Mutations in the NSUN2 gene cause autosomal recessive intellectual disability in Middle Eastern populations with elevated frequency. *L. Abbasi Moheb[1], S. Mertel[2], L. Nouri Vahid[3], K. Kahrizi[3], A. Tzschach[1], D. Wieczorek[4], M. Garshasbi[1], S. Cirak[5], SS. Abedini[3], H. Najmabadi[3], HH. Ropers[1], S. Sigrist[2], AW. Kuss[1,6].* 1) Human Molec Gen, Max Planck Inst Molec Gen, Berlin, Germany; 2) Genetics, Institute for Biology, Freie Universität Berlin, Berlin, Germany; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 4) Institut für Humangenetik, Universitätsklinikum , Essen, Germany; 5) The Dubowitz Neuromuscular Centre, University College London Institute of Child Health London, UK; 6) Current address: Institute for Human Genetics, Interfaculty Institute for Genetics and Functional Genomics, Ernst Moritz Arndt University, Greifswald, Germany.

During the course of our investigations into the autosomal recessive causes of intellectual disability (ARID) we have previously identified numerous new loci for this condition.Interestingly, so far no more than six hotspot loci for unspecific or non-syndromic autosomal recessive intellectual disability (NS-ARID) have been identified (Kuss et al. 2011, Human Genetics Vol.129, 141-148). In this study we now resolved the underlying gene defect of MRT 5 and report three deleterious mutations in NSUN2. These were found in two independent consanguineous Iranian families and one Turkish family with several patients suffering from non-syndromic ARID. NSUN2 encodes a methyltransferase, which catalyzes the intron-dependent formation of 5-methylcytosine at C34 of tRNA-leu(CAA). Two of the observed changes were nonsense mutations (p.Q227X and p.Q372X), which cause a complete loss of NSUN2 transcripts in the patients. In the third family we found an intronic exchange of an adenosine for a guanine 11 nucleotides upstream of exon 6. This change causes exon 6 to be skipped during splicing and results in the loss of the main transcript. Hence all mutations lead to a loss of NSUN2 protein function in homozygous mutation carriers and thus in all likelihood cause the patient phenotype. In order to gain further evidence for an involvement of NSUN2 in cognitive functions, we studied fruit fly mutants that lack the NSUN2 ortholog. These experiments revealed a marked learning impairment in mutant flies, which clearly underscores the relevance of NSUN2 in higher brain functions.

Identification and Mapping of locus on the long arm of chromosome 4 that is associated with mental retardation and optic atrophy in a Qatari family with undelineated autosomal receive disease. *Y. Al-Saraj, M. Osman, Y. Bejaoui, G. Billedo, E. Abuazab, H. El-Shanti, J. Alami.* Molecular Genetics, Shafallah Medical Genetics Center, Doha, Qatar.

Autosomal recessive diseases are the single largest category of single-gene disorders among Arab population. Our goal is to identify undelineated autosomal recessive disorders among families in the Arab world especially in the gulf region and discovery the genetic causes of these recessive disorders. A Qatari family includes 6 individual from 3 related consanguineous sibships, with mental retardation. The clinical picture comprised significant mental retardation, retinal degeneration, Optic nerve atrophy, and ataxic gait. They suffer also from oedemal puffiness of hands and feet. All parents and the unaffected family members are healthy. Homozygosity mapping revealed a 19.6 MB segment in the long arm of chromosome 4 flanked by rs4345237 (4q12) and rs422140 (4q13.3). This interval contains more than 100 genes, none of which has been implicated in any of the above mentioned phenotype so far. Candidate genes were selected and we are in the process of sequencing them.In addition, whole exome sequencing will be perfomed to expedite the mutation identification.

1102W

The Syndrome of Mental Retardation, Epilepsy and Cerebellar Atrophy Maps to Chromosome 20p11.21-q11.23. *F. BAYRAKLI[1], M. CANPOLAT[2], H. PER[2], S. KUMANDAS[2], E. PINARBASI[3], I. GUNEY[4].* 1) NEUROSURGERY, CUMHURIYET UNIVERSITY SCHOOL OF MEDICINE, SIVAS, Turkey; 2) CHILD NEUROLOGY, ERCIYES UNIVERSITY SCHOOL OF MEDICINE, KAYSERI, Turkey; 3) MEDICAL GENETICS, CUMHURIYET UNIVERSITY SCHOOL OF MEDICINE, SIVAS, Turkey; 4) MEDICAL GENETICS, MARMARA UNIVERSITY SCHOOL OF MEDICINE, ISTANBUL, Turkey.

Aim To locate chromosomal locus which is possibly disease causative gene lie in Methods The family was identified in Eastern Turkey after the index cases presented to medical attention with symptoms of mental retardation, epilepsy and gait disorders. Genotyping and linkage analysis was done using the GeneChip Mapping 250K Nsp I Array (Affymetrix Inc., Santa Clara, CA) containing nearly 250000 SNP markers for genome wide linkage analysis, according to the company's protocols using affected children and their parents. Multipoint linkage analysis was performed using the Allegro software. We assumed an autosomal recessive inheritance pattern and assigned a penetrance of 0.999. Results SNP allele frequencies were estimated from Affymetrix data on the Caucasian population. Using these parameters, a theorical maximum logarithm of the odds (LOD) score of 2.69 was identified at chromosome 20p11.21-q11.23. Interpretation Parametric linkage analysis of consanguineous pedigrees has proven a powerful means for disease gene discovery in Mendelian disorders and an important approach for identifying biological pathways relevant in common, complex phenotypes. Here we demonstrated the power of linkage analysis to identify possible causative gene's chromosomal locus which is novel in a family presenting with epilepsy, mental retardation, and cerebellar atrophy.

Genetic basis of a new form of hereditary hyperekplexia. *J. Capochichi[1,2], L. Patry[1,2], M.E Samuels[1,2], J.L Michaud[1,2].* 1) Centre de Recherche du CHU Sainte-Justine, Montréal, Québec, Canada; 2) Centre of Excellence in Neuroscience of Université de Montréal (CENUM).

Hyperekplexia (HK; [MIM 149400]) is a rare genetic disorder characterized by neonatal hypertonia and startle reflex induced upon tactic or auditory stimuli. HK is associated with the disruption of glycine signaling, which inhibits synaptic activity in motor systems. In humans, mutations in the genes coding for the presynaptic glycine transporter (GLYT2), the glycine receptor (1 (GLYRA1) and) 1 (GLYRB1) subunits and the receptor clustering proteins Gephyrin (GPHN) and Collybistin (ARHGEF9) are known to cause HK. We observed a new form of HK in four female siblings from a consanguineous family from Cambodian origin. In addition to severe HK, all four girls showed small birth weight, microcephaly with simplified gyral structure, and burst suppression on the electroencephalogram. They could not breathe by themselves and died a few days after birth. Sequencing of known HK genes did not reveal any pathogenic mutation. To study the molecular basis of this new phenotype, we performed whole genome SNP genotyping of all four siblings using the Illumina 610 Quad panel. Using Plink software, we identified 12 regions of homozygosity (RH) composed of at least 25 consecutives SNP that are shared by the 4 siblings. The largest RHs (/ 2 Mb) were: 1) chr11:41 539 163-93 695 503 (~52 Mb); 2) chr22: 45 396 830-49 562 479 (~ 4 Mb); 3) chr18: 1 458 409-4 439 084 (~3 Mb); 4) chr10: 132 462 359-135 372 744 (~3 Mb).None of the known HK genes lie in the candidate RHs reinforcing our conclusion that the cause of this phenotype is due to an as yet unidentified gene. These RHs contain 8 genes (ACP2, ALG8, DHCR7, NDUFS3, NDUFS8, NDUFV1, RNASEH2C and SLC35C1) that have been associated with severe neonatal encephalopathy. Sanger sequencing of these genes did not reveal any pathogenic mutation. We are currently performing whole-exome sequencing in one of the affected siblings using the 50 Mb Agilent SureSelect biotinylated RNA library. We will establish a list of rare variants that are located in the candidate RHs. We will prioritize the validation of variants in genes that may play a role in inhibitory systems such as those mediated by GABA and glycine.

1104W

VCP gene analysis in sporadic ALS patients. *F.L. Conforti[1], W. Sproviero[1,2], I.L. Simone[3], G. Logroscino[3], P. Valentino[2], M.R. Monsurrò[4], V. La Bella[5], C. Rodolico[6], F. Bono[2], A. Patitucci[1], A. Magariello[1], L. Citrigno[1], M. Muglia[1], A. Chiò[7], A. Gambardella[1], R. Mazzei[1].* 1) Institute of Neurological Sciences, CNR Mangone, Cosenza, Italy; 2) Institute of Neurology,University Magna Graecia, Catanzaro, Italy; 3) Department of Neurological and Psychiatric Sciences, University of Bari, Italy; 4) Second Division of Neurology, Second University of Naples, Italy; 5) ALS Clinical Research Center, Bio.Ne.C, University of Palermo, Italy; 6) Department of Neurosciences, Psychiatric and Anaesthesiological Sciences, University of Messina, Italy; 7) ALS Center, Deaprtment of Neurosciences, University of Turin, Italy.

Valosin containing protein (VCP) is a highly conserved member of the AAA+ATPase family. It is highly expressed in all tissues where it has a variety of cellular functions, including protein homeostasis through the ubiquitin proteasome system (UPS) and autophagy pathways. It has been proposed that VCP mutants lead to TDP-43 mislocalization from the nucleus to the cytoplasm of transfected cells and transgenic mice; this results in neurodegeneration within motor neurons in the spinal cord. In accordance with these experimental data, it has been shown that mutations in the TDP-43 gene may cause Amyotrophic Lateral Sclerosis (ALS) in 2% of familial cases (FALS) and 1% of sporadic cases (SALS). The recent finding of mutations in the VCP gene as the cause of familial ALS, prompted us to investigate this gene in our cohort of SALS patients to better define the role of VCP as cause of neurodegeneration. Two hundred fifty-seven unrelated patients from South Italy with adult-onset ALS were diagnosed according to the El Escorial criteria. Following informed consent, DNA was extracted from whole blood using standard procedure. Molecular screening of the exons 2, 3, 5, 6, 10 and 14 of the VCP gene (NM_007126.3) has been performed by DHPLC and direct sequencing of the whole cohort of DNA samples. The DNA of all patients have been previously tested negative for mutations in SOD1, ANG, VAPB, TDP-43 and FUS genes. Genetic analysis of the VCP gene showed four intronic variants in 120 patients. One of these, c.129+47G>A has been found in 55 patients and has been already described (rs10972300; http://browser.1000genomes.org). The other substitutions detected represent three new viariants: c.576+10C>G was found in intron 5 in one patient, c.1194+38T>C found in intron 10 in 14 patients, and c.1082-21INS[TTGTGTACTGT] located in intron 9 and detected in 50 patients. Moreover, two silent mutations have been identified in exons 14, p.Q568Q, in four patients, and p.L574L, in one patient. Carrying any of these variants did not have any impact on ALS phenotype. Despite the biological evidence that VCP could be implicated in ALS, the current study suggests that VCP mutations are not a common cause of adult-onset sporadic ALS. However, it remains to be elucidated the role of the silent VCP variants, since these variations might affect mRNA's shape, its translation and degradation, as well as led to errors in the splicing process.

1105W

Spatacsin gene mutations are a frequent cause of recessive spastic paraplegia but are rare in juvenile recessive forms of amyotrophic lateral sclerosis. *C. Gellera, B. Castellotti, V. Pensato, R. Fancellu, E. Salsano, D. Pareyson, D. Di Bella, C. Mariotti, F. Taroni.* Unit of Genetics of Neurodegeneration, IRCCS - Istituto Neurologico Carlo Besta, Milano, Italy.

Mutations in the spatacsin gene are the major cause of spastic paraplegia with thin corpus callosum (HSP-TCC). The gene has been mapped to chromosome 15q21. It encodes a predicted protein of 2,443 amino acids, and has been associated to the phenotype classified as SPG11 (Stevanin G. et al, 2007). Moreover, a new form of recessive amyotrophic lateral sclerosis (ALS) was mapped to the same locus designated ALS5 (Hentati A. et al, 1998). More recently, mutations in the spatacsin gene have been found in association to recessive forms of ALS linked to 15q21 (Orlacchio A. et al, 2010). We have studied spatacsin gene in two different groups of patients affected by juvenile forms of HSP and ALS. Methods: Direct sequencing of spatacsin gene (40 exons) in i) 48 index cases presenting a sporadic (27 patients) or recessive (21 patients) juvenile form of lower limb spasticity, negative for paraplegin (SPG7) mutations. In this cohort TCC was present in 43% of cases (21 patients) and mental retardation in 35% (17 patients); ii) 45 index cases presenting a sporadic (18 patients) or recessive form (27 patients) of juvenile onset ALS. Results: i) In the HSP cohort we found 12 out of 48 patients positive for spatacsin mutations (25%). Three index cases, from healthy consanguineous parents, were homozygous for three different frame-shift mutations. Nine patients were compound heterozygous either for nonsense, splicing, frame-shift and missense mutations. Overall, we have identified 21 different pathological mutations that are predicted to cause absence of the spatacsin protein. ii) In the ALS cohort we found only one positive patient presenting as a compound heterozygous for two different missense mutations in exon 1. Conclusions: We have identified spatacsin gene mutations in 25% of patients with HSP(±TCC) and in 2% of juvenile ALS. The large majority of mutations are novel and they predicted to cause absence of the spatacsin protein. Our results favor the hypothesis that spatacsin mutations have a large prevalence in patients presenting a phenotype characterized by spastic paraplegia. We should also take in consideration that ALS5 is an intermediate form between ALS and spastic paraplegia, and although classified by some as ALS, it most closely resembles spastic paraplegia with atrophy of the lower extremities without bulbar involvement.

Identification of ANK3 as a novel gene for autosomal recessive intellectual disability. *Z. Iqbal[1], A. Razzaq[2], M. Shahzad[2], K. Neveling[1], L. Vissers[1], M. Yasir Zahoor[2], L. Tomas Roca[5], C. Gilissen[1], A. T. Vulto-van Silfhout[1], A. Schenck[1], J. A.Veltman[1], A. P.M. de Brouwer[1,3], S. Riazuddin[2,4], H. van Bokhoven[1,3].* 1) Department of Human Genetics, Nijmegen Centre for Molecular Life Sciences, Radboud University Nijmegen Medical Center, Nijmegen, The Netherlands; 2) National Centre of Excellence in Molecular Biology, University of the Punjab, Lahore 53700, Pakistan; 3) Department of Cognitive Neurosciences, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, The Netherlands; 4) Allama Iqbal Medical College, Lahore 54550, Pakistan; 5) Department of Human Anatomy and Psychobiology, School of Medicine, University of Murcia, Murcia, Spain.

Identification of the causative genes of autosomal recessive intellectual disability (ARID) has been challenging due to the extreme heterogeneity of the condition. Homozygosity mapping in consanguineous families has been proven to be very helpful in these type of disorders. Here, we have ascertained 60 ARID families from the Pakistani population in which there is a high degree of consanguineous marriages (>70%). Homozygosity mapping data revealed one or more homozygous regions per family ranging in size from 1-51Mb. No pathogenic copy number variations (CNVs) were found. On the basis of homozygosity mapping, we selected seven families with novel ARID loci for targeted next generation sequencing (NGS) of the specific homozygous regions, and six families for exome sequencing. Our NGS data revealed a number of potential mutations that are validated at the moment. In one family, PKMR14, this strategy has proven to be successful as we have identified a homozygous frameshift mutation in the ANK3 gene, affecting the largest brain specific isoform 1. A cohort of ID patients (from different ethnic backgrounds) with shared homozygous intervals encompassing ANK3 gene is being tested to identify additional mutations in this gene. Ankyrin 3 is an adaptor protein that links spectrin cytoskeleton to the integral membrane proteins. It has a crucial role in maintaining the neuronal polarity and molecular organization of the axon initial segments (AIS). Recently, in several independent genome wide association (GWAS) studies, ANK3 has strongly been associated with bipolar disorder, and also with schizophrenia, suggesting an important role of ANK3 in psychiatric and cognitive disorders. This result confirms that homozygosity mapping together with NGS is a powerful method to locate the genetic defect in consanguineous families.

Massively parallel sequence analysis reveals the causative gene of an autosomal recessive neurodegenerative disorder, posterior column ataxia with retinitis pigmentosa. *H. Ishiura[1], Y. Fukuda[1], J. Mitsui[1], Y. Nakahara[1], B. Ahsan[1], Y. Takahashi[1], Y. Ichikawa[1], J. Goto[1], T. Sakai[2], S. Tsuji[1].* 1) Dept Neurology, Univ Tokyo, Tokyo, Japan; 2) Dept Neurology, Himeno Hospital, Fukuoka, Japan.

[Background] Posterior column ataxia with retinitis pigmentosa (PCARP) is an autosomal recessive neurodegenerative disorder characterized by early-onset retinitis pigmentosa and slowly progressive sensory ataxia. Previous studies showed a linkage to 1q31-q32. However, detailed investigations on the clinical presentations as well as molecular genetics of PCARP have been limited. [Method] DNA samples from two affected siblings, an unaffected sibling, and consanguineous parents were obtained. Parametric linkage analysis was carried out under an autosomal recessive model using SNP arrays, a pipeline software SNP-HiTLink, and Allegro. After removal of repetitive regions, target capture with Sequence Capture 2.1M array (NimbleGen) was performed, followed by massively parallel sequence analysis (Illumina GAIIx). Short reads were aligned to a reference genome (hg18) with BWA and variant calling was performed with SAMtools. [Results] The patients suffered from childhood-onset retinitis pigmentosa and slowly progressive sensory ataxia. They also showed mild mental retardation, which had not been described in patients with PCARP. Linkage analysis revealed a highest LOD score of 1.93 in chromosome 1 and 20, spanning 30.3Mb. Candidate region on chromosome 1 was overlapped with known PCARP locus, refining the minimum candidate region to 7.1Mb. Massively parallel sequence analysis produced 37M reads with an average coverage of 89X. More than 10X coverage was obtained in 99.2% of bases with designed probes. Five novel nonsynonymous SNVs were found, two of which were called heterozygous and not confirmed by direct nucleotide sequence analysis. In one of the error site, the coverage was only 4X. In the other error site, biased strand balance was observed. Of the remaining three SNVs, only a novel homozygous missense mutation (c.1477G>C, p.G493R) in *FLVCR1* (feline leukemia virus subgroup C recepter 1) was located in the minimum candidate region. The mutation was not observed in 192 control chromosomes and G493 is evolutionally well conserved amino acid located in a transmembrane domain. [Conclusions] A recent study has also identified three independent mutations in *FLVCR1* in the original and other families. Our results further confirmed that mutations in *FLVCR1* cause PCARP. Our experience showed that high-throughput sequencing analysis along with SNP-based linkage analysis and target capture efficiently identified the causative gene even with a small family.

1108W

Novel disease mechanisms underlie ATP7A-related distal motor neuropathy. *S. Kaler[1], L. Yi[1], A. Donsante[1], P. Steinbach[2], J. Hicks[1].* 1) Unit on Human Copper Metabolism, Molecular Medicine Program, NICHD, NIH, Bethesda, MD; 2) Center for Molecular Modeling, Center for Information Technology, National Institutes of Health, Bethesda, MD.

ATP7A is a P-type ATPase that regulates cellular copper homeostasis via activity at the trans-Golgi network (TGN) and plasma membrane (PM). Alterations in ATP7A lead to Menkes disease, or its variants occipital horn syndrome and distal motor neuropathy, a newly discovered condition for which the precise pathophysiology is obscure. We characterized two ATP7A-related distal motor neuropathy mutations (T994I, P1386S). Confocal imaging of patient fibroblasts showed diffuse ATP7A signal. Total internal reflection fluorescence microscopy (TIRFM) indicated a shift in steady-state equilibrium of ATP7A-T994I and ATP7A-P1386S with increased plasma membrane (PM) localization. Transfection of 293T cells with the mutant alleles tagged with Venus fluorescent protein showed higher PM localization. Endocytic retrieval of the mutant alleles to the TGN was delayed. Sucrose gradient experiments suggested no abnormal association with PM lipid rafts. Transfection of NSC34 motor neurons indicated PM and axonal membrane localization of ATP7A-T994I and ATP7A-P1386S. In pull-down assays, we identified an abnormal interaction between ATP7A-T994I and VCP97, a TGN-resident protein implicated in the causation of two other inherited motor neuropathies. Co-transfections with a dominant negative VCP97 mutant and siRNA knock-down of VCP each resulted in correction of defective ATP7A-T994I localization. In flow cytometry experiments, we documented that non-permeabilized ATP7A-P1386S fibroblasts bound a C-terminal ATP7A antibody, consistent with intermittent relocation of the 8th transmembrane segment and a di-leucine endocytic signal to the extracellular from the cytoplasmic face of the PM. Based on these findings, we propose two hypotheses: 1) ATP7A-T994I causes disease via abnormal interaction with VCP9 and 2) ATP7A-P1386S induces motor neuron Cu deficiency by constitutive PM localization via partial loss of an endocytic signal. Our findings provide insights about ATP7A structure, function, and trafficking, and highlight the importance of copper homeostasis in the peripheral nervous system.

1109W

Why X? super X-ome sequencing for monogenic neuronal disease classes: intellectual disability and chemosensory impairment. *D. Lancet[1], D. Oz-Levi[1], T. Olender[1], E. Ben-Asher[1], I. Keydar[1], M. Khen[1], E. Ruzzo[2], K. Pelak[2], H. Resnik-Wolf[3], B. Ben-Zeev[3], Y. Anikster[3], D. Goldstein[2], E. Pras[3].* 1) molecular genetics, Weizmann Institute of science, Rehovot, Israel; 2) Molecular genetics and microbiology, Duke university, Durham, NC, USA; 3) The Genetic Institute, Sheba medical center, Ramat-Gan, Israel.

Malfunctioning of the central nervous system may result in diverse phenotypes, from significant intellectual disability (ID) to congenital general anosmia (CGA), a complete inability to perceive smells. We maintain that such broadly-defined disease classes, with equal probability of gene disposition on all chromosomal genome territories, are statistically more likely to be visible in an X-linked disposition. A very large number of underlying genes are known for ID, of which nearly 200 are found on human chromosome X (a large number, as argued). In contrast, precious little is know about the genetic underpinning of CGA. However, we predict that for CGA, with expected highly heterogeneous etiology, X chromosome excess will be observed too. ID still constitutes a major challenge, as it seems that the gamut of causative mutations is far from being exhausted, leaving numerous families without prenatal diagnosis. We have recruited a dozen Israeli families of different ethnic origins, showing both syndromic and non-syndromic ID, as well as other X-linked neuronal disorders. In parallel, we identified 10 families and ~60 sporadic cases of CGA. In at least one case, the identified syndrome includes both ID and CGA. Among syndromic families, ID is also accompanied with neurological anomalies causing a neurodegenerative disease and early death. In a preliminary study, we have identified by standard whole exome-sequencing two causative genes for rare neurodevelopmental autosomal recessive diseases. Based on the above statistical argument, we now focus on generating an enhanced capacity for mutation detection on chromosome X. To this end, we designed a novel X chromosome `super X-ome' capture kit. This includes all coding and non-coding exons, with extended splice junction regions for protein-coded genes. We have also included MiRNAs and other RNA genes, regulatory regions, promoters and enhancers, as well as highly conserved genomic regions. Also included are the entire genomic regions for 93 known XLMR related genes (Chiurazzi et al. EJHG 16:422-34 ,2007). For the relevant analyses, we are developing next-generation-sequencing bioinformatics tools suitable for super X-ome. Deciphering the disease-causing mutations will shed new light on the mechanisms of the ID and CGA disease classes, with implications to other neuronal deficits, and would provide the relevant families with accurate genetic testing and prenatal diagnosis.

Mechanism of recurrent expansion of a 700kb deletion on chromosome 14q causing dopa-responsive dystonia and ptosis. *K. Lohmann[1], H. Tönnies[2], S.B. Bressman[3,4], I. Nagel[2], A. Rakovic[1], A. Haake[2], J.I.M. Subero[2], K. Wiegers[1], F. Hinrichs[5], Y. Hellenbroich[5], D. Raymond[3], L.J. Ozelius[6], E. Schwinger[5], R. Siebert[2], R. Saunders-Pullman[3,4], C. Klein[1].* 1) Section of Clinical and Molecular Neurogenetics at the Department of Neurology, University Lübeck, Lübeck, Germany; 2) Institute of Human Genetics, Christian-Albrechts-University Kiel and University Hospital Schleswig-Holstein, Campus Kiel, Kiel, Germany; 3) Department of Neurology, Beth Israel Medical Center, New York, NY, USA; 4) Department of Neurology, Albert Einstein College of Medicine, New York, NY, USA; 5) Institute of Human Genetics, University Lübeck, Lübeck, Germany; 6) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY, USA.

DNA rearrangements are increasingly recognized as disease causes. We previously identified a patient with dopa-responsive dystonia (DRD) who carried a heterozygous deletion of all six exons of the GTP cyclohydrolase 1 (GCH1) gene on chromosome 14q22. The deletion not only comprised the GCH1 gene but also 23 additional annotated genes in a 3,370kb region. Mutational analyses in his family members revealed the same mutation in the three affected relatives (paternal aunt and two of her sons) tested. All mutation carriers also presented with ptosis, and two had congenital digit abnormalities. Surprisingly, the father of the index patient who was considered an obligate carrier of the deletion did not carry this deletion, despite confirmed paternity. This person and his mother carried a smaller 670kb-deletion downstream of GCH1 as demonstrated by haplotype analysis. Notably, this deletion expanded twice independently in this family to the same deletion of ~3,370kb. All deletions were confirmed by quantitative PCR, by array comparative genomic hybridization (aCGH), and by fluorescence in situ hybridization (FISH). The expansion was mediated by a 13kb-duplication at the centromeric breakpoints of both deletions. This suggests that intrachromosomal nonallelic homologous recombination between low-copy repeats is the underlying cause for the recurrent expansion. Our data demonstrate that (1) co-occurrence of apparently unrelated disorders (in this case DRD and ptosis) may suggest a polygenic deletion, and (2) that the elucidation of the genetic mechanism leading to recurrent expansion of a deletion contributes to a better understanding of the origin of large deletions, an important type of mutation.

1111W

A patient affected by CADASIL carrying a novel mutation on the exon 7 of the NOTCH3 gene. *R. Mazzei[1], C. Ungaro[1], M. Muglia[1], F. Ruscica[2], W. Sproviero[1], A. Patitucci[1], L. Citrigno[1], A. Magariello[1], A. Gambardella[1], F.L. Conforti[1].* 1) Institute of Neurological Sciences CNR, Mangone (CS), Cosenza, Italy; 2) Fondazione Istituto San Raffaele - G. Giglio, Cefalù, Palermo, Italy.

CADASIL is an autosomal dominant disorder leading to cognitive decline and dementia. Mutations in the NOTCH3 gene, encoding a transmembrane protein involved in cellular signalling and cell differentiation, are responsible. These highly stereotyped mutations are located within the 22 exons, encoding for the 34 Epidermal Growth Factor (EGF)-like repeats of the extracellular domain of the Notch3 receptor, all mutations resulting either in a gain or loss of a cysteine residue. Therefore it has been suggested that the unpaired cysteine residues, generated by these mutations, may cause aberrant interaction of the Notch3 receptor with its ligand. In the present study we examined the NOTCH3 gene exons in a patient with clinical and radiological findings consistent with CADASIL. After clinical evaluation the patient underwent MRI investigation, and then she was analyzed for mutations in the NOTCH3 gene using the DHPLC analysis and direct sequence. The DHPLC analysis revealed a variant profile in exon 7. Sequencing of the exon 7 showed a nucleotide change leading an amino acid substitution at position 379 (C379G), resulting in a loss of a cysteine residue in the 9th EGF-like domain. This is the first time that we find a mutation in the exon 7 in more than 700 patients recruited in our Institute with clinical suspect of CADASIL. We believe that C379G is pathogenic due to four main points: 1) It is a typical mutation of CADASIL patients, involving a cysteine residue substitution. 2) No other pathogenic mutation previously reported was seen by direct sequencing of exons 2-23 of NOTCH3 gene in this patient. 3) This mutation was not seen in more than 100 population-matched controls. 4) A mutation involving the same cysteine residue (C379S) was reported as pathogenic.

1112W

iPS cells to model Rett spectrum disorders. *I. Meloni[1], M. Amenduni[1], R. De Filippis[1], A.Y. Cheung[2], F. Ariani[1], F. Mari[1], M.A. Mencarelli[1], Y. Hayek[3], J. Ellis[2,4,5], A. Renieri[1].* 1) Medical Genetics, Department of Biotechnology, University of Siena, Siena, Italy; 2) Developmental & Stem Cell Biology Program, SickKids, Toronto, Ontario, Canada; 3) Child Neuropsychiatry, University hospital of Siena, Siena, Italy; 4) Ontario Human iPS Cell Facility, SickKids, Toronto, Ontario, Canada; 5) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Rett syndrome (RTT) is a progressive neurologic disorder that represents one of the most common causes of mental retardation in females. Mutations in 3 genes have been associated with this condition. Classic RTT is caused by mutations in the *MECP2* gene, while variants can be due to mutations in either *MECP2*, *FOXG1* or *CDKL5.* In particular, mutations in *CDKL5* gene have been identified in females with the early onset seizure variant of RTT but also in males with X-linked epileptic encephalopathy. CDKL5 is a kinase protein highly expressed in neurons, but its exact function inside the cell is unknown. To address this issue we employed the recently developed technology of genetic reprogramming that allows to reprogram patients fibroblasts into induced Pluripotent Stem Cells (iPSCs); these cells can be subsequently used to model the disease in vitro by inducing neuronal differentiation. We successfully derived iPSCs from two patients with CDKL5 mutations: one female with p.Q347X and one male with p.T288I mutation. Analysis of CDKL5-mutated clones confirmed that female iPSCs retained X-chromosome inactivation and we could identify clones expressing either the mutant or the wild type CDKL5 allele. These last clones represent the ideal experimental control since they are genotypically identical to those expressing the mutant allele and only differ for CDKL5 expression. The clones could be successfully differentiated into neurons in vitro with variable but reproducible efficiency. Interestingly, clones derived from the same fibroblasts but expressing different alleles (either wild type or mutant) differentiated with comparable efficiency. Results of comparison of neuronal differentiation in wild type and mutant CDKL5 expressing clones will be presented. Future experiments comparing neuronal differentiation in clones derived from patients with mutations in *MECP2*, *CDKL5* and *FOXG1* will allow to define the functional role of the three genes and to check whether they might participate to common pathways, as suggested by the similar phenotypes resulting from their mutations. These cells will also represent an invaluable tool for in vitro testing of new therapeutic compounds.

A novel *SACS* mutation in a family with atypical phenotype of autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS). *S. Miyatake[1,2], N. Miyake[1], K. Ogata[2], M. Kawai[2], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University, Yokohama, Kanagawa, Japan; 2) Department of Neurology, National Hospital Organization Higashi-Saitama Hospital, Saitama, Japan.

Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS) is an inherited neurodegenerative disorder with the clinical features of early-onset spastic ataxia, nystagmus, axonal and demyelinating neuropathy, pyramidal tract signs, finger and foot deformities, and hypermyelination of retinal nerve fibers. We encountered a patient with spinocerebellar ataxia from a Japanese consanguineous family. He first walked after two years of age. Walking unsteadiness was obvious in his first decade, and was slowly progressive. He became wheelchair-bound at 44 years of age. On neurological examination at 54 years of age, he had cerebellar ataxia, positive Babinski sign, diminished or disappeared deep tendon reflexes except for patellar tendon reflex, muscle atrophy and weakness of lower extremities without spasticity, decreased deep sensation. Interestingly, he showed the autonomic symptoms such as urinary urgency, impotence, and severe constipation. Pes cavus and hammer toe deformity were noticed. He had normal intellectual ability. Hypermyelination of retinal nerve fibers was not observed. There were no abnormal biochemical findings. MRI findings revealed cerebellar atrophy, especially in the upper vermis, linear pontine hypointensities, and cervicothoracic spinal atrophy. Based on their consanguinity suggesting that this disease inherits in autosomal recessive fashion, we performed homozygosity mapping using a proband and three unaffected siblings by GeneChip Human Mapping 10K XbaI (Affymetrix) and Allegro version2.0. We identified 10 informative homozygous regions. Within these regions, *SACS*, which was located on 10.3-Mb homozygous region at chromosome 13 with the maximum LOD score 1.55, was the only known causative gene for spinocerebellar ataxia. Although he lacks a few major symptoms of ARSACS such as spasticity and hypermyelination of retinal nerve fibers, other clinical symptoms were similar to those of ARSACS. By direct sequencing, a novel homozygous missense mutation was identified in the patient. In this pedigree, cosegregation of this homozygous mutation with the disease in the autosomal recessive manner was confirmed. This missense mutation occurred at the evolutionally conserved amino acid. Four of 5 computational prediction algorithms predicted this mutation to be pathogenic. This mutation was not detected in 186 normal Japanese chromosomes. This patient was diagnosed as atypical ARSACS, demonstrating the clinical diversity of ARSACS.

1114W

Aniridia and autism in a Greek male child with a de-novo heterozygous PAX6 (Arg317X) mutation. Is there a linked etiopathogenesis? *A. Psychogios.* Department of Pediatrics, Quillen College of Medicine , Johnson City, TN.

PAX6 gene, a member of the paired box gene family, encodes a transcriptional regulator involved in early human developmental processes, predominantly in the eye, brain and pancreas. PAX6 mutations primarily cause aniridia characterized by iris hypoplasia, foveal hypoplasia and nystagmus presenting in early infancy. Different types of mutations lead to different ocular phenotypes in later life including cataract, glaucoma, keratitis, Peter's anomaly, microphthalmia, and coloboma. Autism is a highly variable brain developmental disorder with a strong genetic basis. There is emerging evidence of the roles of PAX6 mutations in behavioral and neurodevelopmental phenotypes such as autism spectrum disorders and mental retardation. We describe a 3 ½ -year-old Greek male child with almost total bilateral aniridia, foveal hypoplasia, pendular nystagmus, and keratopathy. The maternal family history is positive for bilateral 2-3 syndactyly and grandfather's colon cancer at age 39. There was no history of consanguinity, chromosomal abnormality, inborn error of metabolism, brain, eye, pancreatic, renal, genital, or mental disease. The proband gradually acquired symptoms of autism-spectrum disorder since the age of 2 years with predominant language and developmental delay,and a peculiar food aversion to all but milk. On examination, his weight was 12.6 kg (<2%), his height 86 cm, had broad forehead, bilateral aniridia, horizontal nystagmus, low set ears with stenotic external canals, round nasal tip, anteverted nares, short neck, inverted nipples, 2-3 toe syndactyly, mild hypotonia, ataxia, and tip-toe walking. Blood karyotype and FISH testing were normal. Sequencing of PAX6 gene revealed an exon 11, c.1311C>T (p.Arg317X) mutation. Parental mutation analysis and eye examination were normal. Brain MRI identified a Chiari I malformation. In conclusion, patients with aniridia or other eye-brain abnormalities and autism may share a common etiopathogenesis. Detailed ophthalmologic evaluation for subtle abnormalities, targeted imaging and functional brain studies, family history interpretation, careful genetic clinical examination and testing for PAX6 mutations may be considered in selected cases in the clinical research setting.

The Genetic Basis of SPG36 - a Novel Disease Mechanism. *R. Schüle[1], N. Schlipf[2], F. Schiele[1], C. Beetz[3], A. Dürr[4, 5], S. Klimpe[6], A. Lossos[7], S. Otto[8], F. Santorelli[9], L. Schöls[1], P. Bauer[2].* 1) Dpt. of Neurodegenerative Disease, Hertie Institute for Clinical Brain Research, Tuebingen, Germany; 2) Dpt. of Medical Genetics, University of Tuebingen, Tuebingen, Germany; 3) Institute for Clinical Chemistry and Laboratory Diagnostics, University Hospital Jena, Jena, Germany; 4) Departmente of Genetics and Cytogenetics, Groupe Hospitalier Pitié-Salpêtrière, Paris, France; 5) INSERM U975, Federation de Neurologie, Paris, France; 6) Department of Neurology, University of Mainz, Mainz, Germany; 7) Department of Neurology, Hadassah University Hospital, Jerusalem, Israel; 8) Department of Neurology, Ruhr-University Bochum, Bochum, Germany; 9) Department of Molecular Medicine, IRCCS Bambino Gesu Hospital, Rome, Italy.

Objective: To identify the gene responsible for autosomal dominant HSP (SPG36) Background: Hereditary Spastic Paraplegias are genetically exceedingly heterogeneous. We have recently mapped a new locus for autosomal dominant HSP (SPG36) in a German family to chromosome 12q23-24. SPG36 is characterized by an adult onset and peripheral nerve involvement. The SPG36 locus comprises 13.09Mb and contains >210 genes. Design/Methods: targeted exon enrichment (NimbleGen Sequence Capture Array), next generation sequencing (454 FLX Genome Sequencer, Roche), high resolution comparative genomic hybridization (CGH custom array, NimbleGen) Results: No pathogenic variations were identified in 29 candidate genes examined by conventional Sanger sequencing. Therefore next generation sequencing was performed after targeted exon enrichment of the whole SPG36 locus. 97.4% coverage of the region yielded 98 variants but no pathogenic variant shared by the two affected family members examined. Screening for genomic deletions by HR-CGH identified a 27kb-deletion that co-segregates with the disease. This deletion partially deletes one gene and the adjacent intergenic region. Loss of the poly-A signal of this gene leads to formation of a fusion mRNA containing parts of two neighboring genes. The fusion transcript was verified by RT-PCR in blood and fibroblasts of affected family members. Conclusions: By applying state of the art genetic techniques we were able to identify a genomic deletion to be the cause of autosomal dominant HSP SPG36. A fusion mRNA is formed, containing parts of two adjacent genes and presumably leading to a combined hyploinsufficiency/overexpression phenotype. Pathophysiological characterization of this unique disease mechanism is underway. Study supported by: Deutsche Forschungsgemeinschaft (grant SCHO 754/4-1), E-Rare program of the European Union (grant to EUROSPA 01GM0807).

Targeted Resequencing for Gene Discovery in Joubert Syndrome. *P. Taylor[1], H. Lee[1], SF. Nelson[1,2].* 1) Department of Human Genetics, University of California, Los Angeles, California, USA; 2) Department of Pathology and Laboratory Medicine, and Psychiatry, David Geffen School of Medicine, University of California, Los Angeles, California, USA.

Background: Next generation sequencing (NGS) builds upon the successes of linkage for disease gene discovery and is particularly powerful for disorders where large pedigrees are not available. In fact, NGS approaches make it possible to identify variants that underlie rare diseases by sequencing just a few cases, and in some instances single individuals suffice. This approach is therefore very promising for the analysis of Mendelian disorders and has already proven to be successful in a number of studies. Methods: We applied this approach to discover novel genes in patients affected with Joubert Syndrome (JBST), a rare brain malformation disorder belonging to the growing class of disorders known as ciliopathies. Although JBST is inherited in an autosomal recessive fashion, it shows marked genetic and phenotypic heterogeneity as several genes have been identified in recent years. There are more than 10 genes that are mutated in patients with JBST, however these mutations account for only about 50% of all known cases. The genes for other forms of the disease have not yet been found. All known JBST disease genes affect the structure and/or function of primary cilia and it is likely that other primary cilia genes are causal for JBST but have yet to be discovered. To maximize the success of gene discovery, we created a custom capture array designed to pull down key cilia genes. The array targets the protein-coding sequence of 169 candidate genes amounting to 1Mb of target. We made libraries for 14 individuals affected with JBST, barcoded each using in-house barcodes, hybridized the pool of libraries to the custom capture array and finally sequenced the pool on a single lane of Illumina HiSeq. Results: We generated 1.5Gb of paired-end sequence data with a mean coverage of 90X per sample. The sequencing data was aligned using Novoalign and variants were called using the Genome Analysis Toolkit. Variants were filtered against common variants found in dbSNP and 1000 genomes. Because JBST is a recessive disorder, we focused on variants causing changes in the final protein product. Conclusions: Targeted sequencing of these 14 individuals has provided a great opportunity for gene discovery by scanning functionally relevant candidate genes to identify novel causal genes in JBST. This approach could also be applied to efficient rare variant detection on more commonly diagnosed disorders such as ADHD and autism.

A Novel STXBP1 Mutation in Genetic Focal Seizure with Neonatal Onset. *M. Vatta[1], M.B. Tennison[2], A.S. Aylsworth[3], C.M. Turcott[3], M.P. Guerra[4], C. Eng[1], Y. Yang[1].* 1) Dept Molecular Human Genetics, Baylor Col Medicine, Houston, TX; 2) Department of Pediatric Neurology,University of North Carolina, Chapel Hill, NC; 3) Department of Pediatric Genetics/Metabolism, University of North Carolina, Chapel Hill, NC, USA; 4) Department of Pediatrics/Child and Adolescent Neurology, University of Texas-Houston Medical School, Houston, TX.

Mutations in the STXBP1 gene have been mainly associated with early infantile epileptic encephalopathy (EIEE), also known as Ohtahara syndrome, which is characterized by suppression-burst pattern on surface electroencephalogram (EEG). In addition to EIEE, mutations in STXBP1 have been identified in subjects presenting with West syndrome, which demonstrates hypsarrhythmia pattern on EEG, and early-onset epileptic encephalopathy (EOEE), a severe form of epilepsy with EEG features diverging from a specific epilepsy syndrome, although mostly evolving to West syndrome within the first five months of age. More recently, the spectrum of phenotypes associated with STXBP1 gene mutations has included non-syndromic intellectual disability (NSID) with or without nonsyndromic epilepsy. So far, 15/24 (62.5%) reported STXBP1 mutations have been associated with EIEE, 2/24 (8.33%) with West syndrome, 4/24 (16.7%) with EOEE, 2/24 (8.3%) with NSID + Epilepsy and 1/14 (4.16%) with isolated NSID. The STXBP1 mutations reported thus far include gross deletions, nonsense mutations, splice site mutations, small deletions and insertions and missense mutations, indicating that haploinsufficiency is the disease-causing mechanism for STXBP1. Here we present a de novo, novel single-nucleotide duplication mutation, c.931dupT (p.S311fsX3), in exon 11 of STXBP1 in a four month-old Caucasian infant who developed focal seizures at two weeks of life. The EEG demonstrated normal background frequency content with multifocal sharp waves and no evidence of suppression-burst pattern or hypsarrhytmia. Therapy with Levetiracetam and Oxcarbazepine effectively managed the seizure episodes. Previously normal testing includes brain magnetic resonance imaging (MRI) and Computerized Axial Tomography (CT) scan and SCN1A, SCN1B and ARX gene testing. In conclusion, we have identified a novel mutation in STXBP1 in a subject with neonatal-onset genetic focal seizures, which broadens the phenotypic spectrum of STXBP1 mutations. STXBP1 gene sequence testing and copy number analysis may be considered for patients with EIEE, EOEE, other neonatal or infantile-onset epilepsies, as well as NSID with or without epilepsy.

A Nijmegen breakage syndrome family with four affected members and three carriers having malignancies. *F. Ozkinay[1], E. Karaca[2], H. Onay[2], N. Karaca[1], G. Aksu[1], B. Erturk[2], N. Kutukculer[1].* 1) Dept Pediatrics, Ege Univ, Izmir, Turkey; 2) Department of Medical Genetics, Ege Univ, Izmir, Turkey.

Nijmegen breakage syndrome (NBS) is a rare autosomal recessive chromosomal instability disorder characterized by progressive microcephaly, “bird-like” facial appearance, short stature, mental retardation, severe combined immunodeficiency, recurrent infections, radiosensitivity and a predisposition to malignancy. Here we present the clinical and pedigree analysis of a large family with Nijmegen breakage syndrome. The proband was a 13 year-old male with typical dysmorphological features of NBS and combined immunodeficiency. His parents were first cousins. They had two previous children having the same clinical findings, both of whom had died from leukemia at an early age. The paternal grandmother and grandfather were also consanguineous and had a child with similar features who died of leukemia at the age of 7.5. Detailed pedigree analysis revealed three different cancers (uterus, breast and thyroid cancers) in three phenotypically normal family members, two surviving, one deceased (uterus cancer). Molecular analysis showed a homozygous 657del5 mutation in the proband's NBN gene. The surviving two family members with cancer were heterozygous for the same mutation. This family successfully demonstrates that homozygous NBN 657del5 mutation causes classical NBS phenotype whereas heterozygous NBN 657del5 mutation appears to be associated with an increased risk of cancer in phenotypically normal carriers.

Study of undelineated autosomal recessive disorder among Arabs. *J. Alami, Y. Al-Saraj, Y. Bejaoui, M. Osman, E. Abuazab, M. El-Dow, H. El-Shanti.* Shafallah Medical Genetics Center, Doha, Qatar.

The aim of this study is to map loci and identify genes that play a role in autosomal recessive disorders among Arab families and to examine their role with the final aim of outlining novel genes and pathways. The investigation capitalizes on utilizing large inbred families, as well as smaller inbred families, by employing homozygosity approaches for mapping the etiologic genes. It includes the recruitment of families and obtaining detailed clinical, genealogical and genotypic data. This is followed by examining these families for linkage and association Families with pedigrees that provided convincing evidence of autosomal recessive mode of inheritance and with consanguinity were selected. We performed homozygosity mapping on one recruited family to seek a region of homozygosity shared by affected individuals. This family includes eight individuals from 4 related sibships in an extended Palestinian family who suffer from isolated congenital cataract. Homozygosity mapping revealed a region flanked by rs4276160 (3p22.1) and rs749512 (3p21.31) on on the short arm of chromosme 3. This interval contains 92 genes, none of which has been implicated in eye disease. Further investigation for this family is currently underway using whole exome sequencing to identify the causative gene mutation.

1120W

Familial Alzheimer's disease with amyloid precursor protein D678N mutation: a case report. *V. Andreoli[1], F. Trecroci[1], A. La Russa[1], M. Liguori[1], P. Spadafora[1], G. Di Palma[1], A. Gambardella[1-2], R. Cittadella[1].* 1) Institute of Neurological Sciences-National Research Council, Pianolago di Mangone, Cosenza, Italy;; 2) Institute of Neurology-Campus di Germaneto, University “Magna Graecia”, Catanzaro, Italy.

Alzheimer's disease (AD) is the most common cause of dementia and may be either familial or sporadic. Genetically, AD is heterogeneous, as it displays no single or simple mode of inheritance. Notably, the clinical presentation of familial forms of AD (FAD) is more complex, and mutations of the Presenilin 1 (PSEN1) gene on chromosome 14, Presenilin 2 (PSEN2) on chromosome 1 and Amyloid-beta precursor protein (APP) on chromosome 21 have also been described in these patients. Overall, mutations in these genes result in an increased amyloidogenic processing of APP: this seems to be the key pathological mechanism of FAD. Nowadays, 24 different missense mutations located in exons 16 and 17 of APP have been reported. Here, we describe a subject bearing the APP D678N mutation who developed a peculiar early-onset (EO) FAD phenotype. The patient was enrolled at the Institute of Neurology, University “Magna Graecia” in Catanzaro, and informed consent was obtained for genetic study at the Institute of Neurological Sciences, National Research Council, Cosenza, Italy. The exonic regions 4-13 of PSEN1, 3-12 of PSEN2 and 16-17 of APP genes were PCR amplified by specific primers, and a mutational screening was done by DHPLC and direct sequencing. The patient is a 71-year-old man who developed, since the age of 58 years, progressive memory loss and visuospatial problems. At follow-up, he became disoriented in time and space, apathic, with reduction in verbal fluency, attention and planning. At the age of 66 years, the result of MMSE was 17. In five affected individuals of the same family, the age at onset of cognitive disorders started from 50 to 65 years, while the age at death ranged between 62 and 80 years. Genetic analysis of the proband's PSEN1 and PSEN2 genes disclosed no abnormalities, whereas analysis of the APP gene showed a GAC to AAC nucleotide substitution in codon 678 EX 16 of this gene, causing an amino acid substitution of aspartic acid to asparagine in heterozygosis. This pathogenic D678N mutation of APP gene was already reported in a Japanese family, in which mean age at onset clustered around the age of 60 years. Our data confirm that APP is actually an EO-AD gene, in which onset occurs primarily prior to 65 years of age and often much earlier; and for a given mutation, ages at onset seem to be tightly clustered.

1121W

Mutations in *RAB40AL* cause Martin-Probst syndrome, an X-linked disorder characterized by sensorineural hearing loss, cognitive impairment, short stature, and craniofacial dysmorphisms. *J.K. Bedoyan[1], V. Schaibley[2], W. Peng[2], Y. Bai[3], K. Mondal[4], A.C. Shetty[4], M. Durham[1], A. Dhiraaj[1], J.M. Skidmore[1], J.B. Kaplan[1], C. Skinner[5], R.E. Stevenson[5], C.E. Schwartz[5], A. Antonellis[2], M.E. Zwick[4], J.D. Cavalcoli[3], J. Li[2,3], D.M. Martin[1,2].* 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 4) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 5) Greenwood Genetic Center, Greenwood, SC.

Martin-Probst syndrome (MPS; MIM 300519) is a rare inherited disorder characterized by sensorineural hearing loss, cognitive impairment (CI), short stature (SS), and distinct craniofacial dysmorphisms (CDs). Interestingly, MPS has some characteristics similar to Costello and Noonan syndromes, including SS, CI, and specific CDs. Previously, microsatellite marker analysis identified a common haplotype region on the X chromosome spanning 68 Mb and containing 683 genes. In this study, SNP array comparative genomic hybridization excluded deletions or duplications in the common region with an average resolution of 1.5 kb. Whole-genome and exome sequencing in two affected males from the same family with MPS yielded 100% sequence coverage for 96.4% of exons and identified a D59G variant in the *RAB40AL* gene. The remaining genes expressed in the fetal nervous system were analyzed by direct sequencing and no additional potentially damaging or pathogenic variants were identified. D59G lies within a highly conserved region of RAB40AL and segregates with the phenotype in the family. We identified, in an unrelated male with clinical features identical to those reported in MPS, two variants (G47A and E113D) in *RAB40AL*. All three *RAB40AL* variants were absent by direct sequencing of 363 control males obtained from the Greenwood Genetic Center and Coriell, and in 206 exomes. *RAB40AL* has been implicated previously in severe CI in a male with an inversion disrupting the *RAB40AL* promoter region. We found that *RAB40AL* is expressed in MPS relevant fetal and adult human tissues, including brain. *RAB40AL* (previously *RLGP*) encodes a distinct Ras-like GTPase protein with one SOCS box. SOCS box-containing proteins act as part of a multiprotein complex and interact with Cullin-RING E3 ubiquitin ligase complexes which polyubiquitinate target proteins for subsequent degradation. HeLa cells expressing RAB40AL-, RAB40AL D59G-, or RAB40AL G47A/E113D-GFP fusions have been constructed to examine the effects of these variants on cell viability, protein localization, and downstream ERK signaling in the Ras/MAPK pathway. We hypothesize that the SOCS box in RAB40AL promotes modulation of extracellular stimuli in signaling pathway(s) by selectively degrading target substrates. Identification of *RAB40AL* as the gene mutated in MPS allows for detailed investigations into the molecular mechanism(s) for this disorder, and may improve diagnosis and treatment of individuals with related phenotypes.

Exome sequencing reveals new gene for autosomal recessive congenital ichthyosis in a consanguineous German family. *K.M. Eckl[1], A. Önal-Akan[1], R. Casper[1], H. Thiele[2], I. Hausser[3], M.L. Preil[4], J. Altmüller[2], G. Nürnberg[2], F. Stock[5], P. Nürnberg[2,7,8], H. Traupe[6], H.C. Hennies[1,7,8].* 1) Div of Dermatogenetics, Cologne Center for Genomics, Univ Cologne, Cologne, Germany; 2) Cologne Center for Genomics, University of Cologne, Cologne, Germany; 3) Dept. of Dermatology, University Hospital of Heidelberg, Heidelberg, Germany; 4) Practice for Dermatology Dres. Krnjaic, Merk und Schäfer, Ansbach, Germany; 5) Inst. of Human Genetics, University Hospital of Leipzig, Leipzig, Germany; 6) Dept. of Dermatology, University Hospital of Münster, Münster, Germany; 7) Center for Molecular Medicine, University of Cologne, Cologne, Germany; 8) Cluster of Excellence on Cellular Stress Responses in Aging-associated Diseases, University of Cologne, Cologne, Germany.

Autosomal recessive congenital ichthyosis (ARCI) is a rare and severe genodermatosis characterized by extensive scaling of the entire skin, variable erythema, and a collodion encasement at birth. ARCI shows clinical and genetic heterogeneity, as mutations in six genes, involved in different pathways, have been known so far. A patient was presented to our outpatient special clinics showing all signs for ARCI. She was born as collodion baby with ectropium and eclabium. In infant life the patient showed a whitish, mild scaling on the entire body but rather sparsely on face, hands and feet. Hair, nails and teeth were normal. The ability to sweat was reduced; allergies and secondary skin infections have not been reported so far. Ultrastructural analysis of skin biopsy specimens showed regular epidermis, mild acanthosis and orthohyperkeratosis with only a slight thickening of the stratum corneum. Mutation analyses in the six known ARCI genes were negative. Family history revealed an extended pedigree of German descent, with a total of six affected members including the great-grandfather of the index patient, and multiple consanguinity. Subsequent linkage analysis and homozygosity mapping using chip-based SNP analysis resulted in a LOD score of 4.5 and a candidate interval of 3.4 Mb in length. By whole-exome sequencing using samples from two patients we identified one single homozygous mutation in the candidate region with a >100-fold coverage. The missense mutation completely co-segregates in the pedigree. It affected a highly conserved residue of predicted structural importance, represented by maximum probability of pathogenicity as determined by various algorithms such as ConSeq, PMut or Polyphen. We have modelled the disease in vitro using 3D full-skin equivalents showing lack of the protein in the epidermis. Disease models demonstrated mild hyperkeratosis and a slightly reduced epidermal barrier function compared to wild-type using Lucifer Yellow penetration assays. This is the first identification of a new gene for a severe genetic skin disorder using the combined methods of whole-genome linkage analysis and exome sequencing with only one, consanguineous family demonstrating again the feasibility and stringency of the approach.

1123W

The *MYH9* and *APOL1* genes are independently associated with Sickle Cell Disease nephropathy. *M.E. Garrett[1], E.C. Okocha[1,2], K. Soldano[1], L.M. De Castro[3], J.C. Jonassaint[3], E.P. Orringer[4], J.R. Eckman[5], M.J. Telen[3], A.E. Ashley-Koch[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Institute for Genome Sciences and Policy, Duke University, Durham, NC; 3) Division of Hematology, Department of Medicine, Duke University Medical Center, Durham, NC; 4) Department of Medicine, University of North Carolina, Chapel Hill, NC; 5) Department of Hematology and Medical Oncology, Emory University Medical Center, Atlanta, GA.

Background: Renal failure occurs in 5-18% of sickle cell disease (SCD) patients and is associated with early mortality. At risk SCD patients cannot be identified prior to the appearance of proteinuria and the pathobiology is not well understood. The *MYH9* and *APOL1* genes have been associated with risk for focal segmental glomerulosclerosis and end-stage renal disease in African Americans without SCD and are excellent candidate genes for SCD nephropathy. **Methods:** We genotyped 26 SNPs in *MYH9* and 2 SNPs in *APOL1* (G1 and G2 from Genovese et al, 2010) in 521 unrelated adult (18-83 years) SCD patients screened for proteinuria. To assess population substructure, we used 392 Ancestry Informative Markers (AIMs) and excluded individuals who were outliers. Using logistic regression, SNPs were evaluated for association with proteinuria, adjusting for important covariates such as age and hypertension. **Results:** Thirty-six percent of our patients had proteinuria and those individuals were on average 6 years older than the patients without proteinuria ($p<0.0001$). Seven SNPs in *MYH9* and one in *APOL1* remained significantly associated with proteinuria after multiple testing correction ($p < 0.0025$). An *MYH9* risk haplotype ($p=0.001$) and the *APOL1* G1/G2 recessive model ($p<0.0001$) were significantly associated with proteinuria, both remaining significant when including them simultaneously in the model. Glomerular filtration rate was negatively correlated with proteinuria ($p < 0.0001$), and nominally associated with *MYH9* and *APOL1* in age-adjusted analyses. **Conclusion:** Our data provide insight into the pathobiology of renal dysfunction in SCD, suggesting that *MYH9* and *APOL1* are both independently associated with risk. *MYH9* is a stronger functional candidate, encoding the heavy chain of non-muscle myosin IIA and in combination with actin, talin, (-actin-4, and vinculin, makes up the cytoskeleton of the podocyte - the cells lining the visceral surface of Bowman's capsule in the kidney- foot process (Drenckhahn and Franke 1988). *APOL1* is associated resistance to *Trypanosoma brucei rhodesiense*, a common African parasite, and this role in host immunity likely contributed to selective pressures on that gene and the surrounding region which includes *MYH9*. Further, *APOL1* has been implicated more strongly in renal disease among non-SCD patients. Thus, functional work will be needed to disentangle this complex genomic region implicated now in multiple types of nephropathies.

Pulmonary arterial hypertension (PAH) is a progressive vascular disorder characterized by the occlusion of pulmonary arterioles as a result of the uncontrolled proliferation of endothelial and smooth muscle cells. It is a devastating disease that, in the absence of treatment, is fatal due to right heart failure. PAH may occur in a familial setting (FPAH) but, more commonly, is idiopathic (IPAH) or associated with other disorders including congenital heart disease, thromboembolic disease and HIV infection (APAH). Heterozygous germ-line mutations of BMPR2, encoding a type II receptor of the TGF-) signaling pathway, represent the principal genetic predisposition to the familial form of PAH. By contrast, BMPR2 mutations are observed at a significantly lower frequency in idiopathic and associated forms of PAH. BMPR-II triggers signal transduction through the receptor SMADs (R-SMADs) 1, 5 and 8, upon ligand binding and complex formation with a type I receptor, namely BMPR-1A, -1B or ALK1. R-SMADs translocate to the nucleus in complex with co-SMAD4 to regulate transcription of target genes. To further explore the molecular genetic basis of PAH we adopted a candidate gene approach to identify deleterious variation predisposing to the disorder. Specifically, members of the canonical BMP pathway, namely SMADs 1, 4, 5 and 8, were analyzed for mutations capable of disrupting BMPR-II signaling. In the largest study of its kind, four variants were identified in SMADs 1, 4 and 8 amongst a cohort of 324 PAH cases and excluded in over 900 matched controls, 60 fully exome sequenced samples and publicly available variation databases. Of the three amino acid substitutions detected, two demonstrated reduced signaling activity when tested by reporter assays. A putative splice site mutation proximal to the terminal exon of SMAD4 resulted in moderate transcript loss in patient cells due to defects in splicing efficiency. These results emphasize the central role of BMPR2 mutation in PAH pathogenesis and, importantly, indicate that potentially deleterious variation within the SMAD family is likely to be an infrequent cause of disease.

Examination of Fuchs endothelial corneal dystrophy (FECD) in African-Americans. *M.A. Minear[1], J. Rimmler[1], S. Watson[1], E. Balajonda[2], Y.-J. Li[1], G.K. Klintworth[2], N.A. Afshari[2], S.G. Gregory[1].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Department of Ophthalmology, Duke University Medical Center, Durham, NC.

Fuchs endothelial corneal dystrophy (FECD) is a late-onset disorder of the corneal endothelium that is a leading indication for corneal transplantation. Much progress has been made in recent years to identify the genetic architecture of FECD, with both linkage and association studies identifying mutations in the *COL8A2*, *SLC4A11*, and *TCF8* (*ZEB1*) genes in FECD patients. The literature on FECD genetics is very biased in that only Caucasian patients have been included in linkage and association studies. Even though a handful of studies have made an effort to include other racial and ethnic groups by screening selected Asian FECD patients for mutations in *COL8A2* and *SLC4A11*, nobody has analyzed African-American patients with FECD. The only published report of an African-American FECD patient was in 1924, and yet questions remain as to whether African-Americans are even susceptible to FECD. The purpose of our study was to perform a comprehensive examination of the clinical, histological, and genetic features of African-American FECD patients we have recruited at the Duke University Eye Center. We have enrolled 70 African-Americans, comprising 32 singleton cases and nine multiplex families. The affected subjects have been examined both clinically and histopathologically (when tissue specimens were available following a corneal transplant) to verify a FECD diagnosis, including the presence of central corneal guttae. In 38 of our 41 singletons/probands, we are sequencing *COL8A2*, *SLC4A11*, and *TCF8* to determine whether or not mutations in these genes are present in African-American FECD cases. Preliminary sequencing in *TCF8* has detected two novel missense mutations in exon 7, p.L708Q and p.P559S, as well as novel intronic mutations and known polymorphisms in dbSNP. Additional sequencing will be needed to confirm these mutations and to confirm their absence in control samples. Our study is the first comprehensive clinical report of FECD in African-Americans and is also the first to examine the genetic basis of FECD in this population.

A Novel Mutation in *PRPF31* Linked with Autosomal Dominant Retinitis Pigmentosa in a large Indian Family. *S. Saini[1], V. Vanita[1], D. Singh[2], J.R. Singh[3], P.N. Robinson[4].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Dr. Daljit Singh Eye Hospital, Sheranwala Gate, Amritsar, India; 3) Central University of Punjab, Bathinda, India; 4) Institute of Medical & Human Genetics, Charité Campus Virchow-Klinikum, Berlin, Germany.

Purpose: To localize and identify the disease linked gene for non-syndromic autosomal dominant retinitis pigmentosa (ADRP) in a large Indian family. Methods: Genome-wide linkage analysis using highly polymorphic fluorescently labeled microsatellite markers was carried out in an ADRP family with 14 living members in 3-generations affected with non-syndromic retinitis pigmentosa. Genotyping was carried out on a DNA sequencer ABI-377, data collected and analyzed by GENESCAN version 3.1.2, and genotyping was done using GENOTYPER 2.5.1 software. 2-point and multipoint linkage analysis were performed by means of the program packages linkage v.5.2, Genehunter v.2.1 and simwalk2 v.2.82. Mutation screening in the potential candidate gene at the mapped interval was carried out by bi-directional sequence analysis of the amplified products. Results: In a genome-wide search, significant positive 2-point lod scores indicative of linkage were obtained with markers D19S921, D19S572, and D19S927 at 19q13.4. Two-point linkage data with these markers was further supported by multipoint lod scores and haplotype analysis. Mutation screening in the candidate gene pre-mRNA processing factor 31 homolog (S. cerevisiae) (*PRPF31*) at the mapped interval resulted in identification of a novel 7 bp deletion i.e. c.59-65del7 (p.Gly20AlafsX43) which leads to premature stop codon in the next exon 43 amino acids downstream. Conclusion: The present study maps the locus for non-syndromic autosomal dominant retinitis pigmentosa in a large Indian family at 19q13.4. The identified novel deletion in *PRPF31* was identified in all the tested 14 affected members and in one asymptomatic individual, consistent with a high, but not complete penetrance of c.59-65del7 (p.Gly20AlafsX43). This deletion was not observed in any other tested unaffected family members or in 100 ethically matched control (200 chromosomes) subjects. The present findings further substantiate the role of *PRPF31* that encodes a component of the spliceosome complex in relation to ADRP.

1127W

Familial amyloid polyneuropathy (ATTRV30M): what can we learn from the study of families of this AD disorder in which the proband had no affected parent at the time of diagnosis? *A. Sousa[1, 2], C. Lemos[1, 2], A. Martins-da Silva[3], R. Magalhães[1], J. Neto[2], I. Alonso[1,2], J. Pinto Basto[1,2], J. Sequeiros[1,2], T. Coelho[3].* 1) ICBAS, Instituto Ciências Biomédicas Abel Salazar, Univ. Porto, Portugal; 2) UnIGENe, IBMC, Porto, Portugal; 3) Unidade Clínica de Paramiloidose, Centro Hospitalar do Porto (CHP), Porto, Portugal.

Familial amyloid polyneuropathy (FAP-ATTRV30M) is an autosomal dominant (AD) systemic amyloidosis manifesting as severe peripheral neuropathy, due to a point mutation in the transthyretin (TTR) gene (chr18q12.1). It was first described by Andrade in Northern Portugal (1952) as a disease occurring between 25-35 yrs. This AD disorder was later shown to present remarkable differences in mean age-at-onset between clusters (Portugal: 35,1; Sweden: 56,7 and Baleares Islands: 45,7). Emphasis is often put in differences between clusters, but a large variability can also be found within each one. Portuguese focus has been characterized by its early onset (o.<40yrs) and assumed to reach full penetrance. However, reality is not that simple: more and more late-onset (o⁄ 50yrs) cases have been ascertained, often descending from old asymptomatic carriers. Moreover, when analyzing the families ascertained over the past 70 yrs, around 40% of probands had no affected parent at the time of the diagnosis (60% of families recently ascertained). We have a unique opportunity to perform a longitudinal study: in CHP (Porto), 2440 patients belonging to 566 different families were diagnosed 1939-2010. Mean age-at-onset is 35,1 yrs (SD 10,7), women having a later onset - 37,4 (SD 10,3) - than men - 33,1 (SD 10,7). This study concentrates on 216 families whose proband, at the time of his/her diagnosis, ignored the existence of the disease in previous generations. The most intriguing aspect is that in those probands, mean age-at-onset was 46,2 (SD 12,5), vs. 33,5 (SD 8,8) in probands of families where the disease was already known (P<0,001). Going further in the analysis of those 216 families, no gender differences were found between male - 45,9 (SD 13.0) and female probands - 46,7 (SD 11,6). However, when considering the 415 non-proband patients belonging to these families, men had a lower onset - 36,7 (SD 12,9) than women - 41,8 (12,5), P<0,01). In these families, when we put the emphasis on whether the patient had one affected parent at the time of diagnosis (which excludes the probands and some others) gender differences are present again, whereas they are not in the group of patients (probands and some others) with no affected parent. Thus, our conclusion is that gender differences in age-at-onset are mostly due to the affection status of the transmitting parent. This reinforces the hypothesis of modifiers close to or within the TTR gene, on which we are currently working.

1128W

Identification of an interaction between LIX1, a feline SMA candidate gene, and DACHSOUS1. *E.N. Wakeling[1], J.C. Fyfe[2,3].* 1) Genetics Program, Michigan State University, East Lansing, MI; 2) Department of Microbiology & Molecular Genetics, Michigan State University, East Lansing, MI; 3) College of Veterinary Medicine, Michigan State University, East Lansing, MI.

The spinal muscular atrophies (SMA) are a group of inherited disorders distinguished by proximal muscle weakness and atrophy due to spinal cord lower motor neuron degeneration. Autosomal recessive SMA is the leading genetic cause of infant mortality and is divided into four subtypes based on severity, age of onset and survival time. In humans, ~97% of autosomal recessive SMA is due to mutation of the survival of motor neuron (SMN) gene. Despite intensive research, the molecular mechanism by which SMN depletion results in motor neuron death remains poorly defined. Feline SMA is an autosomal recessive, juvenile onset lower motor neuron disease that resembles Type 3 human SMA. Molecular analysis identified a 140 kb deletion on feline chromosome A1q that abrogated expression of limb expression 1 (LIX1), a gene of unknown function that is highly expressed in spinal cord. We conducted a yeast two-hybrid screen of a human fetal brain cDNA library to identify putative LIX1 interacting partners and thus assign a function for LIX1. This screen of 2 x 10^7 clones identified 12 unique preys, some of which were identified multiple times. Confirmation of the protein interactions was accomplished by in vitro co-immunoprecipitation and band shift assays. The cytoplasmic domain of DACHSOUS1 (DCHS1) was identified 20 times and was the only prey that interacted with LIX1 in vitro. DCHS1 is a transmembrane protein that contributes to the planar cell polarity of the wings, legs, and eyes of Drosophila. In transfected Cos7 cells, GFP-tagged Lix1 and Lix1alt, a murine specific transcript with an alternative promoter, both localized throughout the cytoplasm and nucleus. When co-expressed with DsRed-tagged Dchs1, GFP-Lix1 was entirely cytoplasmic and co-localized strongly with DsRed-Dchs1. GFP-Lix1alt also co-localized with Dchs1-DsRed, however, GFP-Lix1alt was not excluded from the nucleus. In NSC34 cells, a motor neuron-like cell line, GFP-Lix1 localized throughout the cell body, neurites and growth cones and co-localized with DsRed-Dchs1. GFP-Lix1alt also co-localized with DsRed-Dchs1 in the cell body, neurites, and growth cones. As was observed in Cos7 cells, co-expression with DsRed-Dchs1 was not sufficient to exclude GFP-Lix1alt from the nucleus. These in vitro experiments and in vivo co-localization support an interaction between LIX1 and DCHS1. As a neuronal function for DCHS1 has yet to be identified, the importance of this interaction in motor neurons remains unclear.

