and kidney. Current therapies for cystinuria are inadequate and little progress has been made in this area. Our recent in vitro studies have shown that cystine dimethyl ester (CDME), a structural analog of cystine, inhibits cystine crystallization by attaching to cystine crystal surfaces, thus blocking their further growth. CDME may provide a paradigm shift for the treatment of cystinuria. Methods: We gave CDME (200 µl of 1 mg/ml) or water only daily by gavage to 2-month old cystinuria male mice for 4 weeks to determine whether this compound reduces bladder stone formation. Following treatment, urine samples were analyzed for amino acids by HPLC. Animals were then sacrificed and bladders examined by micro computed tomography (micro CT). Analysis of urine and stone samples was carried out by LC-MS. Results: In the CDME group (n = 14), 7 mice had small stones and 7 had no stones. In the control group (n = 11), 6 mice had small-to-large stones and 5 had no stones. The number of stones per bladder in the CDME group ranged from 16-45 (total 181). The number of stones per bladder in the control group ranged from 1-19 (total 47). All stones in the CDME group were in the size range 0.5 to 2 mm except one, which was 3 mm. The control group had a wide variation in stone size, ranging from 0.5 to 2.0 mm (41 stones) to 9 mm (1 stone). In the CDME group, mean weight of the stones was 29.2 +/- 14.8 mg and in the control group it was 55.2 +/- 28.0 mg. The difference in stone burden in the bladder between the CDME and water groups was clearly evident by micro CT. There was no difference in cystine excretion between the CDME and water groups, suggesting that urine was saturated with cystine in both groups. Analysis by LC-MS of urine and stone extracts from the CDME group demonstrated the presence of cysteine methyl ester, suggesting that a metabolite of CDME, rather than CDME itself, was incorporated into the crystal structure. Conclusions: CDME-treated mice had a significantly smaller stone mass and more stones, but the stones were of a smaller size range compared with the water-treated mice. These studies strongly suggest that, as in vitro, CDME is inhibiting the growth of cystine crystals into large stones in vivo. CDME had no apparent side effects, suggesting that this compound may have potential for the treatment of cystinuria.

1470F

Restoration of impaired nitric oxide production in MELAS syndrome with citrulline and arginine supplementation. *A. El-Hattab[1], J.W. Hsu[2], L.J. Wong[1], W. Craigen[1], F. Jahoor[2], F. Scaglia[1].* 1) Dept Molec & Human Gen, Baylor Col Med, Houston, TX; 2) Dept Ped, Baylor Col Med, Houston, TX.

Background The mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome is one of the most common mitochondrial disorders. The pathogenesis of stroke-like episodes remains unclear. However, it has been suggested that mitochondrial proliferation may result in endothelial dysfunction and decreased nitric oxide (NO) availability leading to cerebral ischemic events. This study aimed to assess NO production in adult subjects with MELAS syndrome and the effect of oral supplementation with the NO precursors arginine and citrulline. Methods Using a stable isotope infusion technique, we measured NO synthesis, amongst other related variables, in 10 control adult subjects and 7 adult subjects with MELAS syndrome before and after arginine or citrulline supplementation. Results Adult subjects with MELAS syndrome had lower NO synthesis rate and plasma arginine and citrulline concentrations, higher plasma arginine clearance rate, and lower citrulline flux and *de novo* arginine synthesis. In subjects with MELAS syndrome, arginine and, to a greater extent, citrulline supplementation increased the *de novo* arginine synthesis rate, the plasma concentrations and flux of arginine and citrulline, and NO production. Conclusions The lower NO production in subjects with MELAS syndrome is primarily due to decreased *de novo* arginine synthesis secondary to decreased citrulline availability. *De novo* arginine synthesis increased markedly with citrulline supplementation, explaining the superior efficacy of citrulline in increasing NO production. The improvement in NO production with arginine or citrulline supplementation supports their use in MELAS syndrome and suggests that citrulline may have a better therapeutic effect than arginine. These findings can have a broader relevance for other disorders where perturbations in NO metabolism occur.

1471F

Bezafibrate differentially impacts respiratory chain deficiencies resulting from various mtDNA mutations. *S. GOBIN-LIMBALLE[1], J. WONG[1], D. CHRETIEN[1], Z. ASSOULINE[1], V. SERRE[1], L. NONNEN-MACHER[2], S. MONNOT[1], A. ROTIG[1], P. DE LONLAY[1], AS. LEBRE[1], M. RIO[1], A. MUNNICH[1], J. STEFFANN[1], JP. BONNEFONT[1].* 1) Paris Descartes University, Inserm unit U781, and Genetics Department, Necker Hospital, Paris, France; 2) Metabolic Biochemistry unit, Necker Hospital, Paris, France.