Congenital heart malformations are a major cause of morbidity and mortality especially in newborns and young children. Failure to establish normal left-right (L-R) asymmetry often results in cardiovascular malformations and other laterality defects (heterotaxy). Using SNP arrays genome-wide linkage analysis and gene sequencing, we identified mutations in NPHP4 in patients with cardiac laterality defects from a consanguineous family. The patients had various combinations of defects that included dextrocardia, transposition of great arteries, double outlet right ventricle, atrio-ventricular septal defects and caval vein abnormalities. To replicate this finding we investigated 146 unrelated individuals with similar cardiac laterality defects originating from United States, Belgium and The Netherlands. Forty-one percent of these patients also had laterality defects of the abdominal organs, including abdominal situs inversus, asplenia or polysplenia, midline liver and intestinal malrotation. Sequence analyses of the 30 exons of NPHP4 in this cohort identified eight additional missense variants that were absent or very rare in ethnically matched control populations. To study the role of nphp4 in establishing L-R asymmetry, we used antisense morpholinos to knockdown nphp4 expression in zebrafish. Depletion of nphp4 disrupted L-R patterning as well as cardiac and gut laterality. We show in vivo that nphp4 knockdown results in shorter Kupffer's vesicle cilia and compromises asymmetric fluid flow that is necessary for normal L-R patterning. The linking of NPHP4 to L-R axis determination and laterality defects will help dissect the complex genetic composition of heterotaxy and related cardiovascular malformations.

Exome Sequencing of Distantly Affected Relatives Effectively and Efficiently Identifies Causative Genes for Familial Thoracic Aortic Aneurysms and Dissections. *D.C. Guo[1], E.S. Regalado[1], R. Zhao[1], C.E. Kibler[1], G. Chang[1], J. Shendure[2], M.K. Rieder[2], D.A. Nickerson[2], D.M. Milewicz[1].* 1) Dept Internal Med, Univ Texas/Houston Med Sch, Houston, TX; 2) Dept Genome Sciences, Univ Washington, Seattle, WA.

Thoracic aortic aneurysms leading to acute aortic dissections (TAAD) can be inherited in families in an autosomal dominant manner with variable expression and decreased penetrance. Familial TAAD demonstrates genetic heterogeneity, with six genes identified to date for familial TAAD that are responsible for 20% of the disease (MYH11, ACTA2, MYLK, FBN1, TGFBR1, TGFBR2). To identify causative mutations in 7 large TAAD families with variable clinical presentations suggesting underlying genetic heterogeneity, exome sequencing was performed on DNA from two distant relatives with TAAD sharing 1/8th or 1/16th of their genome from each family. Approximately 230 unique heterozygous missense, splice-site, or indel variants were identified on each individual that were not present in public databases or in-house controls. For each family, 12 - 29 heterozygous rare variants were shared between the affected relatives of each family; relatives that shared 1/8th of the genome had average 27 candidate variants and relative with 1/16th of genome had average 14 candidate variants ($P = 0.006$). Sanger sequencing was used to validate the shared rare variants and only 2 out of 159 variants failed to validate. Segregation of the rare variants with TAAD in other family members narrowed the candidate rare variants for familial TAAD to between 3 to 7 per family in 5 families and 15 to 16 per family in 2 families. Variants under genome-wide linkage peaks for TAAD in 3 families also significantly narrowed the list of variants ($P < 0.001$). PolyPhen-2 analyses predicted that 42% of candidate variants are probably damaging and 19% are possibly damaging. Amino-acid conservation of the altered amino acid and tissue specific expression of candidate genes were also analyzed. Finally, we sequenced genes with candidate variants in an additional 188 affected probands from unrelated TAAD families to confirm genes as disease-causing. Using these criteria, SMAD3 was identified as the cause of disease in a family with TAAD and intracranial aneurysms; 2% of 188 affected probands also had SMAD3 mutations. Using these same criteria, additional novel genes for TAAD were identified in a family with TAAD associated with decreased penetrance in women and a family with TAAD associated with BAV. In conclusion, exome sequencing on two distantly affected family members and linkage analysis of large TAAD families can rapidly decrease the number of potential rare variants causing disease.

1131W

Novel Insights Regarding the Mechanism and Treatment of Stress-Induced Cardiomyopathy in Marfan syndrome. *R. Rouf[1], E. Takimoto[1], D. Bedja[1], N. Koitabashi[1], D.P. Judge[1], D.A. Kass[1], H.C. Dietz[1, 2].* 1) Johns Hopkins School of Medicine, Baltimore, MD; 2) Howard Hughes Medical Institute.

Marfan syndrome (MFS) is a systemic connective tissue disorder caused by a deficiency of extracellular fibrillin-1, a core component of extracellular microfibrils that negatively regulates transforming growth factor) (TGF)) bioavailability by sequestering latent TGF) to the matrix. Common cardiovascular manifestations of MFS include mitral valve prolapse and aortic root aneurysm and dissection. Many manifestations of MFS are attenuated or prevented by TGF) antagonists, including the angiotensin II type 1 receptor blocker losartan. Heart failure is the leading cause of death in severely affected children and many patients with more typical MFS show myocardial dysfunction out-of-proportion to any volume overload imposed by valve regurgitation. On this basis, we hypothesized that the myocardium in MFS may be more sensitive to cardiovascular stress, and that this may relate to excessive TGF) signaling. Adult male wild-type (WT) and fibrillin-1-deficient mice (Fbn1C1039G/+) underwent either sham operation or transverse aortic constriction (TAC) to induce mild pressure overload. WT mice remained well compensated after TAC, with chronic preservation of heart size and function. This correlated with an induction of fibrillin-1 expression in the myocardium. In contrast, Fbn1C1039G/+ mice failed to upregulate fibrillin-1 deposition and showed a significant increase in end-systolic (4.7 vs. 1.5 mm) and end-diastolic (5.4 vs. 4.28 mm) LV dimensions and a decline in fractional shortening (12.9 vs. 54.23 %) within 48 hours of TAC, when compared to WT littermates; the majority of Fbn1C1039G/+ died secondary to heart failure within 3 weeks. Compared with WT mice, MFS mice had increased LV mass (LV/BW 14.11 vs.6.25 mg/g), myocyte hypertrophy, and perivascular and interstitial fibrosis. Fibrillin-1-deficient mice also showed activation of both the canonical (pSmad2) and noncanonical (pERK1/2) TGF) signaling pathways in the myocardium in response to pressure overload. Finally, in vivo treatment with losartan normalized TGF) signaling and completely rescued cardiac decompensation, myocyte hypertrophy and fibrosis despite an ongoing pressure overload imposed by a fixed obstruction (TAC). These data suggest a primary regulatory role of fibrillin-1 in cardiac tissue homeostasis. Abrogation of TGF) -dependent signaling emerges as a therapeutic strategy for MFS-associated cardiac failure and perhaps in other presentations of pathologic LV remodeling.

1132W

The Profession as a Cause for Mutation Identification. *H. Yonath[1,2], H. Reznik-Wolf[1], L. Zeler[3], E. Pras[1,2], M. Frydman[1,2].* 1) Inst Human Gen, Sheba Med Ctr, Ramat Gan, Israel; 2) Sackler Medical School, Tel Aviv University. Israel; 3) Ben Gurion University of the Negev, Israel.

The majority of Marfan syndrome patients are ascertained by their Marfanoid phenotype, though there are some familial cases that have minimal manifestations. We present a sporadic patient with minimal and atypical features which was ascertained following a routine echocardiography. A 30 year old professional soccer player was referred for genetic evaluation due to a dilatation of the proximal ascending aorta identified on routine echocardiography. His past medical history included repair of bilateral inguinal hernia, right undescendent testis and left hydrocoele, and an operation for abdominal muscle strengthening. His parents, two siblings and only child were normal. On physical examination: Height 182 cm, arm span: 186.5 cm, arm span/height 1.024, upper/lower segment 0.89. Normal palate and uvula were obserbved without dental crowding, normal chest wall, no joint laxity, negative wrist and thumb signs, normal scars and no striae. Ophthalmological evaluation was normal and there was no evidence of dural ectasia on lumbar CT. Though he did not have sufficient criteria to establish the clinical diagnosis of Marfan syndrome (MIM # 154700), molecular testing was recommended due to the impact on his profession. Sequencing of FBN1 identified a c.3509G>A missense mutation resulting in Arg1170His substitution. The combination of the dilatation of the aorta, and a known, amino acid altering mutation, inguinal hernia and probably incisional hernia established the diagnosis of Marfan syndrome, followed by a recommendation to discontinue professional soccer. This case illustrates that occasional patients may have minimal manifestations, that might not meet the diagnosis based on the Ghent Nosology, and argues in favor of mutation analysis in atypical cases.

1133W

Acid fatty metabolism: a new therapeutic target for Epidermolysis Bullosa Simplex. *M. Bchetnia[1], M. Tremblay[1], G. Leclerc[2], A. Dupérée[2], J. Powell[3], C. McCuaig[3], C. Morin[2], V. Legendre-Guillemin[1], C. Laprise[1].* 1) Dept sciences fondamentales, Université du Québec à Chicoutimi, Saguenay, Canada; 2) Centre de santé et de services sociaux de Chicoutimi, Saguenay, Canada; 3) Hôpital Sainte-Justine, Montréal, Canada.

Epidermolysis bullosa simplex (EBS) is a skin disorder resulting from a weakened cytoskeleton and caused by mutations in keratin 5 (KRT5) or keratin 14 (KRT14) genes which encode for the major keratins of the basal cell layer of the epidermis. The altered cellular mechanisms underlying this disease are still unclear and effective therapies are still lacking. Therefore, we propose to sequence KRT5 and KTR14, to compare the gene expression profile of EBS and healthy controls and to test several therapeutic strategies for this disease in vivo. We performed direct sequencing of KRT5 and KRT14 genes in six EBS patients (2 EBS Dowling Meara (EBS-DM), 4 EBS localised (EBS-loc)) in order to identify the pathological mutations. These patients were paired to six healthy individuals according to age and gender. RNA was extracted from skin biopsy specimens and analyzed with HuGene-1_0-st-v1 GeneChip microarrays. Real-time PCR of five selected genes were performed to confirm GeneChip results. Next, we evaluate the therapeutic efficiency of three chemical chaperone molecules: sodium 4-phenylbutyrate (4-PBA), trimethylamine N-oxide (TMAO), and sulforaphane (SF) in attenuating keratin aggregation observed in heat stressed immortalized EBS cells. We identified six pathogenic mutations from which two are novel R125S (K14) and R559X (K5). Expression profiling comparisons show that 28 genes are differentially expressed in all the EBS patients compared to control subjects and 41 genes in EBS-DM compared to their paired controls. Nine genes involved in fatty acid metabolism (AWAT2, DGAT2L6, ELOVL3, THRSP, FADS2, FAR2, ACSBG1, AADACL3, and CRAT) and 2 genes in epidermal keratinisation (SPRR4 and KRT79) are common higher expressed genes between the two subgroups. Pre-treatment of EBS cells with the low molecular weight fatty acid 4-PBA, TMAO, and SF show variable effects in reducing the load of keratin aggregates in heat stressed EBS cells. Taken together, our results show that fatty acid metabolism and epidermal keratinisation pathways are higher expressed in EBS-DM patients. These two biological pathways, which might be involved in EBS disease, contribute both to the formation of the cell envelope barrier. Our findings on fatty acid metabolism support the therapeutic efficiency of 4-PBA chaperone molecule that seems, with TMAO, and SF, to be promising therapeutic tools for EBS and other protein misfolding disorders.

1134W

Combined malonic aciduria and methylmalonic aciduria (CMAMMA): exome sequencing reveals mutations in the *ACSF3* gene in patients with a non-classical phenotype. *L. Dempsey Nunez[1, 2], A. Alfares[1, 2], K. Al-Thihli[1, 2], J. Mitchell[3], S. Melançon[1, 2, 3], N. Anastasio[1], J. Majewski[1], K.C.H. Ha[1], D.S. Rosenblatt[1, 2, 3], N. Braverman[1, 2, 3].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Division of Medical Genetics, McGill University Health Centre, Montreal, Canada; 3) Department of Paediatrics, McGill University Health Centre, Montreal, Canada.

Combined elevated malonic acid (MA) and methylmalonic acid (MMA), or CMAMMA, is a rare autosomal recessive condition that is classically characterised by metabolic acidosis, developmental delay, seizures, and cardiomyopathy. Most cases of CMAMMA are due to malonyl-coenzyme A decarboxylase (MCD) deficiency. Two patients with CMAMMA, one of French Canadian and one of Ashkenazi Jewish origin, were identified by newborn screening for elevated MMA. Unlike the classical form, these patients had a higher level of MMA than MA and have been clinically asymptomatic. MCD activity was found to be normal in patient fibroblast extracts and no mutations were found in *MYLCD*. To identify the underlying molecular cause of the non-classical form of CMAMMA seen in these patients, we performed exome capture and sequencing. This powerful technique has been successfully used to identify the genetic basis of rare Mendelian conditions with only one or few affected individuals. Exome sequencing was performed in the French-Canadian proband from a consanguineous family and revealed a homozygous missense mutation, c.1075G>A (p.E359K), in exon 5 of the *ACSF3* gene, a member of the acyl-CoA synthetase (ACS) family. Members of the ACS class of proteins catalyze the activation of fatty acids by forming a thioester bond between a CoA and a fatty acid, to form acyl-CoA. A different homozygous missense mutation in *ACSF3*, c.1411C>T (p.R471W), was identified in the Ashkenazi Jewish patient. Both substitutions were in residues that are highly conserved within signature domains of the ACS family and the changes were predicted to be damaging. Segregation analysis of family members further supported these findings. Sequencing of both mutations in ethnically matched controls revealed one carrier in 139 French Canadian controls and one carrier in 176 Ashkenazi Jewish controls. This represents an allele frequency of less than 0.5% of their respective control populations. These results suggest that *ACSF3* is a candidate gene for the non-classical form of CMAMMA seen in these two patients and reinforces the value of exome sequencing of a limited number of patients for the identification of novel disease genes.

1135W

Mitochondrial mistargeting causes autosomal dominant renal Fanconi syndrome. *E. Klootwijk[1], M. Reichold[2], A. Helip-Wooley[3], H. Stanescu[1], J. Reinders[2], D. Bockenhauer[1], W.A. Gahl[3], R. Warth[2], R. Kleta[1].* 1) University College London, London, United Kingdom; 2) University Regensburg, Regensburg, Germany; 3) NHGRI, NIH, USA.

Renal Fanconi syndromes are characterized by a generalized renal proximal tubular dysfunction leading to aminoaciduria, glucosuria, phosphaturia, small molecular weight proteinuria, and metabolic acidosis. The clinical consequences in childhood include rickets and growth problems. We investigated the genetic basis and the underlying molecular pathology in an extended family with autosomal dominantly inherited renal Fanconi syndrome without kidney failure. Whole genome multipoint parametric linkage analysis was performed, revealing a significant LOD score (> 3) for a single locus. All genes in the linked area were sequenced resulting in the identification of a heterozygous mutation in a gene, which we call Fanconin; the mutation leads to de-novo formation of a mitochondrial targeting motif. This mutation was not found in ethnically matched controls. To assess its functional impact, a stable permanently transfected inducible renal proximal tubular cell model was generated. Immunohistochemical analysis using these cells showed appropriate intracellular localization of the wild type human Fanconin, but mitochondrial mistargeting of the mutant human Fanconin. Immunohistochemical studies of mouse kidney showed that the Fanconin protein is expressed in renal proximal tubules, consistent with the proximal tubular dysfunction observed in our patients. Knockout mice for Fanconin did not exhibit a proximal tubular transport defect, as assessed by aminoacid analysis using GC-MS. This was consistent with the hypothesis that the renal Fanconi phenotype in our family is not caused by haploinsufficiency, but rather by a dominant negative effect of the Fanconin protein. Since Fanconin is mistargeted to mitochondria, we studied the impact of this mutation on mitochondrial function. Oximetric analyses showed a complex coupled ATP synthase deficiency (oxidative phosphorylation) in cells expressing the mutant Fanconin. Transport studies documented abrogated transepithelial water transport. To our knowledge this is the first description of a genetic defect leading to intracellular mistargeting of a mutant protein resulting in mitochondrial pathology.

1136W

Novel recurrent CFTR mutation in Chilean cystic fibrosis patients. *G. Lay-Son[1,3,6], M. Vasquez[1], F. Vial[1], M.L. Boza[2], I. Contreras[3], J. Lozano[4], D. Zenteno[5], F. Bello[5], G.M. Repetto[1,3].* 1) Human Genetics Center, Faculty of Medicine, Clinica Alemana-Universidad del Desarrollo, Santiago, Chile; 2) Hospital San Borja-Arriaran, Santiago, Chile; 3) Hospital Padre Hurtado, Santiago, Chile; 4) Hospital Roberto del Rio, Santiago, Chile; 5) Hospital Clinico Regional Dr. Guillermo Grant Benavente, Concepcion, Chile; 6) Hospital Dr. Luis Calvo Mackenna, Santiago, Chile.

Cystic fibrosis (CF) affects about 1 in 10,000 newborns in Chile. A 36 most frequent mutation panel has an 80-85% detection rate in North American and Northern European CF patients but a lower detection rate of approximately 50% in Chile. This suggests that some of the so-far unidentified mutations in Chilean patients may be of local/regional origin and raises a challenge to certify the diagnosis and for the genetic counseling. We carried out sequencing analysis of select exons of the CFTR gene by PCR amplification and direct sequencing in Chilean patients with CF and incomplete allele identification by 36 CFTR mutation panel. Four unrelated patients had a previously unreported deletion of two nucleotides (c.2462_2464delGT/p.Ser821ArgfsX4), which is predicted to cause a frameshift at 821 codon with a subsequent premature stop codon at codon 824. This mutation is located in exon 14 at the regulatory domain of the CFTR protein. These four patients were heterozygous for p.F508del and they have pancreatic insufficiency. Parental studies in one of the patients confirmed that these 2 mutations were in trans. Prevalence in Chilean patients from the National Program of CF is currently being evaluated. This mutation should be included in current studies in CF patients with Chilean origin. Further analyses are necessary to determine prevalence and geographic distribution in other Latin Americans and Hispanics populations.

Contribution of *GH* an *GHRHR* mutations to isolated growth hormone deficiency - Identification and functional characterization of new variants. *S. Amselem[1,2,3], ML. Sobrier[2], F. Dastot-Le Moal[1,2], N. Collot[1], S. Rose[1,2], A. Soleyan[1], P. Duquesnoy[2], B. Copin[1,2], M. Legendre[1,2].* 1) Génétique clinique et moléculaire, Hôpital Trousseau, APHP, Paris, France; 2) Inserm U933, Hôpital Trousseau, Paris, France; 3) Université Pierre et Marie Curie, Paris, France.

Growth is a complex phenomenon that depends on several factors including growth hormone (GH), the GH releasing hormone (GHRH) and its receptor (GHRHR). Although GH and GHRHR have been recognized as key etiologic factors in non-syndromic forms of isolated growth hormone deficiency (IGHD), a small number of mutations have been identified in this rare condition. Depending on the studies, *GH* and *GHRHR* defects would account for 6-12.5% and 0-6.7% of IGHD cases. So far, as for GHRHR, very few functional studies have been performed in order to assess the consequences of the identified variants.

With the aim to assess the contribution of the *GH* and *GHRHR* genes in the pathogenesis of IGHD, we screened for mutations all coding exons and flanking intronic sequences of these two genes in a large cohort of patients presenting with a non-syndromic form of IGHD characterized by a small or normal anterior pituitary and an eutopic posterior pituitary.

The *GH* gene was first analyzed in a total of 191 independent patients. Mutations were identified in 28 patients (15%), 10 of them (10/191, 5%) representing familial forms of IGHD. These include 8 novel mutations, among which 2 frameshift mutations, 1 splicing defect and 5 missense mutations. The *GHRHR* gene was subsequently analyzed in the remaining 144 independent patients in whom no *GH* defect was identified and for whom DNA was available. This led to the identification of mutations in 22 patients (15%), 7 of them (7/144, 5%) representing familial cases. The *GHRHR* mutation spectrum, which comprises 7 novel mutations, consists of 2 nonsense mutations, 4 frameshifts, 1 splicing defect and 10 missense mutations. In vitro functional studies of several missense mutations, which are underway, include the assessment of GHRH response through a CRE-dependent luciferase assay. The first results are consistent with a loss of function associated with 4 of these missense variations.

Noteworthy, up to 66% (33/50) of the patients with a *GH* or *GHRHR* germline mutation represent sporadic cases. Overall, this study performed in a large cohort of patients, which identified molecular defects in the *GH* or *GHRHR* gene in 50 out of 191 independent patients (26%), reveals the importance of those two genes in the pathogenesis of non-syndromic IGHD with a normal location of the posterior pituitary.

1138W

A novel spontaneous autosomal recessive mutation/deletion that causes a multifarious alopecia-like phenotype in mouse. *H. Beauchemin[1,2], C. Polychronakos[1,2].* 1) Pediatric Endocrinology, Montreal Children's Hospital-RI/MUHC, Montreal, Quebec, Canada; 2) McGill University, Montreal, Quebec, Canada.

Alopecia Areata is an autoimmune disease characterized by temporary local hair loss. Here we report a yet to be identified spontaneous mutant (*Alo1*) that exhibits an elaborate and very consistent complex phenotype reminiscent of Alopecia Areata along abnormal sebaceous gland/hair follicle morphology. This *Alo1* spontaneous mutation occurred in a male NOD mouse and is now currently being transferred into the C57Bl/6 background, showing an autosomal recessive pattern of transmission with 100% penetrance, regardless of the genetic background. Interestingly, this mutation that involves a single genetic locus, leads to a complex phenotype progression: Young mice (<6 weeks) showed a sparse abnormal-looking fur often associated with lacrymating/purulent/bulging eyes. At six weeks of age, mice enter a remission phase as from then, mice looked fairly normal, showing only temporary patch-like hair losses that were very reminiscent of Alopecia Areata in humans. However, after several months, mice showed systematically greasy fur and an ill-looking general appearance but no skin injuries. In addition, these older mice developed chronic eye abnormality. Histological analysis revealed impaired hair growth associated with hyperplasic sebaceous glands. Because Alopecia Areata is a CD8-mediated autoimmune disease, we looked at the cellular compartment of the immune system in *Alo1* mice by multiparametric flow cytometry. Surprisingly, we found no deficiency in either the CD8 or the CD4 T-cells as they present normal CD4/CD8 ratios in thymus, spleen and in lymph nodes. Furthermore, no evidence of impairment of any other cellular compartment of the immune system was found (including in the memory/naive CD8 or CD4 T-cells, regulatory T-cells, natural killer cells, B-cells, macrophages and monocytes), suggesting that the phenotype observed does not have an autoimmune component. Mapping of the *Alo1* mutation is currently underway. In conclusion, we report here a novel mutation affecting integument that exhibits a complex phenotype reminiscent of a juvenile non-T-cell mediated alopecia associated with sebaceous gland hyperplasia.

1139W

Exome Sequencing strategy in a family with Congenital Fiber-Type Disproportion and Insulin resistance reveals an unexpected excess of non synonymous variants. *T. Esposito[1], D. Formicola[1,2], S. Magliocca[1], M. Simonetti[2], O. Farina[2], F. Cipullo[2], S. Sampaolo[2], F. Gianfrancesco[1], G. Di Iorio[2].* 1) Inst Gen & Biophysics, Italian Natl Res Council, Naples, Italy; 2) Department of Neurological Sciences, Second University of Naples, Italy.

Whole-exome sequencing is a new strategy that enables to rapidly identify rare variants in about 1% of the proteins coding genome and to detect pathogenic variants in families not informative for linkage analysis. We chosen to use this approach to define the complex genetic substrate of a family, with consanguineous parents, affected from an unusual syndrome characterized by insulin resistance, left ventricular noncompaction (LVNC), long QT, and congenital fiber type disproportion (CFTD) in the index case. This latter died when she was 11 years old by sudden cardiac death. The exome sequencing was performed on DNA obtained from two affected members of the family using SureSelect Exome target enrichment technology, followed by paired-end sequencing on a Solid 4 System. 11,432 synonymous changes, 13,089 non-synonymous changes and 181 frameshifts were identified in each patient. Using both dbSNP and HapMap exomes as filters to remove common variants, we disclose that 200 novel heterozygous coding variants were shared between two patients. Using a recessive model of transmission we were able to reduce this list to 50 genes. At least 10 of these genes are involved in determining muscle and cardiac phenotypes (ACTA1, ACTC1, SEPN1, MYH11, MYH7B, etc). Missense variants in this subset of genes were analysed for segregation with the disease phenotype. We hypothesize that novel missense variants detected in ACTA1 gene combined with novel missense variants in ACTC1 and MYH7B could explain the complex phenotype observed in our family. Functional studies are ongoing to verify their role in the etiopathogenesis of the disease.

1140W

The novel M1304R mutation in the von Willebrand factor gene (VWF) causes defective VWF multimerization and storage and results in type 2 von Willebrand disease (VWD). *J. Hinckley[1], J. Chen[2], R. Montgomery[3], S. Haberichter[3], R. Wong[4], J. Lopez[2], J. Di Paola[1].* 1) Human Medical Genetics Program and Department of Pediatrics, University of Colorado Anschutz Medical Campus, Aurora, CO; 2) Puget Sound Blood Center, Seattle, WA; 3) Medical College of Wisconsin, Milwaukee, WI; 4) Barbara Davis Center for Childhood Diabetes, Aurora, CO.

VWD, the most common genetic bleeding disorder, is characterized by incomplete penetrance and variable expressivity. Clinically, it presents with mucocutaneous bleeding which is often not concordant with VWF protein levels or activity. Qualitative defects in the VWF protein define type 2 VWD. We characterized a 24-member pedigree with VWD type 2 that demonstrates autosomal dominant inheritance and exhibits clinical and biochemical phenotypic variability. Focused mutational analysis of exon 28 of VWF, which harbors most type 2 mutations, was performed in all individuals. A novel T>G missense mutation at position 3911 that predicts a methionine to arginine (M1304R) change in the A1 domain of the VWF peptide segregated in all members with VWD. Exonic sequencing of VWF in 1 affected and 1 non-affected member did not identify additional mutations or VWF polymorphisms previously reported to alter VWF levels or activity. Evaluation of allele-specific mRNA levels by a novel primer extension assay demonstrates consistent mRNA ratios that cluster within wild-type (WT) relatives (95% WT allele) and VWD patients (76% WT allele), ruling out a hypomorphic WT allele, and ratios are stable within individuals over eight years. Protein analysis by Western blot demonstrates variability of VWF multimers among individuals with the M1304R allele. By ELISA, a nanobody that detects the mutated A1 domain binds with a wide range of variability among affected members, suggesting VWF multimers contain different amounts of mutant protein. In vitro expression of the M1304R allele shows decreased VWF secretion and lack of formation of storage granules. When co-expressed with the WT allele, total VWF secretion is also decreased and multimerization is nearly normalized but no storage granules are formed, suggesting that this particular mutation affects multimerization and trafficking. In summary, we characterized a family with VWD caused by a novel VWF mutation. Phenotypic variability does not appear to be due to polymorphisms in VWF or allele-specific mRNA expression, suggesting the importance of other modifier genes that interact with VWF through biosynthesis, clearance, or hemostatic pathways. In order to further understand the clinical and laboratory variability of VWD, it is important to map genetic variants that influence VWF levels and activity and develop new technologies to quantify the amount of mutant VWF in plasma from VWD patients.

1141W

CHD7 mutations causing CHARGE syndrome are predominantly of paternal origin. *J. Kohlhase[1], N. von Velsen[2], P. Burfeind[2], M. Steckel[2], J. Maenz[2], A. Buchholz[1], W. Borozdin[1], S. Pauli[2].* 1) Center for Human Genetics Freiburg, Germany; 2) Institute for Human Genetics, University of Goettingen, Goettingen, Germany.

CHARGE (coloboma, heart defects, atresia of the choanae, retarded growth and development, genital hypoplasia, ear anomalies and deafness) syndrome is a congenital malformation syndrome caused by mutations in the *CHD7* gene in approximately 2/3 of cases. In the vast majority of cases, CHARGE syndrome is sporadic. There are only a few reports of parent-to-child transmission and somatic or gonadal mosaicism. To determine the parental origin of *CHD7* mutations in sporadic CHARGE syndrome, we screened 30 families for informative exonic or intronic polymorphisms located near the detected *CHD7* mutation. An informative polymorphism could be identified in 13 out of 30 families. Linkage analysis was performed between the *CHD7* mutation and the polymorphism in the child. In 12 out of 13 families, the mutation affected the paternal allele (92.3%). In our cohort, the mean paternal age at birth was 32.92 years. Comparing the age of fathers of an affected CHARGE patient with the paternal age of the German population in general, we could not observe any paternal age effect. Taken together, we show in this study that *de novo CHD7* mutations occur predominantly in the male germ line, and we present a series of new *CHD7* mutations in CHARGE syndrome.

1142W

Mutations in MAP3K1 cause 46, XY DSDs by shifting the balance in downstream signaling pathways. *J. Loke[1, 2], A. Pearlman[1, 2], S. Blais[3], T. Neubert[3], H. Ostrer[1,2].* 1) Human Genetics Program, NYU School of Medicine, New York, NY; 2) Pathology and Genetics, Albert Einstein College of Medicine, Bronx, NY; 3) Proteomics Core, NYU School of Medicine, New York, NY.

Mutations in MAP3K1 are a common cause of 46,XY disorder of sex development (DSD), accounting for up to 18% of cases (Pearlman, et al. AJHG 87:898-904, 2010). All of the mutations identified to date are non-truncating and are found near the N-terminus, a region that harbors binding domains to a number of co-factors. To determine the effects of these mutations, we performed immunoprecipation of lymphoblastoid cell lysates using an anti-MAP3K1 antibody, then identified the interacting proteins by tandem mass spectrometry (MS/MS) and standard Western blots or flow cytometry-based Western (Flow Western). By MS/MS, we observed increased binding of WNT-signaling proteins, including FRAT1 and PKCalpha, to the MAP3K1 complex in mutants from one familial case (p.Gly616Arg) and in two of eleven sporadic cases (p.Leu189Pro, p.Leu189Arg) versus wildtype cell lines. The increased binding of the interacting proteins was confirmed by Western blot analysis. Furthermore, we have demonstrated that these mutants enhanced the binding of RHOA to the MAP3K1 complexes, an effect that is known to inhibit SOX9 transcription. Thus, these results demonstrate that MS/MS and/or Flow Western co-IP analysis represent a rapid means for vetting new gene variants that are identified by sequencing the genomes of patients with genetic disorders by using readily accessible primary lymphoblastoid cells. In the case of 46,XY DSD, these methods and experiments demonstrated that the identified mutations enhanced the binding of factors that promote the WNT/beta catenin signaling of ovarian development and that suppress SOX9 transcription of testicular development. This provides a mechanism to account for the 46,XY DSD phenotypes observed in individuals with MAP3K1 mutations.

1143W

Identification of a Novel Missense Mutation in Exon 4 of the Human Factor VIII Gene Associated with Sever Hemophilia A Patient. *H. Onsori[1], M.A. Hosseinpour Feizi[2], Sh. Mintasser Kouhsari[3], A.A. Hosseinpour Feizi[4].* 1) Department of Biology, Islamic Azad University, Marand, Iran; 2) Faculty of Sciences, University of Tabriz, Tabriz, Iran; 3) Department of Biology, Faculty of Sciences, University of Tehran, Tehran, Iran; 4) Tabriz University of medival sciences, Tabriz, Iran.

Hemophilia A is an X-linked congenital bleeding disorder affecting approximately 1 in 10000 males, and is caused by deficiency of factor VIII (FVIII). The FVIII gene is on the long arm of the X chromosome at Xq28, spans 186 kb, and consists of 26 exons. In this research, we report a new mutation in FVIII gene in Hemophilia A patient recourse to Tabriz children's hospital in 2006. The patient was a boy with 6 years old (HA10) that for the reason of gum of the teeth bleeding recourse to Tabriz children's hospital in 2006. Sever bleeding, low rate of FVIII and medical inspections showed probability of sever hemophilia A. So, for detection of causal mutation, we used PCR-SSCP method in this research. In this study we report a novel missense mutation in exon 4 of FVIII gene that had not been reported in the list of FVIII gene mutations. The novel mutation due to T→C transition at codon 153 (TGC) of the factor VIII gene, which replaces a cysteine with an arginine residue. This mutation was recorded in GenBank with accession number EF581382. In this research observed that a point mutation in FVIII gene can be cause of sever hemophilia A. So, this study shows that the methodology of PCR-SSCP may be useful in detecting most of the genetic defects of hemophilic patients. Also, disease screening and genetic consulting before marriage are necessary for inhibition of the birth of affected Childs.

1144W

Histone acetylation deficits in lymphoblastoid cell lines from Rubinstein-Taybi syndrome patients. *C. Gervasini[1], J.P. Lopez-Atalaya[2], S. Spena[1], F. Mottadelli[1], M. Piccione[3], A. Selicorni[4], A. Barco[2], L. Larizza[1].* 1) Medical Genetics, University of Milan Milano, Italy; 2) Instituto de Neurociencias de Alicante (Universidad Miguel Hernández-Consejo Superior de Investigaciones Científicas), Alicante, Spain; 3) Dipartimento Materno Infantile, Università di Palermo,Palermo, Italy; 4) Ambulatorio Genetica Clinica Pediatrica Clinica Pediatrica Università Milano Bicocca Fondazione MBBM A.O S Gerardo Monza, Italy.

Rubinstein-Taybi syndrome (RSTS, #180849) is a congenital neurodevelopmental disorder characterized by postnatal growth deficiency, characteristic skeletal abnormalities and mental retardation caused by mutations in either of the genes encoding for the transcriptional co-activators with intrinsic histone acetyltransferase (HAT) activity CBP and p300. Recent studies have shown that neuronal histone acetylation is reduced in mouse models of RSTS. We selected nine patients, who carry mutations at the CREBBP locus that differ in the strength of the predicted consequences at the protein level and recapitulate different grades of the clinical variability in the spectrum of the syndrome, to generate lymphoblastoid cell lines. The patients were sorted out from a large cohort of 110 RSTS-diagnosed patients recruited from different Italian Clinical Units and screened for mutations in the entire coding sequence and intronic flanking regions of CREBBP gene by DHPLC (Denaturing High Performance Liquid Chromatography) analysis and direct sequencing. The group comprises one whole gene deletion, one truncating mutation, four missense mutations affecting the HAT domain, and three splicing mutations, all characterized at DNA, RNA and protein level. We assessed histone acetylation in the lymphoblastoid cell lines to correlate the possible deficits with the type of mutation in the CREBBP gene and with the severity of the phenotype, focusing on mental impairment. The comparison of RSTS and control cell lines revealed significant deficits in the acetylation of histones H2B and, in lower degree, in histone H2A. The most severe defects were observed in the cell lines carrying CREBBP whole gene deletion and the truncating c.2356delC mutation that lead to a haploinsufficiency state. Interestingly, the treatment with an inhibitor of acetytransferases rescued the histone acetylation deficit observed in the cell line showing the most pronounced impairment. Our results validate the seminal observations in mouse models of the disease and identify molecular markers of the disease such as specific acetylation deficit.

1145W

Identification of a new gene involved in IHH and ataxia by positional cloning of a patient with a balanced translocation t(3;12)(p13;p13). *H. Kim[1], R. Ullmann[2], H. Ropers[2], V. Kalscheuer[2], L. Layman[1].* 1) Dept OB/GYN, Georgia Health Sciences University, Augusta, GA.USA; 2) Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Ihnestrasse 63-73, Berlin, 14195 Germany.

Patients with idiopathic hypogonadotropic hypogonadism (IHH) present with absent puberty due to a hypothalamic-pituitary defect, and may be either normosmic (nIHH) or anosmic -Kallmann syndrome (KS). Although mutations in genes such as FGFR1, KAL1, CHD7, PROKR2, and GNRHR constitute the most commonly encountered etiologic genes in IHH/KS, the molecular basis for most patients remains unknown. Approximately 1/2,000 liveborns possess a de novo balanced translocation, and about 6% of these patients manifest the phenotype of a significant, developmental disorder. These rare, but exceedingly informative patients provide the unique opportunity to identify new genes causing birth defects. We were able to ascertain a male patient with a mos46,XY,t(3;12)(p13;p13)[18]/46,XY[3] with nIHH and cerebellar ataxia, which affords the opportunity to identify a gene important in pubertal development. Array Comparative Genome Hybridization (CGH) analysis of patient DNA was consistent with a balanced translocation and excluded Copy Number Variation (CNV) as the cause of the IHH phenotype. In this patient with the mosaic 3;12 translocation, homogeneous lymphoblastoid cell lines with the balanced translocation were successfully transformed from peripheral white blood cells. IHH and cerebellar ataxia often occur together and they are seen in Gordon Holms syndrome and Boucher-Neuhauser syndrome. We hypothesize that one of the breakpoints of this translocation case is likely to harbor a gene responsible for this phenotype. A positional cloning technique was applied to clone each of the breakpoints. FISH mapping for a breakpoint at 12q13 and array painting in this patient is underway. This chromosome translocation affords the potential to identify a gene involved in IHH and ataxia.

1146W

Microarray-based copy number analysis can identify genomic disruptions of PHEX causing X-linked hypophosphatemic rickets. *S. Mumm[1,2], D. Wenkert[2], M. Huskey[1], V.A. Wollberg[1,2], M.P. Whyte[1,2].* 1) Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA, 63110; 2) Center for Metabolic Bone Disease and Molecular Research, Shriners Hospital for Children, St. Louis, MO, United States, 63131.

Heritable forms of hypophosphatemic rickets (HR) include X-linked dominant HR (XLH, caused by de-activating mutations in the PHEX gene), autosomal recessive HR (ARHR, caused by de-activating mutations in the DMP1 gene), and autosomal dominant HR (ADHR, caused by activating mutations in the FGF23 gene). Over the past 27 years, we have cared for 268 pediatric HR patients from throughout the United States. After excluding 12 patients with HR from McCune-Albright syndrome, epidermal nevus syndrome, tumor-induced rickets, or cystinosis, etc., there were 72 sporadic cases diagnosed clinically with XLH. We are investigating 30 of these 72 sporadic patients (those for whom DNA is available) to identify their genetic defect causing rickets. In 2009, we reported that no mutations in the DMP1 or FGF23 genes were identified among these 30 sporadic HR cases (Mumm et al, 2009 ASHG meeting). We have now sequenced the PHEX gene in all 30 cases and identified mutations in 8 patients, (including splice site and nonsense mutations, and small insertion/deletions) and used microarray-based copy number analysis using Affymetrix SNP 6.0 arrays to identify apparent genomic disruptions in the PHEX gene for another 4 patients. Genomic DNA was isolated from blood leukocytes. All 22 coding exons and adjacent mRNA splice sites of the PHEX gene were amplified by PCR and sequenced. The patients' DNA sequences were analyzed by alignment to a control sequence using VectorNTI AlignX software, and by examining DNA sequence electropherograms. Microarray data analysis was performed with Partek Genomics Suite. Copy number changes, indicating genomic disruption of the PHEX gene, were found in 4 spordic HR patients. One girl had a large heterozygous deletion that removed exons 13-22 and extended beyond the 3' end of the gene, but did not appear to disrupt neighboring genes. Two unrelated male patients had an apparent copy number amplification of exons 13-15, and another boy had an apparent copy number amplification of exons 6-9. All of these disruptions must be confirmed using a complementary method. No copy number changes in PHEX, DMP1, or FGF23 were seen in the remaining sporadic HR patients. After a search for genetic defects in PHEX, DMP1, and FGF23, only 40% of our sporadic HR patients have PHEX mutations (27% identified by PCR/sequencing - 13% identified by microarray). For 60% of our sporadic HR patients, their underlying genetic defect remains unknown.

1147W

Approach to the genetic dissection of Primary Ciliary Dyskinesia (PCD) in the Qatari population. *A.S. AL-DOSARI[1], Y.A. ALSARRAJ[1], I.A. JANAHI[2], A. Saadoon[2], S.F. MOHAMMED[1], J. ALAMI[1], H.I. ELSHANTI[1].* 1) Molecular genetics, shafallah Medical Genetics Center, DOHA,Qatar; 2) Department of Pediatrics, Hamad Medical Corporation, Doha, Qatar.

Primary ciliary dyskinesia (PCD) is a heterogeneous autosomal recessive genetic disorder that leads to ultra-structural and functional defects in cilia and is characterized by recurrent and chronic respiratory infections, male infertility and occasionally situs inversus. PCD can result from mutations in at least 12 genes; however, these mutations explain the disease in only 40% of patients. We identified several extended Qatari families with multiple individuals affected by PCD according to clinical criteria. We performed whole-genome SNP genotyping assays using an Illumina platform for all families, after the development of a homozygosity map of the regions harboring genes known to play a role in PCD. If the affected individuals show homozygosity in a region identified by the homozygosity map, we resequenced that gene first. Families showing homozygosity in regions outside the regions identified by the homozygosity map, are further studied by linkage analysis and candidate gene positional cloning approach. However, in these families, we resequenced all known genes to exclude compound heterozygotes. We examined the homozygous region of each family and compared it to the developed homozygosity map. In one family, we encountered homozygosity in the region harboring DNAH11 on chromosome 7. Mutation analysis by direct resequencing of DNAH11 exons, flanking intronic sequences and splice sites showed a novel splice site mutation (c.5945+1 G>C) in exon 34, which produces a truncated protein. The mutation segregates with the disorder in this family, is not present in 338 control chromosomes and is inherently a deleterious mutation. We are currently studying the frequency of this mutation in the Qatari population and its effect on the transcription and translation of the protein. In another family, we identified a 35 Mb homozygous region on the long arm of chromosome 3. While examining candidate genes in the region guided by the human celiome, a recently published study identified CCDC39 as a PCD gene through studying an animal model and currently we are examining this gene in the family by resequencing. In a third family, we identified a 46 Mb homozygous region on chromosome 5. Candidate genes were prioritized based on conservation through evolution and expression in cilia and are being examined by resequencing. In conclusion, we have developed a population specific tailored approach to identify the genetic cause of PCD in families in Qatar.

1148W

The ciliopathy gene cc2d2a controls zebrafish photoreceptor outer segment development through a role in Rab8-dependent Vesicle trafficking. *R. Bachmann-Gagescu[1, 4], I.G. Phelps[1], G. Stearns[2], B.A. Link[3], S. Brockerhoff[2], C.B. Moens[4], D. Doherty[1].* 1) Pediatrics, Univ Washington, Seattle, WA; 2) Biochemistry, Univ Washington, Seattle, WA; 3) Cell Biology, Neurobiology & Anatomy, Medical College of Wisconsin, Milwaukee, WI, USA; 4) Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA.

Ciliopathies are a genetically and phenotypically heterogeneous group of human developmental disorders whose root cause is the absence or dysfunction of primary cilia. Joubert syndrome is characterized by a distinctive hindbrain malformation variably associated with retinal dystrophy and cystic kidney disease. Mutations in CC2D2A are found in ~10% of patients with Joubert syndrome. Here we describe the retinal phenotype of cc2d2a mutant zebrafish consisting of disorganized rod and cone photoreceptor outer segments resulting in abnormal visual function as measured by electroretinogram. Our analysis reveals trafficking defects in mutant photoreceptors affecting transmembrane outer segment proteins (opsins) and striking accumulation of vesicles, suggesting a role for Cc2d2a in vesicle trafficking and fusion. This is further supported by mislocalization of Rab8, a key regulator of opsin carrier vesicle trafficking, in cc2d2a mutant photoreceptors and by enhancement of the cc2d2a retinal and kidney phenotypes with partial knockdown of rab8. We demonstrate that Cc2d2a localizes to the connecting cilium in photoreceptors and to the transition zone in other ciliated cell types and that cilia are present in these cells in cc2d2a mutants, arguing against a primary function for Cc2d2a in ciliogenesis. Our data support a model where Cc2d2a, localized at the photoreceptor connecting cilium/transition zone, facilitates protein transport through a role in Rab8-dependent vesicle trafficking and fusion.

1149W

Mutational Analysis of *SDCCAG8* in Bardet-Biedl Syndrome Patients with Severe Renal Disease. *G. Billingsley[1], C. Deveault[1], E. Héon[1, 2].* 1) Genetics and Genome Biology Program; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada.

Ciliopathies are a heterogeneous group of diseases that present overlap in both clinical features (retinal degeneration, obesity, renal abnormalities, digit anomaly, cognitive impairment) and genetic basis. Mutations of *SDCCAG8* (serologically defined colon cancer antigen 8, OMIM 613524) were recently identified as the cause of a retinal-renal ciliopathy which included both Senior-Loken syndrome (SLSN) and Bardet-Biedl syndrome (BBS) patients. All patients had end stage kidney failure, retinal degeneration and no polydactyly. In our BBS cohort (105 cases), mutational analysis of *BBS1-BBS12* identified disease-causing mutations in 76% of families. We selected a subset of BBS cases with no disease causing gene presently identified, to undergo mutational analysis of *SDCCAG8*. Seven BBS cases (6 probands) with severe renal disease and retinal dystrophy were selected for mutational analysis of *SDCCAG8* (NM_006642.3). Five patients had no digit anomaly, 4 patients had some degree of cognitive impairment and 3 patients were obese. Direct sequencing of PCR amplified coding exons (n = 18) and flanking introns was performed. Family segregation and control screening (n=150) confirmed the pathogenicity of novel sequence changes. Two East Indian sibs were found to carry previously published (Indian) compound heterozygous mutations in exon 12 (c.1444delA, p.Thr482LysfsX12) and exon 14 (c.1627-1630 delATAG, p.Asp543AlafsX24) which segregated with the disease phenotype. These sibs underwent kidney transplant at ages 11 and 9. The family also carried a novel polymorphism (c.1473 + 48 insA, MAF = 0.3) in cis with the exon 12 mutation. In addition, the following novel BBS variants were observed in one sib: *BBS5* c.751 A>G, p. N251D and *BBS11* c.896 G>A, p.R299Q. The phenotype information collected did not support a significant functional influence of these *BBS* changes on phenotype severity. In conclusion, results to date show that *SDCCAG8* may play an important role in “BBS patients” with severe renal disease and no digit anomaly. Further screening is ongoing. Comprehensive phenotyping of ciliopathy-related diseases will help direct the prioritization for genetic screening of newly identified patients.

A Critical Review of the Human Ciliopathy-Related Literature Reveals a Need for Revision of Diagnostic Criteria. *C. Deveault[1], G. Billingsley[1], E. Héon[1,2].* 1) Department of Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada.

Introduction Ciliopathies are an emerging group of disorders, often pleiotropic, characterized by significant genetic heterogeneity and clinical overlaps. Bardet-Biedl syndrome (BBS) is a pleiotropic ciliopathy disorder that has been shown to overlap clinically and genetically with other ciliopathies such as McKusick-Kaufman syndrome (MKKS), Alström syndrome (ALMS), Meckel-Gruber syndrome (MKS) and Joubert syndrome (JBTS). The diagnostic features of these conditions are evolving with our increasing understanding of their molecular background. For these 5 ciliopathies, we performed a comprehensive literature review of cases published with two principal mutations and their reported clinical features.

Methods Publications up to May 2011, discussing the molecular characterization of those five related ciliopathies (BBS, JBTS, MKS, MKKS and ALMS) which presented cases or families with two principal mutations were included. For every case, the mutations and complete clinical features provided were tabulated and compared with the proposed current diagnostic criteria.

Results The literature review of JBTS syndrome showed strong and well defined clinical data for each of the genes in which principal mutations are found. Correlations of certain features with specific genes were observed and the molar tooth sign was consistently present However, for the BBS literature, over half (54.66%) of the cases with mutations reported did not show detailed phenotype information and in some cases was limited to a mention of whether or not the patients fit the published criterias. Trends are observed but correlations are not possible due to the inconsistent clinical phenotype information provided. A diagnostic algorithm is presented.

Conclusions Phenotype-genotype correlation in JBTS now enables a strategized mutational analysis based on the phenotype of the patient. This is not possible for BBS. This highlights the need for a more systematic clinical characterization of BBS cases in order to determine potential correlations, guidelines for genetic screening and optimize patient management.

Genetic and phenotypic characterisation of an ovine large animal model of the MKS/JBTS/NPHP ciliopathy, Meckel-Gruber syndrome. *M.R. Eccles[1], B. Lett[1], C. Stayner[1], A. Wiles[2], L. Slobbe[1], K. Parker[2], A.C. Johnstone[3], R.J. Walker[2], A.C. Poole[2], J. McEwan[4], D. Markie[1].* 1) Dept Pathology, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand; 2) Dept Medicine, Dunedin School of Medicine, University of Otago, Dunedin, New Zealand; 3) Institute of Veterinary, Animal and Biomedical Sciences, Massey University, Palmerston North, New Zealand; 4) Invermay Agricultural Centre, AgResearch, Mosgiel, Otago, New Zealand.

Background: Cystic renal diseases are among the most common genetically inherited disorders in humans, and frequently cause end-stage renal failure. All are associated with defects in primary cilia function. Autosomal recessive polycystic kidney disease (ARPKD) mainly affects infants and young children, and may be present in a number of different syndromes, including Meckel-Gruber Syndrome (MKS). We have identified a unique ovine model of MKS, and are characterising the ovine phenotype and genotype. Methods: New Zealand inbred Coopworth breed sheep carrying the disease allele were maintained for research purposes. Homozygosity mapping was chosen to map candidate disease loci. DNA isolated from 14 affected lambs and 1 carrier ram was analyzed using a recently developed single nucleotide polymorphisms (SNPs) Beadchip (SNP50; International Sheep Genomics Consortium / Illumina Inc, USA). Results & Discussion: Three candidate chromosomal regions were identified by homozygosity mapping, involving chromosomes 4, 9, and 11. The strongest candidate region on chromosome 9 contains the *TMEM67*/*MKS3* gene, which has been implicated in many ciliopathies, including Meckel-Gruber syndrome. The characteristic abnormalities of human infants with Meckel-Gruber syndrome match the phenotype in the affected sheep, except for absence of encephalocoele and polydactyly more commonly associated with *MKS1* mutations. Sequencing of all 28 exons of the ovine *TMEM67*/*MKS3* gene revealed two novel missense variants, both in exon 20, which were co-inherited in every affected lamb and known carrier sheep examined, but not observed in >30 unrelated Coopworth sheep. The exon 20 variants led to amino acid substitutions at two closely spaced isoleucine residues (I680N and I686S) in the predicted MKS3 protein, meckelin, at positions conserved across all vertebrate species, suggesting that the isoleucines play an important role in meckelin structure/function. Modelling of these sequence variants using structure/function prediction programmes (A-GVGD, SIFT, Polyphen) uniformly predict that either variant would have a deleterious effect on protein function. Meckelin is now thought to form part of a protein complex responsible for delivery and `gate keeping' of proteins destined for the primary cilium, and our on-going studies are aimed at determining whether a shift in the localization of meckelin from the plasma membrane has occurred in affected cells when compared with wild-type cells.

The short rib-polydactyly (SRPS) group belongs to the ciliopathy spectrum and includes four distinct lethal autosomal recessive conditions (type I-IV) characterized by short ribs, inconstant polydactyly and variable malformations. Among them, Majewski syndrome or SRP type II (MIM 263520) is characterized by short tubular bones with smooth ends, pre- and postaxial polysyndactyly, and characteristic short ovoid tibiae. Other features include cleft lip/palate, malformed epiglottis and larynx, renal cysts, genital, cardiac and intestinal abnormalities. It is closely related to Beemer-Langer syndrome or SRP type IV (MIM 269860) which is distinguished by inconstant pre-axial polydactyly, short and often bowed long bones, tibia longer than fibulae and high frequency of brain defects. Recently, mutations in *NEK1* have been identified in three families with SRP type II. *NEK1* encodes a serine/threonine kinase with proposed function in DNA-double strand repair, neuronal development and coordination of cell-cycle-associated ciliogenesis. The aim of our study was to screen *NEK1* in SRP type II or type IV either by linkage analysis in consanguineous families or by direct sequencing in sporadic cases. Among the SRP type II cases, five were from consanguineous families originating from Lebanon, India, Madagascar, Tunisia, and six were non-consanguineous cases originating from Europe and Brazil. Among the SRP type IV cases, two were consanguineous originating from Tunisia and two were non-consanguineous cases originating from Europe. In three consanguineous SRP type II families, we identified three distinct *NEK1* mutations present in the homozygous state in the affected children including two missense mutations (c.433G>A; p.G145R) and (c.758T>C; p.L253S), and one frameshift mutation (c.2846_2847insGG-2847delT; p.D949EfsX6) respectively. These mutations cosegregated with the disease, were located in regions encoding conserved kinase and C domains and were not observed in 200 control chromosomes. Furthermore, *NEK1* was excluded in the other SRP II families and in all SRP type IV cases. A genome wide search is currently performed for two consanguineous families with SRP type II and type IV respectively. We conclude that *NEK1* is not the only gene responsible for SRP type II and is not involved in SRP type IV supporting locus heterogeneity in this group of disorders. Ongoing studies will hopefully identify other genes presumably also involved in ciliogenesis.

1153W

Strain-specific differences in perinatal viability support genetic modifiers in Bardet-Biedl syndrome. *R.L. Gottlieb[1], D. Nishimura[2,3], C. Searby[2,3], K. Bugge[2,3], V.C. Sheffield[2,3].* 1) Internal Medicine, University of Iowa Hospitals and Clinics, Iowa City, IA; 2) Pediatrics, University of Iowa Hospitals and Clinics, Iowa City, IA; 3) HHMI.

Bardet-Biedl Syndrome (BBS) is an autosomal recessive disorder caused by mutations in as many as 16 different genes. The cardinal feature of BBS are central obesity, retinal degeneration, developmental delay, renal defects, and polydactyly. BBS phenotypic modification via either complex inheritance or modifier loci has been suggested. Low weights at weaning precede progressive adult-onset obesity in several murine models of BBS. We report highly skewed non-Mendelian ratios of BBS2 knock-out mice ($Bbs2^{-/-}$) following seven generation backcrossing of heterozygous carriers to the C57/Bl6 murine strain, in contrast to nearly Mendelian ratios present in litters of $Bbs2^{-/-}$ mice on the 129 inbred murine strain, and intermediate skewing on the mixed background. The litters display Mendelian ratios late in utero, and non-Mendelian skewing occurs predominantly due to the neonatal death of $Bbs2^{-/-}$ mice between P0-P3. Together, these data indicate that the fitness of $Bbs2^{-/-}$ mice is dependent on genetic background effects consistent with inheritance of one or more modifier alleles. Our current data indicate that that the decreased viability of $Bbs2^{-/-}$ mice on the C57/Bl6 genetic background is neither due to an overt cardiopulmonary defect nor due to an overt defect in lateralit We have also begun similar experiments using a BBS1 knock-out model ($Bbs1^{-/-}$). We have previously created a knock-in mouse that harbors the BBS1 M390R mutation ($^{Bbs1M390R/M390R}$). Crossing of heterozygous mice Bbs1+/- was found to produce homozygous knockout offspring ($Bbs1^{-/-}$) at a level far below expected values (2.9%, n=173, $p=2e^{-8}$) at weaning. Necropsy of $Bbs1^{-/-}$ mice with spontaneous neonatal demise has not revealed any overt cardiovascular defect to-date. However, several mice have survived the first two weeks of life by which point a failure-to-thrive phenotype becomes overt with acquired microsomia. Echocardiography of a live microsomic pup indicates a structurally normal heart. We hypothesize that understanding the mechanism of the failure-to-thrive phenotype in these mice will lead to a better understanding of BBS related pathophysiology.

1154W

***PKD1* hypomorphic alleles act as major modulators of disease severity in Autosomal Dominant Polycystic Kidney Disease (ADPKD).** *K. Hopp[1], S. Rossetti[2], C.J. Ward[2], C.M. Heyer[2], J.L. Sundsbak[2], V.E. Torres[2], P.C. Harris[2].* 1) Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN; 2) Nephrology and Hypertension Research, Mayo Clinic, Rochester, MN.

ADPKD is a dominantly inherited kidney condition normally caused by single inactivating mutations to *PKD1*/*PKD2*. End stage renal disease (ESRD) typically occurs at 54y in PKD1 and 74y in PKD2. However, we recently described *PKD1* hypomorphic alleles that result in very mild PKD in heterozygotes and modify the typical disease to *in utero*/early onset disease when found in *trans* with a truncating mutation or a second pathogenic missense allele. To further investigate the role of hypomorphic alleles, we screened additional ADPKD families with atypical presentations (*in utero*, early, or late onset disease). This analysis identified a number of distinct *PKD1* genotypic patterns that likely explain the phenotype. In mild cases we found one or two likely hypomorphic alleles segregating with the disease, but rarely resulting in ESRD even in old age. Mutations in this group include L2816P and co-segregation of I3167F/R3277H. Two alleles in *cis*, such as V609G and N970K, can also result in typical ADPKD. In two *in utero* onset cases the likely hypomorphic alleles (S4189F or R4276W) were found in *trans* with a truncating mutation. A similar arrangement with a weaker hypomorphic allele, G2452C, resulted in ESRD at 25y. These studies indicate that hypomorphic alleles either as pathogenic mutations or modifiers often significantly modulate ADPKD severity. To further validate the concept and to understand the mechanism of disease, we generated a mouse knock-in model of one of the initially identified hypomorphic alleles, *PKD1* R3277C. Compound heterozygous animals ($Pkd1^{C/-}$) mimic *in utero* ADPKD, presenting with progressive cystic disease initiated by E16.5d and resulting in grossly enlarged kidneys by 1 month. In contrast, homozygous mice ($Pkd1^{C/C}$) present with mild disease including slightly but significantly enlarged kidneys with a few medium sized cysts at 3 month of age. Ultrasound analysis of these animals highlights the slow but progressive disease development, similar to typical ADPKD patients. We further developed an *in-vitro* system to study the pathobiology of these alleles in respect to protein folding, function and localization. Initial analysis shows that the pathobiology of the *PKD1* R3277C allele is not associated with disrupted membrane integration or protein cleavage. Together, our data highlights that the level of functional protein is key to disease development/severity. This is of clinical importance for the molecular diagnostics and prognostic of ADPKD.

Next-generation exon re-sequencing of 86 ciliopathy candidate genes in 480 individuals using a DNA pooling strategy. *E.A. Otto[1], J.L. Innis[1], F. Hildebrandt[1,2,3].* 1) Dept Ped, Univ Michigan, Ann Arbor, MI; 2) Dept Hum Genet, Univ Michigan, Ann Arbor, MI; 3) Howard Hughes Medical Institute.

Background: Nephronophthisis-related ciliopathies (NPHP-RC) comprise a group of autosomal recessive cystic kidney diseases that include nephronophthisis (NPHP), Senior-Loken-(SLS), Joubert-, and Meckel syndrome. 23 causative genes have been identified, rendering Sanger re-sequencing tedious and expensive. To overcome this problem we devised a DNA pooling and NextGen sequencing (NGS) strategy. **Methods:** We performed mutation analysis in 480 individuals with NPHP-RC by exon re-sequencing on a Illumina HighSeq next generation sequencer platform. 1,400 exons derived from 23 known NPHP-RC genes (*NPHP1-NPHP11, AHI1, ARL13B, TTC21B, TMEM216, TMEM138, CC2D2A, INPP5E, TCTN1, TCTN2, ATXN10, XPNPEP3, MKS1*) and 63 ciliopathy candidate genes were resequenced. We generated 5 equimolar DNA-pools derived from 96 patients each, and 1 pool of 96 control individuals as PCR templates. PCR products were enzymatically processed using DNaseI- and exonuclease BAL-31 to generate small random fragments followed by library preparation and paired-end sequencing of 100 bases on 6 lanes of an Illumina HighSeq platform. Alignment of sequence reads to the human reference genome and variant/mutation calling were performed using CLC Genomics-Workbench™ software. A mutant frequency below 0.3% or a nucleotide coverage below 1000X were used as a cutoff. Potential mutation carriers were identified by MALDI-TOF analysis (Sequenom™) or by direct Sanger sequencing of all 96 patients from the respective DNA-pool. **Results:** NGS (6 lanes) generated about 1 billion reads (100 Gb). The median coverage per exonic nucleotide was 27,183 (mean: 38,873). We identified 25 loss-of-function mutations e.g. in *NPHP1* (M1V, E38X), *INVS* (2069-1G>T), *NPHP3* (R1207X, R1259X), *NPHP4* (R59X, 1763+1G>A), *IQCB1* (R332X, R461X, R364X, W444X, R445X), *CEP290* (Q662X, R751X, Q1268X, K1575X, 3103-2A>G), *RPGRIP1L* (A1183G), *SDCCAG8* (E262X, Q371X), *TMEM67* (R198X), *AHI1* (R891X), *CC2D2A* (337-2A>G), *XPNPEP3* (793-2A>G), and *TTC21B* (W119X). Furthermore, we found 108 different missense variants of unknown significance. Mutation analysis in 63 additional candidate genes revealed further nonsense- (3), frameshift- (2), obligatory splice site- (3), and start codon mutations (2) in seven of these novel ciliary/centrosomal candidate genes. **Conclusions:** The combined approach of DNA pooling followed by NGS facilitates mutation analysis in broadly heterogeneous single-gene disorders and accelerates identification of novel disease genes.

Primary Ciliary Dyskinesia Caused by Homozygous Mutation in DNAL1 Encoding Dynein Light Chain 1. *R. Parvari[1,3], M. Mazor[1], S. Alkrinawi[2], V. Chlifa-Caspi[3], E. Manor[4], V.C. Sheffield[5], M. Aviram[2].* 1) Department of Virology and Developmental Genetics, Ben Gurion University of the Negev, Beer Sheva, Israel; 2) Division of Pediatrics, Soroka University Medical Center, Beer-Sheva, 84101 Israel; 3) National Institute of Biotechnology in the Negev, Ben Gurion University of the Negev, Beer Sheva 84105, Israel; 4) Institute of Genetics, Soroka Medical Center, Beer Sheva 84105 and Faculty of Health Sciences, Ben Gurion University of the Negev, Beer Sheva 84101, Israel; 5) Department of Pediatrics - Division of Medical Genetics, Howard Hughes Medical Institute, University of Iowa, Iowa City, IA 52242, USA.

Genetic defects affecting motility of cilia and flagella cause chronic destructive airway disease, randomization of left-right body asymmetry, and, frequently, male infertility in primary ciliary dyskinesia (PCD). The most frequent defects involve outer and inner dynein arms (ODAs and IDAs) that are large multiprotein complexes responsible for cilia-beat generation and regulation, respectively. Although long suspected that mutations in DNAL1 encoding the outer arm dynein light chain1 may cause PCD such mutations were not found.We demonstrate here that a homozygous point mutation in this gene is associated with PCD with absent or markedly shortened outer dynein arms. The mutation (NM031427.3: c.449A>G; p.Asn150Ser) changes the Asn at position150 which is critical for the proper tight turn between the beta strand and the alpha helix of the leucine rich repeat in the hydrophobic face that connects to the dynein heavy chain. The mutation reduces the stability of the axonemal dynein light chain 1 and damages its interactions with dynein heavy chain and with tubulin. This study adds another important component to understanding the types of mutations that cause PCD and provides clinical information regarding a specific mutation in a gene not yet described to be associated with PCD.

1157W

Mutations of NEK1 cause short rib-polydactyly syndrome type Majewski with defective Ciliogenesis. *C.T. Thiel[1], K. Kessler[1], A. Giessl[2], A. Dimmler[3], S.A. Shalev[4, 5], S. von der Haar[6], M. Zenker[7], D. Zahnleiter[1], H. Stoess[8], E. Beinder[9], R. Abou Jamra[1], A.B. Ekici[1], N. Schroeder-Kress[2], T. Aigner[10], T. Kirchner[11], A. Reis[1], J. Brandstaetter[2], A. Rauch[12].* 1) Institute of Human Genetics, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany; 2) Animal Physiology, Friedrich-Alexander University Erlangen-Nuremberg, Erlangen, Germany; 3) Institute of Pathology, St. Vincentius Hospital, Karlsruhe, Germany; 4) Genetic Institute, Emek Medical Center, Afula, Israel; 5) Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel; 6) Private Clinic Kossakiewicz, Nuremberg, Germany; 7) Institute of Human Genetics, Otto-von-Guericke University Magdeburg, Magdeburg, Germany; 8) Institute of Pathology, St. Johannisstift, Paderborn, Germany; 9) Department of Obstetrics, University Hospital, Zurich, Switzerland; 10) Institute of Pathology, University of Leipzig, Leipzig, Germany; 11) Institute of Pathology, Ludwig-Maximilians University Munich, Munich, Germany; 12) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Switzerland.

Defects of ciliogenesis have been implicated in a wide range of human phenotypes and play a crucial role in different signal transduction pathways and cell cycle coordination. We thoroughly delineated the clinical, radiographic, and histological phenotype of the autosomal-recessive short-rib polydactyly syndrome Majewski type (SRPS II). Parametric multipoint linkage and haplotype structure analysis confirmed a linked interval with a maximum LOD score of 2.95 on chromosome 4. Assuming an overlap of the phenotypic spectrum of our patients with other ciliopathies, we used known genes of the cilia proteome database and compared them with the genes in our candidate interval. The NIMA-related kinase 1 (NEK1) gene was highlighted as homozygous mutant mice show polycystic kidney disease, craniofacial anomalies, and growth reduction. Sequencing of NEK1 identified nonsense, splice-site and frame shift mutations in patients with SRPS II. NEK1 encodes a serine/threonine kinase with proposed function in DNA double-strand repair, neuronal development, and coordination of cell cycle-associated ciliogenesis. With immunofluorescence analyses we confirmed that the absence of functional NEK1 significantly decreases the number of ciliated fibroblasts and alters the structural morphology of the primary cilium in vivo as well. Transmission electron microscopy indicated a defect in progression from stage I after vesicular accumulation of ciliogenesis to stage II and subsequent failure of axoneme growth. Furthermore, the effect of the known SRPS genes, DYNC2H1 and IFT80, and NEK1 on the cilia associated pathways in siRNA experiments explained the phenotypic overlap of different SRPSs. We further substantiate a proposed digenic diallelic inheritance of ciliopathies by identification of heterozygous mutations in NEK1 and DYNC2H1 in a further non-consanguineous family.

KIF7, the human ortholog of *Drosophila Costal 2*, represents a key component of the Hedgehog (Hh) signaling pathway which in vertebrates is dependent upon primary cilium. Here we report mutations in *KIF7* in 11 unrelated individuals with two overlapping disorders, the rare Hydrolethalus (HLS, OMIM 236680) and Acrocallosal syndromes (ACLS, OMIM 200990) sharing polydactyly, midline brain and facial abnormalities confirming these two syndromes as members of the ciliopathy group, and extending the phenotypic spectrum of ACLS. Transcriptome-wide analysis on *KIF7* mutated patient RNA showed a specific up-regulation of most of the known Gli transcription factor target genes associated with impaired GLI3 processing and consistent with a major role of KIF7 in the transduction of the Hh signaling pathway in humans. *KIF7* is also a likely contributor of alleles across the ciliopathy phenotypic spectrum; sequencing of a cohort of patients with diverse ciliopathies revealed several heterozygous missense changes which, upon *in vivo* testing in zebrafish were shown to be detrimental to protein function. Furthermore, consistent with an epistatic role for such alleles, *in vivo* genetic interaction studies in zebrafish indicated that *KIF7* hypomorphic alleles could exacerbate the phenotype induced by the loss of other ciliopathy loci. Our data demonstrate the conserved role of KIF7 in human primary cilia to ensure the transduction of the Hedgehog signaling pathway through the regulation of Gli transcription factor activity and expand the clinical spectrum of ciliopathies.

1159W

The MDM2/MDMX complex is required for control of p53 activity in vivo. *L. Huang[1], Z. Yan[1], X.D. Liao[1], Y. Li[1], J. Yang[1], Z.G. Wang[1,2], Y. Zuo[3], H. Kawai[4], M. Shadfan[5], S. Ganapathy[5], Z.M. Yuan[5].* 1) Dept Med Gen, Shanghai Jiaotong Univ Sch Med, Shanghai 200025 , China; 2) Shanghai Research Centre for Model Organisms, Shanghai 201203, China; 3) Department of Biochemistry and Molecular and Cell Biology, Shanghai Jiao Tong University School of Medicine, Shanghai 200025, China; 4) Institution of Radiation Research, Hiroshima University, Hiroshima 732-0068, Japan; 5) Department of Radiation Oncology, UTHSCSA, Texas 78229 USA.

There are currently two distinct models proposed to explain why both MDM2 and MDMX are required in p53 control, with a key difference centered on whether these two p53 inhibitors work together or independently. To test these two competing models, we generated knockin mice expressing a point-mutation MDMX mutant (C462A) that is defective in MDM2 binding. This approach allowed a targeted disassociation of the MDM2/MDMX heterocomplex without affecting either the ability of MDMX to bind to p53 or the MDM2 protein itself at all. Significantly, MdmxC462A/C462A homozygous mice died at around day 9.5 of embryonic development, resulting from a combination of apoptosis and decreased cell proliferation, as shown by TUNEL and BrdU incorporation assays, respectively. Interestingly, even though the MDMX mutant protein abundance was found elevated in the MdmxC462A/C462A homozygous embryos, both the abundance and activity of p53 were markedly increased. A p53-dependent death was demonstrated by the finding that concomitant deletion of p53 completely rescued the embryonic lethality in MdmxC462A/C462A homozygous mice. Our data demonstrates that MDM2 and MDMX function as an integral complex in p53 control, providing new insights into the nonredundant nature of the function of MDM2 and MDMX.

1160W

Analysis of splice variants of the *FANCC* gene and their impact in FANC-BRCA DNA repair pathway. *S. Bélanger, C. Joly Beauparlant, C.S. Pedneault, N. Litim, O. Ouellette, Y. Labrie, F. Durocher, INHERIT.* Cancer Genomics Laboratory, CHUL Research Centre, CHUQ, Laval University, Quebec, Canada.

Recent attention and research efforts have been drawn toward the Fanconi Anemia gene family due to their implication in what is known as the FANC-BRCA DNA repair pathway. Until now, 15 genes have been identified in the FA family and they are all essential for its proper functioning. Regarding breast cancer, three FA genes are now known to be responsible for an increase in the risk of developing breast cancer : *FANCD1/BRCA2*, FANCJ/BRIP1 and *FANCN/PALB2*. Following the sequencing of the complementary DNA (cDNA) of the gene *FANCC* in high-risk French-Canadian women and unrelated, unaffected women from the same population, at least three distinct splicing events were observed. Of these transcript variants, one is the skipping of exon 7 (*FANCCdel7*) and another is the insertion of an intronic fragment between the exon 4 and 5 (*FANCCins4a*). RT-PCR demonstrated the presence of these variants in the majority of tested tissues and cell lines. Moreover, none of these splicing events seemed to be affected by nonsense-mediated mRNA decay. Since the *FANCCdel7* variant does not alter the open reading frame, localization testing was performed with the vector pEGFP and demonstrated that contrary to the wild type FANCC protein, the variant FANCCdel7 is not recruited to the nucleus following treatment with a potent DNA crosslinker like mitomycin C. The optimization of the minigene technique allowed to clarify the impacts of different genomic variants in the skipping event of the 7th exon of *FANCC*. Monoubiquitylation experiments were performed with the same variant in order to evaluate its implication in the DNA repair pathway. Other experiments such as coimmunoprecipitation and colony survival assays are currently underway and will help to unravel the different effects that the different alternative transcripts of *FANCC* may have on the FANC-BRCA DNA repair pathway and in the maintenance of genomic integrity.

Analysis of FANCA sequence and splicing variants in French Canadian women with high risk of breast and ovarian cancer. *F. Durocher, Y. Labrie, S. Desjardins, N. Litim, G. Ouellette, INHERIT BRCAs.* Cancer Genomics Lab, CHUQ Research Center (CHUL) and Laval University 2705, Laurier Blvd Quebec, PQ, Canada.

Sequence alterations in FANCA gene account for approximately 60-70% of Fanconi Anemia (FA) cases, a rare recessive disease characterized by bone marrow failure, genomic instability and predisposition to cancer. The majority of genes associated with breast cancer susceptibility, including BRCA1 and BRCA2 genes, are involved in DNA repair mechanisms. Moreover of the four genes recently associated with an increase susceptibility to breast cancer, three are FA genes: FANCD1/BRCA2, FANCJ/BACH1/BRIP1, and FANCN/PALB2. FANCA is implicated in DNA repair and has been shown to directly interact with BRCA1. It has been proposed that the formation of FANCA/G (regulated by the phosphorylation of FANCA) and FANCB/L sub-complexes altogether with FANCM, represent the initial step for DNA repair activation and subsequent formation of other sub-complexes leading to ubiquitination of FANCD2 and FANCI. As only approximately 25% of inherited breast cancers are attributable to BRCA1/2 mutations, FANCA therefore becomes an attractive candidate for breast cancer susceptibility. We thus analyzed FANCA gene in high-risk French Canadian non-BRCA1/2 breast cancer individuals as well as in healthy control individuals from the same population. Among a total of 85 sequence variants found in both series, 26 are coding variants and 17 are missense variations leading to amino acid changes. Three of the amino acid changes, namely Thr561Met, Cys625Ser and particularly Ser1088Phe, which has been previously reported to be associated with FA, are predicted to be damaging by the SIFT and PolyPhen softwares. Haplotype analyses using variants having a frequency >5% or coding variants, identified 9 and 7 haplotypes, respectively, with a frequency >3%. In both analyses, specific haplotypes were significantly over-represented in one sample set while global haplotype analyses led to significant Fisher's p-values (0.01 for MAF>5%; 0.0006 for coding variants). cDNA amplification revealed significant expression of 4 alternative splicing events (ASEs): one leading to the insertion of an intronic portion of intron 10, and the skipping of exons 11, 30 and 31. In silico analyses of relevant genomic variants have been performed in order to identify potential variations involved in the expression of these ASEs. Sequence variants in FANCA could therefore be potential spoilers of the Fanconi-BRCA pathway and as a result, they could in turn have an impact in non-BRCA1/2 breast cancer families.

1162W

Functional implications of the FancLdel4 splice variant on DNA repair in the FANC-BRCA pathway. *C.S. Pedneault, S. Belanger, G. Ouellette, K. Plourde, N. Litim, Y. Labrie, F. Durocher, INHERIT.* Cancer Genomics Laboratory, CHUL Research Center, CHUQ, Laval University, Quebec, Canada.

The 15 known Fanconi proteins (*FANCA, B, C, D1, D2, E, F, G, I, J, L, M, N, O, P*) function altogether to repair DNA interstrand cross-links (ICLs) in response to DNA damaging agents. Biallelic mutation carriers for a single FANC gene suffer from Fanconi Anemia, while a monoallelic mutation can confer breast cancer susceptibility. This type of association has already been demonstrated for the *FANCD1*/*BRCA2*, *FANCJ*/*BRIP1*, *FANCN*/*PALB2* and *RAD51C*/*FANCO* genes. FANC2 monoubiquitilation activates the recruitment of the DNA repair proteins at the ICL lesions, thus making this step the key event of the Fanconi pathway. The monoubiquitilation is catalyzed by FANCL, which is the only known Fanconi protein to possess an ubiquitin ligase activity. A *FANCL* splicing variant showing exon 4 skipping has been isolated and is expressed in several breast cancer and Fanconi-deficient cell lines. The deletion does not alter the reading frame, which most probably makes the transcript unaffected by nonsense-mediated decay (NMD) and can indeed be over-expressed in human cells by transfection. In silico analysis shows that 4 of the 19 amino acids are perfectly conserved in all species down to the drosophilia, and 5 others are semi-conserved, thus suggesting an essential function to this portion of the protein. To this day, results obtained with FANCL-GFP fusion proteins show that the alternative form loses its capacity to translocate to the nucleus, where it normally performs its activities. A minigene assay will allow to evaluate the contribution of certain sequence variants to exon skipping in the exon 4 region. Co-immunoprecipitation experiments and monoubiquitilation studies are in progress to better understand the functions of this new splicing variant.

Molecular signatures of Tissue Inhibitor of Metalloproteinases-1 over-expression in breast cancer cells. *K.C. Belling[1], C.A. Bjerre[2], L. Vinther[2], L. Fogh[2], K. Do[1], A.S. Rasmussen[2], U. Lademann[2], W. Jun[3], L. Bolund[3], N. Brünner[2], J. Stenvang[2], R. Gupta[1].* 1) Center for Biological Sequence Analysis, Technical University of Denmark, Kgs Lyngby, Denmark; 2) Sino-Danish Breast Cancer Research Centre at Faculty of Life Sciences, University of Copenhagen, Copenhagen, Denmark; 3) Beijing Genomics Institute, Shenzhen, China.

Tissue Inhibitor of Metalloproteinases-1 (TIMP-1) is present in many breast tumour cells and possesses several cancer-promoting functions such as stimulation of growth and inhibition of apoptosis. Lack of TIMP-1 has in clinical studies been shown to predict increased sensitivity to the topoisomerase 2 inhibitor epirubicin in adjuvant treatment of breast cancer. Also, low plasma TIMP-1 levels have been shown associated with increased benefit from the topoisomerase 1 inhibitor irinotecan in patients with metastatic colorectal cancer. The molecular reasons behind these observations are still unclear. In order to gain detailed insight into the molecular mechanisms of TIMP-1 interference with benefit from these drugs, we transfected MCF-7 human breast cancer cells with a plasmid conferring TIMP-1 expression. Twelve clones representing different levels of TIMP-1 expression and protein levels were applied to Agilent whole human genome oligo microarrays 4x44K. The data were analyzed using the limma R/Bioconductor package. Transcripts with expression correlating either negatively or positively with TIMP-1 expression were identified using linear regression. A subset of transcripts highly correlated with TIMP-1 expression has been identified. A systems biological analysis of these genes is currently ongoing, including analysis of pathways and protein-protein interaction complexes. The combined analyses should provide insights into how TIMP-1 affects cancer cells and response to topoisomerase inhibitors. Data presented here will focus on the transcriptomics and its network biology interpretation.

Detection of viral sequences in cancer transcriptomes using high-throughput sequence analysis. *I. Borozan[1], S. Wilson[1], A.M.K. Brown[1], P. Laflamme[1], S. Gnaneshan[2], R. Rottapel[1], J.D. McPherson[1], V. Ferretti[1].* 1) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) Ontario Agency for Health Protection and Promotion, Toronto, Ontario, Canada.

In a recent worldwide study by the World Health Organization it was estimated that 18% of human cancers were caused by infection, of these 12% have been shown to be of viral origin. For example, the papillomavirus HPV is now known to be responsible for 70% of cervical cancers, which represents 500,000 new cases per year worldwide. The discovery of new human cancer viruses is still challenging despite the advance of molecular technologies. Recently novel computational methods have been successfully applied to the discovery of new pathogens. Here we present an innovative genome-wide computational pipeline for identifying both exogenous and endogenous viral nucleotide sequences in tumor genomes and transcriptomes with the ultimate goal to elucidate new viruses that may cause human cancer.

The pipeline is composed of four main components: the digital transcriptome subtraction pipeline for both the Illumina and SOLiD sequencing platforms written in R, a suite of R based statistical tools for assessing the statistical significance of viral genomes hit, a high-performance database for storing alignment results and sequence annotations, and a web application, called Xeno, for the visualization (using GBrowse), query and analysis of aligned reads. The digital transcriptome subtraction was implemented to subtract in silico known human sequences from cancer transcriptome datasets leaving candidate non-human sequences for further analysis. Reads from each sample within each cancer type are first filtered according to their mapping quality metrics and then the coverage across known viral sequences and their gene coding regions is calculated. Viruses that show hits are ranked according to the degree of coverage across their nucleotide sequences.

We demonstrate the effectiveness of our pipeline by applying it to a total of 56 transcriptome samples from different cancer types sequenced by the OICR's Cancer Genomics Group. Our results indicate the presence of a number of significant hits across both samples and viruses. We further discuss the biological significance of our results in terms of the cancer types and coverage across relevant viral gene coding regions. The new pipeline will be released as freely available software under the GNU General Public License.

Whole genome sequencing of tumor-normal pairs from 5 African Americans with late stage or metastatic prostate cancer. *N.J. Cardin[1], R. Kazma[1], J.A. Mefford[1], T.J. Hoffmann[1], A. Levin[2], D. Chitale[2], B. Rybicki[2], J.S. Witte[1].* 1) Epidemiology and Biostatistics, University California San Francisco, San Francisco, CA., California; 2) Henry Ford Hospitals, Detroit, MI.

Prostate cancer is a common but complex disease, with 186,000 new cases and 28,600 deaths in 2008 [1]. African-American men have the highest incidence and mortality of this disease worldwide. Deciphering the genomic basis for this high disease burden, and why some tumors progress rapidly while others remain relatively latent, are critical to understanding the biology and appropriate therapy for this disease. Previous work has detected numerous somatic mutations in prostate tumors. This includes the recent sequencing of seven prostate tumor-normal pairs in European-American men which found that genomic rearrangements may be related to aberrations in chromatin or transcription patterns [2].

Here we present results from sequencing five paired prostate tumor-normal samples from African-American men with metastatic or very late stage disease. Preliminary data show ~20,000 somatic SNPs and indels per sample, with ~2,000 in or near genes. Of these close to 10 per sample are non-synonymous, including some frame shifts, insertions and nonsense mutations. We also find approximately 50 somatic SNPs and indels per sample in or near known cancer associated genes. Interestingly, we observe a ~4 fold enrichment of these in genes that contained non-synonymous mutations in [2].

We also find multiple large scale somatic copy number changes, including events affecting whole chromosome arms. In particular, the loss of chromosome arm 8p, which harbors known cancer suppressor genes. We also observe a large deletion on chromosome 17 between 5.6Mb and 8Mb; a region which harbors TP53, a major cancer suppressor gene. In addition to these copy number changes we observe multiple rearrangements, including balanced rearrangements both within and across chromosomes.

These genome-wide re-sequencing data allow detection at greater resolution of a range of mutations, while confirming previous reports of numerous loss of function and large scale genomic changes in prostate cancer samples.

Amplified Haplotype Calling in Next Generation Tumor Sequence Data. *N. Dewal[1], Y. Hu[2], M. Freedman[3,4], T. LaFramboise[5], I. Pe'er[2].* 1) Department of Biomedical Informatics, Columbia Univ, New York, NY; 2) Department of Computer Science, Columbia University, New York, NY 10027, USA; 3) Department of Medical Oncology, Dana-Farber Cancer Institute, Boston, MA 02115, USA; 4) Medical and Population Genetics Program, The Broad Institute of Harvard and MIT, Cambridge, MA 02142, USA; 5) Department of Genetics, Case Western Reserve University School of Medicine, Cleveland, OH 44106, USA.

During tumor initiation and progression, cancer cells acquire a selective advantage, allowing them to out-compete their normal counterparts. Identification of the genetic changes that underlie these tumor acquired traits can provide deeper insights into the biology of tumorigenesis. Regions of copy number alterations and germline DNA variants are some of the elements subject to selection during tumor evolution. Integrated examination of inherited variation and somatic alterations holds the potential to reveal specific nucleotide alleles that a tumor “prefers” to have amplified. Next-generation sequencing of tumor and matched normal tissues provides a high-resolution platform to identify and analyze such somatic amplicons. Within an amplicon, examination of informative (e.g. heterozygous) sites deviating from a 1:1 ratio may suggest selection of that allele. A naïve approach examines the reads for each heterozygous site in isolation; however, this ignores available valuable linkage information across sites. We therefore propose a novel Hidden Markov Model-based method - Haplotype Amplification in Tumor Sequences (HATS) - that analyzes tumor and normal sequence data, along with training data for phasing purposes, to infer amplified alleles and haplotypes in regions of copy number gain. Our method is designed to handle rare variants, somatic mutations, and biases in read data. We assess the performance of HATS using simulated amplified regions generated from varying copy number and coverage levels, followed by amplicons in real data. We demonstrate that HATS infers the amplified alleles more accurately than does the naïve approach, especially at low to intermediate coverage levels and in real tumor data containing stromal contamination.

GST an emerging threat to north Indian population for head and neck squamous cell carcinoma: A meta analysis of case control studies. *S. Gupta[1], A. Srivastava[2], M.C. Pant[3], B. Mittal[2], P. Seth[1].* 1) Bioinformatics, Biotech Park, Lucknow, India; 2) Department of Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow,Uttar Pradesh, India; 3) Department of Radiotherapy, C. S. M. Medical University, Shahmina Road, Lucknow, Uttar Pradesh, India.

BACKGROUND: Genetic polymorphisms in Glutathione S-transferase (GSTT1null, GSTM1null, and GSTP1 Ile105Val) results in the toxification and detoxification of (pre)-carcinogens, which plays an important role in progression of not only head and neck squamous cell carcinoma (HNSCC) but also in second primary malignancy after index HNSCC and to individual susceptibility to HNSCC. GSTP1 is markedly over-expressed in case of smoking related HNSCC as compared to other cancers. STUDY DESIGN: The purpose of the present study was to determine the outcome of the metabolic GST genes polymorphism and interaction with environmental factors on susceptibility to the risk of HNSCC. SEARCH CRITERIA: Electronic searches for comprehensive literature PubMed, Springer, EBSCO and iLibrary were undertaken up to April 2011. References lists of the selected papers were also screened to collect missing potential articles. SELECTION CRITERIA:Case-control studies were selected to examine the association of HNSCC with GSTT1, GSTM1null and polymorphism in GSTP1Ile105Val gene. The genotype distribution of these polymorphisms were described in details and the status were determined by using molecular methods of PCR or PCR-Restriction Fragment Length Polymorphism (PCR/PCR-RFLP). Moreover, the results were expressed as odds ratio (OR) and corresponding 95% confidence interval (95% CI), were included. DATA COLLECTION AND ANALYSIS: Total 110 studies regarding GSTT1null, GSTM1null and GSTP1with respect to HNSCC were identified after careful review, irrelevant 89 papers were excluded and finally 12 concerning GSTT1null, 11 concerning GSTM1null and 9 concerning GSTP1 were included in the anaysis. To estimate more precise consequence of the association, a meta-analysis has been performed for 24 appropriate case-control studies including 6709 cases and 7302 controls. Crude odds ratios (ORs) with 95% CI were used to assess the strength of the association. RESULTS: Our result suggests that GSTM1null (OR: 1.046; 95% CI: 0.942-1.161, P=0.402) and GSTT1null (OR: 1.011; 95% CI: 0.885-1.155, P=0.872) are associated with an increase in risk of HNSCC patient where as GSTP1 Ile105Val polymorphism (OR: 0.786; 95% CI = 0.590-1.047, P=0.072) was not associated with altered susceptibility to HNSCC. Whereas, In Indian population, we found that there is a significant association of GSTP1Ile105Val polymorphism with HNSCC due to higher content of Benzo[a]pyrenediol consumption through chemicals.

1168W

Meta-analysis of genome-wide mRNA expression profiles with computational analysis identifies miR-x and miR-y associated with recurrence of colorectal cancer. *E. Hsi[1,2,3], T. Kuo[2,4], I. Yang[2,4], P. Tsai[2,4], S. Juo[2,3,4].* 1) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 3) Cancer Center, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 4) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan.

Colorectal cancer (CRC) is one of the leading malignant cancers with the rapid increase in incidence and mortality in Han Chinese. The recurrences of CRC are sometimes unavoidable and half of them will recur in the first year. MicroRNAs can act as biomarkers to predict early recurrence of CRC, but identifying them from over 1000 microRNAs is challenging and time-consuming. In this study, we systematically searched and extracted four studies (GSE12032, GSE17538, GSE4526 and GSE17181) for mRNA expression data of CRC from gene expression omnibus (GEO). We identified miR-x and miR-y using the IMRE method with miRbase that includes 568,071 miRNA-target connections between 711 miRNAs and 20,884 gene targets. We also performed meta-analysis and showed that the two miRs are highly significant based on the fisher p-value combination (p=9.14×10-9 for miR-x and p=1.14×10-6 for miR-y). Further more, we used our human CRC samples (46 CRC patients with early recurrence and 38 patients without early recurrence) to validate the result (p=0.0007 for miR-x and p=0.0033 for miR-y). Our empirical results showed that the two miRs are significantly downregulated in the recurrent CRC patients. This study indicated that the miR-x and miR-y could be an important tumor suppressor of CRC and potential targets for treatment.

1169W

Identification and differentiation between driver and passenger mutation applying clustering algorithm on next gen sequencing data. *S. Karmakar[1], A. Ghosh[1], A. Basu[2].* 1) Indian Statistical Institute, Kolkata, India; 2) National Institute of BioMedical Genomics, Kalyani, India.

Identification of driver mutations in cancer cells is a challenging endeavor. We hypothesize that these driver mutations arise early in the original cancer cells providing it a selective advantage to form distinct clones. Next generation sequencing data provides an opportunity to de-construct the allele frequency spectrum for all somatic mutations in a particular tumor. Partitioning the allele frequency spectrum in distinct clusters hence can provide an idea of the number of clones present in the tumor cell mass. We here simulate data that mimics the output of tumor sequence data as generated on the 454 platform (Roche Sequencing) and applied AIC and BIC model selection and clustering algorithms methods to develop a model delineating driver and passenger mutations.

1170W

Dealing with Sample Aneuploidy and Mosaicsm Using the ASCAT Algorithm on Different SNP Array Platforms. *R. Keshavan, S. Verma, S. Shams.* BioDiscovery Inc, El Segundo, CA.

Cancer samples pose a challenging problem for analysis using microarray technology. The basic Array CGH (aCGH) approach can confidently detect changes in copy number when a sample is measured against a normal control. However, the necessary normalization pre-processing step will essentially wash away the information associated with hyperdiploid samples. This can be an issue especially with cancer samples. Additionally, mosaic samples, due to different mixture of cells in the sample, can also severely complicate the analysis and interoperation of samples with microarray technology. One of the recently proposed approaches to simultaneously deal with these issues is called the Allele Specific Copy Number Analysis of Tumors (ASCAT) algorithm[1]. The approach takes advantage of the SNP information from SNP microarrays to combine the change in total signal strength (log-R value) with the B-Allele Frequency (BAF) to create an optimization function that has local minimas at values corresponding to possible sample ploidy and percent normal contamination. Here we demonstrate an efficient implementation of the ASCAT algorithm on processing cancer samples generated by The Cancer Genome Atlas (TCGA) project. Using Affymetrix and Illumina SNP array data, results are compared between the different platforms as well as with and without application of the ASCAT algorithm. Characterization of a percentage of the cells as normal contaminants within the samples using the ASCAT algorithm reveals many more gains and losses in the aberration profile of the tumors than in samples processed without ASCAT. ASCAT also identified that a large percentage of samples contain high ploidy numbers. With the sample ploidy and extent of normal contamination identified using ASCAT, clearer and more accurate calls can be made for cancer samples.

The European Genome-phenome Archive (EGA). *I. Lappalainen, J. Almeida-King, V. Kumanduri, P. Marin-Garcia, P. Flicek.* European Bioinformatics Institute, Cambridge, United Kingdom.

The European Genome-phenome Archive (EGA), a service of the European Bioinformatics Institute (EBI), provides a permanent archive for all types of potentially identifiable genetic and phenotypic data generated in the course of biomedical or genetics research. The EGA contains data collected from individuals when the applicable consent agreements prevent open, public data distribution. As of 2011, data from more than 60 studies and 100 000 samples have been submitted to the EGA and are available for researchers who have applied for and been granted access to them. These studies include raw DNA sequence data from re-sequencing or transcriptomics projects as well as array-based genotyping experiments. The EGA also stores the submitted phenotype data associated with the samples. Data access decisions are made by a data access-granting organisation (DAO) and not directly by the EGA project. The DAO is typically part of the same organisation that approved and monitored the initial study. The EGA website includes information about the relevant DAO for each submitted dataset and instructions for interested researchers to apply for access to the data. Once DAO authorization has been granted, the EGA provides secure tools for downloading and decrypting the authorized files and general support for questions related to the data content. The EGA ensures high quality data and provides additional useful resources for our users in many different ways. All public components of the submitted study are integrated into the central EBI search tools. The EGA and NCBI's Database of Genotype and Phenotype (dbGaP) provide a shared catalogue of studies that have been submitted to either archive, which allows easy access to related studies and contact information on access control. All submitted data is required to pass basic quality and consistency analysis, and, we are able to phase submitted data or impute unobserved genotypes using public reference resources such as the 1000 Genomes project. Future developments will include the ability to view aligned sequence data and called variants through genome browsers or other visualisation tools supporting appropriate security methods. The EGA website is available at http://www.ebi.ac.uk/ega/.

Genome-wide association study of classical Hodgkin Lymphoma and EBV status-defined subgroups. *J. McKay[1], U. Urayama[1], R. Jarrett[2], H. Hjalgrim[3], K. Ekström Smedby[4], M. Melbye[3], A. Diepstra[5], A. van den Berg[5], M. Lathrop[6,7], P. Brennan[1], IARC HL GWAS.* 1) International Agency for Research on Cancer, Lyon, France; 2) MRC University of Glasgow Centre for Virus Research, Garscube Estate, University of Glasgow, Glasgow, United Kingdom; 3) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 4) Department of Medicine Solna, Clinical Epidemiology Unit, Karolinska Institute and Karolinska University Hospital, Stockholm, Sweden; 5) Department of Pathology and Medical Biology, University Medical Centre Groningen, University of Groningen, Groningen, The Netherlands; 6) Centre National de Génotypage, Institut Génomique, Commissariat à l'énergie Atomique, Evry, France; 7) Fondation Jean Dausset-CEPH, Paris, France.

Accumulating evidence suggests that risk factors for classical Hodgkin lymphoma (cHL) differ by tumor Epstein-Barr virus (EBV) status. We conducted a genome-wide association study (GWAS) of 1,200 cases and 6,417 controls to identify common genetic variants associated with cHL with an evaluation by tumor EBV status. Two novel loci in the major histocompatibility complex (MHC) region, one residing adjacent to MICB (rs2248462, OR= 0.61, P=1.3x10-13) and the other at HLA-DRA (rs2395185, OR=0.56, P= 8.3x10-25), were associated with cHL irrespective of EBV status. Consistent with previous reports, EBV-positive cHL associations were observed within the class I region (rs2734986, HLA-A, OR=2.45, P=1.2x10-15; rs6904029, HCG9, OR=0.46, P=5.5x10-10), and an EBV-negative cHL association was observed within the class II region (rs6903608, HLA-DRA, OR=2.08, P= 6.1x10-31). Further heterogeneity was observed within EBV-negative cHL, with the rs6903608 association confined to nodular sclerosing cHL (Phet= 0.002). Evidence for a predominately EBV-negative cHL association was found for rs20541 (IL13, 5q31) (OR=1.53, P=5.4x10-9), a variant previously linked to psoriasis and asthma. However, the evidence for replication was less clear. Notably, one additional psoriasis-associated variant, rs27524 (ERAP1), showed evidence of an association in the GWAS (OR=1.21, P= 1.5x10-4) and replication series (P=0.028). Overall, these results provide strong evidence that EBV status is an etiologically important classification of cHL, but suggest that some components of the pathological process are common to both EBV-positive and -negative cases.

Visualizing and Exploring Genomic Alterations in The Cancer Genome Workbench. *C. Yan[1], R. Finney[1], M. Edmonson[2], N. Cu[2], Y. Hu[2], D. Meerzaman[2], K. Buetow[1,2].* 1) NCI/CBIIT, Rockville, MD; 2) NCI/LPG, Bethesda, MD.

The Cancer Genome Workbench (CGWB, http://cgwb.nci.nih.gov) provides a variety of tools with enhanced functionalities and unique features for visualizing and analyzing genomic data. CGWB consists of extended version of UCSC browser, Bambino, PathOlogist, Heatmap viewer and Protein structure viewer. Genomic data includes copy number alteration, somatic mutation, mRNA and miRNA expression, methylation, and nextgen sequencing data. Key features and their uses are highlighted below. First, integrated display of those genomic data at the individual gene level can be used to evaluate the significance of regulatory processes such as methylation and microRNA expression in controlling gene expression. The protein structure viewer illustrates the impact of mutations on protein function in the context of 3D structure models and LogR.E-value/SIFT scores for detecting deleterious mutations. Second, the heatmap viewer offers interactive displays of gene expression and copy number changes in parallel along with clinical features. The data can be sorted and clustered on a set of genes in a pathway to identify the distinct copy number and expression patterns. Third, PathOlogist transforms a large set of gene expression data into quantitative descriptors of pathway-level behavior. It provides straightforward means to identify the functional processes, rather than individual molecules, which are altered in disease. Fourth, Bambino allows users to examine the nextgen sequencing data at base level and to identify SNPs/indels from nextgen sequence mapping files in SAM/BAM format. Bambino can be invoked from browser view of sequence coverage track which is useful for examining sequencing quality, RNASeq expression and structure alteration in whole genome sequencing. Lastly, CGWB is hosting data from the following projects: The Cancer Genome Atlas (TCGA), Therapeutically Applicable Research to Generate Effective Treatments (TARGET), the Sanger Institute's Catalog of Somatic Mutations in Cancer (COSMIC), and the NCI60 cell lines. Much of the data in CGWB is available on caGrid. With comprehensive genomic alteration data from large numbers of tumor samples and cell lines, CGWB will help researchers gain new insight into cancer biology.

A chemical genetics screen identifies a novel drug that targets steroid biogenesis and receptor signaling leading to growth inhibition of pediatric malignant astrocytoma cell lines. *N. Ajeawung[1], D. Poirier[2], D. Kamnasaran[1,3].* 1) Pediatrics Research Unit - Centre de recherche du CHUL-CHUQ; 2) Laboratory of Medicinal Chemistry, Oncology and Molecular Endocrinology - Centre de recherche du CHUL-CHUQ, Québec, Canada; 3) Department of Pediatrics, Laval University, Québec, Canada.

Background: Brain tumors are among the leading cause of cancer-related deaths in children, with least 60% manifested as astrocytomas. Malignant astrocytomas represent 8-12% of all pediatric supratentorial brain tumors, with an overall median survival of 11-14 months. While those that arise in the brainstem represent an additional 10-20%, with a 10-year overall median survival of <10%. Despite current therapies, challenges still exist in the treatment of pediatric malignant astrocytomas, leading to the need to explore new therapies. Since a wide range of genes involved in steroid biogenesis and signaling are expressed in pediatric malignant astrocytomas, our objective was to investigate whether novel classes of drugs that target these gene products can be effective in inhibiting growth. **Methods and Results:** We screened using a candidate chemical structure approach, a library of 400 drugs which can potentially inhibit steroid biogenesis and cell signaling. By using a panel of human pediatric malignant glioma cell lines established from surgical specimens, we discovered a potent drug that inhibits androsterone (male sex pheromone) biogenesis and with the ability to significantly reduce the viability of pediatric malignant astrocytomas in a dose dependent manner. Cells treated with this drug responded by undergoing apoptosis, cell cycle regulatory, and invasive changes. Furthermore, significant inhibition of transformation was noted. Cells also become increasingly radiosensitive upon drug treatment. Most remarkable, the toxicity on human astrocytes (control) was minimal. **Conclusion:** We have discovered a novel drug from a chemical genetic screen which can significantly inhibit the growth of pediatric malignant astrocytomas, with minimal toxicity on non-transformed human astrocytes.

Germline deletion in the *INI1/SMARCB1* gene in a child with ependymoma and in his father with multiple schwannomatosis. *JG. Pappas[1], E. Reich[1], JC. Allen[2], J. Wisoff[3], I. Mikolaenko[4], LM. Messiaen[5].* 1) Dept Pediatrics,Human Gen, New York Univ, Sch Med, New York, NY; 2) Dept Pediatrics, Div Ped Hematology/Oncology, New York Univ Langone Med Ctr, New York, NY; 3) Dept Neurosurgery, New York Univ Sch Med, New York, NY; 4) Dept Pathology, New York Univ Sch Med, New York, NY; 5) Dept Genetics, Univ Alabama at Birmingham, Birmingham, AL.

We present a 6 year boy (case 1) with brain ependymoma and his 40 year father (case 2) with multiple schwannomatosis. Case 1 presented at 6 years with behavior changes (aggression), neck spasms and fatigue. He had history of mild global developmental delay, functioning about a year and a half below age level. Clinically he had macrocephaly and no dysmorphic features or other apparent malformations. Brain CT and MRI revealed 4-5 cm lobulated, heterogeneously enhancing mass arising contiguous to the right frontal horn of the lateral ventricle, extending into the third ventricle. A gross total resection was accomplished and there was no evidence of CNS metastases. The pathology revealed glial neoplasm with findings consistent with ependymoma. Involved field radiation therapy was administered thereafter and the patient remains in continuous remission for more than 3 years. Case 1 had a 13 month old brother with no medical problems. Case 2 had three palpable schwannomas on his upper extremities, one small cafe au lait macule and he had schwannomas excised in the past. He was diagnosed with depression. He had multiple blood relatives with multiple schwannomatosis, central nervous system tumors, sarcoma, breast cancer and depression. Both cases carry a novel heterozygous in frame deletion of 6 amino acids in exon 1 of the *INI1/SMARCB1* gene: c.57_74del; p.Glu20_Phe25del in the blood. The mutation was absent in the blood of the mother and the brother of case 1. Germline and somatic mutations in the *INI1/SMARCB1* have been associated with multiple schwannomatosis (Hulsebos TJ et al, 2007; Rousseau G at al 2011) and rhabdoid tumors (Eaton KW et al, 2011; Pfister S et al, 2009). There is no report in the medical literature of a case with ependymoma and germline mutation in the *INI1/SMARCB1*. The BAF47 immunostain was performed on the brain tumor tissue form case 1 and revealed extensive loss of INI-1 staining in many tumor nuclei. Whole genome chromosome microarray copy number analysis (1.8 million SNP/CN targets, Affymetrix, Inc.) in the blood of case 1 revealed no clinically significant copy number variations. Sequencing and deletion / duplication testing of the *TP53* gene in case 1 revealed no mutations. Our cases further confirm the association of mutations in the *INI1/SMARCB1* gene with schwannomatosis and expand the phenotype to include ependymomas.

Association of Estrogen Receptor-) Gene Polymorphisms with Breast Cancer Risk in Iran. *S. Abbasi.* Tehran University of Medical Sciences, Tehran, Iran.

Background: Receptor-mediated estrogen activation participates in the development and progression of breast cancer. Evidence suggests that alterations in estrogen signaling pathways, including estrogen receptor-((ER-( ) and -) (ER-)) occur during breast cancer development. ER-(gene polymorphism has been found to be associated with breast cancer and clinical features of the disease in Caucasians and we expected ER-)) also might have such influence. Epidemiologic studies have revealed that age-incidence patterns of breast cancer in Middle East differ from those in Caucasians. Genomic data for ER-) is therefore of value in the clinical setting for that ethnic group and we have investigated whether polymorphisms in the ER-) gene are associated with breast cancer risk among Iranian women.

Methods: A case-control study was conducted to establish a database of ER-) polymorphisms in Iranian women population for the first time and to evaluate ER-) polymorphism as an indicator of clinical outcome. Two selected coding regions in ER-) gene (exons 3 and 7) were scanned in Iranian women with breast cancer referred to Imam Khomeini Hospital Complex clinical breast cancer group (150 patients) and in healthy individuals (147 healthy control individuals). PCR single-strand conformation polymorphism technology was performed.

Results: A site of silent single nucleotide polymorphism (SNP) on exon 7 was found, but, any variation on exon 3 was found. The frequency of allele 1 in codon 392 (CTC → CTG was found only in breast cancer patients (5.7%) (χ^2=17.122, P=001). The allele 1 in codon 392 (C1176G) was found has a direct association with the occurrence of lymph node metastasis.

Conclusions: These data suggest that ER-) polymorphisms in exon 47 codon 392 is correlated with various aspects of breast cancer in Iran. ER-) genotype, as determined during presurgical evaluation, might represent a surrogate marker for predicting breast cancer lymph node metastasis.

Keywords: breast cancer, estrogen receptor-) , polymorphism, LN metastases, SSCP-PCR.

Survival analysis for genetic variants associated with colorectal cancer susceptibility. *A. Abulí[1,2], X. Bessa[2], R. Jover[3], C. Ruiz-Ponte[4], C. Fernández-Rozadilla[4], J. Muñoz[1], A. Carracedo[4], A. Castells[1], M. Andreu[2], S. Castellvi-Bel[1], Gastrointestinal Oncology Group of the Spanish Gastroenterological Association.* 1) Gastroenterology Department, Hospital Clinic-IDIBAPS-CIBERehd-CEK, Barcelona, Catalonia, Spain; 2) Gastroenterology Department, Parc de Salut Mar-IMIM-UPF, Barcelona, Catalonia, Spain; 3) Department of Gastroenterology, Hospital General d'Alacant, Alicante, Spain; 4) FPGMX, Genomics Medicine Group, Hospital Clinico-CIBERER-USC, Santiago de Compostela, Galicia, Spain.

Colorectal cancer (CRC) represents in Spain the most frequently detected neoplasm in men and women and the second cancer in mortality. Environmental factors have an important role in cancer development although genetic components seem to have major relevance. Recently, new common low-penetrance single nucleotide polymorphisms (SNP) for CRC have been identified by case-control genome-wide association studies (GWAS) permitting to point out so far 16 loci for CRC genetic susceptibility in chromosomal regions 1q41, 3q26.2, 8q23.3, 8q24.21, 10p14, 11q23.11, 12q13.3, 14q22.2, 15q13.3, 16q22.1, 18q21.1, 19q13, 20p12.3 and 20q13.33. However, the prognosis significance of the SNPs on disease-free and overall survival remains controversial. Our aim was to evaluate the prognostic and predictive value of the reported SNPs for CRC genetic susceptibility in order to identify cases at a higher risk of recurrence that may benefit from more intensive treatment and follow-up surveillance. We included 1,229 CRC cases recruited by the EPICOLON consortium, a Spanish epidemiologic, prospective, multicentre and population-based study. Present results are referred to the first 10 evaluated SNPs (8q23.3, 8q24.21, 10p14, 11q23.11, 14q22.2, 15q13.3, 16q22.1, 18q21.1, 19q13, and 20p12.3). Genotyping was performed in TaqMan and Sequenom genotyping platforms. Evaluated clinical and tumor variables included age, gender, carcinoembryonic antigen (CEA), stage, location, microsatellite instability, differentiation, histology, chemotherapy treatment, recurrence and death. Median follow-up of the whole series was 40 months (range, 1 -72). Statistical analysis was performed with the SPSS package. The primary outcomes were overall survival (OS) and disease free survival (DFS). Probability curves were calculated according to the Kaplan-Meier method and compared using the log-rank test. A multivariate analysis of hazard risk including all 16 SNPs, adjusted for TNM stage of disease, age and gender, is being performed using Cox proportional hazards regression in a stepwise manner. As expected, tumor stage was strongly associated with OS and DFS. So far, although not achieving statistical significance, three SNPs could be related either to OS (10p14, p=0.04; 16q22.1, p=0.06; 19q13, p=0.05), or DFS (16q22.1, p= 0.06). In conclusion, some CRC genetic susceptibility variants may influence OS and DFS and have prognostic value.

Detection of BRCA1 and BRCA2 mutations by High-Resolution Melting curve analysis in breast cancer patients from Thailand and Pakistan. *J. Ahmad[1,6], S. Daud[2], S. Sangrajrang[3], F. Le Calvez-Kelm[6], N. Kakar[1], C. Voegele[6], O. Sinilnikova[4], S. Tavtigian[5], F. Lesueur[6].* 1) Department of Biotechnology , BUITEMS, Quetta, Balochistan, Pakistan; 2) National Centre of Excellence in Molecular Biology, University of the Punajab, Lahore, Pakistan; 3) National Cancer Institute, Bangkok, Thailand; 4) Centre Léon Bérard, Lyon, France; 5) Huntsman Cancer Institute, School of Medicine, University of Utah, Salt Lake City, USA; 6) International Agency for Research on Cancer, Lyon, France.

The spectrum of BRCA1 and BRCA2 mutations has been characterized in different populations worldwide with significant variation of the relative contribution of these genes to breast cancer between the populations. However, the contribution of mutations in these two genes to breast cancer patients in Pakistani and Thai populations remains relatively unexplored apart from a few genetics studies. Hence, we aimed to perform comprehensive BRCA mutation screening to characterize the frequency and spectrum of mutations within these two genes in a group of high-risk familial or early onset cases, which forms the largest group of breast cancer patients in these two Asian populations. One hundred and forty three Thai cases and 85 Pakistani cases were enrolled in the study. The entire coding sequence of both genes was scanned for mutation using High Resolution Melting curve analysis (HRM) followed by DNA sequencing. Two known BRCA1 mutations (p.E1250X and p.G1770fs) and two BRCA1 mutations that are not reported in the BIC database (p.S423fs and p.S1057fs) were observed. The nonsense mutation p.E1250X was identified in two unrelated Thai cases. The frameshift mutation p.S423fs was identified in a Thai case whereas the two other frameshift mutations were identified in two Pakistani cases. In the case of BRCA2, three 3 frameshift mutations (p.E1577fr, p.R1704fr and p.S2559fr) and one nonsense mutation (p.Q1107X) were identified. The nonsense mutation was identified in a Pakistani case and was already reported in BIC database, whereas the three frameshift mutations are novel. p.E1577fr was identified in a Pakistani case, p.R1704fr in two Thai cases, and p.S2559fr in one Thai case. In addition to the known or novel pathogenic mutations described here, we report one known inframe deletion in BRCA1 (p.K1110del), two evolutionarily unlikely missense substitutions (p.G1788C in BRCT domain of BRCA1 and p.G2901D in DNA binding domain of BRCA2) that are predicted to affect protein function, as well as a number of likely to be neutral missense variants, silent variants and intronic variants in both genes. In summary, our findings show that BRCA1 and BRCA2 account for a substantial proportion of hereditary breast cancer and early-onset breast cancer cases in Thailand and in Pakistan and suggest that genetic testing for predisposing BRCA germline mutations may be justified for high-risk women from these two countries.

PTEN exon four and five mutation analysis of Iranian sporadic Breast cancer patients. *M. Akouchekian[1], S. Henati[2], M. Akbari Azirani[3].* 1) Department of genetics & molecular biology, Tehran University of Medical Science, Tehran, Iran; 2) Departments of Oncology, Isfahan University of Medical Science, Isfahan, Iran; 3) KNTU University of Technology, Tehran, Iran.

BACKGROUND: Allelic loss of human chromosome 10 short arm which contains three tumor suppressor genes (TSG) , is one of the common genetic events in cancer. These TSGs on human 10q are ERCC6, PTEN and DMBT1. PTEN gene is reported as one of the most frequently mutated tumor suppressor gene in human cancer. The PTEN gene maps to 10q23.3 and encodes a 403 amino acid dual specificity phosphatase (protein tyrosine phosphatase). It was shown to play an important role in human malignancy. Previously studies were reported somatic PTEN mutations and deletion in sporadic breast, prostate, kidney and brain cancer (Tate et al, 2007 & Yoshimoto et al. 2007). The tumor suppressor role for PTEN was further supported by the discovery that the autosomal dominant multineoplasia syndrome, Cowden disease, is associated with germ-line PTEN mutations. Family members with Cowden disease, both male and female, have an increased incidence of breast cancer. Increasing data have implicated PTEN loss in breast carcinogenesis. While loss of heterozygosity (LOH) of the PTEN locus is frequently reported in sporadic breast carcinoma. The aim of the present study is to determine mutations in PTEN gene in Iranian sporadic Breast cancer patients by direct sequencing of the exons.

METHODS: Patients with sporadic breast cancer diagnosed at the Isfahan's Sayedalshohada Hospital in year 2011 were ascertained for this study. Genomic DNA was isolated from peripheral blood lymphocytes and the entire PTEN coding region of the exons four and five were screened for mutations by PCR and direct sequencing analysis.

RESULTS: Complete sequence analysis of exon four and five demonstrated two heterozygous G to A transversions of the patient's PTEN gene. This mutation was absent in DNA from 10 unrelated healthy individuals as the control group in this study.

CONCLUSIONS: PTEN alterations were detected in fifteen of twenty Iranian Breast cancer patients. We investigated this two LOH variation in our controls and no alterations were seen in the exon four and five of our control groups. Our finding show that sporadic breast cancer seems to be associated with LOH at the PTEN locus, partially involving the mutant allele, further supports the role of PTEN insufficiency for increased proliferation of breast carcinomatos cells.

BRCA2:E3002K, a new recurring mutation in the founder French Canadian population of Quebec. *S.L. Arcand[1], S. Côté[2,3], S. Nolet[4,5], P. Ghadirian[6], W.D. Foulkes[1,7,8], M.D. Tischkowitz[7,8], A.-M. Mes-Masson[9,10], D. Provencher[9,11], P.N. Tonin[1,12,13].* 1) The Research Institute of the McGill University Health Centre, Montreal, Canada; 2) Service de médecine génique, Département de médecine, Centre hospitalier de l'Université de Montréal, Montreal, Canada; 3) Département des sciences biomédicales, Université de Montréal, Montreal, Canada; 4) Département de pathologie, Centre Hospitalier de l'Université de Montréal, Montreal, Canada; 5) Département de Pathologie et Biologie Cellulaire, Université de Montréal, Montreal, Canada; 6) Epidemiology Research Unit, Centre de recherche du Centre hospitalier de l'Université de Montréal (CRCHUM), Montreal, Canada; 7) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Canada; 8) Lady Davis Institute, Segal Cancer Centre, Jewish General Hospital, Montreal, Canada; 9) Centre de recherche du Centre hospitalier de l'Université de Montréal (CRCHUM), Institut du cancer de Montréal, Montreal, Canada; 10) Département de médecine, Université de Montréal, Montreal, Canada; 11) Division of Gynecologic Oncology, Université de Montréal, Montreal, Canada; 12) Department of Medicine, McGill University, Montreal, Canada; 13) Department of Human Genetics, McGill University, Montreal, Canada.

Hereditary breast cancer (HBC) and/or ovarian cancer (HBOC) families of French Canadian (FC) descent in Quebec harbor recurring mutations in BRCA1 and BRCA2 cancer susceptibility genes due to common founders. Although most mutations identified are predicted to cause truncation of the encoded protein, and thus are classified as pathogenic mutations, missense mutations are often classified as variants of unknown significance (VUS). The occurrence and segregation of VUS and cancer in families often has been used to establish pathogenicity in the absence of a functional assay for these genes. Recently, we reported the BRCA2:E3002K VUS in two of 82 HBC FC families with three or more confirmed cases of invasive breast cancer under the age of 66, although it was not reported in 54 HBOC families with a case of invasive ovarian cancer and two or more cases of ovarian cancer or breast cancer under age 66. A very young age of diagnosis (<40 years) of breast cancer occurred in both VUS-positive families. Since this report, six HBC/HBOC FC families have been identified in hereditary cancer clinics in Montreal. All but two of the VUS-positive families harboured a very young age at diagnosis case of breast cancer (<40 years). To further characterize the contribution of this VUS in FC cancer families, we have investigated 52 HBC/HBOC FC families previous shown not to harbour the most common BRCA1/2 mutations reported in the FC population. Thus far no new mutation-positive families were identified. This variant has also been reported in cancer families from other populations and has recently been reclassified as likely pathogenic by commercial sequencers. The very young age at diagnosis of breast cancer in our VUS families would support this reclassification. The history of the FC population of Quebec, ascertainment of the families from a common geographic area (within or near the Island of Montreal) and occurrence of the VUS in HBC families suggest that BRCA2:E300K carriers share common ancestors and that this mutation could be added to the roster of pathogenic BRCA1/2 variants screened for in this population.

Activation of p53 as a possible therapeutic strategy for treatment of cancer. *A. Avan[1,2], M. Maftouh[2], A. Avan[3, 4], R. Mirhafez[5], H. Fiuji[6].* 1) Clinical Genetics Department, VUmc, Amsterdam, Netherlands; 2) Department of Medical Oncology, VU Medical Cancer Center Amsterdam, VUmc, PO Box 7057, 1007 MB, Amsterdam, The Netherlands; 3) Clinic of Wilson's disease, Imam Reza Hospital, Tabriz University of Medical Sciences, Tabriz, Iran; 4) Department of Emergency, Dr. Chamran Hospital, Ferdows, Birjand Medical University of Medical Sciences, Iran; 5) Department of Modern Sciences and Technologies, Faculty of Medicine, Mashhad University of Medical Science, Mashhad, Iran; 6) Institute of Biochemistry and Biophysics, University of Tehran, Tehran, Iran.

P53 is a tumor suppressor gene that plays a central role in the protection of cell against cancer. Cancer cells contain two types of mutations: mutations that cause uncontrolled growth and increase in number of cells, and other mutations that block the normal defenses of cells against unnatural growth. Mutation in p53 is in the second category. Interestingly, mutations in p53 gene can lead to about half of the human cancer. Most of these mutations are no synonymous mutations. Over 90% of mutations are located in the DNA-Binding Domain (DBD) of p53. Understanding the molecular mechanisms of p53 allow us to modulate these pathways and also it would also help us to find a way in therapeutic reactivation of p53 favors apoptotic cell death in tumor cells. Activity of p53 is tightly controlled by physiological conditions. On the other hand, cellular stress signals are needed for activation and accumulation of p53 through interaction with various proteins and also posttranslational. For instance, Phosphorylation in serine and threonine residues that are located in NTD, carboxy-terminal domain, and DBD of p53. Furthermore, the half of p53 is regulated by ubiquitin modification on lysine residues in the carboxy-terminal region and degradation by proteasome pathway. Consequently, targeting p53 facilitates cell-cycle arrest and DNA repair mechanisms. For example, phosphorylation of human p53 on serine 46 has been contributed to the activation of apoptotic target genes, and mutation of this phosphorylation site reduces the ability of p53 to induce cell death but not proliferative arrest. Therapeutic strategies that result in the activation of p53 would benefit from an ability to modulate or the differential responses to p53 activation. One of the possible mechanisms for activation of p53 is stress to cancer cells, such as oncogene activation, hypoxia and loss of normal environment might result in a differential and sensitivity to undergo apoptosis compared with normal tissue.

Genetic Sequence Variants (GSV) and Head and Neck Cancer (HNC) Outcome: a Genome-Wide Association Study. *A.K. Azad[1], I. Bairati[4], L. Cheng[2], D. Waggott[3], E. Samson[4], D. Cheng[1], M. Mirshams[1], S. Savas[1], J. Waldron[5], C. Wang[6], D. Goldstein[7], P. Boutros[3], G. Liu[1,8], F. Meyer[4], W. Xu[2].* 1) Applied Molecular Oncology, Princess Margaret Hospital, Toronto, Ontario, Canada; 2) Biostatistical Unit, Princess Margaret Hospital, Toronto, Ontario, Canada; 3) Informatics and Bio-computing Platform, Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 4) Centre de Recherche en Cancerologie de l'Universite Laval, l'Universite Laval, Quebec City, Quebec, Canada; 5) Department of Radiation oncology, Princess Margaret Hospital, Toronto, Ontario, Canada; 6) Département de Radio Oncologie, Centre Hospitalier Universitaire de Québec, Quebec City, Quebec, Canada; 7) Department of Otolaryngology, Princess Margaret Hospital, Toronto, Ontario, Canada; 8) Department of Environmental Health, Harvard School of Public Health, Boston, Massachusetts, USA.

Background: Carcinomas of the oral cavity, pharynx and larynx are referred to as head and neck cancers; together they account for 2-3% of all newly diagnosed cancers in North America. Between 40-50% of HNC are early diagnosed at stages I-II. The 5-year and 10-year relative survival rates are 61% and 50%, respectively. Germline GSV has become increasingly studied and showed as potential prognostic or predictive markers of outcome in a variety of cancers. Identifying these GSV may therefore increase the accuracy and validity of outcome prediction models in HNC patients. **Methods:** We conducted a genome-wide scan in 531 Stage I-II radiation-treated HNC patients (originally recruited for an alpha-tocopherol/beta-carotene placebo-controlled secondary prevention study) using Illumina HumanHap 610K BeadChips platform. Sample quality filtering was applied to control the missing rate, Hardy-Weinberg equilibrium, population stratification, and heterozygousity rate that resulted in a total of 541,903 GSV. We generated multivariate models adjusted for the potential clinical factors and principal components using the genome-wide genotype data to detect association with clinical outcome of overall survival (OS). Follow-up time was calculated from the time of randomization until the date of last visit, the date of death or December 31, 2006. Survival rates were estimated by using the Kaplan-Meier estimator. Cox proportional hazards models were used to test for associations between the GSV and OS. Each GSV was modeled using an additive, dominant and recessive model of genetic inheritance effect. **Results:** In all, 330 (62%) patients had Stage I and 201 (38%) patients had Stage II disease. The most frequent tumor location was the larynx 443 (83%) and the remaining 88 (17%) were in the oral cavity and pharynx. If we only considered patients who had not experienced the outcome, the median follow-up time for overall survival (OS) was 9.21 years. Five-year OS was 77% (95% CI: 0.73-0.80); 312 patients were alive at December, 2006 the last date of follow-up for survival. Two OS associated GSV were genome-wide significant: *TGM2*:c.1099+651C>T: (aHR 2.00 (1.56-2.57); p=1.3E-8) and *CACNA1S*:c.258+5737A>G: (aHR 6.41(3.39-12.14); p=5.1E-8). **Conclusions:** Our study suggests that GSV in *TGM2* and *CACNA1S* may contribute to HNC outcome. Further validation of our findings in independent populations is ongoing.

Somatic mutations in esophageal squamous cell carcinoma revealed by exome sequencing. *J. Bai[1], Q. Wang[2], W. Chen[1], H. Cai[2], C. Zeng[1].* 1) The laboratory of disease genomics and individualized medicine, Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) School of Oncology, Peking University, Beijing, China.

Esophageal squamous cell carcinoma (ESCC) is the major histological type of esophageal cancer. To find key somatic mutations during carcinogenesis of ESCC, we conducted exome sequencing of tumor tissues and matched blood samples from 9 patients of Chinese Han descent. Sequencing was performed on Illumina GAII by paired-end protocols. Reads that passed the pre-processing filters were used to do alignment and mutation calling. The average non-redundancy coverage of the targeted region was 31×, and ~76.5% was at least covered by 10 distinct reads. Mutation analysis was conducted only in regions with their sequencing coverage no less than 10× in both tumor and blood samples. A variation was identified as a somatic mutation if it existed in at least 20% of distinct reads from the tumor but the reads in matched blood sample were wild type. All somatic mutations identified by exome sequencing were validated by genotyping in SEQUENOM MassARRAY® or by Sanger sequencing.

In total we identified 85 somatic mutations in 80 genes among nine patients. Only two genes, TP53 and DMD, showed to have mutations in more than one sample. DMD, the largest gene in the human genome, was excluded for further analysis since numerous mutations in this gene were shown as non-cancer mutations in our in-house database. In consistence with our previous result that TP53 had the most frequent molecular alterations in ESCCs, mutated TP53 was seen in five of the nine tumors (55.6%). Most of the remaining 78 genes were also involved in TP53-related processes as shown in the protein-protein interaction analysis. Therefore we removed these genes in the analysis in attempt to locate mutations involved in other pathways. Among the remaining 5 genes, two of them, SMARCD3 and TSPYL2, participate in chromatin remodeling, an enzyme-assisted nucleosome movement involved in transcriptional activation or repression. These results imply that the malfunction of chromatin remodeling caused by somatic mutations may also contribute to tumorigenesis of ESCC. Verification of mutations in these two genes in more ESCC samples is in the process.

Identification of men with a genetic predisposition to prostate cancer: targeted screening of *BRCA1/2* mutation carriers and controls. The IMPACT study. *E.K Bancroft[1,2], E. Castro[2], E.C. Page[2], R.A. Eeles[2,1], IMPACT Study Steering Committee and Collaborators.* 1) Cancer Gen Unit, Royal Marsden Hosp, Sutton, United Kingdom; 2) Oncogenetics Unit, Institute of Cancer Research, Sutton, United Kingdom.

Introduction: IMPACT is a multi-national targeted prostate cancer screening study of men with a known germline mutation which is thought to predispose to the disease. The study is recruiting male *BRCA1/2* mutation carriers and a control group, who have tested negative for a mutation present in their family, from 43 centres in 14 countries. Method: Eligible men aged 40-69 years are offered annual serum PSA testing for five years. The PSA threshold used to determine prostate biopsy is >3ng/ml. All men are offered a biopsy irrespective of PSA level after 5 years of screening. A subset of men are also invited to take part in a Quality of Life sub-study. Results: To date 1200/1700 men have been recruited, 86 have undergone biopsy and 37 men have been diagnosed with prostate cancer (22 *BRCA2* carriers, 9 *BRCA1* carriers and 6 controls). 60% of cases diagnosed in *BRCA1/2* carriers were Gleason score ⁄ 7 and T2 or higher (in the intermediate/high risk group for immediate radical treatment and not active surveillance, according to NICE guidelines) while in the general population (ERSPC study), 72% had a Gleason ≤6 and 61% were T1 (low risk group, suitable for active surveillance). The estimated positive predictive value for PSA screening in BRCA carriers is 44% vs 24% in the general population (ERSPC study). 160 men have joined the Quality of Life study and baseline health-related quality of life (HRQOL) and psychosocial measures have not identified any increased levels of distress in this sub-group. Conclusions: Our preliminary results show that annual PSA screening using a cut-off of 3.0ng/ml detects aggressive prostate cancer in *BRCA* carriers. The higher risk of PrCa observed in *BRCA1* and *BRCA2* carriers will need to be confirmed with further data. Early data indicate that a larger proportion of gene carriers have developed clinically significant prostate cancers (those that would need radical treatment on UK treatment guidelines) compared with the control group.

1185W

Somatic mutations in CCKBR alter receptor activity and promote tumor progression. *T. Barber[1], M. Lajiness[1], I. Wulur[1], B. Feng[3], M. Swearingen[1], M. Uhlik[1], K. Kinzler[2], V. Velculescu[2], T. Sjoblom[4], S. Markowitz[5], S. Powell[6], B. Vogelstein[2], M. Willard[1].* 1) Departments of Translational Science and Cancer Angiogenesis, Lilly Research Laboratories, 355 East Merrill Street, Indianapolis, IN, 46285, USA; 2) Ludwig Center for Cancer Genetics and Therapeutics, and Howard Hughes Medical Institute at Johns Hopkins Kimmel Cancer Center, Baltimore, MD, 21231, USA; 3) Center for Molecular Recognition, Columbia University, College of Physicians and Surgeons, New York, NY, 10032, USA; 4) Department of Immunology, Genetics and Pathology, Uppsala University, SE-751 85 Uppsala, Sweden; 5) Department of Medicine and Comprehensive Cancer Center, Case Western Reserve University School of Medicine and Case Medical Center, Cleveland, OH, 44106, USA; 6) Division of Gastroenterology/Hepatology, University of Virginia Health System, Charlottesville, VA, 22908, USA.

The roles of cholecystokinin B receptor (CCKBR) in numerous physiological processes in the gastrointestinal tract and central nervous system are well-documented. There has been some evidence that CCKBR alterations play a role in cancers, but the functional significance of these alterations for tumorigenesis is unknown. We have identified six mutations in CCKBR among a panel of 140 colorectal cancers and 44 gastric cancers. We demonstrate that these mutations increase receptor activity, activate multiple downstream signaling pathways, increase cell migration and promote angiogenesis. Our findings suggest that somatic mutations in CCKBR promote tumorigenesis through deregulated receptor activity and highlight the importance of evaluating CCKBR inhibitors to block both the normal and mutant forms of the receptor.

1186W

Landscape of Somatic Structural Alterations in Chronic Lymphocytic Leukemia (CLL) Detected by Whole Genome Sequencing. *L. Bassaganyas[1], J.C. Tubio[1], G. Escaramis[1], C. Tornador[1], S. Bea[2], X.S. Puente[3], D. Gonzalez-Knowles[1], R. Guigo[1], I. Gut[4], C. Lopez-Otin[3], E. Campo[2], X. Estivill[1] on behalf of the CLL Genome Project Consortium.* 1) Genes and Disease, Center Genomic Regulationn (CRG), Barcelona, Catalonia, Catalonia, Spain; 2) Hospital Clinico, Barcelona, Catalonia, Spain; 3) University of Oviedo, Oviedo, Asturias, Spain; 4) Centro Nacional de Analisis Genomicos, CNAG, Barcelona, Spain.

Cancer is driven by somatically genetic mutations that can be acquired gradually overtime or by single catastrophic events. Chronic lymphocytic leukemia (CLL) is one of the most frequent cancers in western countries, representing 35% of all cases of leukemia. Different genetic alterations have been identified in CLL, including chromosomal aberrations detected by cytogenetic analysis, FISH and aCGH. The limitations of these techniques do not allow the identification of the full set of somatic structural variation at molecular level. Our understanding of oncogenesis has benefited greatly from next-generation sequencing technology (WGS). Massively sequencing, in combination with computational approaches, offers the potential to carry out genome-wide screening of all sort of chromosomal rearrangements. Using the toolkit PeSVFisher that includes several algorithms to identify structural variations in genomic sequencing, we have analyzed WGS to annotate the entire complement of genomic rearrangements in 10 patients with CLL. By identifying read pairs that did not map correctly with respect to each other on the reference genome, we have catalogued 9,994 potential somatic rearrangements. Then, a bioinformatic tool called FinalCountDown allowed us to filter 1,989 moderate and 64 high-confidence potential somatic events, after removing those rearrangements with breakpoints involving complex regions of the genome (i.e., segmental duplications, simple tandem repeats, and low-divergent transposable elements). 53% of these high-confidence somatic rearrangements were confirmed in silico by the presence of split-reads in the predicted breakpoints. Moreover, we combined these results with the depth of coverage data of WGS in order to obtain a comprehensive catalogue of copy number variation. The analysis of these 10 CLL cases by WGS represents the first step in a comprehensive characterization of the genomic alterations at the structural level, coupled with functional analysis, of CLL in the framework of the CLL Genome Project, to decode the genetic changes that are responsible for the development and progression of CLL.

Detection of somatic mutations in hepatocellular carcinoma: a prerequiste for individualized immonotherapy. *P. Bauer[1], C. Schroeder[1], S. Junker[1], M. Loeffler[2], S. Stevanovic[2], H.G. Rammensee[2], S. Nadalin[3], A. Koenigsrainer[3], C. Hann von Weyhern[4], O. Riess[1].* 1) Dept of Medical Genetics, Univ Tuebingen, Tuebingen, Germany; 2) Department of Immunology, Institute for Cell Biology, Univ Tuebingen, Tuebingen, Germany; 3) Dept. for Surgery, Univ Tuebingen, Tübingen, Germany; 4) Department of Pathology, Univ Tuebingen, Tuebingen, Germany.

Hepatocellular carcinoma is the fifth most common cancer in the world [1]. Over 500.000 patients are diagnosed hepatocellular carcinoma per year, the total number in Europe and the USA is rising over the last decades. The project IndividualLiver has the aim to establish individualized immunotherapy for hepatocellular carcinomas and is supported by the BMBF. Prerequisite for a successful immunotherapy is the detection of somatic mutations in genes presented on the cell surface. In this context, we sequenced a total of 11 patients, diseased with hepatocellular carcinoma by means of next-generation sequencing. After surgery, two liver specimen were taken from each patient - one tumor sample and one normal liver tissue. Both samples were conditioned and sequenced using a targeted whole-exome resequencing approach (NimbleGen SeqCap V2, Illumina 2x76PE sequencing). We established a bioinformatic pipeline for detection of new somatic mutations within tumor tissue. In average, we found 582 (± 161) new somatic, coding sequence changes per sample pair. The average on-target-ratio was 0.48 (± 0.05), overall coverage at a depth of at least 10x reached 0.84 (± 0.1). The overall processing-time can be estimated to be 3-4 weeks. Though further validation of our results is under way including conventional variant sequencing and data comparison with proteome analysis sets of the respective patients, plausibility and filter criteria suggest a high quality of our data. Using this approach, we are able to detect new somatic sequence changes within tumor tissue that ultimately give rise to a patient specific tumor-directed peptide vaccine.

Identification of ethnic specific gene expression differences in breast cancer and normal breast tissue. *L.L. Baumbach-Reardon[1], C. Gomez[1], J. Yan[2], T. Halsey[2], K. Ellison[2], M.E. Ahearn[1], M. Jorda[1], M. Peagram[1].* 1) University of Miami Medical School, Miami, FL; 2) Almac Diagnostics, Durham, N.C.

Disparities in breast cancer (BC) stage of presentation and survival are well documented in patients of different ethnicities. These differences are undoubtedly a result of a combination of factors: socio-economic, lifestyle, tumor characteristics and inherent factors, such as genetic composition. Our group is focused on the genetic contributions to these disparities, to increase understanding of underlying biology, leading ultimately to individualized, ethnic-specific diagnostic and therapeutic approaches. We report results of a recently completed study focused on gene expression profiling in a multi-ethnic cohort of triple negative breast cancer patients. We analyzed BC and self-matched normal tissue samples from 10 African-American (AA), 10 Hispanic (His), and 10 non-Hispanic white (Caucasian) patients from south Florida. Study samples were cut from FFPE (Formalin Fixed Paraffin-embedded tissue) blocks marked by pathology as normal vs. tumor tissue, and sent to Almac Diagnostics for RNA isolation, cDNA preparation, and hybridization to a breast cancer enriched gene expression array (Breast Cancer DSA Research Tool). From the BC DSA data, a two-way ANOVA (disease state and ethnicity) was used to identify transcripts with a p-value less than 0.01. Data QC showed that samples clustered well with respect to ethnicity and adjacent normal vs. tumor tissue. We have identified ethnic-specific expression patterns in the matched normal and tumor samples. Initial pathway analysis indicates a number of genes in DNA repair are differentially expressed across ethnicities. In a set of ten DNA repair/cell cycle genes, the direction of change (increased or decreased expression) was the same for all three ethnic groups; however, the level of change differed greatly between ethnic groups. Fold changes ranged from -6.54 to +5.53, with all being >2 fold change in at least one ethnic group. Additional pathway analysis and validation of results are ongoing. We are completing a parallel analysis of normal tissue samples (reduction mammoplasty) from AA and Cau non-cancer patients to investigate potential normal differences. Combined analysis of tumor and normal breast expression (transcriptome) data will help to better understand the possible significance of gene expression differences in breast tissue between ethnic groups. These studies have important implications for addressing BC ethnic disparities, as well as tailored approaches to prediction, prevention and treatment.

1189W

Arsenic-related genomic and epigenomic alterations in lung squamous cell carcinomas. *D. Becker-Santos[1], V. Martinez[2], E. Vucic[1], S. Lam[1], W. Lam[1].* 1) Department of Integrative Oncology, British Columbia Cancer Research Centre, Vancouver, BC, Canada; 2) Department of Molecular and Cell Biology, University of Chile, Santiago, Chile.

Background: Arsenic is a well-established skin, bladder, and lung carcinogen. It is estimated that over 100 million people worldwide are exposed to toxic levels of arsenic, mainly through drinking water. Lung cancer is the main cause of deaths due to arsenic exposure, with this metalloid acting as the major etiological agent in cancers that occur in never smokers. Relative to other subtypes of lung cancer, lung squamous cell carcinomas (SqCCs) occur at higher rates following arsenic exposure. The mechanisms by which arsenic causes cancer is still under investigation, and it has been proposed that both genetic and epigenetic processes may be involved. In this study, a rare panel of lung tumours from a population with chronic arsenic exposure, including SqCC tumours from patients with no smoking history, was analyzed to identify arsenic-associated copy-number alterations (CNAs) and DNA methylation changes. Methods: A total of fifty-two cases of lung SqCC were analyzed by whole-genome tiling-set array comparative genomic hybridisation. Twenty-two specimens were collected from arsenic-exposed patients from Northern Chile (10 corresponding to never smokers and 12 to smokers). A panel of thirty cases was obtained for comparison from North American smokers without arsenic exposure. In addition, 22 blood samples from healthy individuals from Northern Chile were examined to identify naturally occurring germline DNA copy-number variations (CNVs) that could be excluded from analysis. DNA methylation analysis was performed using Illumina's Infinium Human Methylation 450K array. Results: We identified several CNAs and DNA methylation changes associated with arsenic exposure. These alterations were not attributable to either CNVs or smoking status. The most recurrent events represented DNA losses at chromosome bands 1q21.1, 7p22.3, 9q12, and 19q13.31. The only arsenic-associated DNA gain occurred at 19q13.33, which contains genes previously recognized as oncogenes. Conclusions: Our study has provided insights into the molecular mechanisms of arsenic-induced lung neoplasia. The distinct and recurrent arsenic-associated genetic and epigenetic alterations suggest that this group of tumours may represent a separate disease subclass.

Caprin1 is Frequently Overexpressed in Human Lymphomas. *S. Berker Karauzum[1], Z. Cetin[1], B. Akkaya[2], A. Timuragaoglu[3], IH. Ozbudak[2], H. Bagci[1].* 1) Department of Med Biol & Genetics, Akdeniz University, Medical Faculty, Antalya, Turkey; 2) Department of Pathology, Akdeniz University, Medical Faculty, Antalya, Turkey; 3) Department of Hematology,Akdeniz University, Medical Faculty, Antalya, Turkey.

Caprin1 endoded by Cytoplasmic Activation/Proliferation-Associated Protein-1 gene located in 11p13 chromosome region. Previous studies using cultivated normal and cancer cell lines indicated that Caprin1 is associated with cell proliferation in various types of cell lineages, including hematopoietic and epithelial cells. We hypothesised that Caprin1 might be overexpressed in some of these tumor cells and that this overexpression could be associated with the clinicopathological parameters in some types of the tumors. Immunohistochemistry was used to carry out expresssion profiling of 110 normal human tissue sections in tissue microarrays and 113 human cancer tissue sections in multiple tumor tissue micoarrays. Additional tests using tissue microarrays for lymphomas also utilized immunohistochemistry and included 16 cases with Hodgkins disease, 98 cases with Non-Hodgkins B cell lymphoma, and 5 cases with Non-Hodgkins peripheral T cell lymphoma. The expression of Caprin1 was observed in different types of tumors derived from different tissues including, esophageal, stomach, small intestinal, colon, rectal, kidney, gall bladder, prostate, breast, ovarian, endometrium, uterine, oronasopharyngeal, lung, liver and lymphoid tissue. Caprin1 overexpression was observed in 4 cases with Hodgkins disease (25%) and in 26 cases with Non-Hodgkins B cell lymphoma (26.5%). Caprin 1 expression was not,however, detected in any Non-Hodgkins T cell lymphoma cases. The higher frequency of Caprin1 overexpression in high grade diffuse large B cell lymphomas than the low grade non-Hodgkin B cell lymphomas indicates that Caprin1 expression levels might be correlated with the cellular proliferation potential of the lymphoma cells. In this study, we revealed the expression profile of Caprin1 in normal human and tumor tissues for the first time. Caprin1 overexpression is likely associated with the development of lymphoid and epithelial tumours derived from different organs and tissues. Further studies on the clinicopathologic importance of Caprin1 overexpression in different types of lymphoma and solid tumours are needed.

Rapid identification of cancer mutations by high throughput sequencing on the MiSeq system. *J. Betley, G. Smith, K. Hall, MiSeq program team.* Illumina Cambridge Ltd, Saffron Walden, United Kingdom.