Inherited disorders of mitochondrial oxidative phosphorylation result from mutations in nuclear or mitochondrial DNA (mtDNA) genes. mtDNA disorders have a maternal inheritance, a high transmission risk, and their clinical severity depends on the tissue distribution of the mutant load (heteroplasmy rate). To date, no therapeutic approach has revealed to be efficient to treat these disorders. Bezafibrate (BZF), an agonist of the PPAR transcription factors, might be a relevant candidate drug, based on its capacity to activate the NRF1-2/PGC1(pathway, a major regulator of mitochondrial biogenesis. A recent study reported an improvement of the respiratory chain (RC) function after BZF treatment of cybrids homoplasmic for mutations of mt.tRNA genes. There are however no available data regarding primary cell lines from patients with mutations of mtDNA genes encoding a RC subunit. We have analyzed the effect of BZF on RC functions, using fibroblasts from 2 controls and 5 patients with a mtDNA mutation affecting either complex I (CI, m.13514A>G in ND5) or complex V (CV, m.8993T>G or m.9185T>C in ATP6, NARP/Leigh syndromes). The two CI-deficient cell lines had 20% and 50% mutant loads, respectively, while the three CV-deficient lines were homoplasmic mutants. Our data indicate that BZF: 1/ does not modify the lactate level in culture media from control and mtDNA mutated cell lines as well, thus ruling out a hypothetical adverse effect of BZF in mtDNA mutated patients, 2/ stimulates CI enzyme activity in ND5-mutant cells and controls as well (+ 50 %), without impacting CV activity in ATP6-mutant cells, 3/ increases the mtDNA copy number in CI-mutant cells and controls as well (+150%), without affecting CV-mutant cells, 4/ mildly decreases the m.13514A>G heteroplasmic mutant loads (- 6 %), but has no effect on m.8993T>G / m.9185T>C homoplasmic mutant loads, 5/ increases a number of transcripts from nuclear (NRF1 and PGC1(transcription factors, POLG1 mtDNA polymerase, superoxide dismutase 2) but also mitochondrial genes (ATP6 and ND5 RC subunits), both in CI and CV-deficient lines. These data indicate that BZF i) has a variable impact on RC deficiencies secondary to a mtDNA mutation, depending on the mutation type and/or the mutant load, ii) is able to rescue in vitro a CI enzyme deficiency resulting from a mutation of a mtDNA-encoded CI subunit, and therefore, iii) might be a candidate drug for treating patients carrying such mutations at a heteroplasmic state.

1472F

Reduction of NADPH-oxidase activity ameliorates the cardiovascular phenotype in a mouse model of Williams-Beuren syndrome. *L.A. Perez-Jurado[1,2], M. Segura[1,2], V. Terrado[1,2], C. Sanchez-Rodriguez[3], M. Coustets[1], M. Menacho-Marquez[4], J. Nevado[2,5], X. Bustelo[4], U. Francke[6], V. Campuzano[1,2].* 1) Unitat de Genetica, DCEX, Universitat Pompeu Fabra, Barcelona, Spain; 2) Centro de Investigación Biomédica en Red de Enfermedades Raras, CIBERER, ISCIII, Spain; 3) Unidad de Investigación, Hospital Universitario de Getafe, Madrid, Spain; 4) Centro de Investigación del Cáncer e Instituto de Biología Molecular del cáncer de Salamanca (IMBCC). CSIC-Universidad de Salamanca, Salamanca, Spain; 5) INGEMM-Instituto de Genética Médica y Molecular / IdiPAZ, Madrid, Spain; 6) Department of Genetics, Stanford University School of Medicine, Stanford, CA. USA.

Williams-Beuren syndrome (WBS) is a developmental disorder with multisystemic manifestations caused by a segmental aneusomy of 1.55Mb at chromosomal band 7q11.23, which includes the elastin gene (*ELN*). A hallmark feature of WBS is a generalized arteriopathy due to elastin deficiency, presenting as stenoses of medium and large size arteries and leading to hypertension and other cardiovascular complications. Currently, there is not enough data available to recommend specific drug therapy for the hypertension in WBS. Deletion of a functional *NCF1* gene copy has been shown to protect a proportion of WBS patients against hypertension, likely through reduced NADPH-oxidase (NOX) mediated oxidative stress. We studied a mouse model for WBS cardiovascular disease, carrying a 0.67Mb heterozygous deletion including Eln (DD). DD mice presented with a generalized arteriopathy, hypertension and cardiac hypertrophy, associated with elevated angiotensin II, oxidative stress parameters, and *Ncf1* expression. We then crossed DD mice with an Ncf1 mutant, to generate double heterozygous mutants (DD/*Ncf1*-), mimicking the genotype of WBS individuals with lower cardiovascular risk. In addition, DD mice were also treated (groups of prenatal and postnatal onset) with either angiotensin II type 1 receptor blocker (losartan) or NOX inhibitor (apocynin), in an attempt to reduce NOX activity. DD/*Ncf1*- and all groups of treated DD mice revealed almost complete control of the hormonal and biochemical parameters, with normalized blood pressure and improved cardiovascular histology with respect to the untreated DD animals. Our data provide strong evidence for implication of the redox system in the cardiovascular pathophysiology of a mouse model of WBS. The phenotype of these mice can be ameliorated by either genetic or pharmacological intervention reducing NOX activity, likely through reduced angiotensin II-mediated oxidative stress. Therefore, anti-NOX therapy merits evaluation to prevent potentially serious cardiovascular complications of WBS, as well as in other cardiovascular disorders mediated by similar pathogenic mechanism.

1473F

Elevated cerebral spinal fluid Calbindin-D levels in Niemann-Pick Disease, type C and response to miglustat therapy. *N.M. Yanjanin[1], A. Remaley[2], M. Sampson[2], F.D. Porter[1].* 1) PDGEN, NICHD/NIH/DHHS, Bethesda, MD; 2) CCS, DLM, CC/NIH/DHHS, Bethesda, MD.