Next generation sequencing has enabled the routine sequencing of whole human genomes at a scale of many thousands per year. One exciting application of this technology has been the complete sequencing of the cancer genomes and the identification of and cataloguing of somatic mutations in a wide variety of cancer types. We have developed a new sequencing system, called Miseq, that generates over 1Gb of data from 2x150 base reads in just over a single day. Miseq integrates all the steps of the Illumina sequencing process from cluster generation, to paired end sequencing reads, into a fully automated `hands-off' workflow that involves 20 minutes of set up time, and includes the steps of primary and secondary data analysis, including variant calling and de novo assembly. A primary application of this new system is the characterisation of variation within individual exons of clinical cancer samples. Starting with FFPE-extracted DNA, we demonstrate that it is possible to amplify and sequence a highly multiplexed set of exons within a panel of cancer samples. We identify single nucleotide variation with a limit of detection less than 1%. The rapid turnaround of the system, coupled with the simple sample preparation and operation of the instrument, makes possible the deployment of Next Generation sequencing in a clinical research setting for cancer.

1192W

Post-genome wide association studies in colorectal cancer. *M. Biancolella[1], C. Yan[1], G. Mendoza-Fandino[1,3], M.J Hitchler[4], G.A Coetzee[1,2], G. Casey[1].* 1) Department of Preventive Medicine, University of Southern California, Los Angeles, California, USA; 2) Department of Urology, Norris Cancer Center, University of Southern California, Los Angeles, California, USA; 3) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA 90033, USA; 4) Radiation Oncology Department Kaiser Permanente 4950 Sunset Boulevard Los Angeles, CA 90027.

Several genome-wide association studies (GWAS) of colorectal cancer (CRC) have been published and have reported a number of significant associations. However, only limited characterization of the biological/functional role of these associations in cancer pathogenesis has been conducted. Meeting this challenge is not simple, since none of the associations identified to date target coding exons of genes, but instead map to non-protein coding regions near genes or within gene-poor regions. A working hypothesis is that risk allele is in linkage disequilibrium (LD) with an adjacent SNP that maps within a regulatory region and affects gene expression elsewhere. To address this we have measured the presence of regulatory elements by assessing histone modifications across the CRC GWAS regions using chromatin immunoprecipitation-sequencing (ChIP-seq) methods. ChIP-seq profiles for H3K4me1, H3K4me3, H3K27me3, H3K36me3, H3K9/14ac as well as RNAPII were generated in two colon cancer cell lines (HCT116 and SW480). Several chromatin regions were identified within susceptibility LD blocks that suggest the presence of putative enhancers. The potential regulatory activities of 11 of these regions were determined by an enhancer transfection assay using 1.5-2kb DNA fragments centered on the ChIP-seq peaks of active chromatin marks. Five of the 11 regions tested showed intrinsic enhancer activity (one region at 18q21; one region at 11q23; one region at 15q13; two region at 9p24). The peak identified at 11q23 showed pronounced unidirectional enhancer activity. Within this 1.5-kb DNA fragment, the risk alleles of two SNPs strongly correlated with the risk variant rs3802842. A 30% reduction in enhancer activity was seen when one of these SNPs was mutagenized. Studies are now in progress to determine the transcription factor binding sites that may be affected by this SNP. Studies are also in progress to correlate genotype of rs3802842 and gene expression of genes mapping within 500kb of the risk SNP using normal colon tissues from >300 subjects to identify candidate genes that may be regulated by this regulatory element.

Developing breast cancer among men and possibility of exposure to endocrine- disrupting chemicals in Iran: A case report. *F. Biramijamal[1], A. Hossein-Nezhad[2], H. Jalaikhoo[3,4], F. Ramezani[4], S.S. Mirgheydari[4], S. Klahroodi[3,4], P. Hemmati[4].* 1) National Institute of Genetic Engineering and Biotechnology- Medical Genetics, Tehran, Iran; 2) Endocrinology and Metabolism Research Center, Tehran, Iran; 3) Artesh 501 Hospital ,Tehran, Iran; 4) Clinic of Oncology, Tehran, Iran.

It is described that interaction between heavy metals such as cadmium (Cd) with estrogen receptor can be increased breast cancer risk, because the heavy metals can act as estrogen mimics. It is shown that urinary cadmium (CdU) is increased among workers in battery plants. It is induced by occupational exposure to Cd. In this study, we are present a case report of breast cancer in a man who worked in battery plants. He diagnosed with invasive ductal carcinoma grade II, and axillaries lymph-nodes showing metastatic mammary carcinoma. At the time of resection (surgery), he was 52 years old. The result of pathology is shown that the tumor surrounded by a chronic inflammation infiltrate and dissociated by bundles of connective tissue. The tumor borders are infiltrative. Stromal fibro-sclerosis and chronic inflammatory reaction is ostensible. All examined lymph-nodes are involved by tumor. Skin and surgical margins are free of tumor. Estrogen receptor (ER) and Progesterone receptor (PR) status were positive and c-erB-2 statue was negative in the tumor tissue. Also, bone Scan of patient was normal. ER and PR status has been described as an indicator of endocrine responsiveness and as a prognostic factor for recurrence too. The some of researchers found no association between these receptors and histopathological status of tumor and metastases among women patients. However, The ER and PR positive status in a man patient may be reflected to exposure to endocrine- disrupting chemicals such as Cd. Also, It is described that c-erB-2 positive rate is not common in ER^+/PR^+ tumors among women patients, and similarity, we found the c-erB-2 negative in our case with ER^+/PR^+. In addition, grade I tumors were more common in receptor positive tumors while grade II and III tumors were more common in receptor negative tumors among women patients. However, in our case, we found ER+/PR+ in grade II tumor. So, we suggest using the risk assessment kits for identification and measurement of environmental risk factors especially in battery industry. This protocol can be helped to reduce the incidence of breast cancer in Iran.

Genome-wide SNP array analyses of benign, low malignant potential and low grade serous epithelial ovarian tumours identify chromosomal anomalies, including a novel fusion gene. *A.H. Birch[1], S.L. Arcand[2], K.K. Oros[3], K. Rahimi[4], A.K. Watters[5], D. Provencher[6,7], C.M. Greenwood[3,8,9], A.M. Mes-Masson[6,10], P.N. Tonin[1,2,11].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) The Research Institute of the McGill University Health Centre, Montreal, Canada; 3) Lady Davis Research Institute, Jewish General Hospital, Montreal, Canada; 4) Department of Pathology, Centre Hospitalier de l'Université de Montréal (CHUM), Montreal, Canada; 5) Department of Pathology, McGill University and McGill University Health Centre (MUHC), Montreal, Canada; 6) Centre de recherche du Centre hospitalier de l'Université de Montréal (CRCHUM), Institut du cancer de Montréal, Montreal, Canada; 7) Division of Gynecologic Oncology, Université de Montréal, Montreal, Canada; 8) Department of Oncology, McGill University, Montreal, Canada; 9) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Canada; 10) Department of Medicine, Université de Montréal, Montreal, Canada; 11) Department of Medicine, McGill University, Montreal, Canada.

Epithelial ovarian cancer (EOC) is the most lethal gynaecological malignancy, and will result in the deaths of approximately 1750 Canadian women this year. Over 50% of all EOC tumours are of the serous histopathological subtype. Accumulating histological and genetic evidence has led to the recent proposal that low grade serous ovarian carcinomas (LGSOC) likely have a different molecular etiology than their high grade (HGSOC) counterparts. While HGSOCs grow aggressively and often exhibit extensive aneuploidy and *TP53* mutations, LGSOCs are more indolent, harbour mutations in *KRAS* or *BRAF*, and display low levels of chromosomal instability. With the advent of whole-genome SNP arrays, it is possible to interrogate the entire cancer genome to detect chromosomal aberrations. Most genome-wide SNP studies of serous ovarian tumours have focused on HGSOCs. Less is known of the genomic events occurring in benign (BOV) and low malignant potential (LMP) tumours, which are proposed precursors of LGSOCs. We have applied the Illumina BeadChip 610-Quad SNP array to genotype over 600,000 markers in 32 serous BOVs, 59 serous LMPs, and 12 LGSOCs. Mutation testing of *KRAS, BRAF* and *TP53* was also carried out, and copy number aberrations were inferred using Genome Studio and the GenoCNA algorithm. Increasing levels of chromosomal aberrations were seen between BOVs, LMPs and LGSOCs. Few BOVs showed evidence of allelic imbalance, whereas 34 of 59 LMPs displayed allelic imbalance and/or intrachromosomal gains and losses. LGSOCs displayed a wide spectrum of aberrations, ranging from aberrant copy numbers of whole chromosomes to multiple intrachromosomal gains and losses. Complex patterns of intrachromosomal breaks were associated with *TP53* mutations, in both LMPs and LGSOCs. A homozygous deletion located on chromosome 6 in an LMP sample resulted in the creation of the *GOPC-ROS1* fusion gene, a rare variant previously reported as oncogenic in a glioblastoma cell line and two cholangiocarcinoma samples. To the best of our knowledge, this is the first fusion gene observed in an EOC context. Whole-genome SNP arrays are useful tools for studying tumour-associated genomic events. Ideally, specific chromosomal signatures may be connected to pathological outcomes, and SNP arrays may be employed as a diagnostic tool to parse histologically similar tumours.

1195W

Analysis of expression profile of VEGF pro and antiangiogenic isoforms in head and neck cancer squamous cells carcinoma. *P.M. Biselli-Chicote[1], G.H Marucci[1], R. Castro[1], J.V. Maniglia[2], D.S. Neto[3], E.C. Pavarino[1,4], E.M. Goloni-Bertollo[1,4].* 1) Genetics and Molecular Biology Research Unit - UPGEM, Medical School of Sao Jose do Rio Preto - FAMERP, Sao Jose do Rio Preto, Sao Paulo, Brazil; 2) Department of Othorrinolaringology and Head and Neck Surgery, Medical School of Sao Jose do Rio Preto - FAMERP, Sao Paulo, Brazil; 3) Patology Service, Hospital de Base, Sao Jose do Rio Preto - FAMERP, Sao Paulo, Brazil; 4) Department of Molecular Biology, Medical School of Sao Jose do Rio Preto - FAMERP, Sao Paulo, Brazil.

Head and neck cancer is a broad term that encompasses paranasal sinuses, nasal cavity, oral cavity, pharynx and larynx epithelial tumors. About 40% of head and neck cancers occur in the oral cavity, 25% in the larynx, and 15% in the pharynx. The vast majority of epithelial tumors are classified as head and neck squamous cell carcinoma. Tumor growth and progression depend on angiogenesis that is a process of new blood vessels formation from a preexisting vascular endothelium. The newly formed blood vessels provide nutrients and oxygen to the tumor, increasing its growth. Therefore, angiogenesis plays a key role in cancer progression and occurrence of metastasis.Vascular endothelial growth factor (VEGF) is a mitogen of endothelial cells and its overexpression is associated whit tumor growth and metastasis. However, the selection of splicing alternative site at the 3' region of the messenger RNA results in expression of isoforms with a different C-terminal region that may have inhibitory effects in angiogenesis and they are downregulated in tumors. Protein VEGF165 is a proangiogenic factor and plays important role in the migration, proliferation and cell survival. On the other hand, altered C-terminal region of VEGF165b (antiangiogenic isoform) allows the inhibition of endothelial proliferation, migration and vasodilatation induced by VEGF165, and inhibition of physiological angiogenesis and tumor growth. We analyzed the expression of VEGF165 e VEGF165b isoforms in 20 samples of head and neck squamous cells carcinoma and adjacent normal tissue. Total RNA was obtained and the correspondent cDNA was synthesized. Specific primers and probes for each isoform were used to expression analyses by Quantitative Real Time PCR. As result no differences was observed in the expression of both genes in tumor compared to normal samples. We hope that with increasing the sample size, our results may serve as a basis for further studies regarding the splicing mechanism of VEGF gene in the head and neck cancer, aiming to identify new therapeutic targets and diagnostics.

1196W

Tylosis with Oesophageal Cancer segregates with RHBDF2 mutations leading to dysregulation of downstream EGF and EphrinB3 signalling. *D.C. Blaydon[1], S.L. Etheridge[1], J.M Risk[2], H-C. Hennies[3], H.P. Stevens[4], J.K. Field[5], A. Ellis[5], I.M. Leigh[6], A.P. South[6], D.P. Kelsell[1].* 1) Centre For Cutaneous Research, Barts and the London, London, United Kingdom; 2) Department of Molecular & Clinical Cancer Medicine, Institute of Translational Medicine, Liverpool, United Kingdom; 3) Division of Dermatogenetics, Cologne Center for Genomics, University of Cologne, Cologne, Germany; 4) Barnet Hospital, Barnet, United Kingdom; 5) The University of Liverpool Cancer Research Centre, Liverpool, United Kingdom; 6) Centre for Oncology and Molecular Medicine, Ninewells Hospital and Medical School, Dundee, United Kingdom.

Oesophageal cancer (predominantly squamous oesophageal cancer) is the seventh leading cause of cancer related deaths worldwide. There is a familial form of susceptibility to oesophageal cancer called “Tylosis” where patients have a very high risk of developing squamous cell cancer of the oesophagus (up to 95% by age 65) - we have now identified the single genetic cause of this condition. Mutations in the inactive rhomboid protease RHBDF2 predispose individuals to Tylosis with Oesophageal Cancer (TOC), an autosomal dominant syndrome with palmoplantar keratoderma, oral precursor lesions and a high lifetime risk of oesophageal cancer. Two mutations identified in 3 families from the UK, US and Germany, c.557T>C (p. Ile186Thr) and c.566C>T (p. Pro189Leu), affect residues translated from a highly conserved region of exon 6. Rhomboid proteins are typically serine proteases that cleave type-1 membrane proteins in the transmembrane region. RHBDF2 lacks protease activity but is predicted to inhibit the active rhomboid protease RHBDL2. Substrates of RHBDL2 include EGF and EphrinB3, proteins important in cell proliferation, adhesion and migration. Dysregulation of EGFR and Ephrin signalling has been implicated in many cancers and EGFR inhibitors have demonstrated clinical efficacy. Immunohistochemical staining of normal skin showed RHBDF2 predominantly at the plasma membrane whereas in tylotic skin, the distribution appeared more cytoplasmic, suggesting altered trafficking or processing. Dysregulation was also observed in the distribution of RHBDL2 and EphrinB3 in tylotic skin. Recombinant EGF had little effect on the growth of immortalised patient keratinocytes (n=2) compared with controls (n=2). In addition, tylosis keratinocytes exhibited increased migration compared with controls, particularly in the absence of EGF ($p<0.005$ in each case). This suggests a key role for RHBDF2 in regulating EGF signalling in both cutaneous and oral keratinocytes. The link with RHBDF2 mutations and oesophageal cancer could lead to new tools for early diagnosis and small molecule RHBDL2 inhibitor development for treatment of oesophageal disease and other epithelial cancers including lung and ovarian cancer.

Identification of fusion transcripts in ovarian cancer by next generation RNA-sequencing. *M. Bonin[1], J. Hoffmann[1], H. Neubauer[3], M. Walter[1], A. Staebler[2], F. Wagner[3, 4], O. Riess[1], D. Wallwiener[3], H.G. Rammensee[4], T. Fehm[3].* 1) Medical Genetics Dept., Institute of Human Genetics, Tuebingen, BW, Germany; 2) Institute for Pathology, Eberhard-Karls-University Tuebingen, Liebermeisterstr. 8, 72076 Tuebingen, Germany; 3) Department of Obstetrics and Gynecology, Eberhard-Karls-University Tuebingen, Calwerstr. 7, 72076 Tuebingen, Germany; 4) Institute of Immunology , Eberhard-Karls-University Tuebingen, Calwerstr. 7, 72076 Tuebingen, Germany.

Ovarian cancer is one of the most malignant tumors in women and the leading cause of death from gynecological cancer in the Western civilization. The standard therapy consists of aggressive cytoreductive surgery followed by platinum-based chemotherapy. In addition to the advanced stage of the disease at the time of diagnosis in most instances, the intrinsic or acquired platinum resistance in the majority of patients leads to its high mortality rate. To gain new insights in resistance mechanisms, mutation load and modified pathways, we performed RNA-seq methods using Illumina next generation sequencing technologies. Chromosomal Translocations and fusion transcripts have been a class of mutations in solid tumors. The development of RNA-sequencing methods provides an opportunity for deep characterization of cancer cell transcriptomes and the discovery of fusion transcripts arising from genomic rearrangements. Six cryopreserved tissues samples from each platinum resistant and platinum sensitive ovarian carcinomas were selected. Tissue sections (10μm) were prepared, stained with hematoxilin/eosin and characterized by a pathologist. Only samples with serous ovarian cancers containing at least 80% malignant tissue were processed further. From consecutive sections RNA was extracted and analysed by using 76nt paired-end reads with Illumina technologies. We identify 18 novel fusion transcripts in the 12 ovarian cancer samples. Supported by the Genomatix® algorithm, we were able to validate 15/18 (83%) fusion transcripts by qRT-PCR and Sanger-Sequencing. Most fusion transcripts were associated with Copy number transitions and were partially common in highly amplified DNA regions. Around 40% of the fusion transcripts partners have either been previously detected in oncogenic gene fusions, or reported by pathway analysis to be oncogenic. The results indicating that RNA-sequencing opens a great opportunity for discovering novel fusion transcripts in ovarian cancer and we are now able to analyze the impact of this alteration for the growth and resistance mechanisms of cancer cells.

1198W

BRCAPRO vs Manchester Scoring System - Experience of Genetic Health Queensland, Australia. *M.J. Boon[1], R.D. Susman[1], J. Bjorkman[2].* 1) Genetic Health Queensland, Brisbane, Queensland, Australia; 2) Pathology Queensland, Brisbane, Queensland, Australia.

Genetic Health Queensland (GHQ) is the sole provider of publically funded clinical genetic services to the 4.5 million residents of the state of Queensland, Australia. As approximately 30% of referrals relate to familial cancer, significant numbers of genetic tests for cancer predisposition syndromes are performed. Due to limitations in funding, criteria exist so that testing is only offered in cases with a considerable likelihood of identifying a pathogenic mutation.

GHQ has primarily used the computer software BRCAPRO to determine eligibility for *BRCA1* and *BRCA2* gene testing, along with clinical judgement in unique cases. Genetic testing is offered when the likelihood of identifying a mutation is 20% or above. Due to ongoing issues with the departmental use of BRCAPRO, the Manchester Scoring System (incorporating the more recent pathology adjustment) was considered as an alternative risk prediction model. Prior to implementing this new method, an audit was performed to review the current mutation detection rates using BRCAPRO and predict the sensitivity and cost-effectiveness of the alternate model. Benefits and limitations of each method were also considered.

Between the period of January 2010 and January 2011, Manchester and BRCAPRO scores were calculated for all patients seen by GHQ with a personal history of breast and/or ovarian cancer. *BRCA1* and *BRCA2* gene testing was subsequently offered to all individuals who had a BRCAPRO score of above 20% or were deemed appropriate by clinical judgement. The resultant number of mutations identified was used to calculate the mutation detection rate of BRCAPRO within our population and predict the approximate detection rate if the Manchester Scoring System had been used. Within the limits of the audit, a comparison was made between the mutations detected and/or potentially missed by each method.

The mutation detection rate using the Manchester Scoring System was predicted to be comparable or better than BRCAPRO, with similar numbers of tests being indicated by both methods. For this reason, the Manchester Scoring System (with the threshold of a combined score of 19 and above) was adopted by Genetic Health Queensland in 2011. Preliminary data from the first four months of implementation will be presented and evaluated against predicted outcomes.

What management for the asymptomatic men carriers of BRCA1 and BRCA2 mutation? Inquest to the French oncogenetics centres. *I. Brachot-Simeonova[1], G. Morin[2], C. Gillaux[1], B. Demeer[2], F. Amram[2], J. Gondry[1], M. Mathieu[2], R. Fauvet[1].* 1) Gynecology and Obstetric, Amiens University Hospital, Amiens, France; 2) Clinical Genetics and Oncogenetics, Amiens University Hospital, Amiens, France.

Objective: To define in the absence of guidelines, the management in France of asymptomatic men bearing a mutation of BRCA1-2 gene. Material and method: This multicentre study is a descriptive survey of practice. A questionnaire was addressed to the professionals working in the 90 French oncogenetics centres. Results: We obtained the answers of 46 practitioners working in 58 centres. 100% of the responders offered this screening to determine the risk of transmission to the descent and 86% to offer a personal follow-up. This follow-up concerned for 94% the prostate cancer, for 68% the breast cancer, for 49% the pancreatic cancer, and for 12% the melanoma. The screening of the prostate cancer was proposed mainly to the men bearing a BRCA2 mutation and from the age of 40 years. It was based on the clinical examination and the prostate-specific antigen. The screening of breast cancer was offered to the patient bearing a BRCA2 mutation. It was proposed by self-palpation and/or medical clinical examination and started between the age of 30 and 50 years. Imagery was only realized in case of symptoms. The screening of the pancreatic cancer was offered after the age of 40 years and by computed tomography and/or pancreatic MRI. It was mainly proposed in case of familial history of pancreatic cancer. The general practitioner was considered to be the best to perform all these screenings. Conclusion: These experts' opinions can help to establish recommendations for the management of the asymptomatic men carriers of BRCA1-2 mutation.

Single Molecule Targeted Resequencing to Individualize Cancer Therapy. *A.M.K. Brown[1], K. Ng[1], L. Timms[1], R. De Borja[1], T. Zhang[2], S. Kamel-Reid[2], J. Dancey[1], L.L. Siu[2], B. Tran[2], P. Shaw[2], S. Ghal[2], V. Ferretti[1], S. Watt[1], N. Onetto[1], T. Hudson[1], J.D. McPherson[1,3].* 1) Ontario Institute for Cancer Research , Toronto, ON, Canada; 2) Princess Marget Hospital, University Health Network, Toronto, ON, Canada; 3) University of Toronto, Toronto, ON, Canada.

Next generation sequencing technology is revolutionizing cancer research with unprecedented amounts of genome-wide data being generated for all tumor types. This is leading to a greater recognition of many of the molecular events associated with the initiation, progression and potential treatment of cancer. It is clear that cancer is a complex disease with most tumors being as unique as the individuals they arise in. A personalized medicine approach that includes the characterization of each tumor to identify key dysregulated pathways will better inform prognosis and enable targeting of therapies to improve outcomes. In order for this individualized approach to be integrated in the clinic the turn-around time, from tumor resection or biopsy to informed reporting to the clinician, needs to be short and the sensitivity and specificity needs to be high in order to accurately identify somatic variants in heterogeneous tumor samples with non-optimal cellularity. Using the PacBioRS platform, we have developed methods for the rapid characterization of a validated set of known oncogenes to uncover potential actionable mutations that can guide therapy. DNA derived from fresh frozen tissue, FFPE and blood has been tested and no appreciable difference in quality or quantity has been observed. Additionally, protocols for whole genome amplified material have also been optimized. We continue to develop library preparation methods and have increased yield over five-fold since the onset of development to over 100 MB of mapped sequence per SMRT cell in two 40 minute sequencing runs. Currently we are recruiting 1-2 patients per week with advanced metastatic cancers who are potential candidates for early phase clinical trials of targeted agents. Initially we focused on 19 oncogenes that overlap the Oncocarta V.1 panel (Sequenom, Inc.) to allow for cross technology comparisons. However, to fully take advantage of the sequencing yield of the PacBioRS, we are expanding to a larger list of ~200 genes. This clinical resequencing is being done in collaboration with a diagnostic CAP/CLIA molecular diagnostic laboratory to provide validation of all results prior to utilization. Logistics of sample handling, validation of this pipeline and reporting mechanisms are all being evaluated and optimized in a clinical trial setting for eventual routine inclusion into the clinical environment.

1201W

The MLH1 c.1-93 G>A SNP is associated with MLH1 promoter methylation and molecular features of serrated pathway colorectal cancer. *D.D. Buchanan[1], M.D. Walsh[1,2], M. Clendenning[1], R.J. Walters[1], B. Nagler[1], S. Pearson[1], D. McKeone[1], E. Pavluk[1], C. Rosty[3], J.L. Hopper[4], M.A. Jenkins[4], D.R. English[4], J.P. Young[1,2].* 1) Familial Cancer Lab, Queensland Institute of Medical Research, Herston, QLD, 4006, Australia; 2) University of Queensland School of Medicine, Herston QLD 4006, Australia; 3) University of Queensland Centre for Clinical Research, Royal Brisbane and Women's Hospital, Herston, QLD 4029, Australia; 4) University of Melbourne, Centre for MEGA Epidemiology, School of Population Health, Melbourne, VIC 3053, Australia.

The c.1-93 G>A SNP (rs1800734) within the MLH1 gene promoter has previously shown an association with MSI-H colorectal cancer (CRC). The majority of MSI-H CRCs is sporadic, resulting from methylation of the MLH1 gene promoter methylation with the remaining proportion of MSI-H CRCs seen in Lynch syndrome, resulting from a mutation in one of the mismatch repair genes (MMR). The aim of this study was to determine the association between the MLH1 c.1-93 G>A SNP and MSI-H CRC resulting from MLH1 promoter methylation. Five hundred and ninety three (n=593) individuals with CRC from the population-based Melbourne Collaborative Cohort Study were characterized for MSI, methylation of the MLH1 promoter and the CpG island methylator phenotype (CIMP) markers RUNX3, CACNA1G, SOCS1, NEUROG1 and IGF2 using MethyLight, the BRAF p.V600E somatic mutation, somatic mutations in codons 12 and 13 of the KRAS gene and loss of MMR proteins (MLH1, MSH2, MSH6 and PMS2) by immunohistochemical staining. DNA isolated from FFPE tissue from the normal colon mucosa was used to genotype for the rs1800734 SNP using a Taqman allelic discrimination assay. In this case-only analysis, carriers of the variant A allele were significantly older age at presentation of CRC (G= 66.4yrs ± 7.9yrs versus A=68.1yrs ± 7.1yrs, p=0.006). MSI-H CRCs were significantly more common in individuals carrying at least one copy of the variant allele (16%) when compared to individuals with the wildtype genotype (8%, p=0.003, OR=2.2, 95%CI=1.3-3.7). CRCs with methylation of the MLH1 gene promoter were increased two-fold in carriers of the GA or AA genotypes (15.4%) when compared to carriers of the GG genotype (8.6%, p=0.01, OR=1.9, 95%CI= 1.2-3.2), displaying an increase in the frequency of MLH1 methylation tumours with increasing variant allele dose (GG (8.6%) < AG (13.8%) < AA (27.6%)). CRCs with a BRAF p.V600E mutation (p=0.04, OR=1.4, 95%CI= 1.1-2.0) or CIMP (≥ 3 positive markers; p=0.007, OR=1.7, 95%CI=1.2-2.4) were associated with carrying at least one copy of the variant allele. No association was observed for gender, tumour site or mutations in the KRAS gene. In patients with CRC, the variant allele of the MLH1 c.1-93 G>A promoter SNP is significantly more common in CRC with methylation of the MLH1 promoter, CIMP and the BRAF p.V600E mutation suggesting that MLH1 promoter methylation and the methylator phenotype of serrated pathway CRC underlies the previously reported association with MSI-H CRC.

1202W

Improved tumour profiling using next generation sequencing approaches. *D. Burgess[1], I. Tomlinson[2], M. Middleton[2], B. Hassan[2], A. Schuh[2], D. Green[1], T. Albert[1], X. Zhang[1], J. Taylor[2].* 1) Research & Development, Roche NimbleGen, Madison, WI; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Next generation sequencing methods have fueled research into the genetic basis of cancer, in particular the somatic mutations in tumours which may influence natural history, tendency to metastasize, response to treatment and potential for adverse events. However, tumour profiling in clinical practice has not kept pace with these developments and remains largely limited to a few selected genetic markers which are known to influence response to therapy, such as EGFR and KRAS to guide treatment with erlotinib and gefitinib in non small cell lung cancer and BRAF for BRAF inhibitors in melanoma.

Although whole genome sequencing is becoming cheaper, it is not yet cost effective in a clinical setting and the bioinformatics pipelines required to manage the wealth of data created on an individual patient basis must also be developed. Robust targeted resequencing methods are therefore critical to realise the prospect of using NGS for molecular profiling of tumours in both research and clinical settings. To address this, we developed a solution capture protocol that is robust, rapid and has high capture efficiency. The technique was evaluated on a panel of colorectal cancer samples that was well characterized by other molecular techniques and was associated with clinical outcome data. We then developed a capture design for the routine screening of a set of high-value cancer gene targets and evaluated this design against a panel of different cancer types, including colorectal, melanoma and sarcoma. The results of this evaluation study, including a comparison with other solution capture protocols will be described.

1203W

Genome-wide DNA methylation pattern analysis of childhood leukemia. *S. Busche[1,2], C. Richer[3], B. Ge[2], J. Healy[3], T. Kwan[1,2], S.H. Chen[2], D. Sinnett[3,4], T. Pastinen[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) CHU Ste-Justine Research Center, Montreal, Quebec, Canada; 4) Department of Pediatrics, Universite de Montreal, Montreal, Quebec, Canada.

Acute lymphoblastic leukemia (ALL) is the most common childhood cancer, and is a leading cause of cancer-related death in children. The most prevalent is the B-cell progenitor subtype (pre-B ALL; ~80%), and cytogenetic analysis has helped further classification into three subgroups based on chromosome number, recurrent genetic translocations, or lack of any known genetic changes (NP). In addition to genetic alterations, cancer cells display a deeply distorted epigenome. DNA methylation is a frequent epigenetic modification occurring almost exclusively in the context of cytosine methylation in CpG dinucleotides. An in-depth understanding of genome-wide methylation patterns, and their correlation/association with available gene expression and SNP genotyping data from the same samples has the potential for identifying novel biomarkers. We collected bone marrow and/or peripheral blood from pediatric pre-B ALL patients of French-Canadian origin at diagnosis (day 0, untreated leukemia) and remission (matched-normal material). The tumor samples display high leukemic blast rates, and represent the three subgroups. Methylation profiling was carried out using the Illumina Infinium HumanMethylation450 BeadChip, which interrogates ~450,000 CpG-sites across the whole genome. Principal component analysis reveals the tumor subgroups as a major determinant of genome-wide methylation differences among pre B-ALL samples (accounting for 22% of variance). Furthermore, we identified significant methylation level alterations of multiple CpG-sites associated with *IGF2BP*, a gene whose expression level was shown to be perturbed in B-ALL. In subsequent approaches, RNA-sequencing derived gene expression levels will be correlated with promoter methylation levels. Regulatory marker methylation is expected to negatively correlate with the corresponding gene expression levels. SNP genotyping will identify genetic variants which might be a source of DNA methylation variation and hence gene regulation. Overall, we hope that our findings will provide the basis for the development of more efficient therapeutic approaches.

High resolution melting (HRM) analysis of BRAF V600E mutation in sporadic colon cancer. *T. Cacev, S. Bulat, S. Kapitanovic.* Division of Molecular Medicine, Rudjer Boskovic Institute, Zagreb, Croatia.

Colorectal cancer arises as a consequence of continuous mutation accumulation in number of oncogenes and tumour suppressor genes. Approximately 50% of colorectal tumours have an aberrant MAPK signalling. Although mutations of genes involved in MAPK signalling pathway are known for sometime, their importance has recently been brought to scientific attention as a consequence of break-troughs in personalized medicine and modern antitumour therapy. Conventional methods of mutation detection are prone to generating false positive or negative results; therefore, in recent years a method of choice for mutation screening is the high resolution melting fluorescent detection of heteroduplexes (HRM). In this study HRM method was introduced in order to detect the most common BRAF gene mutation, V600E in sporadic colon cancer tumours. A total of 120 tumour samples were analyzed and in 6 (5%) BRAF V600E mutation was detected and confirmed by DNA sequencing. Finally, HRM method has proved itself to be the simplest and faster alternative to conventional methods of mutation detection and can be used for molecular profiling of other tumours where BRAF mutations have an important role.

Evidence for a strong genetic contribution to lethal prostate cancer. *L. Cannon-Albright[1,2,3], C. Teerlink[1], N. Agarwal[2], R. Stephenson[2].* 1) University of Utah School of Medicine, Salt Lake City, UT; 2) Huntsman Cancer Institute, Salt Lake City, UT; 3) George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, UT.

Decades of investigation into the genetic causes of prostate cancer and prostate cancer aggressiveness has yet to clearly identify genes or variants which explain much more than a small amount of risk for prostate cancer among a small population of men. Even less progress has been made in understanding why 30% of all patients with localized prostate cancer eventually develop recurrent, and subsequently fatal, prostate cancer. Here we investigate familial clustering for the distinct subset of prostate cancer cases whose disease recurs, those cases who go on to die from their prostate cancer. Using the Utah Population Database, a computerized genealogy of Utah combined with Utah death certificates from 1904, we analyzed the familial clustering of prostate cancer cases. We utilized only those 1.2 M individuals in the genealogy who had data for both parents, all 4 grandparents and 6 of 8 great grandparents. We identified a total of 17,207 men with a diagnosis of prostate cancer, of which 4,388 also had a death certificate including prostate cancer as a primary or contributing cause of death. It has been well demonstrated that prostate cancer shows significant excess familial clustering. Analysis of the subset of prostate cancer cases dying from prostate cancer shows a similar result. We tested the hypothesis that the subset of men dying from prostate cancer clustered even more closely than all prostate cancer cases. We performed the Genealogical Index of Familiality (GIF) test for excess relatedness on the cases dying from prostate cancer. We compared the observed relatedness of this distinct set of cases to the expected relatedness among all prostate cancer cases. Significant excess relatedness for the men dying from prostate cancer was observed beyond second cousin relationships; even when close relationships were ignored, the significant excess relatedness was observed. These data provide strong support for a genetic contribution to lethal prostate cancer and identifies a set of high-risk pedigrees who should be studied to identify the responsible genes.

Quantitative analysis of the expression of anti- and pro- angiogenic isoforms of VEGF in breast cancer by qPCR. *R. CASTRO[1], P.M. Biselli-Chicote[1], V.R. Regiani[2], D.S. Neto[3], N.A.B. Junior[4], J.L.E. Francisco[4], J.A. Thome[5], E.C. Pavarino[1], D.A.P.C. Zuccari[2], E.M. Goloni-Bertollo[1].* 1) Research Unit in Genetics and Molecular Biology, Faculty of Medicine of Sao Jose do Rio Preto, Sao Paulo, BR; 2) Center for Studies and Research on Cancer Faculty of Medicine of Sao Jose do Rio Preto, Sao Paulo, BR; 3) Pathology Service, Hospital de Base, São Jose do Rio Preto, Sao Paulo, BR; 4) Department of Gynecology and Obstetrics, Hospital de Base, Sao Jose do Rio Preto, Sao Paulo, BR;; 5) Institute of Anatomical Pathology and Cytopathology, Sao Jose do Rio Preto, Sao Paulo, BR.

Cancer is the second leading cause of death in the world after cardiovascular diseases and female breast cancer is the most frenquently diagnosed cancer and the leading cause of cancer death in females worldwide, accounting for 23% of the total new cancer cases and 14% of the total cancer deaths in 2008. About half breast cancer cases and 60% of the deaths are estimated to occur in economically developing countries. Angiogenesis plays a critical role in local growth of solid tumors and subsequently in the process of distant spread. Numerous studies have demonstrated the importance of angiogenesis in cancer. Nevertheless, 3' alternative splice site selection in exon 8 of VEGF gene results in a sister family of isoforms, VEGFxxxb, which are anti-angiogenic and downregulated in tumor tissues. We quantitatively analyzed the expression of pro-angiogenic and anti-angiogenic VEGF isoforms in breast carcinoma and adjacent normal tissue samples. For that purpose, total RNA from 15 tumor samples and their respective margins were obtained and synthesized cDNA from. We designed and synthesized primers and specific probes for each isoform, which were used for the analyses of expression by real time PCR. So far, we have not observed different expression between the anti- and pro- angiogenic isoforms in the tumor samples compared to normal tissue. These results evidence that the selection of different splicing sites do not interfere in tumor angiogenesis and consequent tumor progression and metastasis. A bigger sample size might help in more advanced studies and collaborate to better development of researches on tumor angiogenesis involving VEGF gene. Studies approaching control of VEGF splicing in order to promote the selection of the distal splicing site (anti-angiogenic) instead of proximal site (pro-angiogenic) might promote an efficient therapy for breast cancer.

1207W

Identification of MMTV/HMTV retrovirus in breast tumor samples from Mexican females. *A. Cedro-Tanda, A. Córdova-Solis, A. Pedroza-Torres, M. Rives-Güendulain, M. Moreno-Arroyo, J. Tórres-López, F. Salamanca-Gómez, D. Arenas-Aranda, N. García-Hernández, X. Rivera-Gonzalez.* Instituto Mexicano de Seguridad Social, México D. F.

Breast cancer tumor is the first cause of dead in Mexican female population. Recently was probed that MMTV retrovirus its related with tumor development and progression. Te aim of this work was to identify HMTV sequences integrated into the breast tumor genome in Mexican females. We study 80-paired tumors (stage II and III) and non-affected tissue. DNA and RNA were obtained. Nested PCR was performed to amplify Env gene fragment (660pb and 220pb) to verify retrovirus presence in all samples, Env gene contained in pBR233 was used as positive control and a housekeeping gene GADPH (500pb was used as a reaction control. Also qPCR was used to double-check the presence of the retrovirus with Taqman probes for Env gene. Total RNA was treated with DNase to use in qRT-PCR that was performed with Taqman probes to evaluated Env and Gag genes expression. Splinkerrette Method was performed to determine insertion sites of the MMTV/HMTV retrovirus in positive samples to contain the provirus. We successfully transformed the pBR322plasmid and determined that it contained Env gene. MMTV infection was determined in 30% of the tumor samples and in none of the non-affected breast tissue. This data was double-checked and confirmed by Taqman PCR. Expression of Env and Gag genes were determined in positive tumors by using TaqMan probes. All amplified fragments were sequenced from positive samples to determine their identity. In positive infected tumors, we developed Splinkerrette method to determine MMTV/HMTV retrovirus insertions, we found several samples containing expressed viruses and with insertions along the genome. We are working in order to determine the possible participation of MMTV/HMTV retrovirus in to the tumor progression and development; we will look forward in to the target genes to evaluate expression and function alterations originated from the mutagenesis insertion.

1208W

Mutations in the Sonic Hedgehog Pathway in Congenital Acute Lymphoblastic Leukemia Cells. *V. Chang[1], K. Sakamoto[1], S. Nelson[2].* 1) UCLA, Department of Pediatrics, Division of Hematology-Oncology. 10833 Le Conte Ave. MDCC A-312, Los Angeles, CA; 2) UCLA, Department of Human Genetics, Pathology and Laboratory Medicine, and Psychiatry, David Geffen School of Medicine. 695 Charles Young Drive S. Gonda 5554, Los Angeles, CA.

Background: Congenital acute lymphocytic leukemia (cALL) is diagnosed in the first month of life and is commonly associated with MLL translocations. cALL has a much worse prognosis compared to older pediatric patients with ALL. This suggests that cALL is a biologically different disease, and thus may result from a distinct set of mutations. The aim of our study was to conduct genomic analysis of paired primary tumor and normal samples from cALL patients and two MLL-positive ALL cell lines (RS411 and HB1119). Methods: Genomic DNA was enriched for coding exons using Sure Select Human All Exon or Human All Exon 50Mb kits (Agilent, Santa Clara, California). The primary sample was sequenced on the Illumina GAIIx, and the two cell lines were sequenced on the HiSeq 2000 (Illumina, San Diego, California). Reads were aligned to the human reference genome using Novoalign (www.novocraft.com). The Genome Analysis Toolkit was used for recalibration of base quality, variant calling, filtration and evaluation. GeneChip Human Genome U133 Plus 2 (Affymetrix, Santa Clara, California) was used to obtain gene expression for all samples and normal lymphocytes. Cel files were normalized and analyzed with dChip to identify differentially expressed genes, using a fold change analysis of the samples compared to normal lymphocytes. Results: We generated 72 million reads of tumor and normal sequences in the primary cALL sample, with oversampling greater than 80% of the bases at 20x. There was a novel, somatic, heterozygous nonsynonymous missense mutation in sonic hedgehog (SHH), which was validated with Sanger sequencing. We generated 312 million reads for RS411, with 91% of bases covered at 20x or greater, and 349 million reads for HB1119 with 92% of bases covered at 20x of greater. There were novel, heterozygous, nonsense mutations in Patch, which is a SHH receptor, in both cell lines. Expression data showed upregulation of SHH downstream transcription factor GLI3 at nearly 8-fold for HB1119 and 12-fold for RS411. Conclusion: This primary cALL sample and two ALL cell lines harbor novel, nonsynonymous mutations in SHH and Patch, with an upregulation of GLI-3 in both cell lines. Therefore, the SHH pathway may be involved in the pathogenesis of cALL.

1209W

***ITPR3* gene haplotype is associated with cervical cancer risk.** *T. Chang[1], Y. Yang[2,3], Y. Lee[1,4,5], T. Chen[2], S. Chang[1], W. Lin[1].* 1) Medical Research Department, Mackay Memorial Hospital, Taipei, Taiwan; 2) Department of Gynecology and Obstetrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Gynecology and Obstetrics, Taipei Medical University, Taipei, Taiwan; 4) Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 5) Pediatrics, Taipei Medical University, Taipei, Taiwan.

Cervical cancer is strongly associated with infection by oncogenic forms of human papillomavirus (HPV). However, HPV infection alone is not sufficient for progression to cervical cancer. It is now recognized that host immunogenetic background play an important role in the control of HPV infection and the development of cervical cancer. Inositol 1,4,5-trisphosphate receptor type 3 (ITPR3) is an intracellular Ca^{2+} release channel that mediates Ca^{2+} mobilization in response to the binding of a second messenger, inositol 1,4,5-trisphosphate (IP3). It has been reported that ITPR3 plays an important role in the regulation of apoptotic signaling in T lymphocytes. The aim of this study is to investigate the association between *ITPR3* gene single nucleotide polymorphisms (SNPs) and the risk of cervical cancer in the Taiwanese population. We genotyped 2 SNPs (rs3748079 A/G and rs2229634 C/T) in 272 cervical squamous cell carcinoma (CSCC) patients and 921 age/sex matched healthy controls by using the Pre-Developed TaqMan Allelic Discrimination Assay. The presence and genotypes of HPV in CSCC patients were determined by PCR. No statistically significant differences of genotype, allele, and carrier frequencies of these *ITPR3* SNPs were found among controls, all women with CSCC, and those with HPV-16 positive CSCC. Intriguingly, we found significant associations of haplotype AT between all women with CSCC and controls (OR = 3.34, 95% CI 1.87-5.97, $P_c = 6.4 \times 10^{-5}$) or between women with HPV-16 positive CSCC and controls (OR = 4.27, 95% CI 2.24-8.13, $P_c = 6.9 \times 10^{-6}$). Our results suggest that AT haplotype in the *ITPR3* gene may confer susceptibility to CSCC in the Taiwanese population.

Viability Screens with Pooled shRNA Libraries Identify Novel and Synthetically Lethal Anti-Cancer Targets. *A. Chenchik[1], D. Tedesco[1], K. Bonneau[1], M. Makhanov[1], C.G. Frangou[2].* 1) Cellecta, Inc., Mountain View, CA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Genes modulating proliferation and survival in oncogenic cells have been identified using pooled lentiviral-based libraries expressing many thousands of shRNAs. A viability assay with leukemic and prostate adenocarcinoma cell lines transduced with these shRNA libraries targeting thousands of genes identified a few hundred essential genes for each panel of cells. Subsequent validation using single shRNA-expressing constructs showed that about 80% of the shRNAs identified in the complex library screen did in fact lead to cell death when transduced in cells. Analysis of the identified essential genes for known biological interactions revealed several non-random clusters of interacting proteins that provide some insight into signaling pathways and protein networks specific to these cancers. Also, we have recently adapted the approach to combinatorially screen shRNA sequences targeting hundreds of genes to discover additive and synergistic combinations that generate a synthetic-lethal phenotype. Analysis of the lethal combinations indicates redundant, complementary, and compensatory responses in cancer cells. This presentation will provide an overview of the screening platform, our approach to shRNA library design, and results from the screens for cancer cell-specific lethal and synthetic-lethal genes.

1211W

A rare intronic *CHEK2* sequence variant in a child with ependymoma and glioblastoma alters substrate recognition in the NMD pathway. *H. Cheung[1], D. Wheeler[2], G. Tomlinson[3], L. Strong[4], R. Gibbs[2], S. Plon[1].* 1) Pediatrics, Baylor College Med, Houston, TX; 2) Human Genome Sequencing Center, Houston, TX, USA; 3) University of Texas Health Science Center San Antonio, San Antonio, TX, USA; 4) MD Anderson Cancer Center, Houston, TX, USA.

Both inherited and somatic mutations in DNA repair genes have been associated with multiple types of childhood cancer. Reduced DNA repair capacity can accelerate genomic instability and tumor development. We analyzed constitutional DNA from probands in kindreds with unusual patterns of childhood cancer for coding mutations in a panel of 45 cancer associated genes with an emphasis on DNA damage response and repair genes. We are now using this dataset to find sequence variants that would affect RNA expression patterns while meeting at least two of the following criteria: not present in 1000 Genomes data, having a minor allele frequency (MAF) of <0.01, and within 100 bp of an annotated alternatively spliced region. Using a custom splicing array, we measured RNA expression patterns and levels from patient-derived, non-tumor lymphoblastoid (LCL) cells from both patients and controls and analyzed for aberrant events. One heterozygous sequence variant in *CHEK2* altered nonsense-mediated decay (NMD) patterns in these transcripts as validated by RT-PCR and inhibition of NMD by cycloheximide. This is a rare intronic variant rs56109140 with MAF of 0.008 and results in increased NMD. We are now confirming this splicing phenotype in heterozygous LCL lines from the 1000 Genomes collection; if confirmed, it will be important to determine the impact of this *CHEK2* variant on cancer risk. Supported by Thrasher Foundation to HCC and 1R01CA138836 to SEP.

A Comprehensive Resequence-Analysis of 166kb *KITLG* Region in Familial Testicular Germ Cell Tumors. *C. Chung[1], M. Yeager[3], J. Boland[3], M. Greene[2], S. Chanock[1], C. Kratz[2].* 1) LTG/DCEG, NCI/NIH, Bethesda, MD; 2) Clinical Genetics Branch/DCEG, NCI/NIH, Bethesda, MD; 3) Core Genotyping Facility/DCEG, Advanced Technology Program, SAIC-Frederick Inc., NCI-Frederick, Frederick, MD.

Among several loci identified through genome-wide association studies, the *KITLG* region on chromosome 12q22 has shown the strongest risk estimate for testicular germ cell tumor (TGCT). Mutations in the KIT/KITLG system, involving the ligand for the membrane receptor tyrosine kinase, c-KIT, have been implicated in both testicular cancer development and infertility, both of which are established TGCT risk factors. We have created a comprehensive catalogue of variants within this region to lay the foundation for further investigation into the underlying functional mechanisms of this association. Our study sample set included a total of 117 individuals from the National Cancer Institute's Familial Testicular Cancer Study (FTCS): 10 parent-son trios, of which 6 trios contained 2 familial TGCT cases, 51 familial TGCT cases and 36 sporadic bilateral cases. We resequenced a 166kbps region (chromosome 12: 87371132-87537273) around *KITLG*, based on linkage disequilibrium patterns and tag analysis using HapMap III CEU and the 1000 genome CEU low-coverage pilot data (July 2010 release). No recombination hotspot was observed within a 1Mb region centered on *KITLG*. We have further extended catalogue of common and rare *KITLG* variants using deep coverage in next-generation sequencing. These study results will facilitate further functional elucidation of TGCT susceptibility loci within this genomic region.

1213W

Evaluation of RAD51C as a new breast cancer susceptibility gene in the Belgian/Dutch population. *K. Claes[1], M. Van Bockstal[1], S. De Brouwer[1], N. Swietek[1], K. Storm[2], J. Van den Ende[2], S. Willocx[2], E.B. Gomez-Garcia[6], B. Blaumeiser[2], K. Leunen[3], C.J. Van Asperen[4], J. Wijnen[4], E. Legius[5], G. Michils[5], G. Matthijs[5], M.J. Blok[6], A. De Paepe[1], B. Poppe[1], K. De Leeneer[1].* 1) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 2) Center for Medical Genetics, University Hospital of Antwerp, Antwerp, Belgium; 3) Department of Gynaecological Oncology, Catholic University of Leuven, Leuven, Belgium; 4) Department of Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 5) Department of Human Genetics, Catholic University of Leuven, Leuven, Belgium; 6) Department of Clinical Genetics, Maastricht University Medical, Maastricht, Netherlands.

Recently, germline mutations in RAD51C were found to be associated with an increased risk for breast and ovarian cancer. Meindl et al. (2010) detected six monoallelic pathogenic mutations in RAD51C by screening 1.100 unrelated German women with gynaecologic malignancies (breast and/or ovarian tumors). Strikingly, all six deleterious mutations were exclusively found within 480 BRCA1/2 negative breast and ovarian cancer families and not in breast cancer only families. With this study we aim to determine the prevalence of germline RAD51C mutations in Belgian/Dutch breast and ovarian cancer families, previously found to be negative for BRCA1&2 mutations. We performed mutational analysis in 482 index patients. Mutation detection was performed with High resolution melting (HRM), followed by Sanger sequencing of the aberrant melting curves. No unequivocal deleterious RAD51C mutation was identified in our study population. In total our mutation analysis revealed 11 unique sequence variations of which 3 are novel. The most interesting is a novel 3'UTR variant: c.*131 A>G, identified in an ovarian cancer patient, diagnosed at the age of 60 and a positive family history of breast and colon cancer. In silico miRNA binding seed predictions (PITA Scan) revealed the creation of a miR-126 binding site. Functional assays are currently ongoing to find out if this variant alters RAD51C expression mediated by miRNAs. Two other novel variants (RAD51C c.-36 A>G (5'UTR) and c.572-17 G>T (intronic)) were detected in our study population, none of them are predicted in silico to affect splicing. Since the initial publication, we and others were unable to confirm a major role for RAD51C germline mutations in breast and ovarian cancer families. Since the investigated cohort is of similar size and geographically close to the patients investigated in the initial report, we conclude that the prevalence of RAD51C mutations may be lower than initially expected. However, further investigations in populations of various ethnic origins are required before RAD51C can be excluded as a major breast and ovarian cancer susceptibility gene.

Mutation deep within an intron of *MSH2* causes Lynch syndrome. *M. Clendenning[1], D.D. Buchanan[1], M.D. Walsh[1], B. Nagler[1], C. Rosty[1], B. Thompson[2], A.B. Spurdle[2], J.L. Hopper[3], M.A. Jenkins[3], J.P. Young[1].* 1) Familial Cancer Laboratory, Queensland Institute of Medical Research, Herston, QLD, AUSTRALIA; 2) Molecular Cancer Epidemiology, Queensland Institute of Medical Research, Herston, QLD, AUSTRALIA; 3) Centre for Molecular, Environmental, Genetic and Analytical Epidemiology, Melbourne School of Population Health, The University of Melbourne, Parkville, VIC, AUSTRALIA.

Background Lynch syndrome, a heritable form of cancer predisposition, is caused by germline mutations within genes of the DNA mismatch repair family, and can be rapidly identified in young onset cancer patients through the detection of loss of expression of at least one of these genes in tumour samples. To date, such causative mutations have only been identified within exonic and splice site regions. Though this approach has been successful in the majority of families, a considerable number remain in which no mutation has been found. Here, we address mutation detection in such a family. **Methods** An alternative mutation discovery procedure involving haplotype analysis of the locus containing the gene lost in the tumour and delineation of segregating haplotypes, followed by an investigation of splicing aberrations was utilised to uncover a cryptic splice site which lays outside the genomic regions routinely examined for mutations. **Results** We show that an intronic mutation 478bp upstream of exon 2 in the *MSH2* gene causes Lynch syndrome through the creation of a novel splice donor site with subsequent pseudoexon activation, thus highlighting the need for more extensive sequencing approaches.

1215W

Association of polymorphisms in antioxidant genes with chronic myeloid leukemia. *E. Cordova[1], E. Crespo-Solis[2], M. Ayala-Sanchez[3], C. Yerena de Vega[4], M. Lopez-Hernandez[4], C. Sanchez-Guerrero[4], I. Chavez-Perez[4], A. Martínez-Tovar[5], A. Aguayo[2], M. Morales-Marin[1], A. Martinez-Hernandez[1], L. Orozco[1,6].* 1) Investigacion, Inst Natl de Medicina Genomica, Mexico D.F., Mexico; 2) Instituto Nacional de Ciencias Medicas y Nutricion Salvador Zubiran, Mexico; 3) Hospital de Especialidades del Centro Médico Nacional La Raza, Mexico; 4) Centro Médico Nacional 20 de Noviembre, ISSSTE, Mexico; 5) Hospital General de México, SS, Mexico; 6) Posgrado en Ciencias Genómicas, UACM, Mexico.

Chronic myeloid leukemia (CML) is the most common form of leukemia in adults, with an annual incidence of 1 to 1.3 cases for each 100,000 individuals. CML is characterized by the presence of the translocation t(9;22)(q34;q11), which generate the fusion gene BCR-ABL. The causes of CML development are barely known and only ionizing radiation has been associated with CML risk. Oxidative stress has been recognized as an important factor in cancer development. In fact, polymorphisms occurring in genes that encode for antioxidant enzymes such as GSTP, NQO1 and HMOX1 have been associated with an increased risk to develop lung, bladder and liver cancer. However, the association between variants in antioxidant genes and CML risk has been poorly studied. Hence, in this study we determined whether polymorphisms occurring in five antioxidant genes were associated with the risk to develop CML in Mexican population. Genomic DNA was obtained from 250 individuals diagnosed with CML and 400 healthy blood bank donors. Cases and controls signed an informed consent and were matched for gender, age and ethnic origin. Allelic discrimination of single nucleotide polymorphisms (SNPs) located on GSTPI (A1404G), GCLM (-588CT), GCLC (-129CT) and NQ01 (C609T) genes was carried out by using the 5' exonuclease reaction (TaqMan). Genotyping of HMOX1 (GC)n repeats was performed by DNA fragment-length analysis. Genotype frequencies were in Hardy-Weinberg equilibrium in cases and controls. Allelic frequencies of SNPs were similar to those reported in other populations. Genotype and allele frequencies of all SNPs studied did not show significant differences between cases and controls. Regarding HMOX1 (GC)n repeats we found 27 different alleles (10-39), showing significant differences with other populations. In Mexican population the most common HMOX1 (GC)n repeat alleles were 22 and 29 repeats and the frequency of the short alleles (10-25) was significantly lower than those reported elsewhere. Interestingly, when HMOX1 (GC)n short allele frequencies were compared between CML patients and controls, a significant association was observed (OR=1.497, CI[1.108-2.022], p=0.008). In conclusion, although more studies are needed with leukemic populations and other ethnic groups, we found a preliminary evidence of association between CML susceptibility and HMOX1 (GC)n repeat polymorphism.

1216W

BRCA1 and BRCA2 diagnosis: feasibility of multiplex amplification coupled to next-generation sequencing. *F. Coulet, F. Pires, M. Eyries, C. Colas, F. Soubrier.* Oncogénétique moléculaire, GH Pitié-Salpêtrière-APHP, PARIS, France.

Screening of the two large BRCA1 and BRCA2 genes are time-consuming with traditional technologies of direct sequencing or even with prescreening heteroduplexes methods. Next generation sequencing has proven to be highly efficient for research purposes, in particular to detect mutations in genetic diseases and in tumoral genomes. In this study we tested the possibility to use multiplex PCR coupled to next-generation sequencing in routine diagnosis of breast cancer predisposition. We tested a Multiplex Amplification (5 multiplex PCR reactions generating 94 amplicons of Specific Targets (BRCA1 and BRCA2) for Resequencing (MASTR by Multiplicom). Seven patients with 32 different known variants scattered over amplicons of BRCA1 and BRCA2 genes were analyzed. The 32 variants were previously detected by High Resolution Melting. All gene variants tested correspond to 7 pathogenic mutations (2 missense, 2 nonsense, and 3 frameshift), 1 unclassified variant and 24 polymorphisms. A 2-step PCR protocol allows incorporation of 7 optimized 454 MIDs (molecular barcodes) in each amplified product to unambiguously link each read to its parent sample. A small DNA amount is necessary (250 ng) for the complete screening of each sample. The 454 Titanium DNA sequencing technology on the genome GS Junior instrument (Roche Diagnostics) utilizes adapter-ligated DNA, emulsion PCR and pyrosequencing system. A single sequencing run containing the 7 biological samples was performed and we obtained 45766 reads (corresponding to a mean of 70X coverage per amplicon). All samples of known genotypes were properly clustered by the Amplicon Variant Analyzer (AVA) software from Roche Diagnostics. The 32 different nucleotide variants were identified, and the multiple polymorphisms are well genotyped (a total of 126 heterozygous or homozygous variations were identified). Fourteen previously unknown polymorphisms were identified because of the extended amplicons sequence as compared to primers previously used for HRM screening. Accurate and rapid variant detection could be additionally done by SeqNext software (JSI Medical Systems) allowing homopolymers to be specifically analyzed. Further experiments need to be done to confirm the high sensitivity and specificity obtained in this pilot experiment. Combination of MASTR assays with massive parallel sequencing technology allows high fidelity, high throughput and cost effective sequencing also for diagnostic purposes.

1217W

Association between CCRN4L gene and Non-Small-Cell-Lung Cancer (NSCLC) in Brazilian patients. *P.G. Couto[1], L. Bastos-Rodrigues[1], A. Vilhena[2], N.F. Amaral[2], L. De Marco[1].* 1) Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Hospital Julia Kubitschek, Belo Horizonte, Brazil.

The circadian rhythms comprise daily oscillations in various biological processes that are regulated by an endogenous clock. Disruption of these rhythms have been associated with cancer in humans and the understanding of these rhythms in cellular growth control, tumor suppression and cancer treatment can reveal how clock genes and clock-controlled genes are regulated in healthy humans. One of these rhythmic genes, Nocturnin (CCRN4L), encodes a deadenylase-a-ribonuclease that specifically removes the poly (A) tails from mRNAs. We genotyped three tag SNPs (rs938836, rs17050680, rs3805213) in the CCRN4L gene in 72 patients with Non-Small-Cell-Lung Cancer (NSCLC) and 67 individuals controls to investigate the association between the CCRN4L gene and NSCLC. One of the three tested markers demonstrated significant association with genotype and allele frequency in lung cancer (rs3805213; p=4.4 e-3 and p=5.7 e-2, respectively). We found a statistically significant association between tag SNP rs3805213 and lung cancer. The results of our study suggest that polymorphisms in the CCRN4L gene can represent a risk factor in the occurrence of NSCLC in Brazilian patients.

1218W

Cancer Risk-Associated Variants Disrupt FoxA1 Genomic Activity. *R. Cowper, X. Zhang, J. Wright, M. Cole, J. Eeckhoute, J.H. Moore, M. Lupien.* Dartmouth Medical School, Lebanon, NH, USA.

Genome-wide association studies (GWASs) have identified thousands of single nucleotide polymorphisms (SNPs) associated with human traits and diseases. But because the vast majority of these statistical associations map to the noncoding regions of the genome their causative mechanisms remain elusive. Employing a new methodology combining cistromics, epigenomics and genotype imputation we annotate the noncoding regions of the genome in breast and prostate cancer cells and identify the functional nature of SNPs associated with breast and prostate cancer risk. Through the holistic analysis of the genomic distribution of risk-associated SNPs we reveal that risk-associated variomes target the cistromes of transcription factors in a cancer type-specific manner and that the genomic activity of the pioneer factor FoxA1 is a key target in both breast and prostate cancer. Finally we computationally predict and experimentally validate the disruption of FoxA1 recruitment for a set of risk-associated SNPs and assess the subsequent alteration of target gene expression and cell proliferation.

Genetic Polymorphisms in NAT1, NAT2, GSTM1, GSTP1 and GSTT1 and Susceptibility for Colorectal Cancer in a Filipino Population. *E. Cutiongco[1], V. Bañez[2], M. Roxas[3], C. Padilla[1], C. Ngelangel[4], R. Santos-Cortez[5], C. Silao[1], F. Rocamora[1], O. Florendo[2], C. Sison[2], A. Roxas[3], F. Doble[6], E. Nuqui[7] for The Philippine Cancer Genetics Study Group.* 1) Inst Human Genetics, Natl Inst Health, University of the Philippines, Manila; 2) Section of Gastroenterology, Department of Medicine, Philippine General Hospital, Philippines; 3) Department of Surgery, Philippine General Hospital, Philippines; 4) Inst of Clinical Epidemiology, Natl Inst Health, University of the Philippines Manila; 5) Phil National Ear Inst, Natl Inst Health, University of the Philippines, Manila; 6) Department of Surgery, East Avenue Medical Center, Philippines; 7) Department of Pathology, College of Medicine, University of the Philippines, Manila.

BACKGROUND: Colorectal cancer is one of the leading cancers of the world. Based on incidence, it ranks fourth in men and third in women, with over one million new cases worldwide. The majority (> 90%) of cancers of the colon and rectum are adenocarcinomas. In the Philippines, cancers of the colon and rectum ranked 6th overall, 4th among males and 4th among females. Polymorphisms in metabolic genes which alter rates of bioactivation and detoxification have been shown to modulate susceptibility to colorectal cancer. METHODS: A total of 276 colorectal cancer cases and 224 controls from the Filipino population were genotyped for selected polymorphisms in GSTM1, GSTP1, GSTT1, and NAT2. Medical and diet histories, occupational exposure and demographic data were also collected for all subjects. Odds ratios for colorectal cancer status were then obtained. RESULTS: Univariate logistic regression of non-genetic factors identified exposure to UV (sunlight) (OR 1.99, 95% CI: 1.16-3.39) and wood dust (OR 2.66, 95% CI: 1.21-5.83) and moldy food consumption (OR 1.61, 95% CI:1.11-2.35) as risk factors; while the NAT2*6B allele (recessive model OR 1.51, 95% CI :1.06-2.16; dominant model OR 1.87, 95% CI: 1.05-3.33) and homozygous genotype (OR 2.19, 95% CI: 1.19-4.03) were found to be significant among the genetic factors. After multivariate logistic regression of both environmental and genetic factors, only UV radiation exposure (OR 1.21, 95% CI: 1.21-3.58) remained to be significantly associated with increasing colorectal cancer risk in the study population. CONCLUSION: The NAT2*6B allele and genotype were found to significantly increase colorectal cancer risk among Filipinos.

5-Fluorouracil induce the expression of TLR4 on HCT116 colorectal cancer cell line expressing different variants of TLR4. *h. davoodi[1], S.R. Hashemi[2], S. Heng Fong[3].* 1) Golestan University of Medical Sciences, Gorgan, Iran , Gorgan, gorgan, Iran; 2) Gorgan University of Agricultural Sciences and Natural Resources, Gorgan, Iran; 3) Department of Pathology, Faculty of Medicine and Health Science, University Putra Malaysia, Malaysia.

Toll-like receptors (TLRs) are a class of proteins that play a key role in the innate immune system. TLR4, which is considered one of the most important TLRs, recognizes LPS of Gram-negative bacteria. Two cosegregating single nucleotide polymorphisms (SNPs) of the human TLR4 gene, namely Asp299Gly (D299G) and Thr399Ile (T399I), have been correlated with hyporesponsiveness to inhaled lipopolysaccharide (LPS). 5-Fluorouracil (5-FU) is widely used for the treatment of patients with advanced colon cancers. Resistance to 5-FU is one of the most prominent obstacles to successful chemotherapy. The propose of this study was to investigate the effect of 5-FU on HCT116 colorectal cancer cell line with different variants of TLR4. HCT116 colorectal cancer cell line was transfected with Flag-CMV1-TLR4 wild-type (WT) and Flag-CMV1-TLR4 mutants, D299G and T399I expression plasmids. Transfected- HCT116 cells were treated with different concentration of 5-FU. The expression of TLR4 on 5-FU-treated HCT116 cells was analysed by FACS and the cytotoxic effect of 5-FU on transfected HCT116 cells was assessed by MTT assay. 5-FU significantly increased the expression of TLR4 protein on HCT116 cell line as analysed by FACS. 5-FU- Induced TLR4 expression in wild-type cells was higher than the other cells ($P<0.05$). Comparison of the cytotoxic effect of 5-FU showed that the highest IC50 value was for D299G variant of TLR4 at 48 hours treatment. As a conclusion 5-FU induce the expression of TLR4 both in cells with wild-type and mutant TLR4. Colorectal cancer cells with D229G TLR4 variant are more resistance to the drug compared to Wild type.

1221W

The role of genetic ancestry in breast cancer predisposition and tumor presentation in Puerto Rican Hispanic. *J. Dutil[1], L. Fejerman[2], E. Ziv[2], S. Huntsman[2], N. Arroyo[1], J. Matta[1], J. Gonzalez-Bosquet[3].* 1) Ponce School of Medicine & Health Sciences, Ponce, PR; 2) University of California in San Francisco, San Francisco, CA; 3) H. Lee Moffitt Cancer Center & Research Institute, Tampa, Fl.

Introduction: The incidence, clinical presentation, and mortality of breast cancer vary among different ethnic subgroups. Despite a lower incidence of breast cancer in US Hispanics, Hispanic women are more likely to die of breast cancer than non-hispanic white women diagnosed at similar age and stage. In the Hispanic population of Puerto Rico, the contribution of genetic ancestral factors in determining breast cancer risk and its clinical presentation is unknown. Methods: The study population consists of 227 breast cancer cases and 364 controls recruited from private practices of surgeons and oncologists from Puerto Rico. A panel of 106 ancestry informative markers was genotyped using the iPLEX Sequenom technology. Individual genetic ancestry was estimated using a maximum likelihood approach, which infers ancestry of each individual as a function of the probability of the genotype at each locus based on ancestral allele frequencies. The distribution of genetic ancestry was compared between cases and controls, and between different tumor subtypes. Results: The distribution of genetic ancestry among the 591 study subjects varied from 0 to 100% African, 0 to 100% European, and 0 to 38% Native American. There was no significant difference in the average European ($p=0.6$), African ($p=0.862$) and Native American ($p=0.2$) ancestry proportions between breast cancer and controls. Interestingly, we observed a 8.3% increase in average African ancestry proportion in women with triple negative tumors (estrogen receptor (ER) -negative, progesterone receptor-negative, and human epidermal growth factor receptor 2 (HER2) -negative tumors) when compared to tumors retaining at least one of the hormonal receptor ($p=0.04$). Conclusions: Global genetic ancestry does not seem to contribute significantly to the risk of breast cancer in Puerto Rican women. However, we present evidence that ancestry may contribute to the breast tumor hormonal receptor status in this population.

1222W

Identification and validation of genetic variants that influence breast cancer prognosis. *D. Eccles[1], I. Politopoulos[1], W. Tapper[1], S. Gerty[1], J.J. Liu[2], F. Couch[3], D. Easton[4], N. Rahman[5], S. Ennis[1], A. Collins[1], POSH study investigators.* 1) Faculty of Medicine, University of Medicine, Southampton, United Kingdom; 2) Genome Institute of SIngapore; 3) Mayo Clinic; 4) University of Cambridge; 5) Institute of Cancer Research.

Aim: to identify common genetic variants associated with an increased likelihood of developing metastatic breast cancer after diagnosis using a GWAS approach in a clinically well characterised patient cohort. Background: Breast cancer prognosis is predicted using tumour characteristics. Rare and common genetic variants clearly influence the tumour phenotype (e.g. BRCA1 carriers typically develop triple negative breast cancers, different variants predispose to ER +ve or ER-ve breast cancer). It is also likely that genetically determined variations lead to variable efficiency between individuals for example in immune surveillance and drug metabolism thereby influencing prognosis by altering risk of metastases or response to adjuvant drug therapy. Method: 870 breast cancer cases diagnosed before 41 years of age and participating in the POSH study (Eccles et al, BMC Cancer 2008) were genotyped as part of three separate GWAS to identify risk SNPs. The raw data from the three studies were merged and SNPs successfully typed across all three studies were included in a Kaplan Meier survival analysis at stage 1. Six additional sub-group analyses using KM survival analysis were conducted in order to try and identify SNPs with differing mechanisms of action (ER negative, ER positive, HER2 negative, HER2 positive, anthracycline and/or anti-oestrogen treated). SNPs to take forward for validation were selected based on low p-values, MAF > 5%, supporting evidence from nearby SNPs with differing MAFs and SNPs in or close to genes with potential functional significance. Results: A total of 497332 SNPs were tested, 832 cases passed all QC procedures for the stage 1 analysis. 260 SNPs were identified in one or more of the sub group analyses with nominal genome wide significance. 160 were picked for replication in stage 2. Two SNPs (located on chromosomes 5 and 15) showed evidence of replication at stage 2 with p-values from a pooled analysis of stage 1 and 2 data exceeding genome wide significance ($P \leq 10\text{-}38$). In addition, the SNP on chromosome 5 retained genome wide significance ($P \leq 10\text{-}13$) in ER-ve and anthracycline treated subsets despite the smaller sample sizes. Conclusions: we have found preliminary evidence for an effect of common genetic variants on breast cancer prognosis at two genetic loci. Additional multivariate analyses and further genotyping in well phenotyped clinical series will be needed to replicate these findings.

1223W

Overview of the Clinical ELLIPSE (ELucidating Loci Involved in Prostate cancer SuscEptibility) Consortium (CEC). *R. Eeles[1], C. Goh[1], Z. Kote-Jarai[1], P. Kraft[2], D. Easton[3], B. Henderson[4], F. Schumacher[4].* 1) The Institute of Cancer Research, United Kingdom; 2) Harvard University, USA; 3) The University of Cambridge, United Kingdom; 4) University of Southern California, USA.

Background: The inherited link of prostate cancer (PrCa) has led to large scale Genome Wide Association Studies (GWASs), which aim to identify susceptibility loci associated with PrCa. Currently, these Single Nucleotide Polymorphisms (SNPs) have only been evaluated against overall PrCa risk and several disease parameters. The challenge now is to translate these genetic risk algorithms into the clinical setting. This has led to NIH (National Institute of Health) funded post-GWAS initiatives in PrCa and the establishment of the Clinical ELLIPSE Consortium (CEC) to harmonise genetic, clinical and epidemiological data from existing consortia around the world. This will provide the necessary guidance in developing useful and powerful risk prediction models for PrCa risk, including screening outcome and treatment effects. These risk prediction models may have an immediate public health impact by providing clinicians with the necessary tools to improve clinical decision making. **Methods:** Several projects are currently underway including the analysis of Active Surveillance outcomes against these SNPs, and the analysis of the PRACTICAL (PRostate cancer AssoCiation group To Investigate Cancer Associated aLterations in the genome) consortium cohort, looking at the association of these SNPs with disease parameters. Collaborations have been established with ERSPC (European Randomized Study of Screening for Prostate Cancer), STAMPEDE (Systemic Therapy in Advanced or Metastatic Prostate cancer: Evaluation of Drug Efficacy) and RAPPER (radiogenomic) consortia, to analyse these SNPs' role in screening and treatment outcomes. **Results:** An inventory collected across the consortium showed that there are 47215 cases and 110811 controls with clinical data. There were also large numbers of tumour (10654 samples) and blood (31700 samples) available. These figures are very encouraging and discussions are currently underway to access and combine data across the groups for analyses. **Conclusion:** The CEC provides the necessary framework needed to foster successful collaborations and begin the transition from `bench-side' research to `bed-side' care. **Acknowledgments:** This project is supported by The NIH grant: No. 1 U19 CA 148537-01 and Cancer Research UK.

Acute lymphoblastic leukemia (ALL) is characterized by the malignant clonal proliferation of lymphoid cells that are blocked at an early stage of differentiation. More than 60%; of patients diagnosed with ALL are children below the age of 15 years. The annual incidence rates of childhood ALL vary worldwide between one and four new cases per 100,000 children younger than 15 years, with a peak incidence at about two to five years of age. The two major genetic subtypes of childhood ALL are characterized by either hyperdiploidy (>50 chromosomes per leukemic cell) or the chromosomal translocation t(12;21)(p13;q22) leading to an *ETV6-RUNX1* (*TEL-AML1*) gene fusion, which account for approximately 25% and 22% of the entire childhood ALL population, respectively. We performed a genome-wide association study of 355,750 SNPs in 474 healthy controls and 419 *ETV6-RUNX1*-positive ALL cases. The eight most strongly associated SNPs were followed-up in 951 *ETV6-RUNX1*-positive ALL cases and 3,061 healthy controls from Germany/Austria and Italy, respectively. We identified a novel, genome-wide significant risk locus at 3q28 (P_{CMH}=8.94×10^{-9}, OR=0.65). The separate analysis of the combined German/Austrian sample only, revealed additional genome-wide significant associations at 11q11 (P=9.14×10^{-11}, OR=0.69) and 8p21.3 (P=6.12×10^{-9}, OR=1.36). These associations and another association at 11p11.2 (P=4.95×10^{-7}, OR=0.72) remained significant in the German/Austrian replication panel after Bonferroni correction for multiple testing. Our findings demonstrate that germline genetic variation can specifically contribute to the risk of ALL subtypes - in this case *ETV6-RUNX1*-positive childhood ALL. The genes identified as risk loci emphasize the role of the *TP53* gene family and the importance of proteins regulating cellular processes including cell growth, differentiation, mitotic cycle and oncogenic transformation in connection with tumorigenesis.

1225W

***ELF3* is a putative oncogene frequently gained and hypomethylated in the adenocarcinoma subtype of non-small cell lung cancer.** *K.S. Enfield[1], R. Chari[2], D. Becker-Santos[1], S. Lam[1], W.L. Lam[1].* 1) Integrative Oncology, British Columbia Cancer Research Centre, Vancouver, British Columbia, Canada; 2) Harvard Medical School, Department of Genetics, Boston, MA, USA.

Lung cancer remains the cause of the most cancer-related deaths each year, with a 5 year survival rate of less than 15%. The predominant type of lung cancer is non-small cell lung cancer (NSCLC) and the majority of these cases consist of the adenocarcinoma (AC) subtype. Oncogenes such as *EGFR* are well defined drugable targets of AC, but *EGFR* mutations are only found in approximately 20% of cases. Additional oncogenes clearly exist to drive this subtype. Genes activated by multiple mechanisms such as copy number gain and hypomethylation are more likely to be drivers of oncogenesis. Identification of such genes will lead to the discovery of novel therapeutic targets to improve NSCLC patient prognosis. Multidimensional genome-wide analysis was conducted on a panel of AC tumors with matched adjacent non-malignant tissues. *ELF3* was identified as frequently gained, hypomethylated and overexpressed. Copy number analysis was performed on 84 AC pairs using the SNP 6.0 platform, methylation analysis was performed on 60/84AC pairs using the Illumina HM27 Methylation platform, and expression analysis was performed on 83/84 pairs using the Illumina expression microarray. The role of ELF3 in cell proliferation and the ability to form colonies in soft agar was assayed using stable *ELF3* mRNA knockdown in AC cell lines with high *ELF3* expression. Knockdown was verified by qRT-PCR. Subcellular localization of ELF3 was determined by western blot on nuclear and cytoplasmic fractions and confirmed with immunofluorescence (IF). *ELF3* was found to be frequently gained (41/84), hypomethylated ($p<0.05$), and at least 2-fold overexpressed (60/83). Interestingly ELF3 is normally highly expressed in the fetal lung and minimally expressed in the normal adult lung. Knockdown of *ELF3* led to significantly reduced cell proliferation, and colony formation assays produced fewer colonies of smaller size. ELF3 is a member of the ETS family of transcription factors, so we sought to examine the subcellular localization of the protein. Western blots and IF revealed ELF3 to be predominantly located in the nucleus, indicating ELF3 behaves through its transcription factor activity. *ELF3* is a gene frequently disrupted by genetic and epigenetic mechanisms, which result in its increased expression in AC. ELF3 plays roles in cell proliferation as well as contact-independent growth. The fact that ELF3 expression is normally restricted to fetal lung development implicates *ELF3* as a fetal oncogene in AC.

1226W

The Lymphoid Cancer Families Study - A resource for identification of genetic factors contributing to lymphoma, lymphoid leukemia, and myeloma: Phase 1 Recruitment. *A. English[1], A. Brooks-Wilson[1], J. Connors[2].* 1) Genome Sciences Centre, British Columbia Cancer Agency, Vancouver, Bristish Columbia, Canada; 2) Medical Oncology, British Columbia Cancer Agency, Vancouver, Bristish Columbia, Canada.

Introduction: Although most lymphoid cancers are sporadic, the occurrence of multiple cases within the same family may indicate the existence of genetic susceptibility factors common to these disorders. By creating a collection of DNA samples with medical, family history and lifestyle information from consenting subjects and family members, we hope to identify genetic factors involved in susceptibility to lymphoid cancer.

Materials & Methods: Probands with a family history of lymphoid cancer were identified from a database begun in 1981 by the Lymphoma Tumour Group at the BC Cancer Agency, and by ascertainment of probands through local hematologists. Eligible subjects are mailed an introductory package including an explanatory letter, information and consent form, and family history questionnaire (FHQ). A pedigree is constructed from completed FHQ and a phone interview is conducted to obtain more detailed information about cancer diagnoses, treatment histories, and vital statistics of family members. Living affected and unaffected family members of participating subjects are invited to join the study. Participation consists of providing a DNA sample, permission to access medical records and stored tissue samples if applicable, and completing an epidemiological/lifestyle questionnaire. Pedigrees are then assessed to determine suitability for genetic mapping studies.

Results: To date 152 families have been ascertained. Introductory packages have been mailed to 495 eligible subjects; 282 individuals from 78 families have consented and are at various stages of participation. DNA samples have been collected from 168 participants including 22 saliva samples and 146 blood samples. Epidemiological/lifestyle questionnaires have been completed by 123 participants.

Conclusions: We have established a DNA sample and medical history collection of families with multiple cases of lymphoid cancer. Recruitment is in progress. This collection, likely applied in collaboration with other researchers in the field, will help to identify genetic risk factors for lymphoid cancers.

Initiative in profiling Filipino colorectal cancer patients based on clinical and molecular genetics criteria. *M. Enriquez[1,2], M. Nuylan[1], J. Pilante[3], L. Cabral[1], E. Cortes[4], E. Bondoc[5], F. Natividad[1], SLMC Colorectal Cancer Study Group.* 1) Research and Biotechnology, St. Luke's Medical Center, Quezon City, 1102 Philippines; 2) Physics Department, CENSER, College of Science, De La Salle University, Taft Avenue 2401 Manila, Philippines; 3) Department of Biological Sciences, College of Science, De La Salle University, Dasmarinas, Cavite; 4) Department of Surgery, SLMC, Quezon City, 1102 Philippines; 5) Institute of Digestive Diseases, SLMC, Quezon City, 1102 Philippines.

Objective: The study was done to (1) determine the presence of KRAS and P53 gene mutations in tumor samples from Filipino patients with sporadic colorectal cancer; (2) determine the degree of heterogeneity of mutation at various stages of cancer, and (3) correlate gene mutations with tumor grade, tumor stage, and site of tumor. Methodology: Paired normal and tumor frozen tissues from 35 Filipinos who underwent surgical resection for colorectal cancer (CRC) in a tertiary hospital in Metro Manila from 2000-2004 were included in the study. The sample population is made up of 19 males and 16 females with ages ranging from 34-77 years and a mean age of 60; 17 (49%) were <60 years old and 18 (51%) were > 60 years old. Seventeen (49%) samples were from distal colon and 26 (74%) were moderately differentiated. From each sample, DNA was extracted and using primers specific for exons 1, 2, 3, 4a and 4b of KRAS gene and exons 5, 6, 7 and 8 of P53 gene. These targeted regions were amplified by PCR. Results: Eighteen samples (51%) carried 20 mutations in the KRAS gene, 11 (55%) were silent type and 9 (45%) were considered pathogenic. Eight (89%) tumors with pathogenic mutations were in stage 3. Among the pathogenic mutations, 6 occurred in exon 1 and 3 in exon 2. For mutations in exon 1 only 1 was in the hot spot codon 13; 4 were in codon 19 and 1 in codon 11. On the other hand, seventeen samples carried eighteen P53 mutations and 16 (89%) were in exon 6; and two were in exon 5. Twelve (75%) samples were in stages 2 and 3. Four pathologically labelled ”normal” tissues had P53 mutation in exon 6. Interestingly, two stage 1 tumor samples carried P53 mutation. Five (42%) of the 17 samples had KRAS-P53 tandem mutations and all were in stage 3. Conclusion: Data presented support the concept of heterogeneity of mutation in cancer evolution and poses questions on the role of these two genes in tumor initiation and progression. This study is among the very few molecular genetics investigation in colorectal cancer among Filipinos.

Tdp1 and PARP-1 are synthetic lethal targets for rhabdomyosarcoma. *H.K. Fam[1], M. Chowdhury[1], S. Bajaj[2], N. Osborne[1], K. Choi[1], C. Walton[1], G. Sun[1], M. Bond[1], T. Triche[2], C. Pallen[1], C.F. Boerkoel[1].* 1) University of British Columbia, Vancouver, BC, Canada; 2) Children's Hospital Los Angeles, Los Angeles, CA.

Background: In mammalian cells, many nuclear proteins are poly ADP-ribosylated in response to DNA strand breaks by the poly ADP-Ribose Polymerase-1 (PARP-1) enzyme. Ribosylated proteins signal for the formation and localization of DNA repair complexes. Interestingly, many cancers are characterized by loss-of-function mutations in DNA repair proteins, and inhibition of PARP-1 has synthetic lethal effects on cancers with defects of double strand break repair. Since tyrosyl-DNA phosphodiesterase 1 (Tdp1), an enzyme that processes dirty 3' DNA termini, is in the same complex as PARP-1 and is highly expressed in rhabdomyosarcoma (RMS), we assessed PARP-1 inhibition and Tdp1 knockdown on RMS cell growth. Hypothesis: Inhibition of Tdp1 and PARP-1 is lethal or growth restrictive to RMS cells. Methods: Human dermal fibroblasts and pediatric RMS cell lines Rh30, Rh18, RD, Birch, A204, CW9019 were used to characterize expression of Tdp1 and sensitivity to Tdp1 knockdown and PARP inhibition. siRNA was used to knock down Tdp1 in RMS cells. Cell proliferation was measured using the MTT assay, apoptosis by TUNEL assay and homogeneous caspase-3/7 activation, and DNA breaks by alkaline comet assay. Mitochondrial function was analyzed with Mitosox red and mitochondrial DNA damage with qPCR of the common mitochondrial deletion. Results: Tdp1 is highly expressed in RMS cell lines compared to normal skeletal muscle and localizes to both the nucleus and mitochondria. siRNA knockdown of Tdp1 and PARP-1 inhibition are lethal to most RMS cells, and the combination of Tdp1 knockdown with PARP-1 inhibition is more lethal than either treatment alone. Both Tdp1 knockdown and inhibition of PARP-1 increase the CPT sensitivity of RMS cells and do so proportionate to the levels of mitochondrial Tdp1. Conclusions: Inhibition of Tdp1 and PARP-1 profoundly reduces RMS cell viability and proliferation. This suggests that RMS tumors have undescribed defects of DNA double strand break repair and that Tdp1 and PARP-1 are potential synthetic lethal therapeutic targets for treatment of RMS. Additionally, the finding that the CPT sensitivity of RMS cells correlates with mitochondrial Tdp1, not nuclear Tdp1, suggests that mitochondrial genotoxicity may be the molecular basis for some anticancer agents.

1229W

CD40 expression in gastric adenocarcinoma. *W. Fan[1], X. Kang[2], G. Ren[3].* 1) School of Life Science, Hebei University, Baoding, Hebei Province, China; 2) 180# Wusi Road, Baoding, Hebei 07002, China; 3) wfan6888@yahoo.com 151-7639-8202 (O).

[Abstract]: Purpose: to explore the possibility for CD40 to serve as an prognostic biomarker in human gastric adenocarcinoma. Mehtods: immunohistochemical detection of CD40 protein in dissected human gastric adenocarcinoma samples and the adjacent normal gastric tissues (i.e., the paracancergastric mucosa) from 100 patients. A forty eight month follow-up was conducted and the correlation between CD40 expression and overall survival time was evaluated. Results: significant differential expression of CD40 was found in gastric adenocarcinoma (65%) and the corresponding paracancergastric mucosa (7%) respectively (P<0.001). Expressions of CD40 protein was significantly higher in advanced cancer stages (TNM stages III & IV) and distant metastasis (71% and 80% respectively) than that in early cancer stage (TNM stages I & II) and primary tumor sites (52% and 39% respectively; P<0.05). After 48 month follow-up, the survival rate of CD40 negative patients was 65% (21/35) and that of CD40 positive patients was 6% (4/65, P<0.002). A significant correlation exists between CD40 expression and overall survival time. Conclusions: The CD40 was highly expressed in gastric adenocarcinoma; its expression on gastric cancer may play a role in distant metastasis and the advanced cancer stages, which may serve as an informative prognostic and survival predictor for patients with gastric adenocarcinoma. Key words: CD40; Gastric adenocarcinoma; Immunohistochemistry Authors: Fan, W., Kang, XJ., and GD, Ren. Address: Tumor Research Lab at School of Life Science, Hebei University, Baoding, 07002, China All co-authors have read and approval of this abstract, and there is no interest conflict.

Mutation Analysis exones 7,8&9 of PTEN Gene in Iranian Colorectal Cancer. *M. Firoozi[1], L. Alidoust Masouleh[2], M. Ghaffarpoor[2], Z. Hajebrahimi[3], M. Arabian[4], L. Najafi[3], N. Salim[5], K. Bidoki[1], M. Houshmand[2].* 1) Payam e Noor University, Tehran, Iran; 2) National Institute of Genetic Engineering and Biotechnology, Tehran, Iran; 3) Tarbiat Moddaress University, Tehran, Iran; 4) Tehran University of Medical. Tehran, Iran; 5) Shahid Beheshti University, Tehran, Iran.

Purpose: PTEN/MMAC1/TEP1 is a tumor suppressor gene encoding a dual-specificity protein phosphatase with homology to the cytoskeleton protein, chicken tenssin and bovine auxilin. PTEN acts by inhibiting the activation of Akt/Protein kinase B and is therefore involved in a major pathway controlling cell proliferation and cellular metabolism PTEN protein has been found to be important for its activity as a tumor suppressor. Recently, mutation at an (A)6 repeat of PTEN exons 7,8and 9 in colorectal cancer(CRC) patients with microsatellite instability(gene instability) have been detected.-Predicting response and limiting drug-induced toxicity for patients with CRC and gastrointestinal are also critical. Methods: Our subjective was to identify PTEN mutation in colorectal tumors and tissue samples from Iranian patients. Histopathological examinations were performed, and all tumors were confirmed as adenocarcinoma. We searched for PTEN mutations which had involved in exones 7,8 and 9. The entire coding region and flanking sites (exons 7,8 and9) PTEN gene was amplified and conformation sensitive gel electrophoresis(CSGE) and sequencing was done to identify alterations. Results: 23(76.66%) patients had adenocarcinomas and 7 (23.33%) had mucinous adenocarcinomas. patient had stage I, II, and III or IV disease with 14.76%, 44.44% and 40.8% respectively and histopathological grade I, II, and III with 66.6%, 25.9% and 7.4% respectively .The frequency of mutation in PTEN was not present in all of the samples. The presence of PTEN mutation was no a significance associated with gender, histipathological grade ,age or cancer stage in patients with adenomacarcinoma of the CRC(p>0.05).Although many study have been shown in CRC , 3 mutational hot spots . our study indicated no mutations in hot spots and more samples should be investigated in 3 hot spots and others exons and also determine expression and methylation profile of PTEN gene. We found no PTEN alterations among the colorectal cancer samples.So we recommend to investigate level of expression of PTEN gene, such as transcriptom, protein and hypermethylation of PTEN. Promoter hypermethylation of PTEN can be accrued in these samples. So we had less of level of transcriptom and protein of PTEN.

Prostate cancer (PC) is one of the most commonly diagnosed cancers in Western societies and up to 42% of PC incidence is estimated to be due to inherited risk. Multiple common, low penetrance risk loci have been identified in recent genome-wide association studies (GWAS), but the discovery of rare, moderate-to-high penetrance mutations has proven difficult. Next-generation sequencing technology combined with a strong family-based study design, however, may facilitate discovery of rare disease mutations. Here we describe a whole-exome sequencing study of 19 hereditary prostate cancer (HPC) families with the aim of identifying such mutations. Whole-exome sequencing was performed on 80 PC cases from 19 families with ⁄3 affected relatives diagnosed with clinically aggressive and/or early onset disease. To increase the likelihood of detecting mutations that segregate with disease, the majority of affected men were ⁄2nd-degree relatives. Eleven elderly male relatives screened negative for PC were also sequenced. Sequencing was performed on the HiSeq Illumina platform; paired-end reads were aligned to the hg19 reference genome using BWA, and the programs SAMtools and GATK were used to perform local realignment and identify SNPs and indels distinct from the reference genome. SeattleSeq and ANNOVAR were used to annotate variants, which were then filtered according to their frequency in dbSNP and the 1000 Genomes Project. Variants that segregated with disease and were not observed in the unaffected relatives were prioritized according to the predicted function of the variant and of the gene in which the variant was present. In addition, data from a prior SNP genome-wide linkage scan of these families was used to prioritize variants present in regions with evidence for linkage. Data generation has been completed and analyses are underway. The results of these analyses and a discussion of our follow-up plans will be presented at the ASHG meeting.

Pooled analysis of GWA studies for survival from clear cell ovarian cancer reveals association at *RASGRF2*, *ANKS1B* and *KSR2*. *B.L. Fridley[1], R.A. Vierkant[1], Z.C. Fogarty[1], S. Armasu[1], Y. Tsai[2], H. Lin[2], H. Song[3], K. Bolton[3], J. Tyrer[3], S.J. Ramus[4], S. Johnatty[5], J.M. Cunningham[1], G. Chenevix-Trench[5], R. Sutphen[6], T. Moorman[7], J.M. Schildkraut[7], N. Wentzensen[8], S. Gayther[4], P. Pharoah[3], T.A. Sellers[2], E.L. Goode[1].* 1) Mayo Clinic College of Medicine, Rochester, MN, USA; 2) H. Lee Moffitt Cancer Center, Tampa FL, USA; 3) University of Cambridge, Strangeways Research Laboratory, Cambridge, UK; 4) University of Southern California, Los Angeles CA, USA; 5) Queensland Institute of Medical Research, Queensland, AUS; 6) University of South Florida College of Medicine, Tampa FL, USA; 7) Duke University School of Medicine, Durham NC, USA; 8) National Cancer Institute, Bethesda MD, USA.

Epithelial ovarian cancer (EOC) is the 6th most commonly diagnosed cancer among women in the world, with 5-year survival rate at 45%. To date, genome-wide association (GWA) studies of EOC outcomes, including overall survival (OS), have or restricted analysis to the most-common histological subtypes of high-grade serous or included all EOC cases, with limited success. Lack of findings could be attributed in part to genetic heterogeneity of effects by histological subtype. For example, women with ovarian clear cell carcinoma (OCCC) have slightly worse OS than women with serous ovarian cancer, as OCCC seems to be more aggressive. Therefore, to identify loci associated with OS, we completed a pooled analysis of 272 OCCC cases (81 deaths) from eight sites which were genotyped on the Illumina 610-quad array as part of three EOC GWA studies. Imputation of untyped markers was computed using MACH and the HapMap CEU genotypes and poorly-imputed markers (r-square < 0.30) were removed. Association analyses was completed for 2,504,879 SNPs using log-additive Cox proportional hazards models adjusted for study site, age at diagnosis and population stratification. Association analysis of OS from OCCC revealed associations at three loci: rs26419 in *RASGRF*2 (minor allele frequency (MAF) = 0.02, HR = 33, p=6.15E-07), rs10492271 in *ANKS1B* (MAF = 0.16, HR = 0.17, p=9.43E-07) and rs10850832 in *KSR2* (MAF = 0.17, HR = 2.50, p = 1.14E-06). However, none of these associations reached genome-wide statistical significance. RasGRF2 is known to interact with KSR2, a kinase suppressor of ras 2 and inhibits MEKK3-activated MAP kinase and the NF-kappa) pathway, and has an indirect interaction with TNF and KRAS. *ANKS1B* encodes EB-1 which is expressed in the ovary, where overexpression can down-regulate APP processing. Additional analyses are on-going to better understand these associations, including analyses by study site, to adjust for additional clinical covariates such as stage and grade, and to examine time to recurrence. In conclusion, these results provide new candidate genes related to OS from OCCC, demonstrating that analysis by histological subtype may better inform detection of variants associated with inter-individual differences in EOC survival.

Comprehensive analysis of somatic mutations in twenty-seven liver cancers by whole genome sequencing. *A. Fujimoto[1,2], T. Tsunoda[1,2], Y. Totoki[3], T. Abe[1], K.A. Boroevich[1], M. Nagasaki[2,4], M. Kubo[1], S. Miyano[2,4], N. Kamatani[1], Y. Nakamura[1,4], T. Shibata[3], H. Nakagawa[1].* 1) Ctr Genomic Med, Riken, Yokohama, Japan; 2) Data Analysis Fusion Team, Computational Science Research Program, RIKEN, Tokyo, Japan; 3) Division of Cancer Genomics, National Cancer Center Research Institute, Chuo-ku, Tokyo, Japan; 4) Human Genome Center, Institute of Medical Science, University of Tokyo, Minato-ku, Tokyo, Japan.

We report the whole-genome sequences of twenty-seven viral or non-viral liver cancers using massively parallel sequencing. We identified 1,000 to 20,000 single nucleotide mutations (SNVs), 40 to 800 short insertions and deletions (indels) and 0 to 60 intra- and inter-chromosomal rearrangements per sample. The pattern of mutations was significantly different among nucleotide sites and a higher mutation rate from C to T in CpG sites was observed. Dozens of genes with recurrent coding or splice-site mutations were also identified. Gene set enrichment analysis revealed that indels and nonsynonymous SNVs were significantly enriched in chromatin remodeling and cell adhesion genes after adjustments for multiple testing. Also, we detected the integration sites of the hepatitis B virus (HBV) genome into cancer genomes in the base resolution by using a paired-end method. Our results represent a comprehensive pattern of somatic mutations in liver cancer and will provide valuable insights for the mechanism of liver carcinogenesis and future molecular therapy.

1234W

Novel methods to integrate genotype and gene expression data reveal pathways genetically associated with ER breast cancer subtypes. *T. Furey[1], Q. Xinog[1], M. Weiser[1], E. Hauser[2], C. Perou[1], S. Mukherjee[3].* 1) Department of Genetics, Carolina Center for Genome Sciences, Lineberger Comprehensive Cancer Center, UNC-Chapel Hill, Chapel Hill, NC; 2) Center for Human Genetics, Duke University, Durham, NC; 3) Department of Statistical Science, Duke University, Durham, NC.

Recent GWAS studies have identified genetic variants associated with different cancers. In these studies, only genotype information is considered. To better understand potential genetic effects, we developed two complementary methods that simultaneously analyze whole genome genotype and mRNA expression to identify molecular pathways associated with cancer or a cancer subtype. Simulation studies support the ability of these methods to identify genetically and transcriptionally linked loci. We applied both methods to a small set of ER+ and ER- breast cancer tumor samples. The first method, Gene Set Association Analysis (GSAA), independently calculates gene-based scores reflecting their association to samples segregated into two classes, such as by ER status, using genotype and expression data separately. These are then combined into a single estimate of each gene's relatedness to class distinction. Using a pre-defined collection of pathway gene sets, a Kolmogorov-Smirnov (KS) statistic along with the combined gene scores then identifies pathways differentially regulated or genetically distinct between classes of samples. A second method places increased focus on genetic contributions to phenotypic differences. For each variant, an association score is calculated as follows: $Score(X_j|S_i) = As(C|S_i) + As(C|E(X_j)) * As(E(X_j)|S_i)$, where S_i is a particular variant, X_j is a gene in close proximity to S_i, $E(X_j)$ is the expression of that gene, and C is a phenotypic class. Each As(A|B) term indicates a measure of association between A and B. The first term, $As(C|S_i)$, reflects the simple association of SNP S_i to phenotype class. The second term, $As(C|E(X_j)) * As(E(X_j)|S_i)$, is product of the association of the expression of gene X_j with phenotype class and the association of SNP S_i with the expression of gene X_j (i.e. an eQTL measure). The overall score quantifies the relatedness of gene X_j to phenotype based on genetic associations of S_i directly to the phenotype and indirectly through the expression of gene X_j. Similar to above, gene scores are then used to identify pathways associated with phenotype class. When applied to a set of ~100 breast cancer samples stratified by estrogen receptor (ER) status, we found both methods indicate that HER2 and P53 pathways are upregulated and genetically associated with ER+ samples, while pathways related to cell cycle control including the BRCA/ATR pathway and pyruvate metabolism are linked to ER- samples.

Genetic and functional evidence of the presence of a tumor suppressor gene in 3p12-cen region in a model of epithelial ovarian cancer. *K. Gambaro[1], P.M. Wojnarowicz[1], M. de Ladurantaye[2], K. Leclerc Désaulniers[2], V. Barrès[2], J-S. Ripeau[4,5], S.L. Arcand[4], J. Lavoie[3], D.M. Provencher[2,6], A-M. Mes-Masson[2,8], M. Chevrette[4,5], P.N. Tonin[1,4,7].* 1) Human Genetics, McGill, Montreal, QC, Canada; 2) Centre de recherche du Centre hospitalier de l'Université de Montréal / Institut du cancer de Montréal, Canada; 3) Department of Pathology, McGill University, Montreal, Canada; 4) The Research Institute of the McGill University Health Centre, Montreal, Canada; 5) Department of Surgery, Urology Division, McGill University, Montreal, Canada; 6) Division de gynécologie oncologique, Université de Montréal, Canada; 7) Department of Medicine, McGill University, Montreal, Canada; 8) Department of Medicine, Université de Montréal, Canada.

Ovarian cancer (OC) is the fifth leading cause of death by cancer in women in western countries. The disease is largely asymptomatic with most patients diagnosed at an advanced stage often resulting in a poor outcome. Little is known of the etiology and mechanisms of tumorigenicity for this disease. Numerous studies have reported recurrent abnormalities of the chromosome 3p arm in epithelial OC (EOC) suggesting the presence of tumor suppressor genes (TSG). We have proposed that the 3p12-pcen region harbours TSG(s) based on loss of heterozygosity (LOH) studies of OC and suppression of tumorigenicity of a 3p haploinsufficient OV90 EOC cell line, which occurred as result of the transfer of chromosome 3 fragments. To identify 3p12-pcen TSG candidates, we performed a functional complementation assay based on the microcell mediated chromosome transfer of a derivative chromosome 3 defined by the 3p12-q11 region into OV-90. Of the 4 microcell hybrid clones generated hybrid 3-1 was unable to form colonies in soft agarose, and exhibited a significantly delayed tumor forming capacity in immunocompromised mice. Genome-wide SNP genotyping analysis revealed that hybrid 3-1 retained the largest amount of transferred DNA with a unique fragment containing 2 hypothetical genes and VGLL3. Comparative expression microarray analysis of OV-90, hybrid 3-1, malignant ovarian tumor samples (N=99) and normal ovarian samples not only supports VGLL3 as a top TSG candidate but also shows that a reprogramming of networks relevant to EOC had occured in the hybrid. Ectopically overexpressing VGLL3 in OV90 failed to yield stable transfectant clones. Stables clones expressing moderately increased levels of VGLL3 transcript resulted in the accumulation of cytoplasmic vacuoles. These clones exhibited tumour latency in SCID mice. Overexpression of VGLL3 using a lentivirus tetracylcine-inducible vector system resulted in the development of a similar cytoplasmic phenotype. Our results taken together suggest that VGLL3 expression plays a role in EOC tumorigenicity.

Evolutionary dynamics of blood cancer revealed by deep sequencing. *H. Gao[1,2], C. Wang[1,2], C. Bustamante[3], M. Mindrinos[1,2], D. Miklos[4], R. Davis[1,2], W. Xiao[1,2].* 1) Biochemistry, Stanford Univ, Stanford, CA; 2) Stanford Genome Technology Center, Stanford Univ, Stanford, CA; 3) Department of Genetics, Stanford Univ, Stanford, CA; 4) Department of Immunology, Stanford Univ, Stanford, CA.

In patients with chronic lymphocytic leukemia (CLL), the immune repertoires of B cells in the blood typically experience a rapid expansion of cancer clones, leading to substantial shrinkage of diversity. This implies that cancer clones go through distinct evolutionary processes from the B cell clones in healthy individuals. To understand the underlying disease mechanism, we applied 454 sequencing technology to sequence the immunoglobulin heavy chain variable region (VDJ) gene segments of B lymphocytes from 30 samples of 6 CLL patients collected at diagnostics, and after transplantation, at 56 days, 180 days, 365 days, and 550 days. Based on this rich data set, we modeled the re-generation of immune repertoire of cancer patients after bone marrow transplantation as a linear birth process with immigration. We performed extensive simulations to demonstrate this stochastic model reflects the evolution of immune repertoire. Then we applied the Ewens sampling test derived from this stochastic process to distinguish the immune repertoires of the cancer patients from the controls and to monitor their recovery or relapse accurately. Moreover, we estimated the immigration rate of donor's B cell clones entering the circulation system and the average time to reconstruct the normal immune repertoire after transplantation, both of which are of clinical importance. We anticipate that our stochastic model will be useful in accurate diagnostics of blood cancer and prognosis after transplantation.

Association of polymorphic variants of Vascular Endothelial Growth Factor (VEGF) gene in relation to risk and androgen therapy response in Prostate cancer patients of North India. *G.P. George, R.D. Mittal.* Urology, Sanjay Gandhi Post Graduate Institute of Med. Sc., Lucknow, Uttar Pradesh, India.

Prostate cancer (PCa) represents a global public health problem. In comparison to the Western countries the incidence rate of PCa in India is low. Simultaneously, Hormone Refractory Prostate Cancer (HRPC) is also a leading cause of aging-related cancer death in men. VEGF is expressed at higher levels in prostate cancer cells in the absence of androgens and might therefore be involved in the onset of androgen refractory prostate cancer. We analyzed —7C>T; —1001G>C; —2578C>A; —2549 Ins/Del SNPs in VEGF, in a population based case-control study of 215 PCa cases and 220 healthy controls of North India. The study protocol was approved by Ethical Committee of the Institute. Clinical outcomes were obtained for 58 patients on androgen-deprivation therapy (ADT). Haplotype frequencies were estimated using the expectation-maximization algorithm using the Arlequin program, version 2.0. All statistical analyses were performed with the SPSS ver. 13.0 (SPSS Inc, Chicago, USA) statistical software package. The mean age (years±SD) for PCa patients and controls was not significantly different (p, 0.203). Overall analysis showed significant association in VEGF —7C>T heterozygous genotype (CT) (p=<0.001; OR=3.14), variant genotype (AA) of —2578C>A was at 2.9 fold risk in patients (p= 0.002) and the heterozygous genotype of VEGF —2549 Ins/Del (I/D) posed a 2.2 fold risk in individuals developing PCa (p=<0.001). Haplotypes T/G/C/I and T/G/C/D showed 3.7 and 2.5 fold increased risk with PCa (p=<0.001 and p= 0.021 respectively). The HR for advancement of PCa to HRPC showed that heterozygous genotype (I/D) of —2549 Ins/Del revealed a protective trend for the patients developing PCa (p=0.051; OR=0.28). The findings suggest inheritance of VEGF variants as a predictor of PCa progression risk among North Indian men, but still require validation in larger observational studies to validate the potential effect of these SNPs in PCa patients on ADT.

1239W

Molecular characterization of pediatric high grade astrocytomas reveals mTOR pathway dysregulation in pediatric anaplastic astrocytomas. *N. Gerges[1], T. Haque[1], A. Nantel[2], N. Jabado[1].* 1) McGill University, Montreal, Quebec, Canada; 2) Biotechnology Research Institute, Montreal, Canada.

Brain tumors are the leading cause of cancer-related mortality in children. Pediatric high grade astrocytomas, including grade IV (glioblastoma, pGBM) and grade III (anaplastic astrocytomas, pAA), are rare but devastating brain tumors accounting for 15% of all brain tumor cases in children. Grade III and IV pediatric astrocytomas are similarly treated and exhibit the poorest overall prognosis in pediatric oncology as 90% will die within 3 years of diagnosis. To identify differences based on tumor grade and age, we investigated high grade pediatric astrocytomas using transcriptome profiling. Our results show independent segregation of pAA from pGBM highlighting distinct molecular characteristics between these subgroups. The 660 differentially expressed genes between grade III and IV pediatric astrocytomas were further investigated using the Ingenuity Pathway Analysis (IPA) software to achieve comprehensive analysis of biological functions. IPA identified a significant dysregulation of the mTOR pathway (p-value = 4.65x10-4) that differentiated, among others, both subgroups. Indeed, 13 genes involved in the mTOR pathway were found to be differentially regulated between pAA and pGBM. PRKCB, a major member of the mTOR pathway involved in apoptosis and transcriptional regulation, was found to be upregulated in pAA compared to pGBM with a fold change of 2.723 that was further validated using immunohistochemical staining on pAA and pGBM primary tumors. This is the first report of its kind in the literature showing differential regulation of pAA and pGBM within pediatric high grade astrocytomas and identifying upregulation in pAA of members of the mTOR pathway including PRKCB. We are further investigating the functional significance of the dysregulation of mTOR pathway in pAA compared to pGBM. These results shed light on a pathway that may be amenable to therapy as drugs targeting it, including rapamycin, are already in the clinical setting and have been used in clinical trials in children including those with neurofibromatosis. They also further emphasize the need for better molecular classification of tumors for optimal therapeutic results in patients who currently have limited options for clinical trials and dismal outcome using current targeted therapies that are conceived without improved knowledge of the inherent biology of the tumor.

PIK3CA , BRAF,KRAS&PTEN mutational alteration and association with clinicopathological features in Iranian Colorectal Cancer Patients. *M. Ghaffarpour[1,4], S. Sobhani[2], M. Firoozi[2], E. Mohammadi Pargoo[2], S. pirmoradi[2], Z. Mostakhdemin Hosseini[3], F. Kamali[3], F. Fereidooni[3], M. Houshman[1,4], Sobhani Firoozi.* 1) Medical Genetics Department,National Institute for Genetic Engineering and Biotechnology, Tehran, Iran; 2) 2Department of Biology, Faculty of Sciences, Islamic Azad University, Science & Research Campus, Tehran; 3) Iranian National Tumour Bank, The Cancer Institute of Iran, Imam Hospitals CompleX, Tehran, Iran; 4) 4Medical Genetics Department,,Special Medical Center, Tehran, Iran.

Colorectal cancer (CRC) is the third most common cancer amongst Males and the fourth amongst females in Iranian cancer patients. The prevalence of PIK3CA,BRAF ,KRAS and PTEN mutations in CRC has been reported to vary between 13.6% to 32%,5%to22%,20% to 50% and1% and 29% respectively. The aim of this study was to identify PIK3CA gene mutations in exons 9 and 20 ,BRAF gene mutations in exon 11,15 , KRAS gene mutations in exon 1and PTEN mutations in exon7,8&9 among Iranian CRC patients, and to consider whether they are associated with the clinicopathological parameters like age, sex, familial history, site of primary and histology. Materials and Methods: Patients and tissue specimens:Tissue samples were obtained from 61 consecutive patients with CRC (26 men and 36 women; age range, 28-88 years; with median age of 57.8 years).Histopathological examinations were performed, and all tumors were confirmed as adenocarcinoma Mutational analysis: We searched for PIK3CA mutations in exons 9 and 20.PIK3CA exon 9 includes codons 542 and 545, PIK3CA exon 20, BRAF mutations in exons 11 and 15,KRAS mutations in codond12 &13(exon 1) and PTEN mutations in exons 7,8&9 where the large majority of mutations occur in these genes .The PI3KCA , BRAF, KRAS and PTEN mutational analyses were made by means of PCR sequencing. Results and conclusion: 53 (85.5%) patients had adenocarcinomas and 9 (14.51%) had mucinous adenocarcinomas. patients had stage I, II and III or IV disease with16.%, 43%and 41.% respectively and histological grade I, II and III with 55.74%,39.36% and 4.9%. respectively. Among the 62 samples analyzed (51were primary tumors and 11were metastases). The frequency of mutations in PIK3CA were present in 4.33% (3 of62) of the samples (4.33%mutation in exon 9(c.1633G>A E545K and no mutation in exon 20). The frequency of mutation in BRAF were present in 2 of 62 of the samples (3.22% mutation in exon 15; V600E and IVS14-4C>T). Mutation in PTEN was not present in the colon cancer patients (0 of 30). The presence of PIK3CA , BRAF and PTEN mutations were not a significance associated with gender, histological grade, age, or cancer stage in patients with adenocarcinoma of the CRC(P>0.05).20.3% of patients in KRAS gene. About 60% of KRAS-mutations were indicated in rectum cancer patients and 41.7% in colon cancer patients. In addition our result indicated that KRAS mutations in codons 12, 13 were less common among Iranian colorectal cancer patients.

Fine-Scale mapping of the 11q13 breast cancer susceptibility locus. *M. Ghoussaini[1], S. Ahmed[1], K. Michailidou[2], K. Gregory[1], E. Dicks[2], K. Driver[1], M. Maranian[1], C. Turnbull[3], N. Rahman[3], P.D. Pharoah[1,2], D.F. Easton[1,2], A.M Dunning[1].* 1) Department of Oncology, University of Cambridge, Cambridge CB1 8RN, United Kingdom; 2) CR-UK Genetic Epidemiology Unit, Public Health and Primary care, University of Cambridge, Cambridge, United Kingdom; 3) Section of Cancer Genetics, Institute of Cancer Research, Sutton, Surrey, UK.

We previously identified a variant at 11q13 (rs614367) associated with breast cancer risk through a genome-wide association study. This variant lies in an LD block of ~700 Kb. Using data from the 1000 Genomes Project, we catalogued ~1600 common variants (Minor Allele Frequency >0.05) in this region, of which 140 have a detectable correlation with rs614367 and were thus considered to be potentially causative. 52 tag SNPs were genotyped in ~13,000 cases and controls from the East Anglian SEARCH breast cancer case-control study, using FluidigmTM technology. We also used genotyping data from 145 SNPs at this locus from two UK population based studies in ~ 3600 cases and ~5200 controls. Genotypes of all other known variants in the locus were imputed using known genotypes in combination with data from the 1000 Genomes Project. Based on the combined data from all studies, 29 variants were convincingly associated with Breast Cancer (P-values 10-8 to 10-19, odds ratios 1.14 to 1.29). Assuming a single causative variant, all but 5 variants could be excluded based on a likelihood of <1:100 compared with the most significant SNP. These 5 variants lie in a 48 Kb LD block upstream of CCND1, FGF3, FGF4 and FGF19 genes. The gene(s) directly under the control of this locus remains to be determined.

SLC39A2 and FSIP1 Polymorphisms as Potential Modifiers of Arsenic-Related Bladder Cancer. *D. Gilbert-Diamond[1], A. Andrew[1], H. Nelson[2], Z. Li[1], T. Punshon[1], A. Schned[1], C. Marsit[1], S. Morris[4], J.H. Moore[1], A. Tyler[1], M. Guerinot[1], K. Kelsey[3], M. Karagas[1].* 1) Dartmouth Medical School, Lebanon, NH, USA; 2) University of Minnesota, Minneapolis, MN, USA; 3) Brown University, Providence, RI, USA; 4) University of Missouri-Columbia, Columbia MO, USA.

Arsenic is a carcinogen that contaminates drinking water worldwide. Over 10% of the unregulated drinking wells in the U.S state of New Hampshire have arsenic concentrations above the current U.S. maximum contaminant limit of 10 μg/L. Accumulating evidence suggests that both level of exposure and genetic factors may influence one's risk of arsenic-induced malignancies. We sought to identify potential interactions between single nucleotide polymorphisms (SNPs) and elevated arsenic exposure in relation to bladder cancer in a US population with low to moderate drinking water levels of arsenic. We first screened a subset of bladder cancer cases using a panel of approximately 10,000 non-synonymous SNPs. We then genotyped top ranking hits on the SNP array (Fisher exact test P < 0.0001) in our population-based case-control study (n=832 cases and 1191 controls). SNPs in the fibrous sheath interacting protein 1 (FSIP1) gene (rs10152640) and the solute carrier family 39, member 2 (SLC39A2) in the ZIP gene family of metal transporters (rs2234636) were identified as potential hits in the initial scan and validated in the full case-control study. The adjusted odds ratio (OR) for the FSIP1 polymorphism was 2.57 (95% confidence interval (CI) 1.13, 5.85) for heterozygote variants and 12.20 (95% CI 2.51, 59.30) for homozygote variants compared to homozygote wild types in the high arsenic group, and unrelated in the low arsenic group (p for interaction = 0.002). For the SLC39A2 polymorphism, the adjusted ORs were 2.96 (95% CI 1.23, 7.15) and 2.91 (95% CI 0.99, 8.52) for heterozygote and homozygote variants respectively, and close to one in the low arsenic group (p for interaction = 0.03). Our findings suggest novel variants that may modify the risk of arsenic-associated bladder cancer.

1243W

Cancer genes are differentially expressed with age in normal tissues. *D. Glass[1], A. Viñuela[1], L. Parts[2], D. Knowles[3, 7], A. Nica[4,2], J. Nisbet[2], A. Barrett[5], M. Sekowska[2], M. Travers[5], S. Potter[2], E. Grundberg[2, 1], K. Small[1, 2], A. Hedman[5], J. Tzenova Bell[5, 1], G. Surdulescu[1], F.O. Nestle[6], P. di Meglio[6], R. Durbin[2], K. Ahmadi[1], J. Winn[7], D. Dermitzakis[4], The Muther consortium.* 1) King's College London, London, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Department of Engineering, University of Cambridge, Cambridge, United Kingdom; 4) Department of Genetic Medicine and Development, University of Geneva, Geneva, Switzerland; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) St John's Institute of Dermatology, King's College London, London, United Kingdom; 7) Microsoft Research, Cambridge, United Kingdom; 8) University College London Cancer Institute.

BACKGROUND: Age is the strongest risk factor for cancer. The relationship between the ageing process and cancer development is not fully understood; this study investigates changes in gene expression in skin and fat with age which may help to further elucidate the mechanisms involved. METHODS: 855 photo-protected abdominal skin samples were taken from female Caucasian twins aged 40 - 85 years. Abdominal fat and lymphoblastoid cell lines (LCLs) were sampled from the same individuals. RNA was extracted from all samples and hybridised with the Illumina Human Sentrix 12 micro-array. A linear mixed model was used to explain gene expression variability with age and confounding factors; (Significance determined from permutations using false discovery rate <0.05). RESULTS: There was a difference in the number of genes differentially expressed with age between the 3 tissues with the skin showing the greatest number of genes differentially expressed with age (n~2000) compared to fat (n~600). No genes were differentially expressed with age in LCLs. 100 common genes were differentially expressed with age in both skin and fat tissues. Multiple genetic pathways implicated in cancer development were significantly differentially expressed with age. These include genes in well known pathways such as MEK1, ERK1/2, EGFR, WNT and Frizzled. These results may shed some light into the complex interactions between ageing and cancer.

1244W

Clinical implications of a prostate cancer risk SNP profile in an Active Surveillance cohort. *C. Goh[1], E. Saunders[1], N. Mahmud[1], M. Tymrakiewicz[1], D. Leongamornlert[1], T. Dadaev[1], E. Castro[1], D. Olmos[1], K. Thomas[1,2], R. Woode-Amissah[1,2], M. Guy[1], K. Govindasami[1], L. O'Brien[1], A. Hall[1,2], R. Wilkinson[1], A.A. Al Olama[3], D. Easton[3], Z. Kote-Jarai[1], C. Parker[1,2], R. Eeles[1,2].* 1) The Institute of Cancer Research, United Kingdom; 2) The Royal Marsden Hospital, Sutton, United Kingdom; 3) The University of Cambridge, United Kingdom.

Background: Genome-wide association studies (GWAS) have identified 39 susceptibility loci associated with prostate cancer (PCa) so far. Currently, these have only been evaluated against overall PCa risk and several clinical disease parameters. The challenge now is to translate the current PCa risk algorithms to the clinical setting. We explore the potential prognostic role that these risk SNPs might play in patients undergoing Active Surveillance (AS) for prostate cancer. **Methods:** The AS cohorts have low-risk PCa with Gleason scores ≤3+4, T1/T2 stage tumours and percentage positive biopsy cores <50%. These patients are offered regular PSA measurements and repeat prostate biopsies (18-24 monthly). DNA from eligible patients were genotyped using the Sequenom MassARRAY iPLEX platform and Taqman assays. The cumulative risk scores for each patient were calculated by summing risk alleles for each loci using the weighted effect as estimated in previous studies. These risk scores were assessed against defined adverse outcomes in AS including, adverse histology on repeat biopsy, time to treatment, and a PSA doubling time of <2 years (PSADT), to determine their prognostic value. **Results:** 391 patients were eligible for analyses. Median age was 66.4 years (range 50-79.4), with a mean PSA of 6.8 (range 0.19-36). At the time of analysis, 35.8% of patients have undergone treatment and 35.7% have histological upgrade on repeat biopsies. On univariate analyses, there was no correlation between the calculated genetic risk scores and upgrade on repeat biopsy, or time to treatment (p=0.573 and p=0.825, respectively). When analysing differences between the higher and lower genetic risk groups (defined as the top 25% and lowest 25% of the genetic risk distribution), there was again no correlation (p=0.850, 95%CI= 0.509-1.839; and p=0.906, 95%CI=0.530-1.570, respectively). For PSADT, there was also no correlation with the genetic risk scores (p=0.317). Subgroup analyses were conducted using risk scores generated from loci thought to be associated with aggressiveness (e.g. SNPs in 8q24 region), which again showed no correlation. **Conclusion:** This study does not support the use of the current PCa risk scores to predict outcomes in an AS cohort. Further analyses to investigate risk algorithms pertaining to treatment outcomes are needed. To our knowledge, this is the first study analysing the potential prognostic significance of GWAS risk SNPs in a PCa treatment cohort.

1245W

Familial aggregation of acute myeloid leukemia and myelodysplastic syndromes in young, but not in adult patients. *L.R. Goldin[1], S.Y. Kristinsson[2], X. Liang[1], A.R. Derolf[2], O. Landgren[3], M. Bjorkholm[2].* 1) Genetic Epidemiology Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD; 2) Department of Medicine, Division of Hematology, Karolinska University Hospital Solna and Karolinska Institutet, Stockholm, Sweden; 3) Medical Oncology Branch, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, Maryland.

Apart from rare pedigrees with multiple cases of acute myeloid leukemia (AML), there is limited data on familial aggregation of AML and myelodysplastic syndrome (MDS) in the population. In a comprehensive population-based study, we estimated risk of AML, MDS, other hematological malignancies and solid tumors among relatives of AML and MDS patients. Swedish population-based registry data were used to evaluate outcomes in 24,573 first-degree relatives of 6,962 AML and 1,388 MDS patients compared with 106,224 first-degree relatives of matched controls. Using a marginal survival model, we calculated relative risks (RR) and 95% confidence intervals (CI) as measures of familial aggregation. AML, MDS, and myeloproliferative neoplasms as a group did not aggregate significantly in relatives of patients with AML, MDS or in the combined group. The risks for any hematopoietic or solid tumor were significantly but modestly increased among relatives of AML patients. In contrast, we found a significantly increased risk (RR=7.53; CI: 1.25-45.13) of AML/MDS and a 3.01-fold RR (CI: 1.09-8.31) for all myeloid malignancies combined among relatives of patients diagnosed under age 21 years. The lack of familial aggregation of AML or MDS is striking and in sharp contrast to findings in patients with other myelo- and lymphoproliferative disorders. However, relatives of young AML patients do seem to be at increased risk of AML/MDS, other hematopoetic and solid tumors suggesting that germ line genes play a stronger role in these patients. The increased risk of any hematopoetic or solid tumor suggests that genes for malignancy in general and/or other environmental factors may be shared in these families.

1246W

Genetic variations in BRAF, CDKN2A, NRAS, and PTEN and the risk of melanoma in melanoma-prone families. *A.M. Goldstein[1], R.M. Pfeiffer[1], D. Maeder[1,2], L. Burdett[1,2], M. Yeager[1,2], S.J. Chanock[1], M.A. Tucker[1], X.R. Yang[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute (NCI), National Institutes of Health, DHHS, Bethesda, MD, USA; 2) Core Genotyping Facility, NCI-Frederick, SAIC-Frederick, Inc., Frederick, MD, USA.

Cutaneous melanoma (CM) is a type of skin cancer with a complex etiology. CDKN2A is the major high-risk susceptibility gene for CM identified to date. In addition, somatic mutations occur frequently in CM tumors. Overall, the genes most frequently somatically mutated in CM are BRAF, CDKN2A, NRAS, and PTEN. To examine whether germline copy number variations (CNVs) in these genes might contribute to the disease phenotype in high-risk CM-prone families, we conducted array-based comparative genomic hybridization (aCGH) studies using the Nimblegen whole-genome tiling (720k exon-focused) CGH array on 153 melanoma patients and 82 unaffected family member/spouse controls from 48 American melanoma-prone families with and without germline CDKN2A mutations. Potential disease-related CNVs were validated using qPCR. In addition, we evaluated evidence for associations between CM and tagging SNPs in BRAF, CDKN2A, and PTEN in 53 families (23 families segregating CDKN2A mutations and 30 families without CDKN2A mutations). For the association analysis, we had genotype data on 64 SNPs for 183 CM patients and 379 unaffected family members/spouse controls using an Illumina iSelect Infinium assay. Conditional logistic regression models were used to estimate the trend p-value for the association between CM and each SNP, using codominant coding for genotypes with the homozygote of the common allele as the reference group. All analyses were adjusted for age, sex, and CDKN2A mutation status. No disease-related CNVs in BRAF, CDKN2A, NRAS, or PTEN were consistently observed in CM cases. Association analyses showed no significant associations with BRAF or CDKN2A. A significant association was observed between rs1234221 in PTEN and CM risk (p-trend=0.00055; OR= 0.59, 95% CI=0.35-0.99 for CA vs CC [ref]; OR=0.11, 95% CI=0.03-0.38 for AA vs CC [ref]). The association remained significant after Bonferroni correction (p-trend=0.035). The effect also appeared stronger in families without CDKN2A mutations versus those with CDKN2A mutations. In summary, we observed no disease-related germline CNVs for the most frequently somatically mutated genes for melanoma in 48 CM-prone families. SNP evaluation of BRAF, CDKN2A, and PTEN showed one SNP tagged for PTEN to be significantly associated with CM risk. Our study is limited by the small sample size and should be considered exploratory. Additional CM-prone families are needed to further evaluate the relationship between rs1234221 and CM risk.

1247W

CYP3A4*1B POLYMORPHISM IS NOT ASSOCIATED WITH PROSTATE CANCER IN MEXICAN POPULATION. *L. GOMEZ-FLORES-RAMOS[1], E. VAQUEZ-VALLS[1], B.M. TORRES-MENDOZA[2], M.P. GALLEGOS-ARREOLA[2].* 1) UIMEC, UMAE de Especialidades, Centro Médico Nacional de Occidente, Instituto Mexicano del Seguro Social; Belisario Dominguez 1000, CP 44340, Guadalajara, México; 2) Centro de Investigacion Biomedica de Occidente, Centro Médico Nacional de Occidente, Instituto Mexicano del Seguro Social; Sierra Mojada 800, CP 44340, Guadalajara, México Occidente,.

Prostate cancer (PCa) is the second most common malignancy in mexican men over 50 years, its etiology is multifactorial, and genetic factors are important in its development. The evidence suggests that steroid hormones and genes that regulate them could influence prostate carcinogenesis. Thus, the CYP3A4 enzime, which facilitates the deactivation of testosterone as a result of NADPH-dependent monooxidative reactions, has been considered. The CYP3A4*1B (-290A> G) polymorphism, has been associated with susceptibility to PCa in various populations, so the aim of our study was to determine the association of the CYP3A4*1B polymorphism in Mexican population. The frequency of the CYP3A4*1B allele was determinate in 257 samples of genomic DNA from general population individuals and 44 patients with PCa. The wild homocygote (AA) genotype was the most common among both groups, occurring in 84% (37/44) of patients and in 79.8% (205/257) of the control group, followed by the heterocigote genotype (AG) with 16% (7/44) in the PCa group and 19.5% (50/257) in controls, the mutant homocigote (GG) genotype was not observed in the patients, and was present at 1% (2 / 257) in the control group, non significant differences were found [p>0.05; OR 0.71, 95% CI (0.28 to 1.73)]. Our results suggest that the CYP3A4*1B polymorphism is not associated with prostate cancer in Mexican population.

1248W

Confronting the Problem of Genetic Heterogeneity in Cancer Tissues: Investigating the Role of the Androgen Receptor Gene in Breast Cancer Ontogeny and Treatment. *B. Gottlieb[1,2,3], C. Alvarado[1], C. Wang[5], B. Gharizadeh[5], F. Babrzadeh[5], B. Richards[1], M. Basik[2,4], L.K. Beitel[1,2,3,4], M. Trifiro[1,2,3,4].* 1) Dept Cell Genetics, Lady Davis Institute for Med ical Research, Montreal, PQ, Canada; 2) Segal Cancer Centre, Jewish General Hospital, Montreal, PQ, Canada; 3) Dept of Human Genetics, McGill University, Montreal, PQ, Canada; 4) Dept of Medicine, McGill University, Montreal, PQ, Canada; 5) Stanford Genome Technology Center, Stanford University, Palo Alto, CA.

The extensive genetic heterogeneity discovered within cancer tissues, has raised many questions with regards to cancer ontogeny. It has been suggested that understanding the origins of genetic heterogeneity could be critical to identifying genetic markers of cancer ontogeny and developing prevention and treatment regimens. A major problem preventing any assessment of the significance of genetic heterogeneity in cancer tissues has been the inability to measure the relative frequency of the different genetic variants. We have examined somatic genetic heterogeneity within individual breast tumors by “over-sequencing” the X-linked androgen receptor gene (AR), up to 37,000 times, to quantify AR CAG repeat length variation, a functional polymorphism associated with breast cancer risk. All samples of laser capture micro-dissected cancer and non-cancer tumor tissues, as well as from matching blood leukocytes, had up to 30 AR CAG repeat length variants, instead of just two. Normal breast tissues had a majority of ARs containing zero CAG repeats, while cancer tissues had a reduced number of ARs with zero CAG repeats, and a majority of ARs with CAG repeat lengths in the normal tissue range (18-25). Blood leukocytes had many fewer AR variants, few, if any, with zero repeats, and a majority with normal length CAG repeats. These results support the observation that shorter AR CAG repeat lengths may be protective against breast cancer, and the hypothesis that selection as a result of particular hormonal microenvironments, of pre-existing minority cell populations with longer AR CAG repeat length variants, may contribute to breast carcinogenesis. One might also consider that tumor genomic heterogeneity introduces significantly greater complexity for `targeted' therapeutic approaches. However, if longer CAG repeats drive breast cancer cell growth and shorter repeats inhibit growth, and if our heterogeneity hypothesis is valid, our work may suggest creative approaches to treatment of breast cancer. One would be by identifying and then selectively eliminating cells containing longer AR CAG 1 repeat variants, and thus enhancing the relative concentration of cells with short CAG repeats. A more challenging approach, that involves targeting host factors, would be the identification and modulation of the micro-environmental conditions that result in the selection of longer AR CAG 1 repeat variants. Thus, important therapeutic implications may arise from these observations.

1249W

Replication of genome-wide discovered breast cancer risk loci in the Cypriot population. *A. Hadjisavvas, M. Loizidou, I. Neophytou, K. Kyriacou.* The Cyprus Institute of Neurology & Genetics, Department of Electron Microscopy/Molecular Pathology, Nicosia, Cyprus.

Genome-wide association studies (GWAS) have identified several loci as being associated with breast cancer in mostly European populations. It is important to evaluate whether these variants confer risk across different populations and also to assess the magnitude of risk conferred. The aim of this study was to evaluate previously GWAS-identified breast cancer risk variants in the Cypriot population. To evaluate whether the GWAS derived risk variants contribute to breast cancer in the Cypriot population, we genotyped them in 1,109 Cypriot female breast cancer patients and 1,177 healthy female controls. Overall, our results show modest concordance for breast cancer GWAS-discovered alleles and their effect sizes in the Cypriot population. The effects sizes of GWAS-discovered SNPs need to be verified separately in different populations.

Association of 8q24.21 locus with the risk of colorectal cancer: A systematic review and meta-analysis. *B.S. Haerian[1], M.S. Haerian[2]*. 1) Deapartment of Pharmacology, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia; 2) Research Center for Gastroenterology and Liver Disease, Shaheed Beheshti University, M.C., Tehran, Iran.

Objective: Recent genome-wide association studies of colorectal cancer (CRC) have identified rs6983267 and rs10505477 polymorphisms as key loci in the 8q24 region to be associated with CRC. In the present study, we performed a meta-analysis to determine whether these loci are risk factors for susceptibility to CRC. Materials and Methods: We meta-analyzed the 22 included studies (47,003 cases and 45,754 controls) that evaluated the role of rs6983267 and rs10505477 polymorphisms with CRC risk under alternative genetic models. Results: Meta-analysis of the pooled data showed allelic and genotypic association of the rs6983267 polymorphism with CRC risk in the Asian, European, and Americans with European ancestry. Sub-analysis of the American studies showed negative results in the studies with non-identified ethnicity of the subjects. Meta-analysis of included studies of rs10505477 polymorphism identified allelic and genotypic association with CRC risk in the American subjects. Further meta-analysis of the American studies demonstrated positive results in the studies with non-identified ethnicity of the samples. Conclusion: Our data suggested that the rs6983267 polymorphism is a risk factor for CRC in the Asians, European, and American with the European ancestry populations.

1251W

Analysis of the 16p11.2 region in congenital primary hypothyroidism and atypical Septo-Optic Dysplasia. *M. Dasouki[1], G. Lushington[2], K. Hovanes[3].* 1) Dept Pediatrics, Univ Kansas Med Ctr, Kansas City, KS; 2) Molecular Graphics and Modeling Laboratory, Univ of Kansas, Lawrence, KS; 3) Combimatrix Diagnostics. Irvine, CA.

The chromosome 16p11.2 region was recently found to be a hot spot for copy number abnormalities and had been associated with autism +/- congenital anomalies (29.5-30.1 Mb) and severe early childhood obesity (28.7-29 Mb). Two genes within this region, *SEZ6L2* and *SH2B1*, are considered to be strong candidates for the autism spectrum disorder and obesity phenotypes respectively. Otherwise, there is no strong genotype-phenotype correlation. In a 2 year old Caucasian girl with severe congenital hypothyroidism, growth hormone deficiency, bilateral optic nerve hypoplasia with retinal drusen and facial dysmorphism, a *de novo* chr.16p11.2 deletion [del(16)(p11.2p11.2)(RP11-301D18-).arr 16p11.2(29,366,195-30,302,387)x1] was identified. Septo-optic dysplasia (SOD) is a highly heterogeneous condition comprising variable phenotypes including midline and forebrain abnormalities, optic nerve and pituitary hypoplasia. Mutations in the transcription factors *HESX1, SOX2, SOX3* and *OTX2* had been implicated in its etiology. While several genes within the deleted 16p11.2 region are expressed in the pituitary and thyroid glands, two (*CD2BP2* & *YPEL3*) were found to interact with known SOD related genes [*CD2BP2-NR5A1-SOX2* & *YPEL3-ONECUT1-HESX1*]. Additionally, *CD2BP2* & *YPEL3* showed interaction loops with *NKX2-1, NKX2-5, HHX* and *TSHR*, genes known to be important for thyroid gland development and morphogenesis. These findings suggest a possible important role for these two genes in the pituitary and thyroid development. It is also possible that additional mutations within the intact alleles in the 16p11.2 region as well as other related genes may have contributed to this unique phenotype.

1252W

Cytogenetic and phenotypic findings in Tunisian children with Fanconi Anemia. *A. AMOURI[1,2], F. TALMOUDI[1,2], S. ABDELHAK[2], O. KILANI[1], I. CHEMKHI[1,2], H. GUERMANI[1,2], S. HENTATI[1], N. ABIDLI[1], O. MESSAOUD[2], M. BEN REKAYA[2], W. AYED[1,2], THE TUNISIAN FANCONI ANEMIA STUDY GROUP.* 1) CYTOGENETIC LABORATORY, PASTEUR INSTITUTE OF TUNIS, TUNISIA; 2) MOLECULAR INVESTIGATION OF GENETIC ORPHAN DISEASES RESEARCH UNIT (MIGOD) UR 26/04, PASTEUR INSTITUTE OF TUNIS, TUNISIA.

Background:Fanconi anemia (FA) is a rare syndrome characterized by bone marrow failure, malformations and cancer predisposition. Hypersensitivity to alkylating agents such as diepoxybutane (DEB) or mitomycin C (MMC) is the gold standard test for the diagnosis of FA. Methods:Chromosomal breakage investigation using MMC induction was carried out in 176 pediatric aplastic anemia (AA) patients suspected with FA. After cytogenetic confirmation, some of the FA-siblings were also investigated to exclude disease especially when donors for bone marrow transplantation are sought. Results:Chromosomal breakage evaluation showed 32 patients with FA among 176 paediatric AA patients (18.18%). FA-patients exhibited a high frequency of chromosome fragility compared with the controls.The rate of consanguinity was 94.11% in FA-patients. Among 21 sibs of 11 FA patients, we found 4 (19.4%) affected. Conclusion:This study is the first in Tunisia to analyses the cytogenetic and phenotypic findings in children with FA. FA seems to be frequent in Tunisia because of the frequent consanguineous marriages. So, this study calls for an urgent nation-wide screening. Results of this study indicate also that is extremely important to rule out FA in all FA-siblings.

1253W

Intrachromosomal events and presence of complexities at the breakpoints are common features in *MECP2* duplication rearrangements. *C.M.B. Carvalho[1], M. Ramocki[2, 3], D. Pehlivan[1], S.W. Cheung[1], L.M. Franco[1], M. Shinawi[4], J.W. Belmont[5], H.Y. Zoghbi[1, 2, 3], P.J. Hastings[1], J.R. Lupski[1, 2, 3].* 1) Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Pediatrics, Baylor College of Medicine, Houston, TX; 3) Texas Children's Hospital, Houston, TX; 4) Division of Genetics and Genomic Medicine, Department of Pediatrics, Washington University School of Medicine, St Louis; 5) Division of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Copy number gain in Xq28 including *MECP2* is the most commonly identified subtelomeric alteration in patients with developmental delay and associated clinical findings. *MECP2* duplications are nonrecurrent, that is each patient presents a unique rearrangement with variable size and gene content. To date, we collected a cohort of 44 patients with *MECP2* duplications through a collaboration established among our research laboratory, Baylor Diagnostic Laboratory (MGL) and the Blue Bird Circle Rett Center clinic at Texas Children's Hospital specifically for boys (and rare girls) with *MECP2* duplication syndrome. Previous partial analysis derived from high-resolution comparative genomic hybridization array assays (aCGH) revealed occurrence of complex rearrangements within our patient cohort, i.e. triplications or stretches of normal copy number interspersed with duplications, in approximately 27% of cases. Here we further studied 18 patients carrying duplications including *MECP2* for whom we were able to accomplish DNA sequencing for each one of the rearrangement breakpoint junctions. Surprisingly, DNA sequencing unveiled the presence of complexities in up to 50% of the rearrangements, most of which could not be anticipated by analysis of aCGH results alone. All of those complex alterations have at least one breakpoint within or flanking the low copy repeats (LCRs) that map nearby the *MECP2* gene, supporting and expanding our previous hypothesis that such LCRs stimulate rearrangements in the *MECP2* locus. In addition, we used SNP array (Illumina Human Omni1-Quad) to assess the status of the SNPs present within the altered genomic region and observed absence of heterozygosity (AOH) in almost all cases strongly suggesting that the *MECP2* duplication is mainly an intrachromosomal event. In summary, our data contributes to further understand the genomic alterations present in the *MECP2* duplication patient cohort and support the contention that the genomic architecture plays an important role for nonrecurrent rearrangement formation.

Significance of small CNVs detected below the clinical cytogenetic laboratory threshold using Affymetrix 2.7M SNP array. *Y. Qiao[1,2], C. Tyson[3], M. Hrynchak[3], E. Lopez-Rangel[2], J. Hildebrand[2], S. Martell[1], C. Fawcett[3], K. Calli[1,2], J. Holden[4], S. Lewis[2], E. Rajcan-Separovic[1].* 1) Dept Pathology (Cytogenetics), Universty of British Columbia (UBC) and Child and Family Res Inst (CFRI), Vancouver, Canada; 2) Dept. Medical Genetics, UBC and CFRI, Vancouver, Canada; 3) Cytogenetics Lab, Royal Columbian Hospital, New Westminster, Canada; 4) Depts Psychiatry & Physiology, Queen's University, Kingston, Ontario, Canada.

Whole genome screening array technology is now an established tool for detecting copy number variants (CNVs) in neurodevelopmental conditions such as autism spectrum disorders (ASDs) and intellectual disability (ID). It is expected that higher resolution arrays detect CNVs more accurately and allow identification of smaller CNVs. However, validation of smaller CNVs requires molecular methods and their clinical relevance is sometimes ambiguous, thus a cut-off of 200kb for deletion (del) and 500kb for duplication (dup) is frequently used in the clinical setting. Our work aims to determine the criteria for reliably detecting smaller CNVs and establishing their clinical relevance. We used the Affymetrix Cyto 2.7M Array first to validate 39 CNVs (31 Kb - 5.4 Mb) previously detected and confirmed by lower resolution arrays in 30 subjects with ASD and/or ID. All 39 CNVs were confirmed by the 2.7M array and in addition 10 previously undetected and unique CNVs, 100-500 Kb in size, were selected for validation using qPCR. Four of the 10 CNVs (40%) were confirmed (3 were maternal and 1 of unknown origin). We noted that array experiments with a high waviness-segment-count >10 tended to have CNVs that could not be confirmed, and we used this experience to select unique CNVs below the clinical size cut-off from 39 new subjects with a normal clinical array report. Eleven small unique CNVs (49~480 Kb) containing genes of potential brain function were assessed using qPCR. Eight (70%) were confirmed, including seven familial CNVs and one de novo dup (140 Kb) which encompasses intron 2 of KCNH7, a gene which regulates neurotransmitter release and neuronal excitability. A maternally transmitted 130 Kb dup covering exons 64-79 of the DMD gene was found in a 3 year old boy manifesting autism and neuromotor delay. Whilst his features were not strongly suggestive of DMD (with normal CPK testing) he did manifest delayed gross motor skills including crawling (at 14 months.), walking (at 20 months) and difficulty climbing stairs independently at 3 years. In light of the CNV finding, repeat CPK and neuromotor testing is continuing. In conclusion, the use of array quality control criteria such as waviness-segment-count helped decrease the number of false negative small CNVs from 60% to 30%. The small CNVs confirmed by qPCR and below the clinical cut-off tend to be of familial origin, and in most, but not all cases would be classified as variants of unknown significance.