Niemann-Pick Disease, type C (NPC) is a rare, autosomal recessive lysosomal storage disorder characterized by impaired transport of glycosphingolipids and unesterified cholesterol. Intracellular accumulation of lipids results in neuroinflammation and microglial activation as well as induction of the autophagic pathway and loss of neurons. Clinical manifestations of NPC range from fetal ascites to adult-onset dementia, but the classic phenotype presents with childhood onset of progressive neurodegeneration. There is currently no FDA approved therapy. A randomized trial using miglustat, an inhibitor of glyscosphingolipid synthesis, showed improvement of neurological symptoms after one year but long-term efficacy has not been established. Protein biomarkers are a recent focus of rare disease research as surrogate endpoints to facilitate development of therapeutic interventions. Protein markers in cerebrospinal fluid (CSF) have been useful in diagnosing and describing neurodegenerative diseases, and provide insight regarding pathological mechanisms and disease status.

Calbindin-D is a vitamin D-dependent calcium binding protein localized predominately in cerebellar Purkinje cells, and is released into CSF as a result of cerebellar damage. Purkinje cell loss is a hallmark of NPC and histology of Npc1-/- cerebella shows progressive loss of Purkinje cells. Calbindin-D from CSF of 42 NPC1 patients enrolled in an observational study at the NIH and 30 pediatric controls was quantified using ELISA.

Initial analysis of Calbindin-D shows significant elevation in NPC1 patients ($p<0.0001$). In a cross-sectional analysis, Calbindin-D levels did not correlate with age or disease status, likely due to the large degree of inter-patient variation. Off label miglustat use in 19/42 (45%) of NPC1 patients resulted in lower Calbindin-D CSF values compared to those not taking the drug, but this was not statistically significant. However, in five patients evaluated prior to initiation of miglustat therapy and 6-15 months after therapy was started, we observed a significant decrease (mean = -33%) of Calbindin-D in the CSF after initiation of miglustat. These results help validate the use of Calbindin-D as a biomarker and support therapeutic efficacy of miglustat for treatment of NPC.

1474F

Recovery of peroxisome dysfunction by flavonoid compounds in fibroblasts from Zellweger spectrum patients having the common allele, PEX1-Gly843Asp. *G. MacLean[1], S. Steinberg[3], N. Braverman[1, 2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Montreal Children's Hospital Research Institute, Montreal, Quebec, Canada; 3) Kennedy Krieger Institute, Department of Neurogenetics, Baltimore, MD, USA.

Zellweger spectrum disorder (ZSD) is due to defects in any one of 12 proteins, encoded by PEX genes, that are required for peroxisome biogenesis. ZSD features neurologic, hepatic and renal abnormalities; however, one common mutation, PEX1-p.Gly843Asp (G843D), confers a milder phenotype and represents 30% of all ZSD alleles. Thus, identifying treatments for this allele will benefit many patients. We recently showed that PEX1-G843D behaves as a misfolded protein amendable to improved function by chemical and pharmacological chaperones. In a small molecule screen, we reported functional recovery of peroxisomal matrix protein import by acacetin diacetate, a flavonoid that may bind to the ATP binding domain of PEX1-G843D to improve conformation. In order to develop a lead compound from this library `hit', we evaluated an additional 40 flavonoids using a patient fibroblast cell line hemizygous for PEX1-G843D and expressing the PTS1-GFP reporter, as described previously. Recovery of PTS1-GFP peroxisomal import was determined by visually scoring the number of cells with punctate vs. cytosolic GFP fluorescence. Eight flavonoids were identified as potential pharmacological chaperones and a dose response experiment showed that diosmetin (EC_{50}, 2.75 μM), acacetin diacetate (EC_{50}, 7.5 μM), acacetin (EC_{50}, 0.5 μM), apigenin (EC_{50}, 15 μM), and kaemferol (EC_{50}, 20 μM) were most effective, while tamarexitin, galangin, and chrysin showed little effect. These findings will aid in determining structure activity relationships, as knowledge of chemicals that are effective and ineffective will be used to determine the interactions that are important in developing a pharmacophore model. We further reasoned that recovery of Pex1p protein folding should improve PEX1p's interaction with PEX6p and localize to the peroxisomal membrane. Thus, we examined the subcellular localization of PEX1p after drug treatment. A PEX1-G843D hemizygote cell line was treated with various flavonoids and peroxisome enriched fractions were isolated by differential centrifugation to obtain the nuclear pellet, cytosolic fraction and peroxisome enriched fraction. Immunoblotting of these fractions showed that following treatment, PEX1p was increased in the peroxisome enriched fraction. We are continuing these experiments to analyze localization of PEX1p binding partners, PEX6p and PEX26p, and the receptor protein PEX5p. Blue Native PAGE will also be utilized to determine complex formation.

1475F

Histone deacetylase inhibitor suberoylanilide hydroxamic acid normalizes the levels of very long chain fatty acids in human skin fibroblasts from X-Adrenoleukodystrophy patients and downregulates the expression of proinflammatory cytokines in Abcd1/2 silenced mouse astrocytes. *J. SINGH, M. KHAN, I. SINGH.* PEDIATRICS, MEDICAL UNIVERSITY OF SOUTH CAROLINA, CHARLESTON, SC., USA.