1255W

A Genetic Study to Understand The Enigma of Holoprosencephaly. *M.I.K. Shehab[1], M. Zaki[2], H. Bassiouny[2], H. Kayed[1], M. Eid[1].* 1) Human Cytogenetics, National Research Center, Cairo, Giza, Egypt; 2) Clinical Genetics, National Research Center, Cairo, Giza, Egypt.

Holoprosencephaly (HPE) is a genetically heterogeneous disorder that affects the midline development of the forebrain and midface in humans. Classic HPE encompasses a continuum of brain malformations including (in order of decreasing severity): alobar, semilobar, lobar, and middle interhemispheric variant (MIHV) type HPE. These subtypes are defined primarily by the degree and region of neocortical nonseparation. Clinical suspicion of HPE is typically based upon compatible craniofacial findings, the presence of developmental delay or seizures, or specific endocrinological abnormalities, and is then followed up by confirmation with brain imaging. The aim of the work is to better understand and elucidate all of the clinical findings of this enigmatic syndrome in Egyptian patients. The study included HPE patients recruited during 2007-2011 from the Pediatric Neurology Clinics and Clinical Genetics Department, National Research Center, Egypt. Their age ranged from few minutes to 9.9 years (mean age is 3.3 ± 1.8 years). Patients were clinically examined to detect malformations and anomalies. A three generation pedigree was constructed with special emphasis on positive consanguinity and similarly affected family members. In addition, magnetic resonance imaging of the brain (MRI), electroencephalogram (EEG) recording, karyotyping and FISH were done for all patients. Furthermore, endocrinal functions, fundus examination and echocardiography were evaluated when indicated. A total of 25 HPE patients were studied; 15 males and 10 females. Brain imaging revealed, alobar in 6 patients (24%), semilobar in 15 patients (60%), lobar in 2 patients (8%) and MIH in 2 patients (8%). Positive consanguinity was present in 10 cases (40 %) while similarly affected family members were detected in 8 cases (32 %). All the living patients presented with delayed milestones. Poor temperature regulation was present in 12 patients (48%). Clinically, microcephaly (>-3 SD) was detected in 20 patients (80%). Chromosomal aberrations were detected in 7 (28%) of the patients . As a step towards elucidating the spectrum of the HPE, facial dysmorphism, cerebral signs and karyotype findings were highlighted.

1256W

Interstitial deletion of chromosome band 2p21 with eye anomalies. *G. LEFORT[1,2], J. PUECHBERTY[1,2], A. SCHNEIDER[1,2], M. TOURNAIRE[1,2], M. GIRARD[1,2], P. SARDA[2], P. BLANCHET[2], L. PINSON[2], D. GENEVIEVE[2], S. TAVIAUX[1,2], E. HAQUET[2], F. PELLESTOR[1,2], C. COUBES[2].* 1) Chromosomal genetics, Hôpital ADV, CHRU Montpellier, MONTPELLIER, Languedoc, France; 2) Medical genetics, Hôpital ADV, CHRU Montpellier, MONTPELLIER, Languedoc, France.

We report a patient with multiple congenital anomalies including bilateral eye anomalies with a 2p21 deletion diagnosed by microarray analysis. The patient was the third child of unrelated parents with an unremarkable family history. Pregnancy was uneventful. At birth, the male child was eutrophic and presented multiple congenital anomalies including lumbar lipoma and myelomeningocele, congenital dislocation of the right hip, right cryptorchidism and complex bilateral ocular malformation. The eye malformation concerned the anterior and posterior chambers of the eye and was interpreted as scleroderma of the cornea associated with chorioretinal atrophy. GH deficit was discovered at the age of 7 years and the patient received hormonal therapy. The patient was addressed to our Department of Medical Genetics at 17 years for genetic evaluation. At this time, the patient presented dysmorphic features (triangular face, prominent nasal bridge, dysplastic ears, microretrognathia, dental anomalies) and nail hypoplasia. The patient is blind but has no mental retardation. Course was marked by severe scoliosis which underwent surgical correction, and by paraplegia which was a sequella of surgery for lumbar lipoma. Standard cytogenetic studies showed a normal karyotype. Molecular biology analyses of the FOXC1, PITX2, and PAX6 genes found no mutations. Microarray analysis (SNP6.0 Affymetrix) revealed a “de novo” 1.46 Mb deletion of the 2p21 band. To date, few pure 2p21 deletions have been reported in the literature and recorded in genetic databases. The phenotypic expression of 2p21 deletion in our patient concerns mainly the ocular system and a few dysmorphic features. Among the 11 genes identified in the 2p21 band, there is no candidate gene for the eye anomalies. However the SIX3 gene, located approximately 375 kb proximal to the boundary of the deleted region, has been reported to participate in murine eye development. We postulate that a dysregulation of the SIX3 gene due to the adjacent deletion might be the cause of the eye anomalies in our patient.

1257W

CDH9 deletion in a patient with profound intellectual disability and autism spectrum disorder. *C. Soler-Alfonso[1], C.P. Schaaf[2], V.R Sutton[2], J. Wiszniewska[2], s.H. Lee Kang[2].* 1) Division of Medical Genetics, University of Texas at Houston, Houston, TX; 2) Department of Molecualr and Human Genetics. baylor College of Medicine, Houston, TX.

This report describes a female patient with a 5.830 Mb deletion at chromosome 5p14.1-p13.3. She presented for evaluation of profound intellectual disability and autistic behaviors. Array comparative genome hybridization revealed the aforementioned copy number variant, deleting only one annotated gene, CDH9. This gene encodes a type II classical cadherin from the cadherin superfamily, integral membrane proteins that mediate calcium-dependent interactions and play an important role in neuronal cell adhesion. In addition, common genetic variants in 5p14.1 have been associated with risk for autism spectrum disorders by genome wide association studies. Here, we report the first patient with CDH9 deletion, and present a detailed clinical and behavioral characterization. This reports strengths the proposed role of cadherin 9 in the etiology of autism spectrum disorders and intellectual disability.

1258W

Nanoscopic analysis of DNA segregation and chromatin accessibility during metaphase. *W.A. Khan[1, 2, 7], R.A. Chisholm[3], S.M. Taddayon[1, 4], A. Subasinghe[1, 5], J. Samarabandu[1, 5], L.J. Johnston[3], P.R. Norton[1, 4], P.K. Rogan[1, 6, 7], J.H.M. Knoll[1, 2, 7].* 1) University of Western Ontario, London, Ontario, Canada; 2) Pathology; 3) Steacie Institute for Molecular Sciences, National Research Council, Ottawa, Ontario Canada; 4) Chemistry; 5) Electrical & Computer Engineering; 6) Biochemistry & Computer Science; 7) Cytognomix Inc.

We have previously shown differences in accessibility of short fluorescence in situ hybridization DNA probes (FISH) to some targets on homologous metaphase chromosomes. To understand these differences, the topography of metaphase chromosomes visualized with atomic force microscopy (AFM) was correlated with the organization of integral chromosomal proteins by immuno-FISH. Initially, centromeric DNA of the alpha-satellite family was examined on chromosome 17 at nanoscale resolution. AFM revealed either two (bimodal) or three (trimodal) major ridge structures along the lateral axis of the centromere. Bimodal ridges demonstrated a wider average lateral extension (0.71 μm) relative to trimodal ridges (0.56 μm). This is indicative of sister chromatids at different segregation stages prior to splitting to their spindle poles. Upon correlating centromere 17 FISH with chromosome topography, alpha-satellite DNA fluorescence was coincident with the centromere ridge in only 23% of the chromosomes, and did not co-localize in the remaining chromosomes (n=22). Integrated intensities quantified by gradient vector flow analysis showed up to 34% difference between homologs, presumably due to polymorphisms in alphoid DNA length or differences in probe accessibility. Immunolocalization of a constitutive centromeric protein (CENP-B) at the base of the kinetochore coincided with the centromere ridge topography. Immuno-FISH studies showed that in ~ 50% of the cells, the alpha-satellite DNA was not coincident with the distribution of CENP-B protein. This suggests that the timing of centromere DNA segregation is not tightly coordinated with structural changes in the kinetochore attachment sites. Variability in chromosome topography was also studied at non-centromeric sequences along the length of the chromosome arms by correlated AFM and FISH. A short sequence-defined low-copy FISH probe spanning 3.4Kb, and detecting 3 separate homologous targets was analyzed. The targets were embedded in a segmental duplicon block in 16p12.1 with its paralogous targets 1.39Mb and 3.58Mb telomeric in 16p13.1. The context of this probe differed among homologs, as it hybridized to both ridge-like (n =11) and groove-like (n = 9) structural targets at similar frequencies. In summary, differences in metaphase hybridization patterns observed with short FISH probes (1.5-5Kb) may be related to the chromatin compaction state or the distribution of underlying epigenetic marks in mitosis.

1259W

A short stature girl with a complex chromosomes X and Y translocation. FISH and array-CGH studies. *V. Català[1,2], K. Torabi[1], E. Masip[1], T. Escabias[1], A. Serés-Santamaria[1], E. Cuatrecasas[1].* 1) Prenatal Genetics, Barcelona, Catalonia, Spain; 2) Unitat de Biologia Cel·lular i Genètica Mèdica. Facultat de Medecina. Universitat Autònoma de Barcelona. Spain.

The cytogenetic prenatal diagnosis in a twin pregnancy of two female fetuses, one of the karyotypes showed a translocation between chromosome X and chromosome Y [46,X,der (X) t(X,Y)(p22.33;q11.2)] and the other showed a normal female karyotype. The parents' karyotypes were normal, implying that the reorganization was de novo. At the time of birth, the karyotype of the twins to determine who was the translocation carrier was carried out. At the age of 10 years, the girl with the translocation has short stature, and the endocrinologist recommended a study of the SHOX gene given karyotype. The study for the SHOX gene by FISH (Cytocell) resulted in a deletion on the translocated X chromosome. Spanish Health administration for the use of Growth Hormone accept the treatment when the patient has an altered gene SHOX. Since in our laboratory was setting up the array-CGH technique, applied microarray platform Constitutional Focus BACS (BlueGnome, Cambridge, UK) and the result obtained was that the translocation involved the majority of the long arm of chromosome Y Including the AZF region genes. The follow up of the patient by the geneticist and the endocrine is very important because premature ovarian failure was descrived in adult patiens with similar translocations.

1260W

X-linked congenital hypertrichosis syndrome is associated with interchromosomal insertions mediated by a human-specific palindrome near SOX3. *X. Zhang[1], H. Zhu[1,2], D. Shang[1], M. Sun[1], S. Choi[3], P. Patel[3], T. Jing[2].* 1) Dept Med Gen, Peking Union Med College, Beijing, China; 2) Lanzhou University School of Basic Medical Sciences, Lanzhou, China; 3) Institute for Genetic Medicine, University of South California, Los Angeles, CA 90033, USA.

X-linked congenital generalized hypertrichosis (CGH), an extremely rare condition characterized by universal overgrowth of terminal hair, was first mapped to chromosome Xq24-q27.1 in a Mexican family. However, the underlying genetic defect remains unknown. We ascertained a large Chinese family with an X-linked congenital hypertrichosis syndrome combining CGH, scoliosis and spina bifida, and mapped the disease locus to a 5.6-Mb critical region within the interval defined by the previously reported Mexican family. Through a combination of high resolution copy number variation (CNV) scan and targeted genomic sequencing, we identified an interchromosomal insertion at Xq27.1 of a 125,577-bp intragenic fragment of COL23A1 on 5q35.3, with one X breakpoint within and the other very close to a human-specific short palindromic sequence located 82-kb downstream of SOX3. In the Mexican family, we found an interchromosomal insertion at the same Xq27.1 site of a 300,036-bp genomic fragment on 4q31.2, encompassing PRMT10 and TMEM184C and involving parts of ARHGAP10 and EDNRA. Noticeably, both the two X breakpoints were within the short palindrome. The two palindrome-mediated insertions fully segregate with the CGH phenotype in each of the families, and the CNV gains of the respective autosomal genomic segments are not present in the public database and were not found in 1274 control individuals. Analysis of control individuals revealed deletions ranging from 173-bp to 9,104-bp at the site of the insertions with no phenotypic consequence. Taken together, our results strongly support the pathogenicity of the identified insertions and establish X-linked congenital hypertrichosis syndrome as a genomic disorder.

1261W

Apparent monosomy 21- revision of the diagnosis Case report. *K. Adamová[1], M. Godava[1], M. Holzerová[2], M. Jarošová[2], V. Koudeláková[3], J. Šantavý[1].* 1) Department of Medical Genetics, University Hospital and Palacky University, Olomouc, Czech Republic; 2) Department of Haematology, University Hospital and Palacky University Olomouc, Czech Republic; 3) Laboratory of Experimental Medicine, Palacky University Olomouc, Czech Republic.

We report a case of a mentally and physically afflicted woman (33) with complete monosomy 21 (45,XX,-21) diagnosed by cytogenetic analysis 30 years ago. Patient presentes with severe mental retardation, cerebellar ataxia, convulsions, incontinence both fecal and urinary and facial stigmatization. As the complete monosomy 21 is rare and suggested to be incompatible with life other techniques were currently used to exclude potential partial monosomy and/or imperceptible structural rearrangement. G- banded karyotype showed repeatedly 45,XX,-21 whereas array utilising Cytogenetics Whole-Geonome 2,7M Array (Affymetrix) detected a large deletion of the proximal part of 21q and a small deletion of the terminal part of 6q. FISH performed both with centromeric and paint probes (CEP 13/21 Kreatech, WCP 6,21 Cambio) showed moreover a loss of the centromeric part of chromosome 21 along with translocation of the distal part of 21q onto the deleted chromosome 6. Revised karyotype of the patient is thus 45,XX,der(6)t(6;21)(q26;q21.3),-21.

1262W

Spectrum of chromosome abnormalities in spontaneous abortions: a chromosome CGH study of consecutive products of conceptions. *L. Apel-Sarid, K. Schlade-Bartusiak, B. Lomax, P. Eydoux.* Pathology, Children's & Women's Hosp, Vancouver, BC, Canada.

Chromosome abnormalities are a major cause of loss of pregnancy in the first trimester of pregnancy. The spectrum of chromosome abnormalities has been well characterized using karyotyping, but the failure rate of cell culture is high. Chromosome Comparative Genomic Hybridization (cCGH) in association with flow analysis allows characterization of the chromosome complement of products of conception without cell culture. We report on our 10-year experience of cCGH performed on 2233 products of conception. In our center, cCGH is performed for the following reasons: 1) Failed karyotype (56.2% of cases); 2) Material not available for karyotyping (11.2%); 3) Possible maternal contamination (Normal female karyotype obtained from chorion: 30.1%); 4) Other indications, including characterization of a chromosome abnormality detected on the karyotype (2.5%). CGH failed in 188 cases (8.4%). Chromosome abnormalities were detected in 796 cases (35.6%). Autosomal trisomy was the most frequent abnormality (509 cases, 63.9%). All chromosomes except 1 and 19 were represented; the most frequent abnormalities were trisomy 22 (11.6%), trisomy 16 (9.2%), trisomy 21 (7.7%) and trisomy 15 (5.7%). Double trisomies were seen in 7.7% of cases and triple trisomies in 1.1% of cases. Sex chromosome abnormalities were present in 74 cases, including 70 cases of monosomy X (8.8%). Monosomy 21 was present in 1.8% of cases and monosomy 9 was seen once. Polyploidy was detected by flow analysis in 6.2% of cases. Structural rearrangements were detected in 9.5% of cases. Four cases of isochromosome 8q were identified: this is a novel de novo recurrent rearrangement in products of conception. These frequencies are significantly different from those obtained after karyotyping in our laboratory or as reported in the literature. This difference is likely to be due to a lower success rate in culturing tissues from products of conception with specific abnormalities. In association with karyotyping results, this study allows better characterization of the overall spectrum of chromosome abnormalities in products of conception.

1263W

Micronuclei in bone marrow cells of mice exposed to chloroquine, in vivo. *I. Aranha.* Univ. do Estado do Rio de Janeiro, Rio de Janeiro Brazil.

Chloroquine is a drug that was initially used for the treatment of malaria but has also been successfully used for the treatment of arthritis and lupus eritematosus. In the present study, the bone marrow cells of mice were used to assess the effect of chloroquine, in vivo using the micronucleus assay. Six animals were injected intraperitoneally with the drug at a concentration of 25% LD_{50}. Chloroquine was injected during 5 consecutive days. On the sixth day the animals were sacrificed by cervical dislocation, femurs were removed, the bone marrows collected and smears were made for slides preparation. After 24 hours the cells were stained with Giemsa Gurr (2%) and analyzed under optical microscope. As positive control, 6 animals received cyclophosphamide once (50 mg/mL)and 6 animals not exposed to any drug served as negative control for the experiment. In the test group 12080 cells were observed, 93 with micronuclei. In the positive control group 12535 cells were analyzed and 173 showed micronuclei. In the negative control group 12697 cells were studied and 9 had micronuclei. The chi-square test for independence showed that chloroquine was the responsible for the micronuclei observed.

1264W

44,X,t(4;12)(q12;q13),der(13;14)(q10;q10).An unusual case in a girl with Turner syndrome and two diferent translocations. *G. Arteaga Ontiveros[1], C. Uria Gomez[1, 2], R. Garcia Cavazos[3].* 1) Genecon Diagnostico Laboratorio, Toluca, Mexico; 2) Facultad de Medicina UAEM Toluca, Mexico; 3) Unidad de Genetica Clinica y Perinatal, Mexico D.F.

The ocurrence of X chromosome monosomy and a Robertsonian translocation is a rare event. But the additional presence of a balanced reciprocal translocation is even more. To our knowledge, there are some reports of patients with Turner syndrome combined with a 13;14 translocation, but no one with an additional balanced reciprocal translocation. A 15 years old girl was referred to our laboratory for cytogenetic analysis because she presented phenotypic characteristics of Turner syndrome. Chromosomal analysis in peripheral blood lymphocytes with GTG bands showed 44,X,t(4;12)(q12;q13,der(13;14)(q10;q10) in all the metaphases. Parental karyotype were 46,XY and 45,XX,der(13;14)(q10;q10). Therefore, Robertsonian translocation in the proband is of maternal origin and balanced reciprocal translocation is de novo. The mother reports that she had two spontaneous abortions and have no more children. At the time of the study, the mother was pregnant. Prenatal diagnosis was offered but she refused to do. Studies in oocytes suggest Robertsonian translocation carriers have a higher risk of generating aneuploid oocytes. Probably in our case, the monosomy X was a consequence of interchromosomal effect, because the Robertsonian translocation could influence non-disjunction. The presence of balanced reciprocal translocation (4;12) could be attributed to the same effect.

1265W

Molecular and clinical characterizations of patients with tetrasomy and pentasomy 15q11q13. *L. Bao[1,2], J. Yang[2], Y. Yang[3], Y. Huang[2], H. Li[2].* 1) Divison Human Gen, Cincinnati Child Hosp Med Ctr, Cincinnati, OH; 2) 2Center for Clinical Molecular Medicine, Children's Hospital of Chongqing Medical University, Chongqing, China; 3) Shanghai Children's Hospital, Shanghai Jiaotong University Affiliated Children's Hospital, Shanghai, China.

Chromosome 15q11q13 contains a group of imprinted genes that play an important role in development. Deletions of paternal and maternal 15q11q13 segment are associated with Prader-Willi syndrome and Angelman syndrome, respectively. Although duplications of 15q11q13, particularly maternally transmitted have been reported in patients with developmental delays and autism spectrum disorders, there have been limited studies on tetrasomy for 15q11q13 and fewer on pentasomy for 15q11q13. Moreover,the relationship between genomic dosage of 15q11q13 and clinical phenotypes remains to be further defined. We identified two pediatric patients with development delays and mental disabilities. Conventional chromosome banding analysis revealed each had a large derivative chromosome 15, one with a karyotype of 47,XY,+del(15)(q14) and the other 47,XY,+del(15)(q21q26). High resolution whole genome SNP microarray analysis (Affymetrix Cytogenetics Whole-Genome 2.7 M Array) and FISH analysis revealed that both derivative chromosomes 15 are the products of duplication or triplication a 12-Mb genomic segment involving 15q11q13. The affected segment overlaps with the PWS/AS critical region on 15q11q13. The 47,XY,+del(15)(q14) was revised to 47,XY,+iso(15)(q13) and contains two extra copies or tetrasomy for 15q11q13, and the other derivative chromosome 15 was derived from triplication of 15q11q13 resulting three extra copies or pentasomy for 15q11q13 (revised karyotype 47,XY,+trp(15)(q11q13)). Gene expression and methylation study correlated maternal origin of the derivative chromosomes. Moreover, it was found that patients with penasomy 15q11q13 showed more severe mental impairments and speech delays than the one with tetrasomy 15q11q13. Our study underscores the importance of microarray analysis in characterizing chromosomal abnormalities and shed some light on molecular genetics of 15q11q13 aberrations and 15q11q13 dosage effects on clinical features.

1266W

Microarray characterization of a partial trisomy 1q23-qter in a premature liveborn male with multiple congenital anomalies. *K. Button, X. Li, J. Kobori.* Genetics, Kaiser Permanente, San Jose, CA.

Partial trisomy 1q is associated with multiple congenital anomalies and is rarely seen in liveborn. We report a case with the largest documented trisomy 1q in a liveborn premature male. A 29 Y old G2P1 female was referred for amniocentesis due to ultrasound anomalies discovered at 18w5d. Ultrasound findings included large left hydrothorax, right displacement of the heart, single umbilical artery, a unilateral left sided cleft lip and palate, nuchal thickening of 7-9mm, and bilateral clenched hands. Follow up ultrasound at 19w2d also showed a small right pleural effusion. The fetal echocardiogram at 19w4d showed no major structural heart defects. The heart is displaced towards the right due to a large left pleural effusion. At 20w2d the patient was notified of the chromosome abnormality and decided to continue the pregnancy. Ultrasound at 21w5d showed increased amniotic fluid, frank hydrops, generalized edema and ascites, and marked increase in the size of the left pleural effusion. Ultrasound at 26w5d showed polyhydramnios, worsening hydrops, massive left hydrothorax with severe mediastinal shift, hypoplastic lungs, severe ascites and skin thickening, ventriculomegaly, and a head circumference consistent with 39w gestation age due to soft tissue edema. At 29w0d the patient went into spontaneous labor. Male infant of 1620 grams was born breech with a weak heart rate of <60/min which dropped to 10-20/min within 5 minutes, and was absent by 7 minutes at time of death. Cause of death was respiratory and cardiac failure due to severe hydrops and pulmonary hypoplasia. The infant was described as mottled, blue, limp, apneic, with notable edema/hydrops of head and body. Autopsy was declined but the following dysmorphic features were noted: midface hypoplasia, microphthalmia, low-set poorly formed ears, cleft lip, and camptodactyly. Karyotype on the amniotic fluid was 46,XY,der(4)t(1;4)(q23;q35). Array CGH (Agilent/ISCA 8x60K) revealed a terminal duplication of 85.83 Mb from band 1q23.3-qter at genomic coordinates chr1:161,347,151-247,179,432 and a terminal deletion of 4.42 Mb from band 4q35.1-qter at genomic coordinates chr4:186,610,285-191,028,016. The patient's father has a balanced t(1;4)(q23;q35). The clinical features reported for patients with 1q duplications overlap with the current case except for the findings of hydrothorax and pleural effusion. Our patient also had some features previously described in association with 4q35 deletions.

1267W

X Chromosome structural variants in patients with intellectual impairment and developmental delay: summary of 2200 cases. *T.-J. Chen[1,2], Y. Wang[2], M. Li[1,3], M. Phelan[1].* 1) Hayward Genetics Center and Dept. of Pediatrics, Tulane University School of Medicine, New Orleans, LA; 2) Dept. of Pathology, College of Medicine, University of South Alabama, Mobile, AL; 3) Dept. of Molecular and Human Genetics, Baylor College of Medical, Houston, TX.

Structural aberrations of the X chromosome are major etiological factors for X-linked mental retardation (XLMR) and developmental delay (DD). We report results of aCGH studies performed as part of the clinical assessment of 2200 patients with unexplained intellectual impairment (II) or DD with or without dysmorphic features. Clinical information and aCGH results of the 2200 patients were collected from two clinical laboratories at Tulane University School of Medicine and University of South Alabama. aCGH studies were performed using the standard protocol recommended by the manufacturer on the Agilent 44K platform. We identified 55 cases (2.5%) of X chromosome abnormalities from the 2200 patients. There were 5 numerical X chromosome abnormalities (5/55, 9.09%), 2 X chromosome mosaics (2/55, 3.64%), 3 translocations (3/55, 5.45%), 27 duplications (27/55, 49.09%), and 18 deletions (18/55, 32.73%). The median size of the duplications was 407 kb (310 kb~9.355Mb), and the median size of the deletions was 1.43 Mb (346 kb~51.363Mb). The most recurrent aberrations were Xp22.31 with 5 cases of deletions and 7 cases of duplications, followed by Xq28 with 5 cases of deletion and 4 cases of duplication. All 5 deletions at Xp22.31 were males with clinical features of DD, II, ichthyosis, and behavior problems, while the 7 duplications at Xp22.31 included 4 females and 3 males. All 5 deletions at Xq28 were females with the deletion size ranging from 340 kb to 3.21 Mb. Three of these 5 deletions resulted in loss of the MeCP2 gene. The 4 cases of duplications at Xq28 included 2 males and 2 females. The duplication size ranged from 313 kb to 669 kb. MeCP2 duplication was identified in two cases. The clinical features of patients with Xq28 abnormalities were widely variable, even among the patients with deletions or duplications of MeCP2. In our previous report, the detection rate by aCGH for all structural chromosome abnormalities of the autosomes and sex chromosomes was about 11-14%. The current study demonstrates that approximately 20% of aCGH positive cases are due to X chromosome numerical and structural aberrations. Identification of these deletions and duplications will facilitate the discovery of XLMR genes, aid in characterizing the associated phenotypes and assist in defining the gene functions of X-linked genes.

A Fugitive Occupational Hazard related to Diamond Workers detected by Cytogenetic Alterations. *S. Chettiar[1], J. Dattani[2], D. Jhala[2].* 1) Depaartment of Biotechnology, Shree Ramkrishna Institute of Comp. Edu. App. Sci., Surat, India; 2) Department of Zoology, School of Sciences, Gujarat University, Ahmedabad, India.

Increasing economy and international trade policy of Government of India has resulted in 300% raise in diamond trade consequently hailing more than 1.5 million of worker in Surat itself engaged in diamond cutting and polishing. The introduction of new high speed grinding tools with a polishing surface of microdiamonds cemented in very fine cobalt powder, resulted in dusts of cobalt silicatic complex formed by the grinding and polishing which enter the physiology of the workers engaged in. Thus occupationally exposed to cobalt and other heavy metals individuals are reported with multiple symptomatic cobalt pneumopathy. Current exercise has been undertaken to evaluate the genotoxic effect of the diamond cutting and polishing process in diamond workers of Surat city. A cross sectional study was undertaken incorporating 14 individuals of diamond occupation with equitant age and sex matched cases controls. Individuals engaged in the occupation for more than five years were included in the study after availing written consent from the subjects. Venous blood (2ml) was collected and subjected to culture by standard Perioheral Blood Lymphocyte Culture (PBLC) and endpoints like chromosomal aberration and micronucleus were scored. Subjects exposed to cobalt and other heavy metals by procedural diamond cutting and polishing showed significant (P=0.001) increased aberration by elevated frequency of chromatid break and gaps. Incidence of micronculie was also enhanced in the individuals exposed as compared to control. Heavy metal exposure definitely brings about genotoxic effect in the individuals, thus curative and precautionary measures should be implemented in the work environment of diamond cutting and polishing industries.

IsoUPD as a mechanism of fetal rescue detected by Oligo-SNP array. *N. Christacos, S. Schonberg, Z. Dai, D. Boles, J. Kelly, M.L. Solvak, K. Burks, T. Simanivanh, P. Mowrey.* Dept Cytogenetics, Quest Diagnostics, Chantilly, VA.

We report the cytogenetic and microarray results of a 6 year old female with known mosaicism for a marker chromosome and clinical features that included macrocephaly, developmental delay and self injurious behavior. Conventional cytogenetic analysis confirmed the presence of a small marker (ring) chromosome. High resolution microarray analysis using an oligo-SNP array (Affymetrix 6.0) determined the ring chromosome to be derived from chromosome 7. Specifically, the ring was observed as a gain of 18.7 Mb at bands 7p11.2 to 7q11.23. Furthermore, there appeared to be an internal duplication within the ring (7) encompassing 2.8 Mb at nucleotide position 70,428,242 to 73,208,896 including bands 7q11.22 and 7q11.23. Such duplications within ring chromosomes have been reported previously and are believed to occur in processes closely related to those that give rise to the more commonly noted inverted duplications with terminal deletions. In addition, homozygosity for nearly all SNP markers on chromosome 7 was observed, corresponding to uniparental disomy or isoUPD7. Only the region encompassed by the ring appeared to retain heterozygosity. The genomic alterations identified are expected to cause phenotypic and/or developmental abnormalities. Duplication of proximal chromosome 7 by the presence of a ring chromosome is rare and as such, a clearly recognized syndrome has not emerged. Reported patients have in common speech and language delay, developmental delay and mild dysmorphic features. UPD for only a few chromosomes has been shown to have a phenotypic effect. The effects of the UPD7 are dependent on parental origin of imprinted regions. Maternal UPD7 is associated with Russell-Silver syndrome. Paternal UPD7 has not been associated with any consistent clinical findings. We hypothesize a mechanism of fetal rescue by early mitotic nondisjunction of the one normal copy of chromosome 7 inherited from one parent serving to rescue the lethal deletion represented by the r(7) inherited from the other parent. This is a unique case with a rare r(7) associated with complete isoUPD7. To our knowledge, cases with this pattern have not been reported. This case also illustrates how oligo-SNP array testing can be informative in demonstrating unanticipated levels of complexity and should be considered for patients with small ring chromosomes associated with abnormal clinical manifestations.

1270W

Molecular cytogenetic prenatal diagnosis of a fetus with a mosaic supernumerary neocentromeric derivative chromosome 13. *K. Chun[1,2], M. Hryshko[3], D. Konkin[3], S. Bal[3], D. Bernier[3], M. Tomiuk[3], S. Burnett[4,5], P. Frosk[4,5], B.N. Chodirker[4,5], A.J. Dawson[3,4,5].* 1) Molecular Genetics Laboratory, North York General Hospital, Toronto, Canada; 2) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Canada; 3) Cytogenetics Laboratory, Diagnostic Services of Manitoba, Winnipeg, Canada; 4) Section of Genetics and Metabolism, Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, Canada; 5) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Canada.

Neocentromeres are defined as a group of mitotically stable human derivative centromeres without alpha satellite DNA that are able to form a primary constriction and participate in kinetochore formation. Neocentromeres provide stability to rearranged chromosome fragments that would otherwise be acentric and rapidly lost. A 33-year-old G1P0 woman of English/Irish ancestry was referred to prenatal genetics following a screen positive maternal serum screen with a 1:129 risk of Down syndrome. Family and pregnancy histories were unremarkable. The patient's partner is 33 years old and of Scottish/English ancestry. There is no known consanguinity. The karyotype of the fetus was found to be: 47,XX,+mar[3]/46,XX[36]. Interestingly, one of these three colonies appeared itself to be a mosaic colony. FISH analysis with the whole chromosome paint (wcp) for chromosome 13 confirmed that the marker was of chromosome 13 origin. Based on the G-banded pattern, this supernumerary derivative chromosome 13 was interpreted as an inversion duplication of segments 13q21 through 13qter, with a neocentromere present at 13q21, in ~8% of colonies examined. A repeat amniocentesis showed the same karyotype in ~11% of colonies examined. Parental blood karyotypes were normal. QF-PCR performed on blood samples from both parents and the second amniotic fluid sample showed evidence of a second maternal allele at markers D13S258 (13q21) and D13S628 (13q31-q32). This suggests that the fetus may have originated as a trisomy 13, with attempted rescue resulting in a supernumerary neo(13), similar to the supernumerary der(15) that is sometimes associated with UPD15. The fetus was not UPD13, however, as evidenced by the inheritance of paternal alleles at D13S258 (13q21) and D13S628 (13q31-q32). After an induced abortion, the fetus was examined and noted to display mild dysmorphism with round facies, hypertelorism, down-slanting palpebral fissures and a bifid nasal bridge. Gross anatomy was unremarkable. Full autopsy was consented to and results are pending. A fetal blood sample at delivery showed mosaicism for the supernumerary neo(13) in 2 of 30 (~7%) cells examined. There is only one report of prenatal detection of a neo(13)(qter->q21:) (Mascarenhas et al., 2008). We report the second prenatally detected case of a mosaic neo(13), but the first case where the origin of a low level mosaic prenatal neo(13) was confirmed by QF-PCR.

1271W

Intragenic and sub-megabase deletions detected on whole genome screens in patients with developmental anomalies reveal loci potentially linked to novel disorders. *J. Compton, L. Schmidt, D.M. Riethmaier, A. Fuller, B. Boggs, G. Richard, J.M. Meck, S. Aradhya.* GeneDx, Gaithersburg, MD.

Chromosomal abnormalities account for a large proportion of the causes of developmental retardation in the pediatric population. Mendelian disorders are often clinically diagnosed and confirmed by sequencing of single genes rather than by molecular cytogenetic analysis. Whole-genome screens, such as high-resolution array CGH, are typically reserved for those patients with syndromic presentations and for whom a diagnosis is elusive. We have used whole genome array CGH in over 10,000 patients and identified pathogenic changes in 18%. Among these causative events, we have found several deletions that each affected only one gene associated with a Mendelian disorder. These genes included MECP2, NSD1, CREBBP, ROR2, and more than 25 others. Most of these were de novo events. We have also identified deletions less than 1 Mb that were de novo and affected less than five genes, one or more of which may contribute to the pathogenesis of hitherto unknown clinical syndromes. Our data highlight the importance of surveying at the individual gene level in whole genome screens for causes of developmental anomalies and point to loci potentially underlying novel genomic disorders.

1272W

Conventional and molecular cytogenetic characterization of a complex rearrangement involving 9p in an infant with craniofacial dysmorphism and cardiac anomalies. *D.L. Di Bartolo[1], M. El-Naggar[3], R. Owen[3], T. Sahoo[3], F. Gilbert[2], V. Pulijaal[1], S. Mathew[1].* 1) Department of Pathology and Laboratory Medicine, Weill Cornell Medical College/ NewYork Presbyterian Hospital, New York, NY; 2) Department of Pediatrics, Division of Human Genetics, Weill Cornell Medical College/ NewYork Presbyterian Hospital, New York, NY; 3) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

We present clinical, conventional cytogenetic, fluorescence in situ hybridization (FISH), array comparative genomic hybridization (aCGH), and single nucleotide polymorphism array (SNP array) data on a one-month-old female infant with a terminal deletion and an inverted duplication of the short arm of chromosome 9. Although numerous cases with either partial trisomy or partial monosomy of 9p have been reported, only four involved both duplication and deletion of 9p. Chromosome analysis of our patient identified add(9)(p23); FISH analysis established the add(9)(p23) as deriving from chromosome 9 and detected a terminal 9p deletion. Array CGH analysis, using more than 3,200 BAC markers genome-wide, further characterized the abnormality as a terminal deletion of about 11 Mb, from 9p23 to 9pter, and a duplication of about 27 Mb, from 9p23 to 9p13.1. The ISCN designation is as follows: 46,XX,der(9)del(9)(p23)dup(9)(p23p13.1).ish add(9)(p23)(wcp9+),del(9)(pter)(305J7T7-). arr 9pterp23(CTD-217316-->CTD-2601L6)x1,9p23p13.1(CTD-2320C9-->RP11-293C6)x3 SNP array, using the Affymetrix 6.0 platform, revealed no normal copy number segment between the deleted and duplicated segments, suggesting U-type reunion between sister chromatids, following a double strand break in both chromatids, as the underlying mechanism. Clinical features included craniofacial dysmorphism: wide open anterior fontanelle and sagittal suture, prominent nose, flat nasal bridge, long grooved philtrum, thin lips, and extra skin at the back of the neck. The patient also exhibited low muscle tone and a single transverse palmar crease on the left hand. An echocardiogram revealed a perimembranous ventricular septal defect, and a secundum atrial septal defect. Normal female external genitalia was present. In short, abnormalities common to both 9p deletion syndrome (trigonocephaly, flat nasal bridge, and long philtrum) and 9p duplication syndrome (hypotonia, bulbous nose, single transverse palmar crease, and cardiac anomalies) were observed. It is possible that cryptic terminal deletions in previously reported cases of 9p duplication may have gone undetected by conventional cytogenetic analysis. Characterization of 9p rearrangements, through the use of aCGH/ SNP array, is critical to provide an accurate genotype-phenotype correlation, to establish 9p deletion-duplication syndrome as a distinct clinical entity, and to define critical regions for the identification of candidate genes.

1273W

Submicroscopic genomic alterations investigated by array-CGH in Finnish and Brazilian patients with Müllerian Aplasia (MA). *E.L. Freitas[1], M. Sandbacka[2,3], H. Laivuori[3,4], M. Halttunen[5], P.A. Otto[1], K. Aittomäki[2,6], C. Rosenberg[1].* 1) Department of Genetics and Evolutionary Biology, Institute of Bioscience, University of São Paulo, São Paulo, Brazil; 2) Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Haartman Institute, Medical Genetics, University of Helsinki, Finland; 4) Research Programs Unit, Women's Health, University of Helsinki; 5) Department of Obstetrics and Gynecology, Helsinki University Central Hospital, Finland; 6) Department of Clinical Genetics, Helsinki University Central Hospital, Finland.

Developmental defects of the Müllerian ducts result in abnormalities of the female genital tract ranging from upper vaginal atresia to total absence of Fallopian tubes, uterus and upper vagina, while ovaries and secondary sexual characteristics are normal. Patients often exhibit additional renal and vertebral defects. In most cases of MA the etiology is unknown. The vast majority of patients with MA have a normal female karyotype. Previously, our group investigated by 1 Mb BAC array CGH syndromic MA patients and found chromosomal imbalances affecting 1q21.1, 17q12, 22q11.21 and Xq21.31 chromosome regions (Cheroky et al., 2008). Recently Nik-Zainal and collaborators (2011) found similar results in patients with isolated and syndromic MA, in addition to describe a recurrent microdeletion on 16p11.2 region. In order to verify whether smaller genomic alterations contributes to the etiology of MA, we investigated by high-resolution array-CGH 30 Finnish and 15 Brazilian MA patients. The Brazilian ones were previously screened and presented negative results on 1 Mb BAC array. For this study, we used a CGH microarray platform from Agilent Technologies containing 180.000 oligonucleotides. Among the Brazilian MA patients only described polymorphic copy number variations of DNA segments (i.e., without a major pathogenic effect) were detected. A possible explanation is that patients with chromosome alterations had already been ascertained by 1 Mb array and, therefore, were not included in the present study. Among the Finnish MA patients we detected two different deletions not commonly found in control populations, respectively at 16p11.2 and 17q12. Deletions in these regions have been previously related to the etiology of MA. The 17q12 deletion contains the LHX1 and HNF1B genes, both related to malformations of the female genital tract. The 16p11.2 deletion was found in 3/63 MA patients studied by Nik-Zainal et al. (2011), and our data supports the finding that this copy number change contributes significantly to the pathogenesis of MA. In conclusion, two out of 30 Finnish and none of the 15 Brazilian MA patients were found to carry deletions not found in control persons. The role of copy number variations need further study in MA.

1274W

Cytogenetic studies in primary amenorrhea cases. *E. Ghadirkhomi, H. Khani, S. Jafarzadeh.* Department of Cytogenetic, Genetic laboratory of ACECR (Jahad daneshgahi), Tabriz, East Azarbaijan,Iran.

Amenorrhea, is the absence of a menstrual period in a woman of reproductive age. It is a symptom with many potential causes such as an abnormality in the hypothalamic-pituitary-ovarian axis, anatomical abnormalities of the genital tract, or functional causes.In this study we aimed to investigate chromosomal abnormalities in patients present with primary amenorrhea employing GTG banding. Chromosomal analysis was carried out in 134 cases that were referred to our laboratory from 2006 to 2010. The karyotype results revealed 77.6% (n=104) with normal chromosome composition and 22.38% (n=30) showed chromosomal abnormalities. Among the patients with abnormal chromosome constituents 53.54% exhibit numerical aberration and 46.66% showed structural abnormalities.Chromosomal abnormalities among the patients can be classifie into five main types with or without mosaicism: 1-The most frequent karyotype was X chromosome aneuploidies (n=14) that include Turner syndrome 45,X (n=6),mosaic Turner 45,X/46,XX(n=7) ,and 48,XXXX(n=1). 2-Male karyotype 46, XY was present in 4 patients. 3-Structural anomalies of the X chromosome were detected in 10 cases .Four patients were found to have isochromosome of long arm of X chromosome [46X,i(Xq)],one patient has isochromosome of short arm of X chromosome [46X,i(Xp)],5 patient has partial deletion of X chromosome . 4-Mosaicism of male chromosome constitution and X chromosome aneuploidy was present in one cases (45XO/46XY). 5-Mosaicism of X chromosome aneuploidy and structural anomalies of X chromosome was found in one case 45,X/46,i(Xq)/47,X i(Xq)i(Xq). The present study has emphasized that karyotyping is one of the fundamental investigations in the evaluation of primary amenorrhea.

Duplication Of Chromosome 12 Due to Familial Balanced Robertsonian Translocation Case Report. *s.s.h. hammad, s.i.h helal, n.a. abdelmeguid, a.k.k kamel.* human cytogenetics, national research center, cairo, Egypt.

ABSTRACT Trisomy of the short arm of chromosome 12 is a rare chromosomal anomaly with an estimated incidence of 0.2:10,000 births and in the majority of reported cases the trisomy 12p results from malsegregation of a balanced parental translocation. Approximately 40 patients have been reported and the majority of reported cases resulted from malsegregation of a balanced paternal translocation, We report a case of a (45; XY) der (12) (qter•p12.3:: 12.3•pter). p13) and rob (13; 14) (q10; q10) by direct FISH. The mother is a carrier of a balanced robertsonian translocation 45, XX; t (13; 14).The father has a normal karyotyping. and in this case the clinical findings also reflect monosomy of the other chromosome involved in the original translocation. Keywards: Trisomy 12, Children with Special Needs.

1276W

Co-occurrence of 22q12.1-12.3 deletion encompassing the neurofibromatosis type 2 (NF2) locus in conjunction with 16p13.11 deletion in an infant with multiple congenital anomalies. *A.M. Jay[3,4], S. Ebrahim[1,2], D. Stockton[3,4], V. Misra[3,4], R. Awwad[3,4], M. Hankerd[1], A.N. Mohamed[1,2].* 1) Detroit Medical Center Univ. Lab. Cytogenetics; 2) Dep of Pathology, Wayne State Univ; 3) Children's Hospital of Michigan; 4) Department of Pediatric, Wayne State Univ, Detroit MI., USA.

We report on the cytogenetic and molecular characterization of two deletions involving chromosomes 22q12.1-q12.3 and 16p13.1 regions in a 3-days-old infant. The infant presented with ambigious genitalia and multiple congenital anomalies. Dysmorphic features included hypertelorism, prominent ear tags, micrognathia, flattened nasal bridge, and high arching palate, as well as duodenal and choanal atresia, intestinal malrotation and Pierre Robin sequence. The infant was born at 38 weeks of gestation to a 31 year G5P4 mother who had a previous infant born with congenital diaphragmatic hernia who died at 5 weeks of age. The mother also had one miscarriage which occurred at 11 weeks into the pregnancy. The current pregnancy was remarkable for severe polyhydramnios diagnosed by prenatal ultrasonography. After delivery via C-section, the patient's apgars were 8,9 and birth weight was 2.270 kg. A head ultrasound identified mild hydrocephalus with dilation of both lateral ventricles. At day two of life the infant had bilious emesis and had not passed meconium. Chromosome analysis revealed a female karyotype with a partial deletion of chromosome 22q. Chromosomal Microarray revealed that the deletion is ~ 8.9 Mb at 22q12.1-q12.3 region including the NF2 gene locus. In addition, a second deletion of ~1.24 Mb was found at 16p13.11 region. Parental testing is being pursued which may contribute further in elucidating the etiology of this patient's aberrations and prognosis. To our knowledge deletions of chromosome 22q12.1q12.3 encompassing the NF2 locus has been reported in two individuals with developmental delays and other congenital abnormalities, and has been implicated in the development of neurofibromatosis type II, a syndrome characterized by multiple tumors on the cranial, auditory and spinal nerves, and by other lesions of the brain. On the other hand, deletions of 16p13.1 region has been reported as a region of recurrent microdeletion, which may contribute to a specific clinical phenotype of epilepsy, significant learning difficulties and distinct facial dysmorphism.

1277W

MTHFR Gene polymorphism in mothers having Down syndrome babies. *A. Kaur, A. Kaur.* Human Genetics, Guru Nanak Dev University, Amritsar,143005, Punjab, India.

Down syndrome (DS) is most common chromosomal aneuploidy and a cause of human intellectual disability, with an incidence of 1-600/1-1000 live births. The origin of the extra chromosome is maternal in 95% of cases and is due to failure of normal chromosomal segregation/non-disjunction during meiosis. Folic acid has an important role in the process of genetic material distribution during cell division, because of its importance to cellular methylation reaction. The most common missense mutation is C-T substitution at the nucleotide 677 in coding region of MTHFR gene converting an alanine to valine residue in the gene product and creating a new Hinf I restriction site resulting in the MTHFR 677 C-T polymorphism and reduction in enzyme activity which may lead to a decrease in the levels of S-adenosylemethionine, inhibition of methyltransferase and subsequent DNA hypomethylation. Cytogenetic investigations of Down syndrome children is being carried out in our department. This study was undertaken with the aim of finding out the prevalence of the MTHFR C677T polymorphism in mothers having Down syndrome children in our region. Study was done on 41 blood samples from mothers of cytogenetically confirmed Down syndrome children and 31 control women with healthy children. Polymorphism was analysed by PCR-RFLP method and statistical analysis was done. The genotypic analysis showed that the frequency distribution of CC genotype was 24.4% while that of CT genotype was 75.6% in cases. Among controls, genotype frequency was observed to be 61.3% for CC, 35.5% for CT and 3.23% for TT. Among cases, allele frequency for 677C and 677T was found to be 0.62 and 0.38, respectively while in controls it was 0.8 and 0.21 respectively. Though chi square revealed statistically significant difference of the genotype frequencies between cases and controls ($\chi 2=12.17$); the odds ratio OR:0.204, 95% CI: 0.95-56 p>0.05) showed no association between cases and controls. The study is being carried out on larger sample.

1278W

Cytogenetic screening for female infertility: A Tunisian report. *O. KILANI[1], W. HAMMAMI[1,2], M. OUNI[1,2], W. AYED[1], A. FADHLAOUI[3], M. MEFTEH[3], F. ZHIOUA[3], S. HENTATI[1], N. ABIDLI[1], S. ABDELHAK[2], A. AMOURI[1,2].* 1) CYTOGENETIC LABORATORY, PASTEUR INSTITUTE OF TUNIS, TUNIS, Tunisia; 2) MOLECULAR INVESTIGATION OF GENETIC ORPHAN DISEASES RESERCH UNIT, IPT, TUNISIA; 3) GYNOCOLOGY OF AZIZA OTHMANA HOSPITAL, TUNIS, TUNISIA.

Infertility is an important health problem affecting 10-15% of couples. Of all couples classified as infertile, female infertility accounts for about 40-50% while 10-30% either is attributed to both male and female infertility or is unexplained. Some major causes underlying female infertility are polycystic ovary syndrome (PCOS), premature ovarian failure (POF) and recurrent pregnancy loss (RPL). The objective of the present study is to investigate the contribution of chromosomal abnormalities in infertile women. This study included 175 infertile women aged from 20 to 45 years who were referred to for routine cytogenetic analysis between January 2002 and January 2011. Chromosomal studies using peripheral blood and RHG-banding technique were performed on all patients. In some cases, FISH analysis using X centromere, Y centromere and SRY probes confirmed the cytogenetic findings. Cytogenetic study revealed chromosomal abnormality in 11 infertile women (6.28%). Structural chromosome abnormalities involving autosomes (45.45%) and sex chromosomes (54,54%) were detected. The results of this study are consistent with those reported in the literature which is associated with a greater prevalence of chromosomal abnormalities in infertile women compared with the general population. These findings show the importance of consider the cytogenetic study in the initial diagnosis protocol of infertile couples.

1279W

Validation studies of a disease-oriented whole-genome scanning as a diagnostic test for genetic and structural variations. *T. Kubota[1], S. Sakazume[2], T. Nagai[2], M. Kamiyama[3], K. Ichikawa[3], H. Sato[4], S. Saito[3].* 1) Fac Med, Epigenetic Med, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Pediatrics, Dokkyo Univ Koshigaya Hosp, Koshigaya, Saitama, Japan; 3) Riken Genesis Co Ltd, Riken Yokohama Inst, Yokohama, Kanagawa, Japan; 4) DNA Chip Research Inc, Yokohama, Kanagawa, Japan.

Thanks to advance of cytogenetic techniques with high resolutional DNA chip devices, a number of new genetic and structural variations have been reported. However, these assays potentially detect non-pathogenic variations, and they usually cost high. A whole-genome scanning panel that only contains disease-associated probes has recently been developed, but we do not know the clinical usefulness by the assay using this panel. Therefore, we validated the assay on the patient samples with various karyotypes.

400 ng of DNA extracted from the peripheral blood of the patients was hybridized on the HumanCytoSNP-12 BeadChip (Illumina) using Infinium beads assay. Karyotyping of the patients had been performed using conventional methods such as G-banding and FISH.

As a result, the new assay demonstrated that (1) there was no change between the original lymphoblast (LB) sample and the advanced passage sample, (2) the previously detected deletions of the patients with Prader-Willi syndrome (PWS) (n=1) and Williams syndrome (WS) (n=2) were precisely recaptured (furthermore, no single nucleotide difference was found between the two WS patients), (3) PWS uniparental disomy (UPD) case showed long range of loss of hetrozygosity, (4) precise deleted regions were shown in two translocation cases [46,Y,der(X),t(X;Y)(p22.3;q12)] and [46,XY,der(X)t(X;15)(p21.1;q11.2),-15], and (5) origin of the marker chromosome of [47,XY,+mar[27]/46,XY,[3]mos] was detected (14q12-q23.33).

These results indicate that the disease-oriented whole-genome scanning assay can accept advanced passage LB samples and that it may be used as a diagnostic test for various deletions, UPD status and marker chromosomes in mosaic cases.

1280W

Pericentric inversion of Y chromosome in an infertile man reported as a normal variant. *E.E. Kurt[1], O. Ozer[1], E.O Ote[1], H.B. Zeyneloglu[2], F.I. Sahin[1].* 1) Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Baskent University Faculty of Medicine Department of Gynecology and Obstetrics, Ankara, Turkey.

Pericentric inversions of Y chromosome have been reported to have an incidence of approximately 0,6-1/1000 in the general population. According to some authors, Y chromosome inversions have been regarded as rare chromosome heteromorphisms; however others report infertility impairment in inv(Y) cases. Here we report a 26 years old infertile male patient with a 46,X,inv(Y)(p11.2;q11.2) karyotype. The result of FISH analysis performed on metaphase spreads of the patient revealed that SRY was located on Yp, excluding a paracentric inversion. Hybridization with whole chromosome X and Y probes resulted in staining of the X and derivative Y chromosome respectively, excluding a translocation. The karyotype was reported as a normal variant and resulted in a pregnancy of the female partner achieved after intracytoplasmic sperm injection, with a male fetus possessing the same karyotype. Although the chromosomal rearrangement has been reported to be normal variant, specific cases could be associated with gene deletions which could not be detected with FISH analysis.

1281W

Monosomy 3p25.3 and trisomy 1q42.13 in a boy with multiple congenital anomalies, profound growth and developmental restrictions and early demise. *C. Li[1], V. Mahajan[2], J. Wang[1], B. Paes[1].* 1) Dept Pediatrics, McMaster Children's Hosp, Hamilton, ON, Canada; 2) Dept Pathology, McMaster University Medical Center.

Both monosomy 3p25 and trisomy 1q42 have been reported in the literature as recurring chromosomal anomalies. However to our knowledge the combination of both anomalies in one patient has not been documented. We report a newborn boy of abnormal karyotype with a combination of monosomy 3p25 and trisomy 1q42. The patient was noted to have multiple congenital anomalies that included brain malformation (under developed frontal lobes with abnormal gyration patterns and mildly to moderately enlarged ventricles), ocular anomalies, tracheo-laryngomalacia, cardiovascular malformation, intestinal malrotation, hypoplastic scrotum and bilateral undescended testes, in addition to hirsutism, melanocytic nevus, dysmorphic features and biochemical anomalies. Birth weight and height were at the 3rd % and the head circumference was at the 25th %. A routine karyotype revealed 46,XY,add(3)(p25). Parental karyotyping revealed a maternal balanced translocation between chromosome 1q42 and 3p25. Array-CGH analysis of the proband showed a gain of 21.556 Mb from 1q42.13 to 1qter and a loss of 10.788Mb from 3pter to 3p25.3. The revised karyotype was 46,XY,der(3)t(-1:3)(q42.13;p25.3)mat. The patient subsequently developed profound growth and developmental restriction. A review at 7 months of age revealed severe growth restriction with weight, height and head size all very significantly below the 3rd %. He also had profound psychomotor retardation without detectable head control, gaze fixation, social smile and localization to sounds. The patient expired at 9 months of age after cardiopulmonary arrest. To our knowledge this is the first case report with this unique chromosomal imbalance. As such it may also be of value to cytogenetics databases such as the ECARUCA (European Cytogenetics Association Register of Unbalanced Chromosome Aberrations).

1282W

A Down Syndrome Patient with a de novo Recombinant Chromosome 21. *G. LULECI[1], Z. CETIN[1], S. YAKUT[1], E. MIHCI[2], A.E. MANGUOGLU[1], S. BERKER KARAUZUM[1], I. KESER[1].* 1) Department of Medical Biology, Akdeniz UNiversity Faculty of Medicine, ANTALYA, Turkey; 2) Department of Pediatric Genetics, Akdeniz University, Faculty of Medicine, ANTALYA,-Turkey.

Pure partial trisomy of chromosome 21 is a rare event and these cases are very important for karyotype-phenotype correlations in Down syndrome phenotype. We present here a Down syndrome patient with a de novo recombinant chromosome 21. According to conventional cytogenetic and FISH analysis his karyotype was designated as; 46,XY, add(21)(p13).ish dup(21)(WCP21+, RUNX1+, KCNJ6++, DSCR4++,DSCR8++, VIJ2yRM2029++). Non-continuous trisomic, tetrasomic, euploid and monosomic chromosomal segments across the recombinant chromosome 21 was detected by Oligoarray CGH analysis. STR analysis showed that this de novo recombinant chromosome 21 was maternal in origin. The dual-specificity tyrosine (Y)-phosphorylation regulated kinase 1A and Down Syndrome Critical Region 1 genes located in Down syndrome critical region supposed to be responsible for most of the clinical findings of Down syndrome. Our case is the first Down syndrome patient with a de novo recombinant chromosome 21 resulting from multiple chromosome breaks did not contain DYRK1A and DSCR1 genes.

1283W

Intrachromosomal arm duplication-deletion rearrangements. *J. Meck, S. Warren, V. Nelson, L. Schmidt, L. Matyakhina, S. Aradhya.* GeneDx, Gaithersburg, MD.

We analyzed 10,000 cases of whole-genome array CGH in individuals referred mainly for developmental disorders. Among the 18% of individuals positive for known clinically significant genomic imbalances, 46 carried coincident duplications and deletions on a single chromosome arm. Five individuals showed mosaicism suggesting a mitotic aberration. The most frequently involved chromosome arms were 8p (n=8), 5p (n=4) and 1p (n=4). The deletions ranged from 200 kb - 29 Mb, while the duplications were 290 kb - 48.5 Mb. Thirty-three (73%) cases had duplications and deletions that were immediately adjacent to each other with no intervening normal copy number region. This observation indicates that a U-type exchange mechanism is more common for complex intra-arm rearrangements than NAHR mediated by low copy repeats, although other mechanisms likely exist. While some individuals carried an interstitial duplication-deletion aberration with a terminal region of normal copy number, most (23/33 = 70%) had terminal deletions. The most frequent aberration, on 8p, was often present as the classic inverted duplication-deletion with an intervening normal copy number segment of 4-5 Mb, a constant deletion size of 7 Mb, and a variable size duplication of 3.7 - 32 Mb. On the other hand, 8p aberrations with an immediately adjacent duplication and deletion and a terminal normal copy number segment, had variable normal copy number (8-13 Mb) and deletion (1.6 - 11 Mb) sizes. One way of correcting telomere loss, the initiating event in many duplication-deletion rearrangements, is by telomere capture from another chromosome. Telomere capture was shown by FISH in four individuals and inferred in another three in whom array CGH showed a terminal duplication on a non-homologous chromosome but FISH confirmation was not available. We also found complex duplication-deletion rearrangements associated with known microdeletion/microduplication syndromes in 17 individuals (37%). These syndromes included the 1p36, 2q37, and 22q13.3 deletion syndromes, as well as Wolf Hirschhorn, Cri du Chat, Williams-Beuren, Prader Willi/Angelman, Miller-Dieker, and DiGeorge/Velocardiofacial syndromes. The involvement of low copy repeats in mediating these recurrent deletions or duplications likely holds true for the more complex duplication-deletion rearrangements at these same loci. These data highlight the complexities of intra-arm rearrangements and offer insight into their frequencies and mechanisms.

1284W

Cytogenomic characterization of a dysmorphic patient with congenital multiple anomalies presenting a normal G-banding Karyotype. *V.F.A. Meloni[1], F.B. Piazzon[4], M.F.F. Soares[2], S.S. Takeno[1], D.M. Christofolini[3], L.M. Kulikowski[4], D. Brunoni[1], M.I. Melaragno[1].* 1) Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Department of Imaging Diagnosis, Universidade Federal de São Paulo, São Paulo, SP, Brazil; 3) Gynecology and Obstetrics Division, ABC School of Medicine, Santo André, SP, Brazil; 4) Department of Pathology, School of Medicine, LIM 03, Universidade de São Paulo, SP, Brazil.

Array techniques are improving the diagnosis success in patients with intellectual disability, dysmorphic features and multiple congenital anomalies revealing the etiology of new microdeletion and microduplication syndromes. We describe a female patient born as the first child of a non-consanguineous young couple. First genetic evaluation at six months of age showed: weight 4370g (< 3rd centile); length 62 cm (10th centile); OFC 37cm (< -2SD); microcephaly, trigonocephaly, prominent metopic suture, bitemporal narrowness, flat occiput, synophrys, arched and sparse eyebrows, strabismus, hypertelorism, upslanted palpebral fissures, prominent eyes, midface hypoplasia, long philtrum, microstomia, three superior oral frenula, small mandible, V-shaped cleft palate, small ears, pre-auricular sinus at left, short broad neck, wide-set nipples, large haluces, dislocation of the left 2nd toe, and hypoplastic labia majora and minora. She also presented hypotonia, tricuspid valve insufficiency and right atrium enlargement, seizures, recurrent pulmonary infection, and a gastrostomy had to be maintained for feeding. At 3 years and 11 months of age the patient died of bronchopneumonia. These clinical findings strongly suggested chromosome imbalance, but the chromosome analysis by G banding was a female normal karyotype. Considering the patient's abnormal phenotype, array and MLPA techniques were used, and a large 9p deletion associated to a 20p duplication was disclosed. FISH analysis was necessary to detect the balanced translocation t(9;20)(p22.2;p12.1) in the patient's mother. Our patient had typical 9p-deletion clinical manifestations and also some features of 20p duplication. This study shows the relevance of using molecular techniques to evaluate patients with dysmorphic features and multiple anomalies suggestive of chromosome aberrations, even if their karyotypes are found to be normal, in order to make the right diagnosis, establish an accurate genotype-phenotype correlation, be able to provide a better patient management and also an appropriate genetic counseling to their families. Key words: duplication 20p; deletion 9p; array; FISH; MLPA. This work was supported by FAPESP (Brazil).

1285W

Isodicentric 15q: Report of two Colombian cases. *P. Paez[1,3], J. Acosta[1,2].* 1) INGM Universidad el Bosque, Bogota, Colombia; 2) Instituto de Ortopedia Infantil Roosevelt, Bogota, Colombia; 3) Hospital Universitario Clinica San Rafael, Bogota, Colombia.

Introduction. Abnormalities of the 15q11-q13 region are a significant cause of autism spectral disorder (ASD), accounting for approximately 1% of cases. The 13 MB region encompassed by the scope of 15q11.2-q13 deletion and duplications syndromes contains at least 30 characterized genes. We present the two first Colombian individuals whit increased dosage of distal 15q and neurodevelopmental delay and ASD.Case1. This is a two years old boy born from of non consanguineous parents with generalized developmental regression, congenital hypotonia, autism spectrum and refractory epilepsy. The pregnancy and delivery were normal. No family history. Physical examination reveals minor facial dysmorphisms, marked truncal hypotonia, horizontal nistagmus, finger contractures in both hands, failure adequately to use eye toe eye gaze, facial expression, body posture and gesture. No language. Normal brain magnetic resonance, normal base line biochemistry (glucose, lactate, pyruvate, creatinkinasa), normal amino and organic acid screening. Karyotype: 47,XY + mar. Array Comparative Genomic Hibridization (CGH): isochromosoma 15 q 11,1; 15q 13.1 (47,XY +der 15q11-15q13.1). Case 2. This is a 6 years old female, born from non consanguineous parents, the patient has severe congenital hypotonia, microcephaly, developmental delay, language absent, sterotypies, refractory epilepsy , ASD and minor facial dysmorphisms. Karyotype: 47,XX,+(mar), SKY FISH analysis report 47,XX,+der(15) and (CGH) :Idic (15)(q11). Discussion. These are the first Colombian cases reported with this cytogenetics and molecular characterization. Chromosome 15q11-13 contains a cluster of imprinted genes essential for normal mammalian neurodevelopment. Idic (15) syndrome (inverted duplication of proximal chromosome 15 or isodicentric 15 chromosome) displays distinctive clinical findings represented by early central hypotonia, developmental delay and intellectual disability, epilepsy, and autistic behavior. These phenotypic features are present in our patients. International literature suggests that patients with ASD should be routinely screened for 15q genomic imbalances. Conclusion.This report let us confirm the utility of molecular and cytogenetic analysis in the clinical approach of these patients.

Ameliorative Potential of Melatonin and Curcumin on Fluoride and Arsenic Induced Genotoxicity in Human Blood Cultures. *H.H. Pant, M.V. Rao.* Department of Zoology, School of Sciences, Ahmedabad, Gujarat, India.

Effect of fluoride and arsenic at concentrations of 34uM and 1.5uM respectively were investigated with respect to Chromosomal anamolies(CAs), sister chromatid exchanges(SCEs) ,micronuclei(MN) and comet assay in human blood cultures. Further protective role of melatonin (0.2mM) and curcumin(7.7uM) were investigated on these treated blood cultures. The data revealed fluoride and arsenic induced significant genotoxic alterations as compared to control cultures. These effects were more in combination of toxicants. Upon addition of melatonin and curcumin these effects were reduced in treated cultures evidenced by percent amelioration. This could be due to antioxidant properties of these products ie., melatonin and curcumin. Further this protective effect of these antioxidents seemed to be similar. The siginificance of these data is highlighted in this investigation.

1287W

The importance of metaphase FISH analysis in parental follow-up of microarray CNVs. *P. Papenhausen[1], J. Tepperberg[1], R. Burnside[1], I. Gadi[1], V. Jaswaney[1], J. Smith[2], R. Potluri[2], E. Keitges[3], H. Risheg[3], S. Schwartz[1].* 1) Dept Cytogenetics, Labcorp America, Res Triangle Park, NC; 2) Dept Cytogenetics, Labcorp America, Houston, TX; 3) Dept Cytogenetics, Labcorp America, Seattle, WA.

Parental studies following the detection of a CNV in microarray analysis generally consist of either region specific BAC/oligonucleotide FISH performed on interphase and metaphase preparations or Q-PCR. The former supplies genomic location as well as dosage while Q-PCR can supply accurate dosage, but not location. While terminal associated gains and losses are strongly associated with transmission from a balanced translocation/inversion carrier parent, the incidence of interstitial imbalance resulting from a balanced parental insertion is not well known. Since these alterations have a high reproductive recurrence risk, are difficult to anticipate and would not be recognized by Q-PCR, their relative incidence is important. We report five cases of balanced insertions found in BAC metaphase FISH follow-up of interstitial CNVs: 1) a maternal carrier of a 9.3 Mb intrachromosomal insertion of 19q into 19p with two children receiving the duplication recombinant , 2) a paternal carrier of a 19 Mb insertion of 8q into 17q (inverted orientation) with the derivative 17 passed to the proband, 3) a maternal carrier of a 8.8 Mb 16q segment inserted into 5p with the proband inheriting the derivative five, 4) a complex maternal carrier of three separate segments of chromosome four (two from 4q and one from 4p) contiguously inserted into 19q13.1 with her son inheriting the derivative 19 and the combined 6.25 Mb insert, and 5) a maternal carrier of a 922 Kb intrachromosomal insertion of a 3q22.3 segment into 3q28 with a 517 Kb deletion at the insertion site. Unbalanced recombination in her son resulted in duplication of the 922 Kb segment along with the directly inherited deletion. These cases provide important information concerning parental follow-up of detected interstitial CNVs. If one makes a reasonable assumption that the common microdeletion/duplication syndrome intervals with flanking segmental repeats are due to NAHR and not subject to insertions (none were found in our studies), these cases represent about 1-2% of our parental follow-up of the remaining interstitial CNVs. The absence of small insertions was notable. All of the five cases involved significant imbalance with pathogenic impact. Since these have very high associated reproductive risk, the importance of utilizing FISH rather than Q-PCR for parental follow-up studies of this alteration subclass is paramount.

1288W

15 Years Experience :Egyptian Metabolic Lab. *E.M. Fateen, A. Gouda, M. Mahmoud.* Biochemical Genetics Departmen, National Research Centre, Cairo, Egypt.

Inherited metabolic diseases are a group of genetic disorders characterized by a specific enzymatic defects leading to accumulation of metabolites and pathologic sequel. The detection of metabolic disorders is either by measuring the enzyme activities or detection of the abnormal metabolites by the different available techniques. The Biochemical Genetics department, NRC started as part of the Human Genetics department 30 years ago and became a Biochemical Genetics unit 15 years later. Staring 2003 it becomes a separate Department serving whole Egypt. This is a retrospective study for the last 15 years of our experience ,where 14220 sample has been analyzed.6320 patient had been screened by thin layer chromatography. Aryl Sulfatase enzyme activity (ASA) had been measured to 502 patients 76 (15%) showed low activity (MLD),) - glucosidase activity had been measured to 1628 patients 200 (12.3%) showed low enzyme active (Gaucher patients), sphingomylinase activity was measured to 450 patients only 16 (2.7%) showed low activity (NPD type A), chitotriosidase activity was measured to 1940 and found high in 330 patients (34%)) galactocerebrosidase activity was measured to 37 patients and all showed normal activity, hexozaminidase A&B activities was measured to 476 patients 36 (7.6%) were diagnosed as Tay Sachs and 4 Sandhoff (1.6%).1145 patients were screened for MPS by quantitative determination of the GAGS. 540 of them (47.2%) showed high GAGS. Electrophoretic separation of GAGS diagnosed 278 (51.5%) MPS patients Morquio 39(14%),Hurler 79(28%),Hunter46(16%-),Sanphilippo 43(15.5%) Maroteaux lamy71(25.5%) 13 cases of Mucolipedosis Out of 2198 patients screened for PKU by quantitative determination of phenylalanine 156 (14.2%) showed high level Out of 447 patients the level of total galactose determined was high for 34 patients (7.6%).

Phenylketonuria Scientific Review Conference: State of the Science and Future Research Needs. *M.A. Parisi[1], T.K. Urv[1], R.R. Howell[1], K.M. Camp[2], P.M. Coates[2], H.D. Hyatt-Knorr[3], L.S. Nerurkar[3], J.H. Ferguson[3], S.C. Groft[3].* 1) Intellectual and Developmental Disabilities Branch, NICHD, NIH, Bethesda, MD; 2) Office of Dietary Supplements, NIH, Bethesda, MD; 3) Office of Rare Diseases Research, NIH, Bethesda, MD.

Phenylketonuria (PKU) is an amino acidopathy and one of the most common inborn errors of metabolism, typically caused by mutations in the phenylalanine hydroxylase gene. Newborn screening for PKU continues to be a successful public health program. Early identification and initiation of treatment in infants with PKU prevents intellectual disability in children and adults, and severe symptoms of untreated PKU are rarely seen. The National Institutes of Health (NIH) last published a screening and management statement for PKU as the result of a Consensus Conference held in 2000. Although the cornerstone for treatment of PKU has been a specialized diet with protein restriction, there is now a pharmacologic intervention, tetrahydrobiopterin (BH4; Kuvan), that can allow liberalization of diet for those who respond. In addition, technological advances now allow for molecular testing that can inform genotype-phenotype predictions, as well as facilitate prenatal diagnosis and identification of carriers. The combination of new treatments, new screening technologies, and a larger body of literature on outcomes for persons with PKU warrants revisiting the 2000 guidelines to determine their current applicability. In order to address this need, an NIH Scientific Review Conference will be held in early 2012, to consider recent research findings, current treatments, the role of BH4, and future research priorities. Five working groups of topical experts (clinicians and researchers), patients and advocacy group members, and federal stakeholders have been established to answer specific questions related to PKU that will be addressed at the conference. These include: Diet Control and Management; Pharmacologic Interventions; PKU and Pregnancy; Long-Term Outcomes and Follow-up; and Molecular Testing, New Technologies, and Epidemiologic Considerations. In a parallel and concordant effort, an Evidence-based Practice Center (EPC) of the Agency for Healthcare Research and Quality (AHRQ) is conducting an evidence-based review of the comparative effectiveness of BH4 and diet in the treatment of PKU. The EPC report will be available in late 2011. Together, the PKU Scientific Conference and the Evidence-based Practice Center report will provide information on important issues, recommend future research, and provide guidance to patients, their families, and health care professionals on the current understanding of PKU.

1290W

Clinical features of L-2-Hydroxyglutaric aciduria and mutations of the L2HGDH gene in 4 Arab kindreds. *M. Ul Haque[1], M. Al-Sayed[3], E. Faqeih[6], M. Jamil[4], M. Amoudi[5], N. Kaya[5], H. Abalkhail[2], A. Al Abdullatif[2], M. Rashed[5], M. Al-Owain[3], M.A. Chishti[1], I. Peltekova[7], S.H.E. Zaidi[8].* 1) Pathology, King Saud University, Riyadh, Saudi Arabia; 2) Department of Pathology and Laboratory Medicine, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Department of Medical Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Department of Radiology, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 5) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 6) Department of Pediatric Medicine, King Fahad Medical Citiy, Riyadh, Saudi Arabia; 7) Department of Medicine, Queen's University, Kingston, Canada; 8) Ontario Institute for Cancer Research, Toronto, Ontario, Canada.

L-2-hydroxyglutaric aciduria (MIM: 236792) is an autosomal recessive neurometabolic disorder in which affected individuals display elevated levels of L-2-hydroxyglutaric acid in urine, blood and other body fluids, central nervous system abnormalities, and elevated risk of brain tumor. In this disease, several mutations have been described in the L2HGDH gene, which encodes for the L-2-hydroxyglutarate dehydrogenase. This study describes the biochemical data, clinical presentations, and radiological findings of patients from consanguineous Arab families and genetic analysis of the L2HGDH gene. We have identified misssense mutations and a single nucleotide deletion in the L2HGDH gene of DNA isolated from the blood of the patients. The missense mutations produce amino acid changes and the single nucleotide deletion produce truncation of the L-2-hydroxyglutarate dehydrogenase protein. Recently it was reported that the single nucleotide mutation in the Italian and the Portuguese patients had a common origin, as they share an identical SNP haplotype of the disease-causing chromosome. Here we show that in Arab patients, this mutation has arisen independently as they carry a SNP haplotype that is different from the hapolotype reported for the Italian and the Portuguese patients. These suggest that mutations in the L2HGDH could arise independently in patients of different ethnic origins. This study is the first detailed description of clinical manifestations and molecular analysis of Arab patients with L-2-hydroxyglutaric aciduria. As such the present study is significant for the diagnosis and management of Arab L-2-hydroxyglutaric aciduria patients.

TIDE-BC: IMPLEMENTATION OF AN EVIDENCE-BASED PROTOCOL TO IDENTIFY TREATABLE METABOLIC DISORDERS CAUSING INTELLECTUAL DISABILITY. *C. van Karnebeek, S. Stockler.* Biochemical Diseases, Pediatrics, B C Chld & Womens Hlth Ctr, Vancouver, Canada.

Background: Intellectual disability (ID) is a debilitating condition with deficits in cognitive functioning (IQ<70) and adaptive skills, affecting 2.5% of children/adults worldwide. Currently, diagnostic yield rather than treatability directs the etiologic work-up. As causal therapy has become available for many inborn errors of metabolism (IEM) with the potential to improve health outcome, this approach might be changed. **Aims:** To collect and transform the available evidence on treatable IEM as a cause of ID into a protocol which prioritizes treatability in the diagnostic evaluation of ID patients. **Methods:** Two independent reviewers performed all systematic review steps according to Cochrane Collaboration guidelines, and translated the data to formulate an evidence-based diagnostic protocol in consensus with international experts in the field in the field. **Results & Discussion:** The review identified 75 `treatable IEMs' presenting with ID as a major feature and provides data to change the following paradigms: 1) treatable IEM are not a rare cause of ID, rather as a group these 75 may comprise a considerable proportion of ID; 2) treatable IEM are not extremely difficult to identify; 50% are identified by routinely available group tests and for the remaining disorders (requiring a `single test for single disease approach') digital tools have been developed to direct the evaluation based on additional neurologic/systemic manifestations (www.treatbleID.org). 3) Therapeutic modalities are not always expensive; aside from 1 IEM requiring substrate inhibition and 8 IEM requiring stem cell transplant) the remaining 56 therapies with proven effect were accessible and affordable (diet, co-factor/vitamin supplements). 4) The level of evidence (LoE) for these treatments is not always limited; 25% ranked at level 1 or 2. Even with a low LoE, the effect on outcome (IQ, developmental performance, behavior, epilepsy, neuro-imaging) can be considerable. **Applications:** This knowledge has been translated into a step-wise protocol prioritizing the identification of treatable ID, which integrates the use of digital tools to help the clinician. Implementation in a tertiary care centre is underway as part of our funded study ` Treatable Intellectual Disability Endeavor in BC (www.tidebc.org)', of which we will report our first experiences (yield, usability, physician satisfaction, effectiveness).

FIVE MAPLE SYRUP URINE DISEASE CASES REPORT IN A 16 YEARS PERIOD OF TIME AT THE HOSPITAL PARA EL NINO POBLANO, MEXICO. *H. Velazquez[1], J. Aparicio[2,4], M.L. Hurtado[3], I. Marroquin[3], A.G. Rojas[3], P. Concha[1], F. Gutierrez[1], R. Herrera[1], E. Huitzil[4].* 1) Neonatology; 2) Genetics; 3) cytogenetics, Hospital para el Nino Poblano, Puebla; 4) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico.

The congenital inborn errors of metabolism (IEM) were identificables diseases since 1908. Some of the most frequent IEM reported are fenilketonuria, galatosemy as albinism, cystinuria and porfiria and more rarely maple syrup urine disease reported in this study. is caused by a deficiency of the branched-chain alpha-keto acid dehydrogenase complex (BCKDC), leading to a buildup of the branched-chain amino acids (leucine, isoleucine, and valine) and their toxic by-products in the blood and urine. Case reported. 102 clinical cases with polymalformed muscle esqueletal and skull and dental dismorfies from this Hospital were already published. Only 5 patients with maple syrup urine disease have been reported in a 16 years period of time. Only the clinical evolution of one of the patients is reported in this study. Conclusions. Actually, the IEM are defined as monogenic inherited diseases or mendelian, due to a metabolic error for a protein or enzyme absence. It might be incompatible with the patient life and sometimes if the patient lives it will modify its quality of life, especially in a severe metabolic disease as it is maple syrup urine disease.

1293W

Hypertrophy of the clava, a new MRI sign in patients with PLA2G6 mutations. *A. Al Maawali[1], G. Yoon[1,2], W. Halliday[3], JTR. Clarke[1], A. Feigenbaum[1], B. Banwell[2], D. Chitayat[1], S. Blaser[4].* 1) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 2) Division of Neurology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 3) Division of Pathology, DPLM, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 4) Division of Paediatric Neuroradiology, The Hospital for Sick Children and University of Toronto, Canada.

Background and Purpose: Heterogeneous phenotype and delayed diagnosis are common in infantile neuroaxonal dystrophy (now infantile PLAN) due to PLA2G6 gene. Onset in infantile PLAN is by 2 years with psychomotor delay. Ataxia, truncal hypotonia, optic atrophy, dementia, tetraparesis and death follow. Onset in atypical INAD (now childhood PLAN) is later with a prolonged course. We characterise clinical and MRI phenotypes in 7 children with PLA2G6 mutations. Materials and Methods: An REB approved retrospective study for MRI and medical record review identified 7 confirmed patients. Results: All 7 had novel PLA2G6 gene mutations. 6 had infantile PLAN, onset by 12 months, psychomotor delays, hypotonia, rapid progression to a non-ambulatory state by 5 years and mean age of death of 10 years. One with childhood PLAN, who presented at 3 years with abnormal behaviour and delays in fine and gross motor coordination and language, remains ambulatory at 17 years. MRI showed hypertrophied clava in 7/7 regardless of age. Previous reports, as well as brain autopsy in one of our patients, note prominent spheroid bodies in the clava nuclei. All 7 had chiasmatic atrophy and abnormal signal surrounding the peritrigonal optic radiations at any age. Vermian-cerebellar atrophy was present as early as 17 months and present in all after 21 months. All developed a bright cerebellar cortex. This finding, present as early as 17 months, was not initially present on MRI in 2 patients who were 25 and 33 months old respectively. All infantile PLAN patients had transient bright signal in nucleus accumbens. Globus pallidus iron deposition was seen in 4/7, the earliest at 29 months. Iron was inconsistently identified as magnet strength and sequence have variable magnetic susceptibility. Only 1 child developed significant supratentorial atrophy. Conclusion: Neuroimaging in children with PLA2G6 mutations may be non-specific early in the disease course, resulting in delayed diagnosis. We identify an additional early MRI finding in patients with PLA2G6 mutations, clava hypertrophy. This feature may predate vermian atrophy and cerebellar cortex signal increase and was present at any age in our patient cohort of PLA2G6 confirmed patients. The presence of clava hypertrophy may aid in earlier identification of those who would benefit from specific PLA2G6 mutations genetic testing, allowing specific genetic counselling including prognostication and prenatal testing.

1294W

Unravelling the leukodystrophies: clinical, biochemical and molecular studies of sixty Brazilian patients with genetic white matter disorders. *C. Lourenco[1], GN. Simão[2], AC. Santos[2], CAR. Funayama[1], C. Sobreira[1], W. Marques Jr[1].* 1) Neurology, Univ Sao Paulo, Ribeirao Preto, Brazil; 2) Internal Medicine, Univ Sao Paulo, Ribeirao Preto, Brazil.

Background: Leukodystrophies are a group of rare genetic diseases that affect myelin, the major constituent of brain and spinal cord white matter. An integrated description of the clinical, neuroimaging and pathophysiological features is crucial for categorizing myelin disorders. Aim: To describe the clinical/biochemical evaluation of 60 patients with a white matter disorder. Methods/patients: All patients were evaluated in neurogenetics clinics. A full medical history was taken and the following were performed: neuroimaging studies (CT, MRI with spectroscopy), ophthalmologic and auditory evaluations, neurophysiologic studies (EEG, ERG, EMG/NCV), hormone and biochemical tests, muscle biopsy with OXPHOS analysis, screening for IEMs (lysosomal studies; peroxisomal/sterol panels; cholestanol dosage; organic acids, sulfatides and aminoacid chromatography; analysis of GAGs) and, when indicated, nerve/skin biopsy for EM studies, karyotype and molecular tests. Results: In forty patients was possible to stablish a diagnosis for the leukodystrophy. X-ALD, metachromatic leukodystrophy and Krabbe disease were the commonest inborn errors of metabolism implicated in the pathophysiological of the “metabolic leukodystrophies”. Infantile Refsum disease, Canavan disease, AMACR deficiency, Niemann-Pick type C were other rare IEMs diagnosed. It was worthy of note the fact that Vanishing White Matter disease was a leading cause of leukodystrophies in our patients (eight patients). Conclusion: Almost 50% of patients with white matter abnormalities remain without a specific diagnosis even after an exhaustive investigation. Therefore a specific protocol for investigation is crucial. Treatment options are becoming a reality for some disorders , so reaching a specific diagnosis is important so that patients can be offered appropriate therapeutics.

1295W

Identification of a novel cause of autosomal dominant, adult-onset distal myopathy. *M.C. Malicdan[1], C.F. Boerkoel[1], Y. Huang[1], J. Kwan[2], C. Groden[1], W.A. Gahl[1], C. Toro[1].* 1) Undiagnosed Diseases Program, Office of Rare Disease Research, and Medical Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD; 2) National Institute of Neurological Disorders and Stroke, NHGRI, National Institutes of Health, Bethesda, MD.

Distal myopathies are genetically heterogenous diseases. Associated disease genes are known to encode proteins in the sarcomere (titin, myosin), plasma membrane (dysferlin, caveolin), or cytoskeleton (desmin, myotilin, (B-crystallin, ZASP, filamin C, and nebulin). Despite this progress, the majority of cases remain undefined and a systematic explanation for a disease mechanism is lacking. Only one cause of adult-onset distal myopathy affecting predominantly the posterior compartment has been genetically characterized. We define a second genetic cause in a two-generation family. Affected individuals have progressive weakness of distal muscles beginning late in the third decade of life without evidence of neuropathy, increased serum creatine kinase, respiratory involvement, or cardiac symptoms. MRI studies showed fatty replacement of the posterior compartments of the legs, mainly of the medial gastrocnemius. Muscle pathology showed variation of fiber size due to fiber atrophy and esoinophilic cytoplasmic inclusions that were devoid of desmin, plasma membrane proteins and oxidative activity. There were no rimmed vacuoles. Ultrastructural studies showed non-membrane bound fibrillary deposits 6-12 microns in diameter in the Z-bands. Whole exome and Sanger sequencing excluded mutations in known genes associated with distal myopathy and identified an intronic splice site mutation causing exon skipping and encoding a frameshift mutation in an unstudied enzyme. Based upon the dominant inheritance and comparable expression of the mutant and wild type mRNAs, the truncated enzyme is an antimorph or neomorph. We present spatiotemporal expression analyses and elucidate the cellular function of the enzyme and the potential disease mechanism.

MUCOPOLYSACCHARIDOSIS: OTORHINOLARINGOLOGICAL AND AUDIOLOGICAL EVALUATION AND TREATMENT. *J.C. Neto, L.S. IKARI, J.C. BERTONCELLO, M.G. ANDRADE, S.M. MARONE, B.B. TAGUCHI, J.A. FRANCISCO.* Genetics, Pontificia Universidade Catolica Faculdade de Medicina , SãoPaulo, São Paulo, Brazil - Adress: Largo de Padre Pericles, 145 cj 12 São Paulo SP 01156-040.

BACKGROUND: The mucopolysaccharidoses are lysosomal storage disorders resulting from the deficiency of a lysosomal enzyme involved in the degradation of glycosaminoglycans. Nowadays this topic has been in evidence because of the morbidity and mortality of the disease and because it causes many disorders since the mucopolysaccharidoses is a progressive multisystem disease and may lead to difficulties in diagnose. About the otorhinolaryngological disorders, these patients may present: hearing loss, otorrhea, recurrent otitis, enlarged tonsils and adenoids, recurrent sinusitis, speech disorders, snoring, apnea, mouth breathing and nasal obstruction. The study of this pathology, the clinical presentation and audiological data provides theoretical support for patients with mucopolysaccharidosis, involving multidisciplinary treatment and resulting in better quality of life for them. OBJECTIVES: Evaluate patients with MPS regarding their ERT, clinical history, audiologic data and therapy at the Clinic of Otorhinolaryngology of PUCC Hospital, during 12 months of treatment with infusion CONCLUSION: According to this study, the results concluded that patients with mucopolysaccharidosis have different changes in otorhinolaryngological physical exams and symptoms. All of them had great improvement in all clinical aspects of the reassessment after 12 months of enzyme infusion. The audiological evaluation of patients was essential for the diagnosis of hearing loss, because it allowed the improvement of the audiological quality with hearing aids. Regular monitoring of the clinical status of patients with mucopolysaccharidosis receiving enzyme infusion is needed to determine long-term benefits.

Gene expression aberrations in brains of CLN3 deficient mice suggest possible pathways in Juvenile Batten Disease. *N. Dolzhanskaya, M. Velinov.* NYS Institute for Basic Research , Staten Island, NY.

Juvenile Batten Disease (JBD) is the most common condition in the group of devastating neurodegenerative disorders referred to as Neuronal Ceroid Lipofuscinoses. JBD is typically the result of homozygocity for mutations in the gene CLN3. Better understanding of this gene's function and the consequences of its deficiency may help develop strategy for treatment of JBD that would include correcting/modifying such downstream consequences. We have studied genome-wide brain expression in a mouse model of JBD referred to as CLN3Δex7/8 mice. This model creates a close molecular approximation to the common human CLN3 mutation. To-date we have studied 6 male and 6 female brains of 5 month - old mice, homozygous for the CLN3 mutation and 12 age and gender matched littermates homozygous for the wild allele as controls. Array expression analysis was done on brain homogenates using the 44K expression array system of Agilent Inc. Analysis of the obtained results was done using GeneSpring 11.0.2 data analysis software. We have observed aberrant expression in over 300 genes, with cutoff of minimum 2 times difference with controls. Some of the expression abnormalities noted in our studies replicated those previously reported in primary neuronal cultures derived from the CLN3-/- mouse model. For instance we also observed up-regulation of genes Frg1 and Synaptoporin. Twelve coding genes in our study had more than 3 times increased expression in homozygous mutant brains compared to controls. These were as follows: Zer1, Pttg1, Phb, Ube2i, Pgpep1l, Ndufa2, Gm10240, A330084C13, Gh, Ccr6, Gdp3. Five genes had 3 or more times decreased expression compared to controls. These genes were: Hoxb 13, Hoxd8, Tlr1, Zfp264, Spint3. From the genes listed above, of most interest to us are Ndufa2 and Ccr6. Ndufa2 is an enzyme that is part of mitochondrial complex I. Homozygous mutations in this gene result in a phenotype of Leigh syndrome in humans. Abnormalities in the mitochondrial function as part of the disease mechanism in JBD were previously suggested. Ccr6 has a possible role in the T-lymphocyte entry into the CNS. Immune abnormalities as part of the disease mechanism in JBD were also previously suggested. In conclusion, our studies further confirm the evidence of several important pathways in JBD progression involving mitochondrial dysfunction, neuronal dysregulation and immune abnormalities.

Association between a new 3216-3217 delGA mutation in AGL gene and common haplotype in Tunisian population: evidence for a founder effect. *M. GRIBAA[1], A. MILI[1,2], I. BEN CHARFEDDINE[1], O. MAMAI[1], L. ADALA[1], T. BEN LAZEREG[1], A. AMARA[1], J. BOUGUILA[3], D. H'MIDA[1], K. LIMEM[2], A. SAAD[1].* 1) Human Cytogenetics, Molecular Genetics and Reproductive Biology Laboratory. Farhat Hached hospital. Sousse - Tunisia; 2) Biochemistry Department. Faculty of Medicine. Sousse - Tunisia; 3) Paediatric Department. Farhat Hached Hospital. Sousse - Tunisia.

Glycogen storage disease type III (GSD III) is an autosomal recessive disorder characterized by excessive accumulation of abnormal glycogen in the liver and muscles and caused by deficiency in the glycogen debranching enzyme, the amylo-1,6-glucosidase (AGL). In this study, we report the clinical, biochemical and genotyping features of two unrelated GSD III patients from the same region in Tunisia. Erythrocytes glycogen concentration and AGL activity were measured by colorimetric and fluorimetric methods respectively. Four CA/TG microsatellite markers flanking the AGL gene in chromosome 1, were amplified with fluoresceinated primers. The full coding exons and their relevant exon-intron boundaries of the AGL gene were directly sequenced for the patients and their parents. The two patients showed a striking increase of erythrocytes glycogen content. No AGL activity was detected in peripheral leucocytes. Sequencing of the AGL gene identified a novel 3216-3217 delGA mutation in the two patients which is predicted to a premature termination, abolishing the AGL activity. Haplotype analysis showed that the mutation was associated with a common homozygote haplotype. Our results suggested the existence of a founder effect responsible for GSD III in this region of Tunisia.

1299W

Characterization of biomarkers during investigative therapy of hydroxy-propyl-beta-cyclodextrin in Niemann-Pick Type C disease. *D.W. Killilea[1], J. Suh[1], N. Mattsson[2], H. Zetterberg[2], E. Portelius[2], K. Blennow[2], Y.H. Hung[3], A.I. Bush[3], C.A. Hastings[4].* 1) Nutrition & Metabolism Center, Children's Hospital & Research Center Oakland, Oakland, CA; 2) Clinical Neurochemistry Laboratory, Sahlgrenska University Hospital, Molndal, Sweden; 3) Oxidation Biology Laboratory, Mental Health Research Institute, University of Melbourne, VIC, Australia; 4) Children's Hospital & Research Center Oakland.

Niemann-Pick Type C (NPC) is a lysosomal storage disease associated with mutations in NPC1 or NPC2 genes and characterized by progressive neurologic dysfunction. Pathological changes include accumulation of unesterified cholesterol, mineral dysregulation, oxidant stress, and neurofibrillary tangles (NFT), but characterization of these biomarkers remains incomplete. Hydroxy-propyl-beta-cyclodextrin (HPBCD) has been used in NPC animal models to reverse cholesterol trafficking defects and significantly lengthen life expectancy. We are currently treating identical twin girls with NPC with HPBCD (intravenously (IV) and intrathecally (IT)) under the FDA's Individual IND exemptions and monitoring changes in specific biomarkers. Oxysterols, beta-amyloid (A-beta) and total-Tau (T-Tau) levels, mineral levels and metabolomic compounds were assessed in plasma and cerebrospinal fluid (CSF). Plasma oxysterols were reduced during the course of the IV infusions. CSF T-Tau levels were higher in NPC patients than in normal controls, decreased following IT HPBCD, increased during a period of time without drug, and (in one twins) decreased again with drug re-initiation; this pattern suggested time-dependent changes in neuronal pathology over the course of treatment. CSF A-beta peptide levels generally decreased over the course of treatment. Initial evaluation of mineral levels in the CSF indicated that homeostasis was altered. CSF copper, iron, and zinc levels fell below the normal pediatric reference range, though were not re-established with IT HPBCD; however, changes in calcium and potassium did return to the normal range following IT drug course. Mineral dysregulation is likely to affect tau expression and promote NFT formation. NPC-dependent changes in mineral homeostasis might contribute to various pathologies in the disease, such as tau expression and NFT formation. Measurements of sulfur amino acid redox states showed decreased plasma GSH and ergothioneine levels, whereas only ergothioneine was found to be decreased in erythrocytes. The lower plasma GSH and ergothioneine content suggest that NPC is associated with impaired thiol antioxidant defense that may contribute to neurodegeneration. Monitoring of oxysterols, trace minerals, tau proteins, and ergothioneine may give us new insight into common pathways of neurodegeneration and might be useful for clinical management and development of new therapeutic strategies for NPC patients.

Abnormal Metabolomic Profiles in Pregnancies Complicated by Small-for-Gestational-Age. *M. Shinawi[1], D. Dietzen[1,2], A. Odibo[3], A. Gronowski[2], K. Moley[3].* 1) Dept Pediatrics, Division of Genetics and Genomic Medicine, Washington Univ in St. Louis, St Louis, MO; 2) Department of Pathology and Immunology, Washington Univ in St. Louis, St Louis, MO; 3) Department of Obstetrics and Gynecology, Washington Univ in St. Louis, St Louis, MO.

Background: Small for gestational age (SGA) babies are prone to increased perinatal morbidity and mortality and increased risk for hypertension and metabolic disorders in later life. The etiology is incompletely understood, and there is no clinically useful early detection test. A significant proportion of SGA infants fail to achieve their optimal and genetically determined growth potential resulting in intrauterine growth restriction (IUGR). There is accumulating evidence suggesting that the SGA may result from uteroplacental insufficiency and/or compromised placental supply of nutrients to the fetus. The aim of this study is to identify maternal metabolomic signatures that specifically characterize SGA in early pregnancy. **Methods:** We conducted a discovery-phase, nested case-control metabolic profiling study using blood samples obtained at 11-14 weeks' gestation from 31 women who subsequently delivered SGA babies and gestational age-matched 31 controls taking part in a study for adverse pregnancy outcomes. Serum samples were analyzed for acylcarnitine species and amino acids using gas chromatography-tandem mass spectrometry (LC-MS/MS). Analyte distributions in the control and SGA group were compared using the Kruskal-Wallis technique (SPSS 18.0.3). **Results:** We found 5 metabolites (cystine, hydroxyproline, ornithine, histidine, and lysine) that were significantly different ($P<0.05$) between pregnancies complicated by SGA and controls. The arginine/ornithine ratio and hydroxyproline were significantly higher ($P<0.005$ and $P < 0.026$ respectively; and $P< 0.001$ when combined) in the cases with SGA. The area under the curve (AUC) using arginine/ornithine ratio and hydroxyproline was 0.75. **Conclusions:** These specific metabolomic signatures offer insight into SGA pathogenesis and suggest a potential presymptomatic screening test for this condition.

1301W

Correlation Assessment among Clinical Phenotypes, Expression Analysis and Molecular Modeling of 14 Uncharacterized Mutations in the Human Galactose-1 phosphate Uridylyltransferase Gene. *M. Tang[1], A. Facchiano[2], R. Rachamadugu[1], F. Calderon[3], R. Mao[3], L. Milanesi[4], A. Marabotti[2,4], K. Lai[1].* 1) Diviosn of Medical Genetics, Departmet of Pediatrics, University of Utah, Salt Lake City, UT. U.S.A; 2) Laboratory of Bioinformatics and Computational Biology, Institute of Food Science - CNR, Via Roma, 64, 83100 Avellino, Italy; 3) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT 84108, U.S.A; 4) Laboratory of Bioinformatics, Institute of Biomedical Technologies - CNR, Via F.lli Cervi, 93, 20090 Segrate (MI), Italy.

Galactose-1 phosphate uridylyltransferase (GALT) catalyses the conversion of galactose-1 phosphate to UDP-galactose, a key step in the Leloir pathway of galactose metabolism. Deficiency of GALT activity in humans caused by deleterious mutations in the GALT gene can lead to a potentially lethal disease called Classic Galactosemia (CG). In this study, we selected 14 uncharacterized nucleotide sequence changes in the GALT gene associated with reduced GALT enzyme activities in patients for expression analysis and molecular modeling. When over-expressed in GALT-less *Escherichia coli* host, all but two (Y34N and H132Q) of the 14 mutant GALT proteins were expressed at level comparable to the wild-type control. Yet decreased abundance in the soluble fraction of the *E. coli* cell extracts were observed for all 14 mutant GALT enzymes, suggesting altered stability and solubility among these mutants. Interestingly, one mutation, I170T (c.509T>C), is located at the second nucleotide of exon 6 and might potentially affect splicing in human patient cells. When the mutant proteins were purified from the soluble bacterial host extracts, six mutant GALT enzymes (R201C, E200K, R233S, I278N, L289F and E291V) had detectable enzymatic activities that correlated with the clinical data. Kinetic studies showed the K*M* of these six mutants for both substrates didn't change significantly, especially for gal-1P. However, the V_{max} of these mutants decreased significantly. To further understand how these mutations affect the enzyme, we performed molecular modeling using MODELLER software, and analyzed mutants searching for variations in their structural features. Major structural effects were predicted for the Y34N, R201C, E220K mutants and some structural effects, especially at local level, were anticipated for all the others mutants but V168L, I278N and L289F. For the H132Q and P185H mutants it is possible to hypothesize a catalytic problem since these residues make an interaction with a residue in the active site. Perturbation in stability was also predicted for the majority of mutants. Overall, these studies confirm the complexity of the effect of mutations on GALT enzyme, since a combination of multiple factors, probably involving also the dynamics of the protein, is responsible for its altered enzymatic activity.

1302W

Transcobalamin deficiency ; a treatable metabolic cause of severe pancytopenia and recurrent infections. *Y.J. Trakadis[1], T. Rupar[2], S. Melancon[1], A. Alfares[1], B. Schrewe[1], D. Watkins[1], D.S. Rosenblatt[1], N. Braverman[1].* 1) Department of Medical Genetics, McGill University Health Centre and Department of Human Genetics, McGill University, Montreal, Qc; 2) Departments of Biochemistry and Paediatrics, University of Western Ontario, London, ON.

Case presentation: After an uneventful pregnancy and delivery, a baby boy born to first cousin consanguineous parents from Sri-Lanka, presented at 3 months of age with failure to thrive, generalized hypotonia and pancytopenia (Hb: 58g/L, MCV: 95.1fL). He became transfusion-dependent for both platelets and red blood cells and required nasogastric feeding. He developed recurrent opportunistic infections and chest abscesses despite intravenous antibiotics, leading to severe respiratory failure requiring intubation. He had persistent neutropenia and lymphopenia with low levels of T and B cells. A bone marrow showed dysplastic features. Cytogenetic studies, including chromosome breakage and 7q31 deletion FISH, were normal. A repeat bone marrow biopsy showed hypercellularity and this time megaloblastic features were also noted. The differential diagnosis included leukemia. A genetic-metabolic work-up showed high blood total homocysteine levels, high methylmalonic acid (MMA) levels in both blood and urine, and low blood methionine levels. The serum cobalamin level was low (112 pmol/L at 4 months of age), but the folate level was within the reference range. A diagnosis of transcobalamin (TC) deficiency was reached based on a very low uptake of [57Co]-cyanocobalamin in cultured fibroblasts in the absence of a source of exogenous TC. Molecular analysis of the TCN2 gene showed a novel homozygous mutation (c.1013_1014delinsTAA) leading to a premature stop-codon at codon 364. Treatment with hydroxycobalamin 1 mg IM QD and folate 1 mg PO QD with regular follow-up in the genetics clinic resulted in normalization of hematological, immunological, and biochemical markers and clinical status improved dramatically. No further transfusions were needed. He was progressively weaned off oxygen and restarted on oral feeds with good weight gain and improved development (currently 15 months of age). **Discussion**: TC transports vitamin B12 from blood into cells. TC deficiency is a rare disorder and has not been detected routinely where newborns are screened for MMA. A delay in diagnosis can result in life-threatening infections, anemia and neurological disease. Similar to the present patient, most mutations reported have been deletions or insertions resulting in frame shifts and predicted protein truncation. TC deficiency should be considered in any newborn suspected for leukemia. Response to treatment is excellent but the long term prognosis is not known.

1303W

Additive effect of variants in TNFRSF11A and TNFRSF11B genes in the etiopathogenesis of Paget's Disease of Bone. *F. Gianfrancesco[1], G. Morello[1], D. Rendina[2], T. Esposito[1], D. Merlotti[3], M. Di Stefano[4], S. Gallone[5], R. Nuti[3], P. Strazzullo[2], G. Isaia[4], L. Gennari[3].* 1) Inst Gen & Biophysics, National Research Council of Italy, Naples, Italy; 2) 2Department of Clinical and Experimental Medicine, Federico II University Medical School, Naples, Italy; 3) 3Department of Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, Italy; 4) Department of Internal Medicine, University of Turin, Italy; 5) Department of Neuroscience, University of Turin, Italy.

Paget's disease of bone (PDB) is a metabolic disorder characterized by focal abnormalities of bone remodelling. Mutations in SQSTM1 gene were identified as a common cause of the autosomal dominant mode of inheritance, but the aetiology of multifactorial inheritance remains unclear. We identified a variant (rs2073617) located in the promoter region of the gene TNFRSF11B (-223 C/T), encoding Osteoprotegerin, associated with PDB in 811 affected individuals and 367 controls ($P=1.62x10-8$, Odds Ratio=1.65, CI=1.38-1.97). T risk allele produces a binding site for the transcriptional repressor Egr1 that decrease the serum concentration of Osteoprotegerin in 56 individuals analysed (3,9 pmol/L, 4,2 pmol/L and 4,5 pmol/L in individuals with TT, CT, CC genotype, respectively). Moreover, we evaluated an additive effect between this variant and the recently identified functional variant in TNFRSF11A (V192A) encoding RANK receptor. OPG risk allele shows an OR of 2.98 while the OR for the Rank risk variant was 1.78. Additive effect between these two variant was confirmed with an OR of 4.09. In conclusion, these results provide evidence that -223 C/T variant in TNFRSF11B gene influence etiopathogenesis of multifactorial form of PDB together with variant in TNFRSF11A.

1304W

New cellular models for MPS IVA and LINCL lysosomal storage disorders using patient specific induced pluripotent stem cells. *A. Swistowski, M. Richards, M. Vellard.* Research and Development, BioMarin Pharmaceutical Inc, Novato, CA.

Mucopolysaccharidosis type IVA (MPS IVA) and Late-infantile neuronal ceroid lipofuscinosis (LINCL) are hereditary diseases of childhood. MPS IVA is caused by a deficiency of N-acetylgalactosamine-6-sulfate (GalNAc-6-sulfate) sulfatase (GALNS) an enzyme, which is needed for lysosomal degradation of keratan sulfate (KS) and chondroitin-6-sulfate (CS). GALNS deficiency has an impact on the phenotypic properties of chondrocytes in particular, resulting in the formation of cartilage that is more prone to degeneration. LINCL is a neurodegenerative disease that is caused by mutations in the gene CLN2 encoding the lysosomal protease tripeptidyl peptidase 1 (TPP1). Lack of TPP1 activity leads to accumulation of storage materials in the brain and consequently to CNS degeneration and neurological decline. Research on these diseases is significantly limited by either complete lack (CLN2) or limited availability of material from patients. Novel cellular reprogramming technologies allow derivation of induced pluripotent stem cells (iPSCs) from patient cells, which can further be differentiated into relevant cell types of interest. Generation of such cells is without doubt a great alternative for researches as it may provide an unlimited source of patient specific material and thus facilitate more accurate research on various types of diseases. We have successfully generated MPS IVA and LINCL disease specific iPSCs by transducing patient fibroblasts with retroviruses individually encoding the four human transcription factors (Oct4, Sox2, Klf4, and c-Myc). Here, we describe the process of derivation of these cells and their characterization, as well as our progress in differentiating them into chondrocytes, macrophages (MPS IVA), neurons and glia (LINCL). The purpose of our work is to generate valid cellular models for studying mechanisms of pathology and development of cell based assays for monitoring efficacy of enzyme replacement therapy in these diseases. To our knowledge these are the first iPSCs based models for MPS IVA and LINCL.

1305W

First clues of a possible inflammation process in MPS IVA (Morquio): keratan sulfate-induced macrophage activation. *Y. Zhu, M. Vellard.* BioMarin Pharmaceutical Inc., Novato, CA, USA.

Mucopolysaccharidosis IVA (MPS IVA or Morquio) is an inherited lysosomal disease that is caused by N-acetyl-galactosamine-6-sulfate sulfatase (GALNS) deficiency. Insufficient GALNS activity leads to the accumulation of keratan sulfate (KS) and chondroitin-6-sulfate (C6S) primarily in chondrocytes and cartilage. Clinical symptoms of Morquio include abnormal bone and heart development, bell-shaped chest, coarse facial features, hypermobile joints and short stature. Recently, emerging evidence suggests that inflammation might play a role in the pathophysiology of other MPS disorders. This study investigates possible inflammation processes in Morquio, particularly focusing on the inflammatory responses of macrophages in the presence of KS. Macrophage cell lines THP-1 and RAW 264.7 as well as human primary peripheral blood mononuclear cells from healthy donors were treated with various doses of KS. The release of cytokines and chemokines and time dependent activation of intracellular signaling pathways were examined. Additional cellular functions (e.g. chemotaxis, cell growth, viability) were also documented using corresponding assays. In summary, we have observed that several cytokines and chemokines were released from macrophages following KS treatment. Furthermore, an acute stimulation of macrophages with KS led to the activation of several intracellular signaling pathways. Our results indicate that KS can induce the activation of intracellular signaling pathways and the release of pro-inflammatory cytokines and chemokines in macrophages. The distinct pattern of the macrophage-derived factors in response to KS suggests the presence of a specific receptor. These data support a pro-inflammatory role of macrophages in MPS IV disease and possibility of finding specific biomarkers of inflammation in Morquio.

Genome-wide expression profiling in the Sjögren-Larsson syndrome (SLS). *J.-B. Roullet[1], S. Impey[1], Q. Yang[1], R.D. Steiner[1], W. Rizzo[2].* 1) Pediatrics, Oregon Health & Science University, Portland, OR; 2) Pediatrics, University of Nebraska Medical Center, Omaha, NE.

Background: SLS is caused by mutations in ALDH3A2 which codes for fatty aldehyde dehydrogenase (FALDH). The typical phenotype includes congenital ichthyosis, spastic diplegia or tetraplegia, and mental retardation. Seizures occur frequently and patients often present with pathognomonic white glistening dots in the retina. SLS pathophysiology remains poorly understood and there is no effective treatment. Objectives: to characterize the molecular changes caused by FALDH deficiency. Methods: Genome wide expression profiling (RNA-Seq) was performed using skin fibroblasts isolated from a patient with SLS in comparison with a skin fibroblast cell line obtained from an unaffected individual. Results: The SLS gene expression profile showed significant ($p \leq 10\text{-}5$) down-regulation of ~2,400 genes (total = 31,400 genes) including genes implicated in skin diseases (ADAMTS2, COL1A1 & COL3A1/Ehrlers-Danlos syndrome, SOCS3/atopic dermatitis, KRT10/bullous ichthyosis, SAT1/keratosis), spastic diseases (KIAA0196, ZFYVE26), psychomotor disorders/mental retardation (B4GALT1 & GBA/Gaucher disease, ATXN1/spinocerebellar ataxia, CSTB1/progressive myoclonic epilepsy, GRIK2/long-term potentiation and memory, NDN/Prader-Willi), neurogenesis (NEFM & NEFL/axonal type Charcot-Marie Tooth disease, GOLSYN/formation of presynaptic boutons, NETRIN/axon guidance), and eye diseases (ADAMTSL4/ectopia lentis, EFEMP1/Doyne-honeycomb retinal dystrophy, C1QTNF5/retinal degeneration, SLC1A47/retinal glutamate transporter, EYA2/forebrain patterning). Approximately 4000 genes were upregulated including genes implicated in the regulation of cell cycle, DNA repair, cytoskeleton integrity, endoplasmic reticulum function and intracellular protein trafficking. An increase in genes particularly relevant to SLS pathogenesis (SOX5/inhibitor of oligodendrocytes differentiation, ARHGD1B/inhibitor of actin cytoskeleton formation, KRTAP-1 & KRT19/keratin production, and PKP1/skin ectodermal structure) was noted. Conclusions: The study provides the first account of the impact of FALDH deficiency on gene expression. The data show that gene expression is severely altered in SLS and suggest potential molecular mechanisms underlying the dermatologic, neurological and retinal manifestations of the disease. Future studies with cell lines from other patients or from brain cells derived from animal models of the disease are needed to confirm and expand these findings.

1307W

Genetics variants implicated in COPII-mediated vesicle formation in chylomicron retention disease. *R. Sanchez[1], E. Levy[1,2], C. Garofalo[1], D. Sinnett[1,3].* 1) Research Center CHU Ste-Justine, University of Montreal, Montreal, Canada H3T 1C5; 2) Department of Nutrition, University of Montreal, Montreal, Canada H3C 3J7; 3) Department of Pediatrics, University of Montreal, Montreal, Canada H3C 3J7.

The COPII coat protein complex II (COPII) mediates formation of transport vesicles that bud from the ER, an essential process for traffic of secretory proteins to the Golgi organelle. Importantly, COPII vesicles play a crucial role in the transport of chylomicrons and VLDL lipoproteins in enterocytes and hepatocytes respectively. The basic functional units of the COPII complex are the proteins Sar1B, Sec23/Sec24, and Sec13/Sec31. To date, three human diseases have been found to result from disruption of COPII-related genes, chylomicron-retention disease (CRMD) (Sar1B gene), cranio-lenticulo-sutural dysplasia (CLSD) (Sec23A gene) and congenital dyserythropoietic anemia (CDAII) (Sec23B gene). Given the wide range of biochemical and clinical manifestation of CRMD, we suspect the presence of new genetics variants (SNPs) in the different genes contributing to the formation of the COPII complex. To detect SNPs that could be associated with CRMD phenotypes, we resequenced the exons of Sar1B, Sec23B, Sec24B, Sec13 and Sec31 genes. Genomic DNA from peripheral blood cells was isolated from 14 CRMD patients that have been treated for a fat malabsorption syndrome associated with diarrhea and steatorrhea. We identified 3 coding SNPs in Sar1B gene; 2 in exon 4 and one in exon 8. However none of these SNPs was polymorphic in the group of patients (n=14). Concerning the Sec genes, we found two SNPs in Sec23B gene (Ile426Val and Leu433-Pro). The allelic frequencies for these polymorphisms (Ile426Val and Leu43-3Pro) were significantly higher in patients versus control individuals. To investigate the impact of these polymorphisms in the COPII function, we performed site directed mutagenesis to create the different alleles combining these two SNPs. We transfected these plasmids in HepG2 cells, while simultaneously silencing the endogenous Sec23B gene. To characterise the role of these Sec23B variants in the function of COPII complex, we will measure enzymes (ACAT, MTP, MGAT, and DGAT) implicated in secretion of lipoproteins. In conclusion modifier genes in the ER to Golgi COPII-dependent transport might play an important role for absorption, assembly transport and metabolism of cholesterol in cells.

1308W

Evaluation of endothelial function by Endothelial Pulse Amplitude Testing in Patients with Mucopolysaccharidosis. *S. Yano, K. Moseley.* Pediatrics/Gen Div, 1G24, LAC+USC Med Ctr, USC, Los Angeles, CA.

Background: Progressive cardiovascular changes have been known as one of the major causes of death in patients with mucopolysaccharidosis (MPS). All types of MPS have been reported to present with cardiovascular manifestations. Evaluation of endothelial function (EF) by flow-mediated dilation (FMD) of the brachial artery has been studied and endothelial dysfunction (ED) characterized by decreased percent mediated dilatation was demonstrated in individuals with risk factors for atherosclerosis. Close relation of EF in coronary and brachial artery has been demonstrated. Studies to evaluate peripheral vascular EF with finger arterial pulse wave amplitude (PWA) with a finger plethysmograph (PAT) have been performed and showed that PAT hyperemia and FMD were significantly correlated. Histopathological studies of the coronary artery stenotic lesions in a patient with MPS-I showed the characteristic findings with abnormal intimal proliferations and decreased nitric oxide synthase activities in the endothelial cells that are also seen in atherosclerosis. Objectives: To evaluate coronary artery ED in MPS patients for early detection of coronary artery lesions. Material and Methods: Finger arterial PWA with a PAT device (Endo-PAT2000) was used to evaluate coronary EF. Total of 17 patients were studied: MPS-I (11), II (2), III (2), VI (1), and Mucolipidosis (1). All MPS-I and II patients have been treated with enzyme replacement therapy with laronidase and idursufase, respectively, more than 3 years. The patient with MPS-VI had bone marrow transplantation at age 3 years. Results: Ten out of 11 patients with MPS-I, and one MPS-II, one MPS-III, and one MPS-VI patients showed abnormal results. Conclusion: A high prevalence rate of ED was demonstrated in patients with MPS by the finger PAT device. Evaluation and monitoring ED in patients with MPS are important and can be life saving. It might be possible that progress of the cardiovascular lesions or improvement due to therapeutic measures could be monitored by this operator independent non-invasive method. Further studies are indicated to verify these hypotheses.

1309W

Generation of a mouse model of the attenuated type I form of sialidosis. *E. Bonten[1], G. Yogalingam[2], H. Hu[1], E. Gomero[1], A. d'Azzo[1].* 1) Deptartment of Genetics, St Jude Children's Research Hospital, Memphis, TN; 2) Dept of Chemical and Systems Biology, Dept of Micro and Immuno, Stanford U School of Med, Stanford, CA.

Lysosomal neuraminidase (NEU1) catalyzes the removal of terminal sialic acid residues from sialoglycoconjugates. The enzyme associates with the protective protein/cathepsin A (PPCA) for its efficient routing to the lysosomal compartment, as well as its intra-lysosomal catalytic activation and stability. NEU1 is linked to the neurodegenerative lysosomal storage disorder sialidosis, which is caused by structural lesions in the NEU1 gene. Different clinical phenotypes of sialidosis are distinguished according to the age of onset and severity of the symptoms; type I or normomorphic sialidosis is an attenuated, non-neuropathic form of the disease that corresponds to the cherry-red spot-myoclonus syndrome, while type II or dysmorphic sialidosis is a severe, neuropathic form of the disease. We have shown previously that the severity of the disease correlates closely with the type of gene mutation, which determines whether a patient has a complete or partial loss of functional NEU1. We have generated a faithful model of the type I form of sialidosis by cross-breeding the Neu1 null mice, a model of type II sialidosis, with a new transgenic mouse line, which ubiquitously expresses a NEU1 variant carrying the amino acid substitution V54M. This mutation was previously identified and characterized in a sialidosis patient with the attenuated form of sialidosis. Type I sialidosis mice have residual Neu1 activity in most organs and cell types. This activity may be increased by augmenting the levels of available PPCA that in this case acts as a molecular chaperone. Unlike Neu1-null mice that have severe neurologic and systemic disease, and a shortened lifespan (5-7 months), Neu1-/-/V54M mice develop normally until the age of 1 year, after which they show a slow progression of lysosomal storage in the visceral organs, predominantly in the kidneys, spleen and liver. We believe that patients with the attenuated form of sialidosis would likely benefit the most from enzyme replacement and/or gene therapy, for which this attenuated sialidosis mouse model may proof to be a valuable tool. (Supported by the American Lebanese Syrian Associated Charities of St. Jude Children's Research Hospital and NIH grant RO1-GM060950).

Genes Mediating Natural Variation in ER Stress Response. *C.Y. Chow, M.F. Wolfner, A.G. Clark.* Department of Molecular Biology and Genetics, Cornell University, Ithaca NY 14853 USA.

The endoplasmic reticulum (ER) is responsible for synthesis and maturation of many proteins essential for cellular function. ER dysfunction can have devastating consequences when misfolded proteins accumulate in the ER. The resulting “ER stress” has been associated with diseases from diabetes to neurodegeneration, as a primary cause or as a secondary exacerbating effect. Cells respond to ER stress with the “unfolded protein response” (UPR). The UPR reduces ER stress by increasing transcription of ER chaperones, attenuating translation and degrading misfolded proteins in the ER. To understand the effect of ER stress resistance on disease, it is important to determine the extent of natural variation in ER stress resistance in a population. We characterized variation in ER stress resistance in the Drosophila Genetic Reference Panel (DGRP), a collection of 192 inbred wild-derived lines whose whole genome sequences are available. We compared their relative survival on food supplemented with tunicamycin, a drug that causes ER stress by inhibiting N-glycosylation. Molecular markers of ER stress, such as Xbp1 splicing, indicate that tunicamycin induces ER stress in the fly. We observed extensive natural variation in ER stress resistance among the DGRP lines. Mortality rates, as measured by the Cox proportional hazard ratio, varied by more than 100 fold, indicating that extensive genetic variation in ER stress response is present in a single population. To understand genetic variation contributing to differential survival to ER stress, we compared gene expression between four lines that were resistant to ER stress and four that were sensitive (based on survival rates upon tunicamycin treatment). Expression measured by Agilent microarrays demonstrate that genes involved in the cellular response to ER stress, such as chaperones and genes previously implicated in human disease, showed a strong response across all eight genotypes. We found that transcriptome responses to ER stress between lines with high vs. low sensitivity to ER stress differed qualitatively and quantitatively. Many of the genes showing these sensitivity differences had not previously been implicated in ER stress. A focused study into a group of ER stress-responsive genes in all 192 lines will be presented. ER stress response is highly variable in a population and this variation likely arises from minor expression changes in genes not previously associated with ER stress.

Plasmalogen deficiency in the PEX7 hypomorphic mouse, a model for rhizomelic chondrodysplasia punctata, causes neonatal lethality associated with abnormalities in late lung maturation. *W. Cui[1], X. He[1], S. Jiralerspong[1], G. Nimmo[1], Y. Chen[1], J. Hacia[2], S. Steinberg[3], A. Moser[3], N. Braverman[1,4].* 1) Montreal Children Hospital Research Institute, Montreal, Quebec, Canada; 2) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, USA; 3) Kennedy Krieger Institute, Department of Neurogenetics, Baltimore, MD, USA; 4) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

The biological functions of plasmalogens (PLs), a specialized class of membrane glycerophospholipids, are largely unknown. Cell-based studies implicate roles in oxidant protection, inflammatory responses, signal transduction and cell-cell interactions. PLs are also integral components of surfactant. Inherited defects of PL synthesis cause rhizomelic chondrodysplasia punctata (RCDP), a heterogenous disorder commonly due to defects in the peroxisome transporter, PEX7. The clinical features of RCDP include growth and developmental retardation, cataracts and skeletal dysplasia. A proportion of patients die in the neonatal period, survivors suffer chronic respiratory compromise that ultimately causes death; the latter has been attributed to the effects of the skeletal dysplasia on pulmonary function. To investigate PL functions, we generated hypomorphic Pex7 mouse models that recapitulated the cataract and small size phenotype, but did not have obvious neurological deficits or chondrodysplasia punctata. These mice survived on a mixed 129/C57Bl6 background, but died within a few days of life on a C57Bl6 background. Pex7 transcript was reduced to <5%, and Pex7 protein to <12%, of wild type levels in both strains. Lung total PL levels were also equivalent in the two strains, suggesting that lethality was due to different downstream effects of PL utilization. Morphometric studies showed that death was associated with increased saccular wall tissue and decreased air spaces, indicating a delay, or arrest, in alveolarization. Using immunohistochemistry, we show that the increased interstitial tissue was mesenchymal in origin, and found increased numbers of terminal bronchiole epithelial cells (Clara cells) and alveolar type II epithelial cells, as well as increased lipid peroxidation protein adducts. Gene expression studies showed significant decreases in the transcription factor, Meox2, and further reduction in the congenic vs. the mixed background strain. We suggest that PL deficiency may affect cell signaling in late lung maturation and independently, also promote oxidant damage. Moving from Pex7 deficient mice to humans, we propose that PL deficiency contributes to early neonatal demise in RCDP as a function of lung maturation, and to the chronic lung disease in survivors, independent of the skeletal dysplasia.

Missense Mutations in the Hemochromatosis (HFE) Gene are Genetic Risk Factors for Secondary Polyosteoarthritis. *J.A. Di Battista[1], V. Martelli[1], P. Panopolis[1], J. Antoniou[2], M. Sebag[1], B. Gilfix[1], H.A. Menard[1].* 1) Medicine, McGill University, Montreal, Quebec, Canada; 2) Orthopaedic Surgery, Jewish General Hospital, Montreal, Quebec, Canada.

Rationale and Objectives: Clinical hereditary hemochromatosis type I (HH-I) is defined as the progressive accumulation of iron in organs caused by missense mutations in the HFE gene. In population studies, two prevalent mutations, the C282Y and the H63D, exhibit clinical penetrance rates varying from 1:400 (frequent) to 1:10,000 (rare) individuals with any manifestation. Rheumatic complaints of the osteoarthritis (HHOA) phenotype are the leading clinical manifestations of HH-I. Yet, nothing is known about the expression in chondrocytes of proteins regulating iron metabolism. Our study aimed at verifying their presence, at exploring variations of OA-related biomarkers in normal vs. HFE-mutation-carrying cultured human chondrocytes and, their variations in normal chondrocytes transfected with normal or mutated HFE. **Methods and Results**: Cultured chondrocytes were derived from tissues obtained at total knee replacement (TKR) of patients not carrying (OA) or carrying mutations (HHOA). Ferroportin, Divalent Metal Transporter 1, ferritin and transferrin receptor 1 were all identified by PCR in human chondrocytes. The in vivo mutated cells spontaneously expressed in vitro, significantly higher levels of MMP-1, MMP-3, MMP-13, iNOS and COX-2 (referred to as an “activation profile”) compared with cells obtained from age-matched patients with idiopathic primary OA. In vitro transfection of a construct expressing the wild type (normal) HFE gene into normal donor-derived chondrocytes had similar effects on basal or cytokine-induced MMP-13 or COX-2 expression as cells transfected with an empty vector or under mock transfection conditions. However, transfecting plasmids with HFE containing the mutations, generated through site directed mutagenesis, resulted in a 3 to 7-fold increase in MMP-1/MMP-13/COX-2/iNOS expression levels under basal and cytokine-induced conditions. Those effects were similar in the presence of normal vs. elevated iron concentrations in the culture medium. **Conclusions:** This is a first attempt to define the molecular mechanisms driving the characteristic HHOA and the role that HFE mutant genotypes may play. Our clinical observations suggest that many patients with the so-called “silent” H63D HFE mutation have early rheumatic symptoms. As such given their high frequency, that mutation while presenting a normal biochemical phenotype, is not clinically silent and may be a major, still insufficiently recognized, genetic risk factor for OA.

Case Report; Cerebrotendinous Xanthomatosis (Sterol 27-HydroxylaseDeficienc). *F. Hadipour[1], Z. Hadipour[1], P. Sarkhail[1], M. Noruzinia[1,3], Y. shafeghati[1,2].* 1) Medical Genetics, Sarem Cell Research Center & Hospital, Tehran, Iran; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Science, Tehran. Iran; 3) Department of Medical Genetics, School of Medical Sciences, Tarbiat Modares University, Tehran Iran.

Abstract: Background Cerebrotendinous xanthomatosis is a rare genetic disorder of cholesterol and bile acid metabolism that results in systemic and neurologic abnormalities. The disease was first described in 1937 by Van Bogaert and has been characterized clinically, biochemically, and genetically. In 1991, mutations in the gene CYP27A1 were discovered as causative, Since then, more than 50 mutations have been implicated. The disease begins in infancy with chronic diarrhea. Cataracts become evident in childhood or adolescence, and xanthomata develop in the second and third decades of life. Significant neurologic impairment includes seizures, dementia, and extra pyramidal dysfunction and begins in the third decade of life and progresses until death. The presentation and course widely varies, and treatment can dramatically alter the natural history, especially with early initiation. Case Report We report an Iranian family with three affected child who are suffering from Cerebrotendinous Xanthomatosis. Cardinal features were: Motor dysfunction, ataxia, spastic paresis, Xanthomas of the Achilles tendon, Cataracts double. MRI of the brain show diffuse cerebral atrophy and increased signal intensity in the cerebellar white matter on T2-weighted scans. In this report, we present 3 patients with Cerebrotendinous Xanthomatosis, who confirmed by Molecular Analysis. The patients are suffering from disease resulting from a homozygous splice- mutation in intron 2 of the CYP27A1 gene. Key word; Cerebrotendinous Xanthomatosis, Motor dysfunction, CYP27A1 gene.

Innate immunity and Toll-like receptors in lysinuric protein intolerance (LPI). *J. Kurko[1], M. Tringham[1], L. Tanner[2], K. Näntö-Salonen[2], H. Niinikoski[2], M. Vähä-Mäkilä[2], O. Simell[2], J. Mykkänen[2].* 1) Dept. of Medical Biochemistry and Genetics, University of Turku, Turku, Finland; 2) Dept. of Pediatrics, Turku University Hospital and University of Turku, Turku, Finland.

Lysinuric protein intolerance (LPI; MIM222700) is a rare autosomal recessive disorder caused by a defect of cationic amino acid transport in the small intestine and kidney tubules. All Finnish patients share the same homozygous mutation c.1181-2A→T (c.859-2A>T) in the *SLC7A7* gene. Altogether 51 mutations have been found worldwide but the Finnish founder mutation has not been detected in any other population. The main symptoms of LPI consist of protein aversion after weaning, failure to thrive, muscle hypotonia, osteoporosis and hepatosplenomegaly. However, some findings vary markedly even in the same family and may include severe pulmonary and renal complications, such as alveolar proteinosis and end-stage renal disease. Some patients also suffer from normochromic anaemia with poikilocytosis and anisocytosis and unexplained immunological problems such as leukopenia, deficiencies in T and B cell functions and severe viral infections.

Immunological problems suggest a defect in innate immunity which functions through the Toll-like receptor signalling pathway. We cultured macrophages from 23 patients and 15 sex and age-matched controls and stimulated them with three PAMPs (pathogen associated molecular patterns) Pam_3CSK_4, LPS and CpG DNA which activate TLR1/2, TLR4 and TLR9 receptors, respectively. We collected plasma, culture medium and RNA samples at three time points in order to measure cytokine and chemokine levels with Luminex technology, and to perform expression profiling of TLR signalling genes with quantitative real-time PCR. Stimulation of the cells with synthetic viral CpG DNA resulted in decreased expression levels of TLR signalling genes. This refers to defects in patients' innate immunity during viral infections which may be connected to the severe immunological and pulmonary complications the patients suffer from.

Metabolic cutis laxa syndromes. *E. Morava[1], T. Gardeitchik[1], M. Mohamed[1], D. Kouwenberg[1], D. Lefeber[2], U. Kornak[4], B. Heuvel[3], R.A Wevers[3].* 1) Institute of Genetic and Metabolic Disorders and Department of Pediatrics, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands; 2) Institute of Genetic and Metabolic Disorders and Department of Neuology, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands; 3) Institute of Genetic and Metabolic Disorders and Laboratory for Genetic Endocrine and Metabolic Diseases, Radboud University Nijmegen Medical Center, Nijmegen, Netherlands; 4) Department of Human Genetics, University Hospital, Charite, Berlin, Germany.

Cutis laxa (CL) is a disorder, either acquired or inherited, in which patients have wrinkled, abundant, sagging skin with abnormal elasticity. Skin symptoms may be associated with variable systemic involvement. Recently, several new genetic defects have been discovered to cause cutis laxa. Surprisingly, a number of these syndromes are inborn errors of metabolism. These include disorders of glycosylation, like COG7-CDG and ATP6V0A2-CDG, as well as deficiencies in enzymes localized in mitochondria and involved in de novo proline synthesis (P5CS and PYCR1). Here we describe eleven children diagnosed with with metabolic cutis laxa and novel mutations and report on the discriminative metabolic and clinical features in our patients. The four children diagnosed with autosomal recessive cutis laxa type 2A (ARCL2A) due to PYCR1 mutations had a triangular face with prominent ears and progeroid appearance, abnormal wrist position and two of them showed athetoid movements. Cerebral MRI detected hypoplastic corpus callosum in three of the four patients, and two of them had increased serum alanine levels. All patients had improvement of their progerioid skin features. In four of the five so far unreported patients with (autosomal recessive cutis laxa type 2B (ARCL2B) or ATP6V0A2-CDG, in the absence of the above described abnormalities, a cobblestone like brain dysgenesis was detected, associated with glycosylation abnormalities and elevated liver enzymes. The patients with P5CS deficiency had similar features without any change of the skin symptoms with time. Discriminating between the different forms of autosomal recessive cutis laxa is challenging due to several overlapping clinical features: the severely affected skin, microcephaly, facial dysmorphisms, joint hyperlaxity, cognitive deficits, growth delay and late closing of the fontanel. We suggest to perform a brain MRI, measure serum alanine levels and liver enzymes additional to screening for glycosylation in patients with cutis laxa syndrome to obtain a timely diagnosis.

The expression pattern of genes involved in the Vitamin B_{12} metabolic pathway during mouse embryogenesis. *M.M. Moreno-Garcia[1], D.S. Rosenblatt[1], L.A. Jerome-Majewska[2].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Pediatrics, McGill University, Montreal, Quebec, Canada.

Vitamin B_{12} (cobalamin, (Cbl)), is essential for human development and survival. A series of inborn errors of cobalamin metabolism have been identified, designated *cblA-cblG*, which affect the ability of cells to generate the two important cobalamin cofactors, methylcobalamin and adenosylcobalamin. These inborn errors result in homocystinuria and methylmalonic aciduria, either isolated or in combination. Those patients with elevation of both homocysteine and methylmalonic acid in blood and urine, have functional defects of both the cytoplasmic (methionine synthase) and the mitochondrial (methylmalonyl-CoA mutase) branches of the pathway. To examine whether genes involved in vitamin B_{12} metabolism show tissue-specific expression during mouse embryogenesis, we are characterizing their sites of expression in wild type mice at 9.5, 11.5 and 12.5 days post conception by *in situ* hybridization. We previously reported cell type and tissue specific expression of *Mmachc* and ubiquitous expression of *Mmadhc*, two genes involved in the early steps of vitamin B_{12} metabolism [Pupavac *et al*, 2011]. Here we describe expression of three genes associated with isolated methylmalonic aciduria (*Mut*, *Mmaa* and *Mmab*). We did not observe any organ, tissue or cell type specific expression for these three genes at 9.5 and 11.5 days. At 12.5, we observed cell type specific expression of *Mmab* in lung and ubiquitous expression of *Mut* and *Mmaa*. At the same time, we found higher expressions of these genes in the developing lung, heart, circulatory and nervous system. This suggests that during organogenesis these three genes may interact in only a subset of cells. In conclusion, this study presents for the first time the analysis of *Mut*, *Mmaa* and *Mmab* gene expression patterns during mouse development and demonstrates overlapping and differential *Mmab* expression, notably in the lung.

Genetic Analysis of Galactosemia genes from Indian Galactosemia Patients: Structural and Functional Implications of Mutations. *R. Singh[1], G. Kaur[2], B.R. Thapa[3], R. Prasad[1].* 1) Department of Biochemistry, Postgraduate Institute of Medical Education and Research (PGIMER), Chandigarh, Chndigarh, India; 2) Department of Physiology, Government Medical College and Hospital, Sector - 32, Chandigarh, India; 3) Division of Pediatric Gastroenterology, Postgraduate Institute of Medical Education and Research, Chandigarh-160012, India.

Introduction: Galactosemia is an inborn error of metabolism resulting from defective galactose metabolism. Three types of galactosemia occur according to the identity of the impaired enzyme: galactokinase (GALK), galactose-1-phosphate uridyltransferase (GALT) and UDP-galactose-4-epimerase (GALE). Disrupted metabolism leads to the accumulation of galactose and its derivatives leading to several symptoms. Objective: To determine blood GALT and GALK activity in infants with cholestasis and congenital cataracts and to establish a spectrum of mutations in GALT and GALK genes. Methods: 450 infants with cholestasis were evaluated for GALT deficiency galactosemia. Basic investigations included hemogram, liver function tests, blood culture, urine culture, urine for non-glucose reducing substances, eye evaluation, abdominal ultrasound, TORCH serology, mebrofenin scan and peroperative cholangiogram were done when indicated. Screening for GALT deficiency was done using Perkin-Elmer neonatal GALT kit. The levels of galactose-1-phosphate were also measured. 140 patients with congenital cataract were screened for GALK deficiency. Mutation analysis for most common Q188R and N314D mutations in GALT gene was performed by Restriction Fragment Length Polymorphism (RFLP). Single Stranded Conformational Polymorphism (SSCP) analysis and subsequently DNA sequencing were done for identification and characterization of unknown and novel mutations in GALT and GALK genes. Structural and functional implications of the mutations were also studied. Results: 55 (12.2%) infants were found to have reduced GALT activity with male: female: 37:18, jaundice in 55 (100%), hepatomegaly in 44 (80%), splenomegaly in 28 (51%), encephalopathy in 8 (15%), coagulopathy in 12 (22%), cataracts in 18 (32%), sepsis in 8 (15%) and failure to thrive in 30 (54%) while three patients died during the hospital course. A significant negative correlation was observed between GALT activity and galactose-1-phosphate levels. A total of 16 mutations and 4 polymorphisms were detected in GALT gene. 10 were novel mutations. N314D and Q188R mutations were detected in 37 and 3 patients respectively. Reduced blood galactokinase activity was found in 16 (11.4%) patients with congenital cataracts. 5 mutations were identified in GALK gene.4 were novel. Conclusion: N314D was the most common mutation in GALT gene from our population. 10 and 4 novel mutations were detected in GALT and GALK genes respectively.

Effects of genetic variants and nutritional factors on metabolic diseases among Chinese populations. *X. Lin.* Inst Nutritional Sci, Shanghai Inst Biological Sci, CAS, 294, Taiyuan Rd, Xuhui District Shanghai, 200031, P.R.China.

Paralleling to rapid nutrition transition in past 3 decades, the prevalence of metabolic diseases like metabolic syndrome and type 2 diabetes have been increased in an alarming rate in Chinese population. Asian people were known to have higher susceptibility of suffering type 2 diabetes than Caucasian, although limited data is available among Chinese. Therefore, we have established a population-based cohort study including 3289 Beijing and Shanghai residents aged 50-70 years. The baseline data indicated that prevalence of obesity, MetS and type 2 diabetes were significantly higher in Beijing than in Shanghai. Approximately 70% of our participants had vitamin D deficiency [25(OH)D <50 nmol/l]. Plasma 25(OH)D level was inversely associated with a higher risk of MetS and insulin resistance. Meanwhile, elevated ferritin level was associated with a high risk of diabetes independent of inflammatory markers, adipokines and MetS. Recently, we also found a unique erythrocytes fatty acids pattern and their associations with metabolic risks. In genetic association studies, common variants in CDKAL1, CDKN2A/B, IGF2BP2, SLC30A8 GCKR and KCNQ1 were found to be independently or additively associated with the risk of type 2 diabetes. However, different genetic architecture and allele frequencies between Chinese Hans and Caucasians were observed for FTO variants with obesity and type 2 diabetes. Moreover, circulating 25-hydroxyvitamin D and ferritin levels were found to be modified by genetic variation related with the genes involving vitamin D and iron regulating pathway. Currently, we are conducting a 6-year follow up study and also using genomic DNA obtained from our baseline survey for whole-genome genotyping as a part of Chinese national type 2 diabetes GWAS project. Collectively, all the efforts have been made to enhance our knowledge about major nutrition/lifestyle, genetic factors and their interaction on in development of metabolic diseases in Chinese population.

Neonatal Multiple Sulfatase deficiency with tetralogy of Fallot: Homozygosity for a Novel Mutation. *F. Al Jasmi[1], J. Hertecant[2], L. Al Gazali[1].* 1) Faculty of Medicine and Healthy Science, Al Ain, United Arab Emirates; 2) Department of Paediatrics, Tawam Hospital, Al-Ain, United Arab Emirates.

Background: Multiple Sulfatase deficiency (MSD) (OMIM 272200) is a rare autosomal recessive condition caused by mutations in the sulfatase-modifying factor-1 gene (*SUMF1*) located at 3p26. MSD is characterized by deficiencies in all 12 known sulfatases and leading to a complex clinical presentation. It may present with clinical features of any or combination of the following diseases: metachromatic leukodystrophy, mucopolysaccharidosis, X- linked ichthyosis and chondrodysplasia punctate. Methods and Results: We describe a female infant, product of a consanguineous union, who presented with tetralogy of fallot, hypoplastic lungs and recurrent chest infection, non immune hydrops, short limbs, inguinal hernia and facial dysmorphism. Urine oligo was negative but Urine MPS TLC analysis showed dermatan sulfate and heparan sulfate. Skeletal survey showed dysosotosis multiplex and short limbs. Sulfatase enzymes measurement in the proband's fibroblast showed low activities of arylsulfatase A, arylsulfatase B and iduronate 2-sulfatase which confirmed the diagnosis of MSD. *SUMF1* gene analysis revealed homozygosity for a novel mutation, c.603-2 A>G predicted to result in the loss of the normal acceptor splice site at the junction between intron 4 and exon 5. Conclusion: To our best knowledge, this is the first case report of MSD in association with tetralogy of Fallot. MSD should be suspected in patients who have clinical features typical of single sulfatase deficiencies enzymes.

1320W

A 680 kb duplication at the *FTO* locus in a subject with extreme obesity. *R.W. Davies[1], P. Lau[2], R. Dent[3], R. McPherson[2].* 1) Cardiovascular Research Methods Centre, Univ Ottawa Heart Inst, Ottawa, Canada; 2) Atherogenomics Laboratory, Univ Ottawa Heart Inst, Ottawa, Canada; 3) Weight Management Clinic, The Ottawa Hospital, Ottawa, Canada.

Background: Common intronic SNPs in the human *FTO* gene are strongly associated with body mass index. In mouse models, inactivation of the *Fto* gene results in a lean phenotype whereas over-expression of *Fto* leads to increased food intake and obesity. The latter finding suggests that copy number variants at the *FTO* locus might be associated with extremes of adiposity. **Methods:** SNP genotyping was carried out on Affymetrix 6.0 arrays in a cohort of 985 obese and 869 lean subjects drawn from the extremes of the BMI distribution (mean BMI 43.1+8.7 and 20.3+1.84 kg/m^2 for obese and lean subjects, respectively). Copy number variation was assessed using Birdseye and subsequently verified by quantitative RT-PCR. **Results:** Single marker analysis confirmed previously shown associations between intronic SNPs in *FTO* and obesity (rs9939609, OR=1.63, p=$6x10^{-13}$). In addition, a ~680 kb duplication, confirmed by real time PCR, was observed putatively between rs11859825 and rs9932411 in a 61 year old male with severe obesity of childhood onset (max BMI 53kg/m^2). The duplicated region on chromosome 16 spans from approximately 53,325,073 to 54,005,163 (build 37), including the entire GWAS risk locus and encompassing *RBL2, AKTIP, RPGRIP1L* and all but the last exon of the *FTO* gene. **Conclusion:** We have identified a novel ~680 kb duplication at the *FTO* locus in an extremely obese subject. Studies are underway to fine map the duplicated region, quantify effects on *FTO* transcript expression, and determine segregation with obesity in an extended kindred.