X-Adrenoleukodystrophy (X-ALD) is a peroxisomal metabolic disorder, caused by mutations in the ABCD1 gene encoding the peroxisomal ABC transporter adrenoleukodystrophy protein (ALDP). The consistent metabolic abnormality in all forms of X-ALD is an inherited defect in the peroxisomal) -oxidation of very long chain fatty acids (VLCFA>C22:0) and the resultant pathognomic accumulation of VLCFA. In addition to the deficient degradation of VLCFA, elongation of very-long-chain-fatty acids (ELOVL) also contributes towards VLCFA cellular homeostasis. The accumulation of VLCFA leads to a neuroinflammatory disease process associated with demyelination of the cerebral white matter. The present study underlines the importance of a potent HDAC inhibitor suberoylanilide hydroxamic acid (SAHA) in inducing the expression of ABCD2 (ALDRP), and normalizing the peroxisomal) -oxidation as well as the saturated and monounsaturated VLCFAs in cultured human skin fibroblasts of X-ALD patients. The expression of ELOVL1, the single elongase catalysing the synthesis of both saturated VLCFA (C26:0) and mono-unsaturated VLCFA (C26:1), was also reduced by SAHA treatment. In addition, using Abcd1/Abcd2-silenced mouse primary astrocytes we also examined the effects of SAHA in VLCFA-induced inflammatory response. SAHA treatment decreased the inflammatory response as expression of inducible nitric oxide synthase, inflammatory cytokine, and activation of NF-2B in Abcd1/Abcd2-silenced mouse primary astrocytes was reduced. The observations indicate that SAHA corrects both the metabolic disease of VLCFA as well as secondary inflammatory disease; therefore, it may be an ideal drug candidate to be tested for X-ALD therapy in humans.

Homocystinuria: Treatment with N-acetylcysteine. *B.M. GILFIX.* Medical Biochemistry, Royal Victoria Hospital, Montreal, Quebec, Canada.

Introduction: Homocsytinuria (MIM 236200) due to cystathionine) -synthase deficiency (CBS; EC 4.2.1.22) is the most common inborn error of sulfur amino acid metabolism. Treatment of CBS deficiency has traditionally been based on the supplying additional cofactor (vitamin B6), substrate restriction (low methionine diet) or activation of an alternative pathway for Hcy metabolism (betaine). Betaine is the current mainstay in the treatment of vitamin B6 unresponsive patients. Unfortunately, it is rather expensive at 233$ per 180 g (Cystadane®, Orphan Medical Inc.). Moreover, individuals treated with betaine may still fail to normalize their tHcy (< 15 µmol/L). Hultberg et al (1994) first demonstrated that oral N-acetylcysteine (NAC) reduced total plasma homocysteine in healthy subjects in a dose-dependent fashion; possibly by increasing renal excretion of tHcy. Based on this and similar observations, we sought to determine if oral N-acetylcysteine (NAC) would reduce plasma total homocysteine levels in subjects with homocystinuria. Methods: Five subjects (4 female; 1 male) with CBS deficiency were recruited. Subject C was vitamin B6 responsive. All were maintained on their usual medications during the course of the study. After 2 visits at one-month intervals to establish a baseline total plasma homocysteine (tHcy), the subjects received oral NAC (2 g p.o. BID) for 2 months. tHcy was measured twice during this period and once more after the NAC had been discontinued for 1 month. DNA from each individual was sent for sequencing to a commercial provider. Results: tHcy levels recorded at one month intervals: Pt. A: 20.5; 26.4; 20.1 (+NAC); 14.6 (+NAC); 28.7 Pt. B: 109.0; 160.0; 202.4 (+NAC); 113.9 (+NAC); 255.4 Pt. C: 209.0; 246.3; 158.5 (+NAC); 177.3 (+NAC); 154.5 Pt. D: 48.4; 88.9; 20.0 (+NAC); 21.3 (+NAC); 17.2 Pt. E: 236.0; 189.3; 156.4 (+NAC); 132.5 (+NAC); 134.6 Mutations Identified [†=not previously described]: Subject A (Eastern European) - c.833C>T (I278T); IVSII-2 A>C; Subject B (French Canadian) - c.313C>G (L105V)†; c.1676G>A (A222T); Subject C (Eastern European) - c.526G>A (E176K); c.1039G>A (G347S); Subject D (Eastern European) - c.430G>C (E144Q)† ; IVSII-2 A>C; Subject E (African & French Canadian) - c.919G>A (G307S); c.941G>C (V314A)†. Conclusions: NAC failed to produce a discernable decrease in tHcy levels. Three novel CBS mutations were identified. [Supported by the March of Dimes Foundation].

1477F

Disease-causing allele specific silencing against the *ALK2* mutants, *R206H* and *G356D*, in Fibrodysplasia Ossificans Progressiva. *H. Hohjoh[1], M. Takahashi[1], T. Katagiri[2], H. Furuya[3].* 1) NCNP, Natl Inst Neuroscience, Tokyo, Japan; 2) Division of Pathophysiology, Research Center for Genomic Medicine, Saitama Medical University, Hidaka-shi, Saitama, Japan; 3) Department of Neurology, Neuro-Muscular Center, National Omuta Hospital, Fukuoka, Japan.

Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant congenital disorder characterized by progressive heterotopic bone formation. Currently, there is no definitive treatment of FOP. The *activin-like kinase 2* (*ALK2*) gene, a bone morphogenetic protein (BMP) receptor gene, has been identified as the responsible gene for FOP, and a recurrent mutation, *617G>A (R206H)*, has been found in both familial and sporadic FOP cases of various ethnic groups. The mutant ALK2 receptors appear to gain function(s) as a constitutively-active BMP receptor, thereby triggering heterotopic bone formation without binding to BMPs in FOP. Chemical inhibitors of the BMP type I receptors are currently considered possible medicinal agents for FOP; but, they appear to affect not only pathogenic (mutant) ALK2 receptors but also normal ALK2 and also other BMP type I receptors. Thus, the risk of side effects of the inhibitors cannot be excluded. In this study, we show small interfering RNAs (siRNAs) conferring disease-causing allele specific RNA interference (RNAi) against the *617G>A* and *1067G>A ALK2* mutants found in FOP patients. Our designed siRNAs successfully inhibited the expression of the mutant *ALK2* alleles without affecting normal *ALK2* allele. Our current study suggest that the siRNAs presented here may be capable of becoming a novel therapeutic agent for FOP, and that disease-causing allele-specific RNAi by the siRNAs may pave the way for the achievement of radical treatment for FOP and/or for the relief of its severe symptoms.

1478F

Small interfering RNAs targeting oncogenic EGFR alleles as a possible cancer agent. *M. Takahashi[1], T. Chiyo[2], T. Okada[2], H. Hohjoh[1].* 1) Department of Molecular Pharmacology, NCNP, Kodaira, Tokyo, Japan; 2) Department of Molecular Therapy, NCNP, Kodaira, Tokyo, Japan.

Selective silencing of dominant oncogenic allele by RNA interference (RNAi) is a promising treatment for certain types of cancers possessing dominant mutations involving nucleotide changes in the coding regions of oncogenes. In the case of medical application of RNAi to cancer therapy, the ability of RNAi on allele discrimination is critical for avoidance of side-effects because many proto-oncogenes (namely, normal alleles) play important roles in normal cells and tissues. In this study, we show small interfering RNAs (siRNAs) conferring allele-specific RNAi (ASP-RNAi) against mutant *epidermal growth factor receptor* (*EGFR*) gene found in lung cancer and glioma patients. We designed and assessed siRNAs targeting two recurrent deletions in *EGFR* by using our in vitro assay system, and selected the most effective siRNAs against such *EGFR* mutations. Allele-specific silencing using the siRNAs in either chemo-sensitive or -resistance human lung cancer cells resulted in the significant inhibition of cell proliferation and induction of cell death. We further carried out *in vivo* studies using xenograft models of chemoresistant human lung cancer cells. The data indicated that a single injection of the siRNA conferring ASP-RNAi were able to remarkably inhibit the growth of xenograft tumors without altering toxicological parameters such as body weight and hematological indexes. When siRNAs targeting wild-type (normal) *EGFR* were used, significant alterations in several hematological parameters were detected, suggesting adverse effects of such siRNAs targeting both mutant and wild-type (normal) alleles. Our present data indicated that cancer therapy using ASP-RNAi against mutant *EGFR* could be a potential treatment with few adverse effects, even though cancers possess anti-cancer drug resistance.

Intrathecal Enzyme Replacement Therapy for Neurological Impairment in Mucopolysaccharidosis 1. *Z. Hadipour, F. Hadipour, P. Sarkhail, Y. Shafeghati.* Medical Genetics, Sarem Cell Research Center & Hospital, Tehran, Iran.

Bachground: MPS1 is an autosomal recessive disorder caused by deficient activity of the lysosomal enzyme alpha-L iduronidase, which leads to accumulation of heparan sulfate and dermatan sulfate, resulting in a progressive multisystem disease with respiratory, skeletal , and neurologic manifestations. Treatment for MPS1 consists of supportive care, symptom - based interventions, and enzyme - replacement therapy with Laronidase. Bone marrow and hematopoietic stem cell transplantation is the treatment of choice for patients suffering from MPS1 with no or minimal central nervous system manifestation. Case Report: A 50 months -old Iranian boy Who has phenotype of MPS1, coarse facial features, prominent forehead, corneal cloudy, sleep disturbance, hepatosplenomegaly, inguinal hernia, joint stiffness, and dysostosis multiplex congenital. He diagnosed MPS1 on the basis of clinical findings, an elevated urinary glycosaminoglycan level and low alpha- L- iduronidase activity in leukocytes. Mutation analysis revealed homozygous splice mutation in the IDUA gene. He has been started injection of aldurozyme intravenously every week from 26 months - old. To prevent neurological impairment before bone marrow transplantation, he receives intrathecal enzyme replacement of aldurozyme and samples of his CSF for testing monthly. He tolerates intrathecal ERT with no adverse events. When he is 50 months - old he receives bone marrow transplantation.

Gene and Stem Cell Therapy for Tay-Sachs and Sandhoff DiseaseS. *B.V. FEINERMAN[1], J. PAINO[2].* 1) RESEARCH, STEMCELLREGENMED, SARASOTA, FL; 2) SAN MARTIN COLLEGE OF MEDICINE, LIMA, PERU CLINICA SAN FELIPE HOSPITAL CONCEBIR HOSPITAL, LIMA, PERU.

Tay-Sachs and Sandhoff diseases have juvenile and infantile onsets. A normal child will start reversing development and be unable to turn over, crawl, sit, walk or talk. Later cognitive and intellectual development will be impaired. Previous treatments have involved giving medications to induce enzyme replacement; substrate reduction or correction of misfolded proteins. Six patients with Tay-Sachs and one child with Sandhoff disease were treated with a combination of gene and stem cell therapy. The children ranged in age from 19 months to eight years of age. Mutations of genes were deleted with specific shRNA. This was followed by retroviral transfection of the Hex A gene in patients with Tay-Sachs and Hex B gene in the patient with Sandhoff disease into neuron stem cells derived from umbilical cord blood. The transfected neuron stem cells were administered into the central nervous system and brain through the spinal canal. In addition brain derived neurotrophic factor, nerve growth factor, glial derived neurotrophic factor and neurotrophins 3 were given intrathecally. The procedure was well tolerated without any adverse effects. Two months following treatment 6 out of the 7 children showed improvment in loss of spasticity; ability to raise their arms and move their legs; 4 out of 7 lost their cherry red spots; 5 out of 7 appeared to have improved hearing; 3 out of 4 that had seizure activity appeared to have stopped; improved motion of head and neck 5 out of 7: improved swallowing in 3 out of 7. The patients came from a wide variety of locations in the USA, Brazil, Germany.

Gene therapy as a potential treatment of cardiomyopathy in propionic acidemia. *R.J. Chandler[1], N. Carrillo-Carrasco[1], S. Chandrasekaran[1], P.M. Zerfas[2], C.P. Venditti[1].* 1) Genetic and Molecular Biology Branch, National Human Genome Research Institute, National Institutes Health, Bethesda, Maryland; 2) Diagnostic and Research Office Branch, Office of the Director, National Institutes of Health, Bethesda, Maryland.

Propionic Acidemia (PA) is autosomal recessive metabolic disorder caused by a deficit in the enzymatic activity of propionyl-CoA carboxylase. Genetic defects in *PCCA* or *PCCB*, which code for propionyl-CoA carboxylase, result in PA. Patients with PA exhibit elevated levels of propionic acid and methylcitrate in their plasma and urine, and can present with potentially lethal metabolic decompensations, hyperammonemia, neurological complications, and a potentially lethal cardiomyopathy. These medical problems can arise and the cardiomypathy does progress in spite of current medical treatments. A therapy that stabilized the patients and/or addresses the progressive and often lethal cardiomypathy would be beneficial to patients. We have previously demonstrated the ability of rAAV8 gene delivery to rescue the murine model of PA from lethality and decrease the levels of disease related metabolites. In light of the cardiomyopathy observed in the human disease, the cardiac histology of the PA mouse model was examined to determine whether cardiac abnormalities were present. Oil red staining revealed an abnormal accumulation of lipid and electron micrographs (EMs) revealed gross abnormalities of the cardiac tissue in the PA mice. Specifically, the cardiac myofibers were poorly organized and reduced in number. However, cardiac EMs from the PA mice treated by rAAV8 gene delivery of the *PCCA* gene exhibited no abnormal histopathological changes. These results demonstrate the potential efficacy of rAAV8 gene delivery as an alternative treatment to transplantation for the potentially lethal cardiomyopathy observed in PA.

1482F

Dye laser photodynamic therapy for Bowen's disease in a patient with epidermodysplasia verruciformis. *K. Fukai[1], M. Sunohara[2], T. Ozawa[2], T. Harada[2], M. Ishii[1].* 1) Dept Dermatology, Osaka City Univ, Osaka, Japan; 2) Dept Plastic and Reconstructive Surgery, Osaka City Univ, Osaka, Japan.

Epidermodysplasia verruciformis (EV) is a rare heritable skin disease that results in unusual susceptibility to infection with specific types of human papillomavirus (HPV). Here we report a 53-year-old man with EV who developed Bowen's disease on his lower eyelid and the chest. Mutation analysis of EVER1 gene revealed homozygous splice acceptor site mutation (IVS8-2, A>T). In this patient, HPV3, HPV14 and HPV38 had been identified from the skin lesions. The Bowen's skin lesion on the left lower eye-led was treated by photodynamic therapy (PDT) using 5-aminolevulinic acid (ALA) and pulsed dye laser (PDL). After two rounds of the PDT treatment, the skin lesion disappeared and a skin biopsy confirmed the efficacy of the treatment. As the light source for PDT, we used a PDL set at the excitation wavelength (585 nm) for PpIX, which is the metabolite of ALA. The 585-nm PDL has been primarily used for the treatment of vascular lesions because it efficiently generates heat and thus damages tumor blood vessels. As HPV is sensitive to heat and warts have more prominent superficial blood vessel than healthy skin, PDL has already been used to treat common warts caused by HPV infection and the efficacy has been confirmed in multiple studies. Moreover, it has been reported that ALA combined with PDL was more effective for eliminating viral warts than either PDT or PDL alone.The fact that EV associated with Bowen's disease and warts are both caused by HPV infection could explain our finding that ALA-PDT with PDL was effective for treating Bowen's disease in the present patient. In other words, the effect of the PDL on tumor blood vessels and heat-sensitive HPV, in addition to the effect of PDT itself, could have contributed to the good response observed in this case, both histologically and cosmetically. This patient had Bowen's disease on the lower eyelid and was the first case to be successfully treated by ALA-PDT combined with PDL. This treatment was a less invasive and simpler method of achieving a satisfactory cosmetic outcome compared with other treatments. Patients with EV are highly susceptible to HPV infection and thus develop numerous and widespread lesions. Because they require repeated treatment, effective and minimally invasive therapy such as PDT described here could be beneficial for these patients.

1483F

Evaluation of the therapeutic potential of Ramipril in a murine model for Marfan syndrome. *B.L. Lima, G.R. Fernandes, L.V. Pereira.* Dept de Genética, Inst de Biociencias - USP, São Paulo, Brazil.

The Marfan syndrome (MFS) is an autosomal dominant disease of connective tissue, which affects 1 in 5,000 individuals. The main clinical manifestations include aneurysms and aortic disruption, excessive growth of bones, scoliosis and thoracic deformities. Mutations in the FBN1 gene, which encodes the fibrillin-1 protein, were genetically linked to the MFS, classifying this disease in the fibrilinopathies group. Studies with animals model for MFS demonstrated a strong negative correlation between overall levels of Fbn1 expression and the severity of the phenotypes. Fibrillin-1 alterations also lead to an increase in the activity of TGF in tissues, resulting in cardiovascular and pulmonary phenotypes. Thus, during the last years, therapeutic strategies, based on the use of drugs, have been studied in animal models and patients with MFS. Among these drugs we find the Losartan, an antagonist of AT1, which may restore the vascular and pulmonary phenotype in animal models. Clinical trials involving patients with MFS revealed that, even with the patients presenting improvements in vascular alterations, the results are far from those seen in animal models. The hypothesis is that the dose given to patients is not sufficient to reproduce the effects observed in animals, which received very high drug dose. During the year of 2010 our group evaluated the effect of Ramipril, an ACE inhibitor, on the phenotypic manifestations of SMF in the murine model mg$\Delta^{loxPneo}$. Treated animals showed an increase of approximately 35% in the FBN1 gene transcription, and a significant improvement in pulmonary and bone manifestation - the last has never been reported in other models for SMF treated with Losartan. Differently of studies involving Losartan, the treatment with Ramipril was realized with doses equivalent to those already used in humans. These results revealed that the restoration of normal levels of fibrillin-1 seem to have the potential to modulate the clinical severity of the disease, indicating new treatment possibilities.

1484F

BMN 111, a CNP analogue, promotes skeletal growth and rescues dwarfism in two transgenic mouse models of Fgfr3-related chondrodysplasia. *F. Lorget[1], N. Kaci[2], J. Peng[1], C. Benoist-Lasselin[2], F. Di Rocco[2], E. Mugniery[2], S. Bullens[1], S. Bunting[1], L. Tsuruda[1], C. O'Neill[1], A. Munnich[2], L. Legeai-Mallet[2].* 1) BioMarin Pharmaceutical Inc. 105 Digital Drive, Novato, California 94949 USA; 2) INSERM U781-University Paris Descartes-Necker Hospital - Enfants Malades, 75015 Paris, France.

Although Fgfr3-related chondrodysplasia genes were identified in 1994, no effective treatments are available to date and therapeutic interventions are limited to surgical procedures. The severity of Fgfr3-related dwarfisms ranges from mild (hypochondroplasia) to severe (achondroplasia) and lethal (thanatophoric dysplasia) depending on the point mutation. Patients with achondroplasia, the most severe form of dwarfism, display short stature with disproportionate shorter proximal bones (rhizomelia), narrow trunk, brachycephaly and spinal stenosis. C-type natriuretic peptide (CNP) is considered to be a potential therapeutic agent due to its inhibition of Fgfr3 downstream signaling. Targeted in vivo overexpression of a CNP transgene or continuous infusion of native CNP were shown to rescue the impaired bone growth in a mouse model of achondroplasia. To overcome the short half-life of native CNP, BioMarin developed a CNP analogue, BMN 111, with a longer half-life allowing daily subcutaneous administration. BMN 111 pharmacological activity was analyzed in two relevant mouse models of Fgfr3-related chondrodysplasia. In the $Fgfr3^{G380R}$ homozygous mouse model (Ach), the transgene expression is restricted to the chondrocytes while it is ubiquitously expressed in the $Fgfr3^{Y367C/+}$ heterozygous mouse model (TD). A more severe phenotype is observed with TD mice (shorter bones, pronounced prognathism, marked spinal stenosis and reduced lifespan). In a culture model using femurs isolated from TD embryos, BMN 111 co-incubation led to increased chondrocyte proliferation and differentiation, thus confirming BMN 111 mechanism of action. In the in vivo assessment of BMN 111 pharmacological activity, the Fgfr3 mice received daily subcutaneous BMN111 administrations from 6 days of age in the TD mice and three weeks of age in the Ach mice. The TD mice were treated for 10 days at dose levels up to 800 μg/kg. The Ach mice were treated for 5 weeks at dose levels up to 280 μg/kg. Overall, the treatment was well tolerated. A dose related increase in the axial and appendicular skeletons was measured in both models (~5-10% increase in the high dose groups). In addition, improvements in clinically relevant features were observed in the TD mice including rhizomelia, shape of the skull and spinal stenosis (normalization of the sagittal diameter of the atlas vertebra). Based on these data, BMN 111 is a potential therapeutic for chondroplastic disorders and warrants further development.

1485F

Modeling Machado-Joseph disease in C. elegans: genetic and pharmacologic rescue. *P. Maciel[1], A. Teixeira-Castro[1,2], A. Jalles[1], A. Miranda[1], C. Bessa[1], R. Morimoto[2].* 1) School of Health Sciences, University of Minho, Braga, Portugal; 2) Department of Molecular Biosciences, Northwestern University Institute for Neuroscience, Rice Institute for Biomedical Research, Northwestern University Evanston, IL 60208, USA.

The risk of developing neurodegenerative diseases increases with age. Although many of the molecular pathways regulating proteotoxic stress and longevity are well characterized, their contribution to disease susceptibility remains unclear. In this study, we describe a new Caenorhabditis elegans model of Machado-Joseph disease, also known as spinocerebellar ataxia type 3, a neurodegerative disease caused caused by expansion of a polyglutamine (polyQ) tract within the protein ataxin-3 (ATXN3). Pan-neuronal expression of mutant human ATXN3 leads to a polyQ-length dependent, neuron subtype-specific aggregation and neuronal dysfunction. Analysis of different neurons revealed a pattern of dorsal nerve cord and sensory neuron susceptibility to mutant ataxin-3 that was distinct from the aggregation and toxicity profiles of polyQ-alone proteins. This reveals that the sequences flanking the polyQ-stretch in ATXN3 have a dominant influence on cell-intrinsic neuronal factors that modulate polyQ-mediated pathogenesis. Aging influences the mutant ATXN3 aggregation and toxicity phenotypes in our model, which can be suppressed by the genetic or pharmacologic downregulation of the insulin/ insulin growth factor-1-like signaling pathway and activation of heat shock factor-1. We are currently using this model to test a library of 1,200 FDA-approved compounds in order to find pharmacological modulators of mutant ATXN3 aggregation and neuronal dysfunction. We have completed the toxicity screening and identified 618 compounds that were non-toxic for the worms. In our screening we are using as endpoints ataxin-3 aggregation, as quantified by an imaging software we developped, and motility assessment of transgenic worms. So far, we have found three promising small molecules that reduce the neurological phenotype of this model, and we are exploring the manner in which they may target cellular pathways linked to disease pathogenesis.

1486F

Truncal obesity in Cohen syndrome and its potential treatment. *H. Wang, A. Bright, L. Nye, B. Xin.* DDC Clinic for Special Needs Children, Middlefield, OH.

Cohen syndrome is a rare autosomal recessive disorder with less than 200 cases reported worldwide. The disease is characterized by facial dysmorphism, microcephaly, hypotonia, developmental delay, myopia and retinal dystrophy, neutropenia, and truncal obesity. Mutations in VPS13B (also known as COH1) gene on chromosome 8q22 are believed responsible for the syndrome. However, the pathogenesis and pathology of the condition is unclear, thus how to treat those signs and symptoms in this disease often becomes difficult. The truncal obesity, for example, as one of the most prominent health issues in patients with Cohen syndrome after they reach their teenage, is still poorly understood and its treatment remains challenging. The purpose of this study is to better understand the development and progress of the obesity, and to find effective measures of weight control. As a part of the comprehensive study, a questionnaire was distributed to the families of the confirmed Cohen patients registered in our National Cohen Syndrome Family Support Center with 54 surveys completed, 27 from Amish and 27 from non-Amish. The average patient age is 16.8 years (range from 1.5 to 45), with 43% male and 57% female. Preliminary data indicated that 46% of parents reported their affected child being overweight, with the average age of developing overweight at 12 years old (Amish 14.6 years old, non-Amish 9 years old). However, at the time truncal obesity developed, 52% of parents reported a fairly normal food intake in these children. Excessive eating was only noted in 20% of patients. Nonetheless, neither significant hypercholesterolemia nor hypertriglyceridemia was observed in this cohort. Various behavior problems such as anxiety and attention deficit and hyperactivity were noted by parents. A stimulant nethylphenidate was used in 5 patients who had attention deficit and hyperactivity, anxiety and obesity. We found significant improvements in the psychosocial behaviors in all 5 patients. The body mass index (BMI) in all five patients was also significantly improved with the treatment. Our preliminary results show that the treatment of psychosocial and behavioral problems with the stimulant may bring a favorable outcome for the truncal obesity in these patients.

Discovery Partnerships with Academia - A New Option for Moving Genetic Learnings to a Medicine. *R.A. Gibson[1], I. Uings[1], M.J. Bamford[1], J. Collins[2], P. Williams[1], D. Holmes[1].* 1) Academic DPU, GlaxoSmithKline, Stevenage, Herts, United Kingdom; 2) Academic DPU, GlaxoSmithKline, Research Triangle Park, North Carolina, USA.

The global academic Genetics community generates many innovative ideas for new therapeutic targets, but translating this innovation into medicines can be challenging and resource intensive. GlaxoSmithKline (GSK) has established Discovery Partnerships with Academia to provide a way to bring together the insight of the academic world with the complementary expertise and capabilities of GSK in joint, target-focused, early drug discovery projects to identify and develop potential medicines. Discovery Partnerships with Academia operates globally and cross-therapeutically, and is looking for partners who really want to be involved in developing a medicine. Suitable projects have a compelling therapeutic hypothesis, and are at a stage where partnership with GSK will make a key contribution to success. GSK applies its resources to these projects in many ways, including development of robust assays, lead identification (using conventional screening, rational design and encoded library technology), medicinal chemistry and preclinical development. This work is fully integrated with the activities ongoing in the academic groups. By aligning this expertise with the academic's deep understanding of disease biology, we ensure that the very best molecules are selected for clinical progression. An overview of the Discovery Partnership model will be presented, highlighting the opportunities that it offers academic researchers to progress their research towards creation of a medicine. Examples of how these partnerships work in practice will also be provided.