Association between BMI variants previously identified in adult populations in association with adolescent BMI in an ethnically-diverse cohort. *M. Graff[1, 2], K.E. North[1, 3], K.L. Mohlke[3, 4], L.A. Lange[3, 4], E.M. Lange[3, 4], C.S. Fox[5], L.A. Cupples[5, 6], K.M. Harris[2, 7], P. Gordon-Larsen[2, 8].* 1) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 2) Carolina Population Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 3) Carolina Center for Genome Sciences, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 4) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 5) Framingham Heart Study, Framingham, Massachusetts, USA; 6) Department of Biostatistics, Boston University School of Public Health, Boston University Medical Campus, Boston, Massachusetts, USA; 7) Department of Sociology, University of North Carolina, Chapel Hill, North Carolina, USA; 8) Department of Nutrition University of North Carolina, Chapel Hill, North Carolina, USA.

Adolescence is a period with a high risk for weight gain, yet nearly all well established genome wide association (GWA) single nucleotide polymorphisms (SNPs) have been identified in middle aged European American adults. Using 9,350 participants of the National Longitudinal Study of Adolescent Health, or Add Health (ages 12-21 years, 52.6 %female), we selected 43 SNPs at 40 loci from previous GWA studies and assessed their association with BMI (measured in 1996) across four ancestrally diverse US subpopulations (5,531 European American, 1,904 African Americans, 1,437 Hispanics, and 478 Asians). Buccal cells from participants were extracted and genotyped using TaqMan (sample call rate: 97.5%, SNP call rate: 100%). Inverse normal transformed BMI residuals, adjusted for gender and age, were analyzed using linear regression models implemented in PLINK. Analyses were stratified by ethnicity and an inverse-variance-weighted meta-analysis was used to combine results across the 4 ethnic groups. Average BMI across all ethnic groups was 23.6±5.2 kg/m2, ranging from 22.6±5.2 kg/m2 in Asian Americans to 24.3±5.8 kg/m2 in African Americans. The effect estimates for all 43 SNPs were directionally consistent across ethnicity with previously published results. Of the 43 SNPs, 19 displayed nominally significant associations with BMI at p<0.05 in the meta-analysis (16 were nominally significant in Caucasians, 7 in African Americans, 4 in Hispanics, and 5 in Asians). Based on t-test comparisons, all but 3 of the 19 SNPs had significantly larger effect sizes (p<0.05) in our adolescent sample than published effect sizes for BMI in adults. Only FTO (rs9939609) had an I2 heterogeneity statistics across ethnicity that was significant, p=0.01. The strongest result in the meta-analysis, TMEM18 (rs6548238; p=4.9E-12), had one of the largest differences in effect size compared to published results (Willer et al 2009, stage 2 GIANT consortium), which was based on 51055 adults, with a beta of 0.74±0.11 kg/m2 in this sample versus a beta of 0.26±0.07 kg/m2 in GIANT (beta difference [SE]=0.48[0.08]; p=4.5E-10 for difference). These results show that variants found to be associated with BMI in adults are also associated with BMI in adolescents, and that some may have larger effects during this vulnerable period. R01HD057194.

1322W

Identification of novel mutations in HEXA gene in children affected with Tay-sachs disease from India. *M. Mistri*[*1], P. Tamhankar*[*2], S. Thomas[3], P. Kondurkar[2], S. Mehta[4], D. Sanghavi[2], J. Sheth[1 #].* 1) Biochemical and Molecular Genetics, FRIGE's Institute of Human Genetics, Satellite, Ahmedabad, Gujarat, India. *(joint first authors), #(Correspondence author); 2) Genetic Research centre, NIRRH, ICMR, Parel, Mumbai, India.*(joint first authors); 3) Biomedical Informatics Center, NIRRH, ICMR, Parel, Mumbai, India; 4) Usha-deep hospital, Naranpura, Ahmedabad, Gujarat, India.

Tay - Sachs disease (TSD) is an autosomal recessive storage disorder caused by impaired activity of the lysosomal enzyme hexosaminidase-A (EC 3.2.1.52) due to the mutation in HEXA gene. As per HGMD database, 134 mutations have been reported from different ethnic groups, although disease causing mutations are not known in Indian children. Hence, the present study was undertaken to identify mutations in HEXA gene in Indian Tay-sachs patients to evaluate genotype-phenotype correlation and to establish the common disease causing mutations that can be utilized for carrier screening in mass population. Five missense mutations were found in 10 patients with infantile onset Tay-Sachs disease, through bidirectional sequencing of HEXA gene using BigDye Terminator v3.1 and capillary electrophoresis was performed on automatic sequencer ABI-3130. The most common mutation detected in six individuals [60%] was c.1385A>T (p.E462V). This homozygous mutation was observed in five unrelated patients with one consanguineous and remaining non-consanguineous parentage of the same ethnic group. Four other patients were found homozygous for mutations viz. c.340G>A (p.E114K), c.964G>A (p.D322N), c.1178C>G (p.R393P) and c.508C>T (p.R170W) respectively. All the mutations identified are novel except c.508C>T (p.R170W) which has been previously identified in French-Canadian population. Protein homology modeling studies further established the effects of novel mutations occurred at highly evolutionarily conserved and functionally active domain residues in the protein leading to conformational changes in HEXA protein. The mutation c.1385A>T (p.E462V) could be a founder mutation in a single ethnic group and can be used for targeted mutation analysis in the affected individuals and mass screening at large. In addition, the study identified the mutational spectrum of Indian TSD patients, which will be helpful in offering precise genetic counseling, carrier detection followed by prenatal diagnosis.

Variants in or near PNPLA3, GCKR and PPP1R3B associate with ultrasound-defined steatosis in NHANES III. *R. Hernaez[1,2,3], J. McLean[4], M. Lazo[1,3], F.L. Brancati[1,3,5], J.N. Hirschhorn[6,7,8], T. Nguyen[6,7], I.R. Kamel[9], S. Bonekamp[9], J.M Clark[1,3,5], W.H.L. Kao[3,5], E.K. Speliotes[7,10].* 1) Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Medicine, Washington Hospital Center/Georgetown University Hospital, Washington, DC; 3) Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 4) NOVA Research Company, Bethesda, MD; 5) Welch Center for Prevention, Epidemiology and Clinical Research, Johns Hopkins University, Baltimore; 6) Divisions of Endocrinology and Genetics and Program in Genomics, Children's Hospital, Boston, MA; 7) Broad Institute, Cambridge, MA; 8) Department of Genetics, Harvard Medical School, Boston, MA; 9) Radiology, Johns Hopkins School of Medicine, Baltimore, MD; 10) Department of Internal Medicine, Division of Gastroenterology, and Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI.

Five genetic variants associated with computerized tomography (CT) measured hepatic steatosis in a genome-wide association meta-analysis of individuals of European ancestry. Here we aim to test whether these variants are associated with ultrasound-measured hepatic steatosis (HS) in 4,804 participants from 3 ancestries [1,825 Non Hispanic Whites (NHW); 1,442 African Americans (AA), and 1,537 Mexican Americans (MA)] in the Third National and Nutrition Examination Survey (NHANES III, Phase 2, 1991-1994). HS was defined as presence of any steatosis versus none. We examined whether HS was associated with rs738409 (PNPLA3), rs2228603 (NCAN), rs12137855 (LYPLAL1), rs780094 (GCKR), and rs4240624 (PPP1R3B) using population-specific logistic regression analysis adjusted for age, age2, gender, and alcohol consumption using an additive genetic model. We estimated overall association across the ancestries using a beta/standard error meta-analysis in METAL if there was no significant heterogeneity across ancestries. In each population, we have >80% power to detect an odd ratio of 1.15 if the allele frequency is at as high as 0.53 (PNPLA3) and an odds ratio of 2.05 if the frequency is 0.01 (GCKR). Of 4,804 participants, 57.2% were female, mean age was 43.2 years, and, the HS prevalence was 40%. The presence of HS was associated with older age, increased BMI, waist circumference, fasting glucose, triglycerides, and the presence of the metabolic syndrome. The G allele at PNPLA3 was consistently associated with HS across ancestries with an overall OR of 1.19 (p=0.0004067; p-heterogeneity=0.71) across all three ancestries. Other SNPs were not consistently associated with HS across ancestries. We observed an association between HS and the T variant in GCKR (OR=1.20, p=0.0099) and the A variant of PPP1R3B (OR=1.30, p=0.0376) in NHW. In conclusion,this is the first study to validate the association between the genetic variation in PNPLA3 (rs738409) and ultrasound defined HS in three nationally representative ancestries from the United States. The lack of consistent associations between variants in NCAN, LYPLAL1, GCKR, PPP1R3B and HS across the populations may be due to lack of power, differences in LD amongst ancestries, or true lack of association, but two of these (GCKR, PPP1R3B) are significantly associated with HS in NHW. More genetic analyses of these variants in larger populations of different ancestries are needed to distinguish amongst these possibilities.

1324W

A Genome-Wide Association Study Reveals a Quantitative Trait Locus of Resistin on RETN That Predicts Metabolic Outcomes. *C. Chung[1,2], T. Lin[3], J. Chen[4], H. Leu[4], H. Ho[5], C. Ting[5], S. Sheu[3], W. Tsai[6], J. Chen[6], W. Pan[1].* 1) Inst Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) Faculty of Public Health, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Division of Cardiology, Department of Internal Medicine, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 4) Cardiovascular Research Center, National Yang-Ming University, Taipei, Taiwan; 5) Taichung Veterans General Hospital, Taichung, Taiwan; 6) College of Medicine, National Cheng Kung University, Tainan, Taiwan.

Objective - The plasma resistin level, a potential upstream and internal facet of obesity and diabetes, has a reasonably high heritability. Whether other novel genes influence the variation in resistin level, and the roles of these genetic variants on subsequent clinical outcomes has not been thoroughly investigated. Therefore, we aimed not only to identify genetic variants modulating plasma resistin levels but also to investigate whether these variants are associated with metabolic syndrome and diabetes. Research Design and Methods - We conducted a genome-wide association study to identify quantitative trait loci associated with resistin levels by genotyping 382 young-onset hypertensive (YOH) subjects with Illumina HumanHap550 SNP chips. The culpable single-nucleotide polymorphism (SNP) variants responsible for resistin levels were then confirmed in another 559 YOH subjects, and the association of these SNP variants with the risk of metabolic syndrome (MS) and type 2 diabetes mellitus (T2DM) was examined in an independent community-based prospective cohort, the CardioVascular Disease risk FACtors Two-township Study (CVDFACTS, n= 3350). Results - The SNP (rs1423096) most significantly associated with resistin levels was located in downstream of RETN gene in the first stage ($p = 2.54\times10\text{-}20$). We replicated and confirmed the association between rs1423096 and plasma resistin levels in an additional 559 YOH subjects ($p = 1.13\times10\text{-}7$). This SNP was further associated with the risk of MS (OR = 1.577, p = 0.0432), and T2DM (OR = 2.213, p = 0.0034) in the CVDFACTS. Conclusion - The results indicate that rs1423096 seems to have a role in the determination of plasma resistin levels and seems to be associated with more deleterious metabolic syndrome and diabetes.

Genetic Risk Assessment of Type 2 Diabetes Associated Polymorphisms in African-Americans. *J. Cooke[1,3,4], M. Ng[3,4], L. Lu[6], J. Li[4], S. An[2,3,4], J. Hester[3,4,5], J. Xu[4], B. Freedman[7], C. Langefeld[6], D. Bowden[2,3,4,8], N. Palmer[2,3,4].* 1) Molecular Medicine and Translational Science, Wake Forest School of Medicine, Winston-Salem, NC; 2) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, North Carolina; 3) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, North Carolina; 4) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, North Carolina; 5) Program in Molecular Genetics and Genomics, Wake Forest School of Medicine, Winston-Salem, North Carolina; 6) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, North Carolina; 7) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, North Carolina; 8) Department of Internal Medicine - Section on Endocrinology, Wake Forest School of Medicine, Winston-Salem, North Carolina.

African Americans have the highest prevalence of type 2 diabetes (T2D) of any American population. Multiple single nucleotide polymorphisms (SNPs) associated with T2D susceptibility have been identified in predominantly European-derived populations. These SNPs have not been extensively investigated for individual and cumulative effects on T2D risk in African Americans. Seventeen index T2D risk variants, including rs10923931 (NOTCH2), rs7578597 (THADA), rs1801282 (PPARG), rs4607103 (ADAMTS9), rs4402960 (IGF2BP2), rs10010131 (WFS1), rs10946398 (CDKAL1), rs864745 (JAZF1), rs13266634 (SLC30A8), rs10811661 (CDKN2A/B), rs1111875 (HHEX), rs7903146 (TCF7L2), rs2237892 (KCNQ1), rs5215 (KCNJ11), rs7961581 (TSPAN8/LRG5), rs8050136 (FTO), and rs4430796 (HNF1B) were genotyped in an 2652 AA cases with T2D and 1410 non-diabetic controls from the southeastern United States. Individual SNPs and cumulative risk allele loads were assessed for association with risk for T2D. Risk allele frequencies ranged from 8.6-99.9%. Eleven SNPs had odds ratios (OR) > 1 and five from ADAMTS9, WFS1, CDKAL1, JAZF1, and TCF7L2 trended or had nominally significant evidence of T2D association (P-value < 0.05). Individuals carried between 13 and 29 risk alleles. Cumulative risk was first assessed by simple counting of the number of risk alleles and statistically evaluating differences in cumulative risk scores between cases and controls. A second analysis weighted risk scores based on European-derived effect sizes (ln[OR]) from prior publications. Association was observed between T2D and increase in risk allele load; unweighted P=0.010, OR=1.04 (95% CI 1.01-1.08), weighted P=8.10x10-5, OR=1.06 (95% CI 1.03-1.10). When the number of TCF7L2 SNP rs7903146 risk alleles was included as a covariate, risk score was no longer associated with T2D in either model; unweighted P=0.33, OR=1.02 (95% CI 0.98-1.05); weighted P=0.40, OR=1.02 (95% CI 0.99-1.06). The trend of increase in risk for T2D with increasing risk allele load is similar to observations in European-derived populations; however, these do not contribute to T2D prediction beyond that of rs7903146 in African Americans. Although differences in risk allele burden exist between cases and controls, T2D genetic risk is primarily mediated through the impact of TCF7L2 in African Americans.

MTHFR C677T and MTHFR A1298C polymorphisms in Mexican patients with Gestational Diabetes Mellitus. *I.P. Davalos[1,2], K.I. Lares-Castellanos[3], J.P. Mena-Ramírez[1,2], M. Salazar-Páramo[4,5], E.L. Chávez-González[4,5], I.M. Salazar-Dávalos[6], M.G. González-Mercado[1,2], M.A. Aceves-Aceves[6], F. Grover-Páez[3].* 1) División de Genética, CIBO, Instituto Mexicano del Seguro Social (IMSS); 2) Doctorado en Genética Humana, IGH, CUCS, Universidad de Guadalajara; 3) UMAE, Hospital de Ginecología y Obstetricia, CMNO, IMSS; 4) División de Investigación, UMAE, HE, CMNO, IMSS; 5) Doctorado en Farmacología, CUCS, Universidad de Guadalajara; 6) Facultad de Medicina, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México.

Introduction: Gestational Diabetes Mellitus (GDM) is a common medical condition during pregnancy. The MTHFR C677T and MTHFR A1298C polymorphisms have been associated with hyperhomocysteinemia, thrombotic and cardiovascular risk, vascular disease in Diabetes Mellitus type 2, pregnant women with obstetric complications and postmenopausal women. Objective: To determine the genotype (GF) and allele frequencies (AF) of the MTHFR C677T and MTHFR A1298C polymorphisms in a group of Mexican patients with GDM. Methods: A group of 49 pregnant Mexican patients with GDM according to ADA criteria (GDM Group) and a group of 54 pregnant Mexican patients without DM (Control Group) were typed for the MTHFR C677T and MTHFR A1298C polymorphisms by the PCR/RFLP's technique. Results: For MTHFR C677T GF, %(n), were in GDM Group: CC 28%(14), CT 41%(20), TT 31%(15); in Control Group CC 30%(16), CT 63%(34), TT 7%(4). AF allele C in GDM Group 49%(48), in Control Group 61%(66), allele T in GDM Group 51%(50) and in Control Group 39%(42). For MTHFR A1298C: GF, %(n) in GDM Group AA 59%(29), AC 33%(16), CC 8%(4), in Control Group AA 61%(33), AC 37%(20), CC 2%(1) AF allele A in GDM Group 76%(74) and in Control Group 80%(86) , allele C in GDM Group 24%(24) and in Control Group: 20%(22). Conclusions: Control Group showed an homozygous deficiency for allele T, the MTHFR 677TT genotype was associated with GDM (p=0.02). The MTHFR A1298C genotype frequency and allele frequency differences between both groups were NS (p>0.05). Additionally, the MTHFR 677CT and MTHFR 677TT genotypes were associated with macrosomic products and the 1298AA genotype with easier management of glycemic control in GDM patients.

1327W

Genetic variation in UBE2E2 is associated with risk of type II diabetes in a European population. *A. Dehghan[1, 2], E.J.G. Sijbrands[3], A. Hofman[1,2], A.G. Uitterlinden[3], J.C.M. Witteman[1,2].* 1) Department of Epidemiology, Erasmus Medical Center, Rotterdam, the Netherlands; 2) Member of Netherlands Consortium for Healthy Aging sponsored by Netherlands Genomics Initiative, Leiden, Netherlands; 3) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands.

Genome-wide association (GWA) studies on diabetes in Asians have identified new genetic loci including *KCNQ1*, *C2CD4A/4B* and *UBE2E2* that were not previously reported in Europeans. The association of type II diabetes with *KCNQ1* and *C2CD4A/4B* has also been shown in Caucasians, however, the association with *UBE2E2* in Caucasians remains to be studied. We examined the association of genetic variants in *UBE2E2* and 60kb up/downstream of the gene with risk of type II diabetes in the Rotterdam Study, a prospective population based cohort study of individuals living in Rotterdam, the Netherlands. The population for analysis comprised of 7464 Caucasian individuals of 55 years and older, including 1411 incident cases of type II diabetes. DNA samples were genotyped using the version 3 Illumina Infinium II HumanHap550 SNP chip array and were used to impute the genotypes of nearly two million SNPs in HapMap based on the observed haplotype structure. Given that the region included 508 SNPs, the significance threshold was set at 9.8×10^{-5} (0.05/508). The three *UBE2E2* candidate SNPs that were formerly reported in a Japanese GWA study (rs6780569, rs7612463, and rs9812056) were not associated with risk of type II diabetes (smallest p > 0.12). However, we found 57 SNPs in the region of *UBE2E2* to be significantly associated with risk of type II diabetes, of which rs7648425 was the most significant one (coded allele G; hazard ratio = 1.24 [95% confidence interval = 1.13 - 1.36]; $p < 4.8 \times 10^{-6}$). This SNP is close to rs7612463 which is one of the three Japanese candidate SNPs (distance = 9.9 kb, $R^2 = 0.03$). All significant SNPs were limited to the *UBE2E2* gene region. In conclusion, genetic variants in the *UBE2E2* gene region are associated with increased risk of type II diabetes in Caucasians. Lack of replication for specific SNPs in our study may be due to the difference in LD patterns between Japanese and Caucasian populations.

1328W

Three obesity-related loci are associated with insulin resistance independently of body mass index. *T. Fall[1], J. Ärnlöv[2], C. Berne[3], E. Ingelsson[1].* 1) Dept of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Department of Public Health and Caring, Uppsala University, Sweden; 3) Department of Medical Sciences, Uppsala University, Sweden.

Decreased tissue sensitivity to insulin (i.e. insulin resistance) and pancreatic beta-cell dysfunction are the two main physiological features of type 2 diabetes (T2D), and thus, an increased understanding of the genetic underpinnings of these conditions are of great importance in predicting and preventing T2D. Despite the rapid development within the field of diabetes genetics, few genetic variants associated with insulin sensitivity have been described, potentially due to the lack of cohorts examined with gold standard methods for insulin sensitivity assessment. There is a strong link between obesity and insulin sensitivity, and obesity susceptibility loci may also affect insulin sensitivity. A cohort of 71-year old non-diabetic men (ULSAM) underwent a euglycemic hyperinsulinemic clamp (n=926). The ULSAM cohort has undergone prior genotyping on the “Metabochip”, a custom iSELECT array, which is designed to interrogate ~195,000 SNPs of interest for cardiovascular and metabolic diseases. For this study, we extracted genotypes representing the 32 loci associated with body mass index (BMI) recently reported by the GIANT consortium. In 23 of 32 SNPs, the lead SNP was available. For the remaining 9 loci, the proxy SNP with highest r^2 was selected (based on phased haplotypes from HapMap rel21). For each locus, the effect allele reported by the GIANT consortium was set to be the effect allele also in our cohort. The effect of these loci on insulin sensitivity expressed as M/I-value (insulin-mediated glucose uptake divided by steady state plasma insulin concentration) was examined using linear regression techniques. The BMI-raising alleles at three loci (*NEGR1* () -0.22±0.1, p=0.03), *MTCH2* () -0.21±0.1, p=0.03) and *SH2B1*() -0.19±0.1, p=0.05)) were associated with decreased insulin sensitivity at a nominal significance (P≤0.05) even after adjustment for BMI. Our study supports earlier reports of *SHB21* to be of potential importance in insulin sensitivity, and suggests a role of *NEGR1* and *MTCH2*. Further studies combining several samples with gold standard measurements of insulin sensitivity to maximize statistical power are needed to further determine the genetic architecture of insulin sensitivity.

1329W

Fine-scale genetic mapping reveals multiple signals of association in type 2 diabetes susceptibility loci. *T. Ferreira[1], J. Yang[2], M.E. Goddard[3], A. Mahajan[1], T.M. Teslovich[4], N.W. Rayner[1,5], B.F. Voight[6], H. Khan[7], P.M. Visscher[2], M.I. McCarthy[1,5], A.P. Morris[1] on behalf of the DIAGRAM Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Melbourne School of Land and Environment, University of Melbourne, Melbourne, Australia; 4) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 5) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK; 6) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 7) Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK.

There are now more than 40 established type 2 diabetes (T2D) susceptibility loci. However, these loci often extend over hundreds of kilobases and contain many genes with plausible functional impact on the disease. In most cases, only the lead SNP is reported for each locus. However, multi-SNP analyses may provide a better understanding of the contribution of genetic variation in each locus to disease susceptibility.

We considered 20,483 T2D cases and 55,630 controls from 24 cohorts of European descent and 1,178 T2D cases and 2,472 controls from a cohort of Pakistani descent. The samples were genotyped using the “Metabochip”, a custom iSELECT array containing ~195,000 SNPs, designed to support replication and fine-scale mapping of established loci for T2D and other cardio-metabolic traits. We also considered GWAS samples imputed up to 2.5M SNPs (17,791 T2D cases and 50,337 controls from 12 cohorts of European descent). We tested for association of each SNP (MAF>1%) with T2D in each cohort and combined results via fixed-effects meta-analysis. We performed approximate conditional analysis using summary statistics from the meta-analysis and the correlation between SNPs obtained from Metabochip genotype data from a reference cohort of 1,117 T2D cases and 4,224 controls from the Warren 2 Repository and 1958 British Birth Cohort.

We identified three independent signals of association (conditional $p<5\times10^{-8}$) at the *KCNQ1* locus: rs231362 ($p=3.1\times10^{-12}$), rs74046911 ($p=6.8\times10^{-9}$) and rs163184 ($p=9.2\times10^{-9}$). We also observe two weakly correlated (CEU $r^2=0.06$) signals of association at the *ANKRD55/MEKK1* locus: rs459193 ($p=8.2\times10^{-15}$) and rs3843467 ($p=1.8\times10^{-8}$). At the *CDKN2A/B* locus, we observe two correlated signals of association (CEU $r^2=0.36$) which have been previously shown to tag three clades of haplotypes: rs10811661 ($p=4.3\times10^{-53}$) and rs10757283 ($p=7.5\times10^{-32}$). At these three loci, including all independent signals of association increases the explained sibling risk ratio from 1.003 to 1.011. These results highlight the importance of fine-mapping to fully reveal the genetic architecture of T2D associations within established loci, and thus show promise for furthering our understanding of the biological mechanisms underpinning susceptibility to the disease.

Mutational spectrum in a sample of Mexican patients with Hunter syndrome (MPSII): A preliminary report. *M. Alcantara, A. González -del Ángngel, L. Fernández-Hernández, B. García de Teresa B.* Dept Genetica, Inst Nacional Pediatria, Mexico City, Mexico.

INTRODUCTION: Over 300 pathogenic mutations have been described in IDS gene leading Hunter syndrome (MPSII). The mutational spectrum of Mexican MPSII patients isn't well known. OBJECTIVE: Identification of IDS mutations in a sample of Mexican patients with a clinical and enzymatic diagnosis of MPSII. MATERIAL AND METHODS: DNA samples from 7 male non-related MPSII patients (2 familial and 5 sporadic) and their mothers were analyzed by a PCR-RFLP assay to identify the IDS/IDS2 inversion and by full sequencing of IDS gene. RESULTS: Six different mutations were ascertained: p.His335Tyr, p.Asp45His, c.508-1G>C, the IDS/IDS2 inversion, a complete deletion of IDS that extends to the IDS2 and FMR2 genes and one complex IDS rearrangement not yet full characterized involving a deletion of exons 4 to 7. Carrier status for p.His335Tyr and the IDS complex rearrangement was confirmed in two pregnant mothers and prenatal diagnosis (PD) was offered in both. CONCLUSIONS: A genotype-phenotype correlation still can't be attempted. However it can be noted that the 3 patients with large rearrangements show classic phenotypes. Large IDS rearrangements are observed in the 10% MPSII cases, yet here they represent 42% (3/7), this last might be due to the small size of our sample. Large deletions that eliminate IDS/IDS2 and FMR-2 genes lead to a modified phenotype featuring seizures and ptosis; however these clinical features were absent in our patient. The p.His335Tyr mutation is still not reported. Availability of molecular diagnosis for MPSII in Mexico opens the possibility of PD and early ERT.

Screening for MPS VI in newborns on a high-incidence area of Northeast Brazil. *F. Bender[1,2], T. Amorim[3,4], A.X. Acosta[5,6], F. Costa-Motta[1], A. Purificacao[3], M.G. Burin[1], R. Giugliani[1,2,7,8], S. Leistner-Segal[1,2].* 1) Med Gen Service, HCPA, Porto Alegre, RS, Brazil; 2) Postgraduate Program in Medicine: Medical Sciences, UFRGS, Porto Alegre, RS, Brazil; 3) APAE, Salvador, BA, Brazil; 4) Esc Bahiana Med Saúde Pública, Salvador, BA, Brazil; 5) FIOCRUZ, Salvador, BA, Brazil; 6) Dep Pediatrics, UFBA, Salvador, BA, Brazil; 7) Dep Genetics, UFRGS, Porto Alegre, RS, Brazil; 8) INAGEMP, Porto Alegre, RS, Brazil.

Mucopolysaccharidosis VI (MPS VI, or Maroteaux-Lamy syndrome) is caused by the deficiency of the lysosomal enzyme N-acetylgalactosamine 4-sulfatase(ARSB). This deficiency causes the storage of dermatan sulphate in tissues, leading to a progressive and severe bone dysplasia and to problems in many organs and systems. MPS VI is a very rare condition, which was a relatively high incidence (13 cases identified so far) in the county of Monte Santo (50,000 inhabitants), in Bahia state, Northeast region of Brazil, where a common mutation (H178L) was found in all cases. As MPS VI could be treated with ERT and as there are indications that a better outcome may be expected in early treated cases, a newborn screening program for this condition was set up on this specific area. To the program already in place for PKU, hypothyroidism and hemoglobin disorders, screening for MPS VI was added by ARSB activity assay and by the detection of the common mutation, both performed on DBS. The standardization of the techniques of enzyme assay, DNA extraction and mutation detection were already completed and the test on newborn samples has started on January 1st, 2011. The possibility of detecting carriers will help to calculate the expected frequency of this disease in the area, and will also be a tool to target genetic counseling to the more susceptible families.

1332W

Screening for MPS IV A in dried blood spots with a practical and reliable fluorimetric method. *M.V. Camelier[1,2], G.E.S. Civallero[1], J.F Mari[1], G. Marasca[1], T.A. Vieira[1,2], M.G. Burin[1], R. Giugliani[1,2,3].* 1) Med Gen Service, HCPA, Porto Alegre, RS, Brazil; 2) Postgraduate Program in Medicine: Medical Sciences, UFRGS, Porto Alegre, RS, Brazil; 3) Dep. Genetics, UFRGS, Porto Alegre, RS, Brazil.

Mucopolysaccharidosis IV A (MPS IV A) is a rare autosomal recessive disease caused by deficiency of the lysosomal enzyme N-acetylgalactosamine-6-sulfatase(GALNS),resulting in storage of keratan-sulfate in many tissues and organs. This accumulation causes a severe skeletal dysplasia with short stature,and affects the eye, heart and other organs. Clinical trials with ERT for this disease are in progress. We describe an innovative fluorometric method for the assay of GALNS in dried blood spots (DBS). We used DBS as the enzyme source and compared it with leukocytes,having studied 25 MPS IVA patients and 54 healthy controls. We optimized the assay conditions in DBS, including incubation time and stability on different storage temperatures and along time. Results in DBS were compared to the ones obtained in leucocytes using the standard technique. The described fluorescent methodology was validated in our laboratory and the assay was found sensitive and specific,allowing reliable detection of MPS IVA patients. The use of DBS simplifies the collection and transportation,and is especially useful for testing patients from more remote areas of large countries,and when samples need to cross country borders. We believe this assay could be easily incorporated by reference laboratories and play a role in the screening for MPS IVA, contributing to the earlier detection of affected patients.

Variation in Heat-Shock 70-kDa Protein 5 (*HSPA5*) is Associated with Longitudinal Change in Body Fat. *M.H. Black[1], R.M. Watanabe[2], M. Takayanagi[1], E. Trigo[3], J. Hartiala[4], H. Allayee[4], J.M. Lawrence[1], T.A. Buchanan[3], A.H. Xiang[1].* 1) Department of Research & Evaluation, Kaiser Permanente Southern California, Pasadena, CA; 2) Department of Preventive Medicine, Division of Biostatistics, Keck School of Medicine, University of Southern California, Los Angeles, CA; 3) Department of Medicine, Division of Endocrinology, Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Institute for Genetic Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA.

ER stress in adipocytes may play a significant role in obesity. *HSPA5* is a mediator of the adaptive unfolded protein response elicited by ER stress and highly expressed in adipose tissue. *Hspa5* $^{+/+}$ mice have increased fat mass and greater insulin resistance than *Hspa5* $^{-/+}$. The contribution of *HSPA5* to changes in human body composition has not been investigated. We screened the *HSPA5* gene region in participants of BetaGene, a family-based study of obesity, insulin resistance and beta cell function in Mexican Americans. Body fat was assessed by DEXA. Insulin sensitivity (S_I), acute insulin response (AIR) and disposition index (DI) were estimated from the frequently sampled intravenous glucose tolerance test (FSIVGTT) with Minimal Model analysis. We hypothesized that variation in *HSPA5* may be associated with longitudinal changes in body fat percentage, with concomitant effects on other glucoregulatory phenotypes. We genotyped 6 SNPs in the *HSPA5* gene region, of which 3 had minor allele frequency (MAF) > 5% (MAF range: 11-26%). We tested these 3 SNPs for association with longitudinal change in phenotypes in a subset of 228 BetaGene participants (mean baseline age: 35 ± 8 years; 69% female) with follow-up phenotyping (mean length of follow-up: 4.5 ± 1.4 years). Analyses were performed assuming a dominant genetic model adjusted for baseline age and sex. All analyses were conducted using SOLAR (v 4.3.1). P-values are Bonferroni-corrected for the number of SNPs tested. The rs12009 C allele and rs391957 T allele were significantly associated with an increasing rate of change in body fat percentage (corrected p = 0.012 and 0.033, respectively). On average, carriers of the rs12009 C allele had a significantly greater increase in body fat percentage over follow-up than non-carriers (mean increase: 0.29 vs. 0.01 percent body fat per year, respectively). SNP associations with rate of change in BMI were similar in direction to those for body fat percentage. Consistent with an increase in adiposity, there was suggestive evidence for association between the rs12009 C allele and a decreasing rate of change in SI (nominal p=0.027). These data suggest that variation in *HSPA5* may contribute to increased adiposity and associated insulin resistance over time in Mexican Americans.

Novel associations for hypothyroidism include known autoimmune risk loci. *B.T. Naughton[1], J.Y. Tung[1], A.K. Kiefer[1], D.A. Hinds[1], U. Francke[1,2], J.L. Mountain[1], C.B. Do[1], N. Eriksson[1].* 1) 23andMe.com, Mountain View, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

Hypothyroidism is the most common thyroid disorder, affecting about 5% of the general population. Here we present the first large genome-wide association study of hypothyroidism, in 2,564 cases and 24,448 controls from the customer base of 23andMe, Inc., a personal genetics company. We identify four genome-wide significant regions, two of which are well known to be involved with a large spectrum of autoimmune diseases: rs6679677 near PTPN22 and rs3184504 in SH2B3 (p-values 3.5E-13 and 3.0E-11, respectively). We also report associations with rs4915077 near VAV3 (p-value 8.3E-11), another gene involved in immune function, and rs965513 near FOXE1 (p-value 3.1E-14). Of these, the association with PTPN22 confirms a recent small candidate gene study, and FOXE1 was previously known to be associated with thyroid-stimulating hormone (TSH) levels. Although SH2B3 has been previously linked with a number of autoimmune diseases, this is the first report of its association with thyroid disease. The VAV3 association is novel.

1335W

Cognitive testing in patients with Fabry disease: a pilot study using a computerized, self-administered tool. *D. Elstein[1], G.P. Doniger[2], E. Simon[2], G. Altarescu[3].* 1) Gaucher Clinic, Shaare Zedek Medical Ctr, Jerusalem, Israel; 2) NeurTrax Corporation, New York, USA; 3) Genetics Institute, Shaare Zedek Medical Ctr, Jerusalem, Israel.

Background: Recently, cognitive profiles of Israeli patients with Fabry disease highlighted neuro-cognitive impairment not solely due to a chronic, pain-ridden disease. Neuro-cognitive tests are time-consuming and patients often are non-compliant. A validated standardized computerized tool for neuro-cognitive testing which is user-friendly and supplies clinically-relevant information was tested. Methods: All males and females with enzymatic and/or molecular diagnosis of Fabry disease seen in our clinic underwent assessment with the Fabry-specific Mainz Severity Score Index (MSSI) with sub-scores (neurological, renal, cardiac, and general) and a MindStreams neuro-cognitive battery (1 hour) for mild impairment evaluating memory, executive function, attention, information processing, visual spatial processing, verbal function, and motor skills; a Global Cognitive Score (GCS) was also computed. Results: Ten patients (3 males, 7 females) were tested (mean age: 41.5 (25-56) years). Males were younger, had moderate nephropathy, and none had had a cerebrovascular accident (CVA). The range of MindStreams GCS among the males was 85.6-107 points. Three females had mild to moderate neurological impairment as reflected by MSSI neurological sub-scores of 8,10, and 15 points; two females had had a CVA in the past. The range of MindStreams GCS among the fe males was 59-107.7 points. Below-average performance was prevalent, particularly in information processing and motor skills, often in a range consistent with mild impairment Average GCS in females (90.3 points) was lower than in males (98.2 points). For individual patients, performances was poorest in information processing (n=4), attention (n=2), motor skills (n=2), verbal function (n=1), and visual spatial (n=1). Conclusion: MindStreams may be useful for rapid cognitive assessment in Fabry disease. Affected domains in Fabry disease were different than in patients with other lysosomal diseases but comparable to those reported by others in Fabry disease using time-intensive batteries.

1336W

Evaluation of plasma globotriaosylsphingosine in patients with Anderson - Fabry disease in Brazil on enzyme replacement therapy with agalsidase alfa. *W. Marques Jr[1], O.M. Vieira Neto[1], M. Moysés Neto[1], I.M. Furquim[2], A.C. Paula[2], J.C. Coelho[3], C.M. Lourenco[1].* 1) Hospital das Clinicas de Ribeirao Preto - USP, Ribeirao Preto, Sao Paulo, Brazil; 2) Hospital Municipal da Criança, Guarulhos, Sao Paulo, Brazil; 3) Universidade Federal do Rio Grande do Sul, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil.

Introduction: Anderson-Fabry disease (AFD) is an inherited disorder due to an enzymatic deficiency of alpha-galactosidase activity, resulting in glycosphingolipid accumulation. As enzyme replacement therapy (ERT) involving recombinant enzyme has been introduced for this disease, finding a reliable surrogate biomarker for monitoring the therapy is very important for evaluation of benefits and better follow-up of patients on ERT. Material and Methods: We studied 06 Fabry patients four males and two females) over a period of 6 months regarding disease progression and clinical outcome under ERT. Plasma globotriaosylsphingosine (lysoGb3) levels were measured in dried blood spots before and 06 months after treatment with agalsidase alfa (Replagal®). Results: Both male and female patients had elevated levels of lysoGb3; in the males subjects, the increase was impressive before starting treatment. After 6 months, plasma lyso Gb3 were reduced in all patients; in males, plasma lyso Gb3 dropped more dramatically than in the females subjects. Pre-treatment plasma lysoGb3 concentrations of Fabry females were relatively low but remained stable or decrease after ERT. At baseline, only only two patients showed abnormal cardiac findings (mild LVH and mitral valvulopathy, respectively). Brain MRI with angiography was abnormal in two patients (multiple hypersignal loci with arterial tortuosity and periventricular white matter changes). Proteinuria and microalbuminuria were present in all patients; after 6 months under ERT, brain MRI changes remained stable and no further kidney deterioration was seen. Cardiac evaluation still showed no abnormal findings in the other patients and remained unchanged in the other two. Conclusion: Our Anderson-Fabry cohort showed reduction of plasma lysoGb3 after ERT introduction. Although it was not possible to evaluate differences in other systems because of the short period of observation, our finding confirms previous studies which show that ERT can correct plasma lysoGb3 in Fabry patients even in a short period of 6 months.

1337W

Enzymatic characterization of *ALDH7A1* (antiquitin) missense mutations associated with pyridoxine dependent epilepsy. *M.B. Coulter-Mackie[1,2], Q. Lian[1], A. Li[2], E. Struys[1,3], S. Stockler[1], P.J. Waters[1,2].* 1) Dept Pediatrics, Univ British Columbia, Vancouver, BC, Canada; 2) Dept Pathology and Laboratory Medicine, Univ British Columbia, Vancouver, BC, Canada; 3) Dept Clinical Chemistry, VU Medical Center, Amsterdam, Netherlands.

Pyridoxine dependent epilepsy (PDE) is an autosomal recessive disorder causing seizures that are uncontrollable by standard antiepileptic medications but which typically respond to pyridoxine (vitamin B6). PDE results from mutations in the *ALDH7A1* gene, which encodes alpha aminoadipic semialdehyde (AASA) dehydrogenase, also known as antiquitin (ATQ). In order to determine post-translational effects of disease-associated missense mutations on ATQ enzyme function, we established an automated assay of enzyme activity using the natural substrate, AASA.

Methods: Missense mutations in a cloned copy of human *ALDH7A1* were generated by site-directed mutagenesis and expressed in E. coli. We developed a novel source of the substrate using a cloned gene for a fungal lysine aminotransferase to produce AASA from lysine and 2-ketoglutarate. Enzymatic activity was determined using an NAD-dependent spectrophotometric kinetic assay monitored by an autoanalyzer.

Results: We have thus far studied the wild-type enzyme and three missense mutants, p.R307Q, p.E399Q and p.S430N. Levels of ATQ protein expression, visualized by SDS-PAGE, were similar for all. Assay linearity with protein and the lower limit of detection of ATQ enzymatic activity were established with the wild type. Activity for each of these three mutants was below the limit of detection (<1%).

Discussion and Conclusions: The lack of activity associated with these three mutations in our *in vitro* system is supportive of their pathogenicity *in vivo*. For the common p.E399Q mutation our findings are consistent with a previous report based on expression in CHO cells. The other two mutations have not previously been studied. We are in the process of characterizing additional mutations, some associated with variant late onset clinical phenotypes. Our method offers a simple rapid first step in evaluating the post-translational effects of missense mutations on the function of ATQ and their correlation with PDE.

Financial support for this project was provided by CURE (Citizens United for Research in Epilepsy) and the Savoy Foundation.

Two Cases of Congenital Disorders of Glycosylation Type II Without Detectable Defect in Conserved Oligomeric Golgi Subunits. *D. Handa[1], R. Gilbert[2], B. Ng[3], M. Kozenko[1], M. Ssybowska[1], H. Freeze[3], C. Li[1].* 1) McMaster University Medical Center, Hamilton, Canada; 2) Southampton General Hospital & University of Southampton, UK; 3) Sanford-Burnham Medical Research Institute, USA.

Congenital disorders of glycosylation (CDG) are autosomal recessive multi-system conditions showing defective glycosylation. To date, 29 mutated genes are known to cause CDG. The best diagnostic test for CDG is analysis of serum transferrin glycosylation status using iso-electric focusing (TIEF) or mass spectrometry. Both methods distinguish two major categories: Type I due to absence of entire glycan chains and Type II due to incomplete glycan chains. There are 18 subtypes in type I and 11 subtypes in type II disorders. For most subtypes of type II, only a few cases have been reported and the defects usually involve one of the components in the Conserved Oligomeric Golgi (COG) subunits. We present here two patients with abnormal TIEF patterns consistent with type II CDG. Patient 1 was a full term boy diagnosed with CDG type II at 6 months of age due to clinically suspected seizure, prolonged neonatal jaundice, rhizhomelic short stature, central hypotonia, failure to thrive, GI bleeding, thrombocytopaenia and nephrotic syndrome with transient, unexplained renal failure which recovered spontaneously. Patient 2 is an infant girl who also has central hypotonia, rhizhomelic short stature, failure to thrive, and a history of GI hemorrhage. In addition, she has inverted nipples, adducted thumbs, 2-3 toe syndactyly bilaterally and retinitis pigmentosa. Further testing of Patient 2 using COG-specific antibodies and brefeldin A treatment showed normal COG subunit expression and function. Patient 1 is undergoing further investigation. Whole Exome Sequencing is also underway to identify the pathological genetic changes in these patients. Prior to receiving their diagnosis of CDG type II, both patients were considered for a host of other genetic and metabolic disorders, in part due to the extremely low prevalence of CDGs, particularly CDG type II. These two cases therefore draw attention to this group of potentially under-diagnosed conditions. The fact that all COG subunits are normal in patient 2 also further highlights the genetic heterogeneity underlying this extremely rare group of disorders.

1339W

Genetic Counseling of Donor Gamete Use: The Problems Presented By Donor Anonymity. *J.L. Lauzon[1, 2], J.R. Guichon[2], I. Mitchell[2, 3].* 1) Medical Genetics, Alberta Children's Hospital, 2888 Shaganappi Trail NW Calgary, Alberta Canada T3B 6A8; 2) Faculty of Medicine, University of Calgary, 3330 Hospital Drive NW Calgary Alberta Canada T2N 4N1; 3) Department of Respirology, Alberta Children's Hospital, 2888 Shaganappi Trail NW Calgary, Alberta Canada T3B 6A8.

It is accepted practice in genetic counseling to present as an option to certain patients the use of donor gametes to conceive a child. Authors of standard genetics textbooks state that there can be “genetic indications” for using donor gametes, including when a prospective parent has an autosomal dominant, autosomal recessive or X-linked disorder, or has a heritable chromosome defect. Yet, in the United States and Canada, most gamete donations remain anonymous. Therefore, when geneticists present gamete donation as an option, they are, albeit perhaps inadvertently, presenting a procreative practice that can make it almost impossible for geneticists to obtain a complete family history of the resulting offspring. The medical consequences of anonymous gamete donation as well as a recent Canadian Court decision that banned donor anonymity will be explored with a view to suggesting richer practice guidelines.

Genetic diseases in the next edition of the International Classification of Diseases: challenges and opportunities. *S. Ayme, A. Olry, B. Bellet, A. Rath.* INSERM, SC11 /Orphanet, Paris, France.

The classification of diseases which is used worldwide and by a wide range of stakeholders is the International Classification of Diseases (ICD10). Most genetic diseases are absent in ICD10 and those with a specific code are often misclassified. As a consequence, morbidity and mortality due to genetic diseases is invisible in health information systems. To overcome this difficulty, Orphanet (www.orpha.net) has established a partnership with WHO to ensure a fair representation of rare diseases in general. Orphanet has collected all published expert classifications and established a database of phenotypes indexed with ICD10 codes, MIM codes, genes, mode of inheritance, age of onset and class of prevalence. Phenotypes are assigned to as many classification systems as necessary to represent them. The visualisation of the classification systems and of the place of each disease within the classification is available on the Orphanet website. The Orphanet nomenclature of rare diseases is a stable one, directly exploitable by information systems and freely accessible at orphadat.org. A Topic Advisory Group on rare diseases has been established to manage the revision process at WHO. The whole community of experts is involved in the validation process. Revised chapters follow a primarily clinical approach, only secondarily an aetiological one, up to the gene level. When several possible names are possible for a disease, descriptive names formed in accordance with a clinical approach are preferred. Every entity is assigned a unique identification number. Rare diseases affecting several body systems are included in every relevant chapter, as ICD11 will be poly-axial, but a main code is proposed to allow for linearisation, according to the most severe involvement and/or the specialist most likely to be relied on for disease management. In some cases, the choice is open to debate. The genetic disease community is invited to take an active part as the results will condition the visibility of all activities in the field. All the revised chapters open for comments are available on the EUCERD website at www.eucerd.eu. The alignment of the Orphanet nomenclature with OMIM poses the question of the fair representation of genetic diseases and of the genetic contribution of genomics to disease definition, in relation with the needs of the end-users.

Digi-ID: From Researcher/Resource Traceability to Participant De-identification. *M. Deschenes[1], A. Brookes[2, 7, 8], P. Burton[6, 2, 8], A. Cambon-Thomsen[3], J. Kaye[4], B.M. Knoppers[5, 1], L. Mabile[3], M. Murtagh[6, 8], A.-M. Tassé[5], G. Thorisson[2, 7], S. Wallace[6, 8], BRIF working group.* 1) P3G Consortium, Montreal, Canada; 2) Department of Genetics, University of Leicester, UK; 3) Inserm UMR 1027 and Université de Toulouse, France; 4) Oxford Department of Public Health, University of Oxford, UK; 5) Centre of Genomics and Policy, McGill University, Canada; 6) Department of Health Sciences, University of Leicester, UK; 7) Gen2Phen Project; 8) Data2Knowledge Center, University of Leicester.

Effective data sharing serves to accelerate biomedical science by optimising the availability of extant information and its use in generation scientific insights. But data sharing also raises challenges, such as how to ensure fair use of the shared information, and how to acknowledge contributions in consistent and transparent manners. It also revives existing privacy concerns. Can digital identifiers enhance global research and make it more efficient? Through Digi-ID, P3G brings together innovative projects to explore these challenges: 1)(BRIF)Bioresource Research Impact Factor (C.-Thomsen et al.)BRIF proposes solutions to the problem of the traceability and the recognition of the contribution of research resources to discovery science. It will provide a global register cataloguing unique identifiers for biobanks, databases, and repositories. Such a unique identifier would acknowledge use of the resource in publications and grants and enable such resources to establish frequency of use. 2)Using Open Researcher and Contributor ID (ORCID) developments to enhance data utility (Brookes et al.). ORCID aims at solving the name ambiguity problem in scholarly communication by creating “a central registry of unique identifiers for individual researchers and an open and transparent linking mechanism between ORCID and other current author ID schemes”. Global identification infrastructure exists for content but not for the producers of that content, creating challenges in establishing the identity of authors/contributors and reliably linking them to their published works. We foresee extensions to ORCID system use in areas such as the unambiguous tracking and accrediting of data sharing, and streamline IT solutions for ensuring control of data access. 3)DataSHIELD (Data Aggregation Through Anonymous Summary-statistics from Harmonized Individual levEL Databases) (Burton et al.)Social expectations of access, security, privacy and transparency and the consequent ethico-legal imperatives shape how we use, share and analyse data. DataSHIELD provides a key solution to new challenges by enabling pooled data analysis to be carried out across several collaborating studies as if one had full access to all of the individual level data. But, under a `parallelized' analysis these data remain completely secure on the host computers at their home bases. In effect, full individual-level meta-analysis is realised without breaching local law or research governance requirements.

1342W

Human Genome shares genes from lower plants and animals:Patenting genes is biologically undesired !! *H.K. GOSWAMI.* Genetics Department, Retired from Bhopal University, BHOPAL, Madhya Pradesh, India.

Genes are being cloned and patented which amounts to copyright of human genes, their forms and functions. Many chromosomes have several patented loci and within a decade or so, we shall have entire chromosomes patented. Hereunder this is argued, that the genes “cloned” and patented, are not exclusively human; exact copies of these genes (DNA sequences) are also present in other organisms. This has been aptly demonstrated by now, that human X and Y chromosomes and other chromosomes too, have evolved by sharing and transferring DNA sequences at various stages of evolutionary steps from diversified groups of organisms. Lately, recent data have even suggested with molecular evidences reagrding the presence of long identical DNA stretches among plant sex chromosomes and human Y chromosomes. Patent for a gene can not amount to patent of that gene present in other organisms; this needs serious scientific review. Apart from this, the patented gene is a chemical copy/pirated gene of the original gene present in a chromosome. How can a copy of the gene (man made) in the laboratory lead to patenting of an original gene present in a chromosome ? This may be a violation of legal, scientific, as well as ethical values. Technically, the genes owned in test tubes can not hold patent for the genes / chromosome domains in situ, because these are not exactly the same.

1343W

Indication of legal abortion in genetic disorders in Iran. *m. amirian[1], z. nafei[2].* 1) Yazd legal medicine organization, Yazd, Iran, yazd, Iran; 2) Yazd medical science university, Yazd, Iran.

Multiple congenital anomalies are common disorders that may be occur in fetus due to acquired, genetical or multifactorial causes.Whenever pregnant women or fetuses are seriously suffering from critical disorders it can lead to infirmity, before 16 weeks from last menstrual period, therefore the legal abortion is recommended . This subject in Iran would be done by requesting from judicial authorities.It would be accepted by three experts who are related to fetus or pregnant women disorders, then the legal abortion is issued by the legal medicine organization and eventually the legal abortion will be done by Obstetrics and gynecologist in public hospital. This case was referred to the legal medicine organization for the permission of legal abortion. Nuchal fold thickness were found by sonography and the amniocentesis were found 47xx+21 too that has shown Down syndrome in female fetus. The proband was gravid 2 and the result of non consanguineous marriage. The previous pregnancy lead to abortion . father and mother age are 36 and 27 years respectively. Bioethics is the most important concept in medical evaluation and legal aspects which is admitted in Islamic parliament of Iran. A recent research has shown that there are important conflicts in main branches of Islam that is related to the legal abortion.This subject is exist in different religions too . any disorders which can lead to infirmity or critical condition for pregnant woman is an issue related to the legal medicine organization in Iran and the legal abortion is issued.

1344W

PERSPECTIVES ON AFRICAN GENOMICS COMMOTION AND ADVANCEMENT: THE NIGERIAN CASE STUDY. *V.A. Counted[1, 2].* 1) Publication & Research, Counted for Christ International , Lagos, Nigeria; 2) Publication, Internet Missionary Journal, Berlin, Germany.

In March 2002, the Advisory Committee on Health Research of WHO issued a report on the implications of genomics in the developing countries, and the role they have to play (as was done for the Hispanics) in ameliorating a fractional imbalance while also aiming at harnessing global genomics. However, in recognizing the potential of genomics in improving health, the unprecedented advances in the science of genomics and its actions, plus its widely predicted revolutionary prevarication - as we look at these realities, how then can we present and apply this scientific knowledge to our global world? Also, while proffering solutions in some genomic problem domain via culminating a positive evolvement of human genome, where do developing countries (for example Nigeria) stand in this revolutionary emancipation? As we mull over this thought, the question of geographical negligence troubles the mind and quakes one to vomit truth. These truths will be exclusively uncovered and harkened to by applying the research questions of “What”, “Why”, and “How” - just as follows: 1. WHAT is the future or hope of maintaining a univocal or unified balance in global managerial genomics, and what should be the expected contributions of these developing countries in advancing the science of genomics? 2. Since the under-developed countries have over the years lacked trained and qualified bioethicists, scientists, geneticists and sufficient regulatory infrastructures, to deal with genomic issues, (a.) WHY is it so important for this “lack” to be met? And (b.) WHY is the discipline of genomics typical to the developed countries and then atypical to under-developed countries? Also (c.) WHY are students of these developing countries (like Nigeria) not embracing this concrete discipline? 3. HOW can we come in as Individuals, Research bodies, Scholars, Bioethicists, Scientists, Researchers, Medical Practitioners, and Geneticists, to workout this problem of parity, to give scientism hope, and rekindle the joy of many in these under-developed nations where the discipline of genomics has been condoned for hollow reasons? The researcher hopes to challenge and engage folks with these resolving questions in order to bring about a balanced polarity in global genomics healthcare through ethical, cultural, empirical, theoretical and comparable evidences.

Simons VIP Connect: The power of an online community for research recruitment. *W. Faucett[1], A. Bibb[2], E. Hanson[5], D. Ledbetter[1], C. Martin[2], A. Paal[2], T. Page[2], E. Sherr[4], J. Spiro[3], J. Tjernagel[3], W. Chung[6], Simons Variation in Individuals Project.* 1) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) Simons Foundation, New York, NY; 4) University of California at San Francisco, San Francisco, CA; 5) Harvard University, Boston, MA; 6) Columbia University, New York, NY.

Recruitment, engagement and retention of study participants are challenges for most genetic research studies, but modern methods of information provision and social networking have dramatically changed the opportunities for recruitment for rare genetic disorders. Simons VIP Connect (www.simonsvipconnect.org) was created as an online community to recruit individuals and families for the Simons Variation in Individuals Project, a study of patients with 16p11.2 deletions and duplications. The second goal of the online community is to provide support and information to families. Contact with families and the enrollment process is managed by two genetic counselors with a website for online registration and a toll-free telephone number available for interested families without internet access. The online community provides information about 16p11.2 deletions and duplications; discussion forums; literature summaries; helpful links, webinars; and an option to “ask an expert.” Participants complete a ten question survey during the registration process and can review the aggregate responses of all registered participants. Our recruitment strategies have included: directed traffic from Google ads, links from other chromosomal disorder patient advocacy websites, Facebook, referrals from molecular cytogenetics laboratories, and referrals from genetic counselors and geneticists we informed through direct mailings. The website was launched on 08/27/2010 and 162 individuals were registered as of 05/30/2011 for an average of 4 new participants per week. This includes 40 registrants from outside North America and 122 from the US and Canada (101 families). The majority of participants with deletions are between age 3 and 17 and the majority of participants with duplications are between ages 3 and 7. In the registration survey participants provided the following sources as to where they first heard about the online community: genetic counselors 28%; Facebook 23%; internet searches 23%; patient advocacy groups 10% and medical geneticist and another family were less than 10%. Of qualified families, approximately 80% agree to participate in the research study. We have found developing an online community to be an effective recruitment tool which facilitates participant engagement and is associated with high participation rate. This may be an effective tool for others to consider when recruiting and retaining study participants for rare conditions.

Stakeholders' perspectives of genetics in primary care: Will patients “slip through the cracks”? *L.E. Forrest[1], B.J. McClaren[2], S.A. Metcalfe[2], J.M. Hodgson[2], J. Emery[3].* 1) APHCRI, Australian National University, Canberra, Australian Capital Territory, Australia; 2) Genetics Education and Health Research, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 3) School of Primary, Aboriginal and Rural Health Care, University of Western Australia, Crawley, Western Australia, Australia.

Rapid developments in genetic technologies will change practice in all specialties of medicine, including primary care, due to the constant generation of new genetic/genomic information, genetic tests and screening procedures. However the ability of general practitioners (GPs) to practise genetic medicine is not only dependent on adequate education but on understanding how genetic medicine can be appropriately integrated in this healthcare setting. There is concern that consumers' genetic needs will not be met by their primary care provider. The aim is to examine how genetics is currently managed in primary care from the perspective of primary care providers, genetic health professionals and consumers, and whether changes to practice will be required in the future. A qualitative approach was taken with stakeholders including primary care representatives, genetic health professionals and health care consumers. Data were collected by semi-structured interviews addressing current practice of genetics in primary care; approaches to referrals and management; views on changes to practice and suggestions for ideal and acceptable practice; models which might deliver genetics in primary care. Thematic analysis was conducted on the transcribed interviews to identify key concepts and ideas. Fourteen interviews have been conducted to date with GPs, practice nurses, genetic counsellors, professional organisation representatives and consumers, with more planned during this year. Preliminary findings suggest that GPs willingly engage genetic health professionals for genetic support and advice as necessary. The generalist nature of general practice, a heavy workload, and time constraints were recognised by all participants as barriers to routine integration of genetics into primary care. Concern exists that patients requiring genetics care may “slip through the cracks”, especially with regard to the urgency of testing in pregnancy. Nevertheless, responses were mixed regarding whether practice will need to change to successfully integrate genetics into primary care and various models of practice were discussed.

1347W

Knowledge and attitudes toward medical genetic services and the new genetic technologies in the Cuban population. *B. Marcheco-Teruel[1], I. Rojas-Betancourt[2], E. Fuentes-Smith[1], N. González-Lucas[3], L. Martínez-Rey[2], A. Lantigua-Cruz[3], O. Mors[4].* 1) Genetic Epidemiology, National Center of Medical Genetics, Havana, La Habana, Cuba; 2) Clinical Genetics Dept, National Center of Medical Genetics, La Habana, Cuba; 3) Consultant, National Center of Medical Genetics, La Habana, Cuba; 4) Center for Psychiatric Research, Aarhus Psychiatric Hospital, Aarhus University, Denmark.

The application of knowledge gained from the characterization of the human genome holds considerable potential for the development of new health care innovations over the next years. The information generated by genomics research may have, in short and long-term, major benefits for the prevention, diagnosis and management of genetic and common diseases. In the last 8 years we have systematically explored the knowledge and attitudes toward medical genetic services and the benefits of new technologies for diagnosis and research of genetic diseases, in the Cuban population. 10630 individuals from 4874 families in contact with genetic services living in 97 out 169 Cuban municipalities were interviewed. 85% participants expressed they are satisfied with medical genetic services at the primary care level. We also explored their opinions about priorities for medical genetic services in the country: 9035 respondents considered primary and secondary prevention of genetic diseases should be the main priority; 75.4% considered that genetic researches should be also a priority in order to increase the benefits of medical genetics for public health; the need of offering medical and social support to families and individuals with genetic disorders and disabilities they may cause, was recommended as four priority by 7377 individuals; and education in medical genetics for health professionals and the broader population was the fifth. In Cuba, abortion is a legally and socially accepted procedure to end pregnancies in case of severe congenital malformations, 94.7% participants expressed that abortion should be offered in every case of severe congenital defect. 75,3% individuals were in favour of non-directiveness in genetic counselling. More specific questionnaires were conducted for complex disorders in Cuban families with Familial Early Onset Alzheimer`s Disease and with Bipolar Affective Disorder, in order to know about their attitudes and expectations toward genetic testing. We found a limited knowledge about genetics in general and the meaning of genetic risk factors for both diseases. We also observed a positive interest in presymptomatic testing including prenatal diagnosis if it would become available. The information derived from these studies is being used for developing educational strategies focused on health promotion and prevention for medical genetic services at the community level in Cuba.

The Duty to Recontact Revisited. *R. Pyeritz.* Dept Medicine, Perelman Sch Med, Univ Pennsylvania, Philadelphia, PA.

The question of whether a duty exists to recontact patients about new genetic information has been discussed for several decades, with no consensus. The emergence of new testing technologies forces reconsideration of this complex matter. A major conundrum is the uncertain meaning of the results of many genetic tests, such as gene sequencing and cytogenomic arrays. Variants of unknown significance (VUS), which comprise 5-30 percent of all results of sequencing a gene, will explode with clinical whole genome sequencing (WGS). What is the duty to keep patients informed about new interpretations of prior results? Ten issues need attention. How can new information be catalogued and make clinically relevant and available? What is the responsibility for dealing with pathologic findings not related to the indication for the original test (incidentalomes)? Who decides whether to recontact a patient—the consultant or the primary care provider? Are any data entered into a medical record (e.g., a WGS, or a direct-to-consumer genotype) obligated to re-interpretation? What are the expectations of patients? What are the implications for relatives of a re-interpretation, and who bears the responsibility for notifying? Can new interpretations be made ignoring a host of modifiers—genetic interactions, the epigenome, the microbiome, the environment, and personal behavior? Do the results of direct-to-consumer testing carry the same responsibilities if the patient wants them inserted in the record? Does an agreement to recontact maintain a physician-patient relationship that would otherwise be vacated and does failure to recontact constitute abandonment? Finally, what strategies are needed to educate all parties about these concerns. The existing policy statement of the American College of Medical Genetics, more than a decade old, is largely silent on these issues. Until science, technology and education improve our capabilities, health care providers would be wise to accept with caution an explicit duty to recontact a patient about new knowledge resulting from genetic tests. Including this perspective in the pre- and post-test counseling, even in an informed consent document, bears consideration. Similarly, the one-time consultant, even if he or she ordered a genetic test and discussed the result, might consider explicitly terminating the physician-patient relationship.

National Institutes of Health Controlled Data Access: Experience of the Genetic Association Information Network Data Access Committee. *C. Din-Lovinescu[1], E. Bookman[1], C. Baker[2], E.L. Harris[3], T. Lehner[4], C. McKeon[5], J. Moss[6], V. Starks[7], G. Godynskiy[8], S. Sherry[8], L. Rodriguez[1], E.M. Ramos[1].* 1) National Human Genome Research Institute, Bethesda, MD; 2) National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 3) National Institute of Dental and Craniofacial Research, Bethesda, MD; 4) National Institute of Mental Health, Rockville, MD; 5) National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD; 6) National Heart Lung and Blood Institute, Bethesda, MD; 7) National Cancer Institute, Rockville, MD; 8) National Library of Medicine, Bethesda, MD.

Genome Wide Association Studies (GWAS), a strategy for identifying genetic variants associated with health and disease, produce vast amounts of data suitable for addressing many research questions. To maximize the scientific uses of GWAS data through broad data sharing, the National Institutes of Health (NIH) developed a controlled-access data repository and data access system designed to provide GWAS data to qualified investigators for research uses consistent with the informed consent of study participants. The Genetic Association Information Network (GAIN), one of the first NIH GWAS programs, has been at the forefront of rapid and broad data sharing since its inception in 2006 and helped shape the development and design of the database of Genotypes and Phenotypes (dbGaP) and its data access system. GAIN includes GWAS of ADHD, diabetic nephropathy, psoriasis, major depression, schizophrenia, and bipolar disorder. Data Access Requests (DARs) for GAIN studies are reviewed by the GAIN Data Access Committee (DAC). The DAC grants access to controlled-access data after ensuring that investigators have adequate credentials and meet the requirements of the data access request process, including proposing research that is consistent with the data use limitations of the requested data. As of April 30, 2011, 808 DARs have been submitted, 654 (81%) of which were approved with an average submission to decision time of 12.9 days. The schizophrenia and bipolar disorder datasets are requested most frequently. 57% of submitted DARs include schizophrenia; 46% include bipolar disorder. The most common proposed research use is to study GAIN-specific phenotypes (53% of submitted requests), followed by methods development (18%) and adding controls to other studies (17%). 316 investigators have been approved to access GAIN data with 165 resulting publications. Eight investigators approved to access GAIN data (2.5%) were involved in a data management incident where the terms of the NIH Data Use Certification agreement were not followed. The majority of these incidents occurred in the early years of dbGaP and all were resolved. As the number of studies deposited in dbGaP continues to grow, a summary of how GAIN data are being accessed and used along with the experience of the GAIN DAC can serve as an example to inform the NIH and the research community about the impact of making GWAS and other large-scale genomics datasets broadly available.

Statewide Genetic Services Patient Management System in New South Wales, Australia: planning, implementation and integration. *M. Tom, A. Colley.* Clinical Genetics, Liverpool Hospital, Sydney, NSW, Australia.

Over the last year New South Wales (NSW) Health has implemented a state-wide genetic services patient management system across all Local Health Networks (LHN). This is a review of the process and integration of the database into the multiple different clinical units across the state with a view to identifying the costs, benefits, successes and barriers. Background: NSW Health is currently divided up into eighteen LHNs. To cover these areas there are six metropolitan clinical genetics services, five cancer genetics services and fourteen outreach genetic counsellors. Historically, each unit's development depended on the services of the base hospital and the needs of the local community, creating independent and unique services. In the past three different database programs were used to collect patient genetic information with data being collected and accessible only by the specific genetics unit. A proposal was put forward for a state-wide genetic database to enable easy identification of patients that have links with existing families and to prevent duplication of information, resources and testing. This database was rolled out across NSW from early 2010 to early 2011. Methods: This was a qualitative review in which questionnaires were used to find specific areas of interest. Fifteen in depth semi-structured interviews were conducted with data managers, administration and/or clinical staff from each of the cancer and clinical genetics units, outreach genetic counsellors, NSW Health and the company providing the database program and support (Kintrak). Results: The interviews identified particular areas of concern, including expectations prior to implementation, changes in work flow, time and staff costs, complexity of data entry, privacy, accuracy, affects on clinical practise and future plans. Conclusions: An effective database system is extremely useful to identify families who have attended other genetic services and assist in more accurate genetic counselling and fewer redundancies of service and testing. However, the process of integrating any new system into the complexities of clinical genetic services involves a number of adjustments and compromises which are difficult to predict in advance.

1351W

The dbGaP data repository: Who is using it for what kinds of research? *L. Walker[1,2], H. Starks[1,2,3], K. West[2,3], S. Fullerton[1,2,3].* 1) IPHG, University of Public Health Genetics, Institute for Public Health Genetics, University of Washington, Seattle, Washington, 98195, USA.Seattle, WA; 2) Center for Genomics and Healthcare Equality, University of Washington, Seattle, Washington, 98195, USA; 3) Department of Bioethics and Humanities, University of Washington, Seattle, Washington, 98195, USA.

The database for Genotypes and Phenotypes (dbGaP) was launched in December 2006 to support NIH policy that strongly promotes sharing data from genome-wide association studies. While secondary use of aggregate and individual-level data in dbGaP is encouraged (with NIH-affiliated Data Access Committee approval), there has been no systematic analysis of how this resource has been used. We manually accessed and reviewed all approved Data Access Requests (DARs) on the dbGaP website from its inception through August 10, 2010 to assess their number, type of proposed secondary use, and to characterize the institutional affiliation and location of each requestor. 2724 DARs were granted to 851 investigators in 330 institutions, located in 28 countries. Reported uses include genetic discovery (39%), methods development (26%), replication (18%), study controls (11%), investigations of population structure (1%), and quality control (1%). Requesting investigators were primarily affiliated with U.S. academic institutions (60%); other affiliations included U.S. non-profits (13%) and for-profits (8%), and non-U.S. academic (13%), non-profits (5%), and for-profits (1%). dbGaP data are being shared widely, yet the full impact on scientific advancement and public benefit is difficult to gauge because publications resulting from secondary uses are not yet identified, and DARs are not readily searchable with respect to the characteristics summarized here. To ensure broad stakeholder support for the on-going development and use of dbGaP and to advance generalizable knowledge of relevance to public health, the database should be made more accessible to primary investigators, research participants, and those responsible for certifying data for dbGaP submission.

1352W

Shwachman Diamond Syndrome diagnosis and care, comparison in six countries. *L.J. Siderius[1, 2, 3], T. Chigladze[3, 4], G. Abesadze[5], O. Kvlividze[4].* 1) Youth Health Care, Icare, Meppel, Netherlands; 2) Shwachman Diamond Syndrome represenative, SSSSH, Waddinxveen, Netherlands; 3) European Academy Pediatrics, Working Group Rare Diseases; 4) Genetic and Rare Diseases Foundation, Tbilisi, Georgia; 5) Tbilisi State Medical University, Tbilisi, Georgia.

Purpose: To access the diagnostics and care provision in for individuals with Shwachman Diamond Syndrome in Canada, Italy, Netherlands, United Kingdom, United States and Georgia. Background: Shwachman Diamond Syndrome initially described in 1964, on the basis of its features now seems to be due to a single gene defect. Canada, Italy, Netherlands, UK and US are listed in the top 20 of world's Gross Domestic product (GDP), Georgia in the lower half. We compared the healthcare systems in relation to diagnosis and care of persons with Shwachman Diamond Syndrome. Methods: A questionnaire addressing the care as perceived by individuals with Shwachman Diamond Syndrome (SDS) was send through the national patient organizations in five countries with a representing patient organization. The situation in Georgia was evaluated with information of national representatives of medical specialist, academy and patient organizations. Results: Considering the expected frequency of SDS 1: 100.000- 150.000, the highest response of persons with SDS was from Italy (7,75%) and the Netherlands (10,2 %) . Predictive health care can be coordinated on the basis of the genetic diagnosis. The Italian persons with SDS perceived significant (p= .040) more frequent coordinated care compared to other countries, and more specific to the persons in Netherlands (p=.031) and USA (p= .017). In Georgia diagnostic tests are not available for confirmation. Conclusion: Health care systems may be an underestimated factor influencing early detection and optimal care provision for persons with SDS, a rare and complex genetic disorder. The data gathered with this questionnaire may be used for the development of optimal model of management of rare diseases and extrapolation of best world practices in the countries with low GDP, and respectively, with different health cares systems, such as Georgia in particular.

1353W

Comparison of Delivery Models of Genetic Risk Information for Type 2 Diabetes. *S.B. Haga[1], W. Barry[2], R. Mills[1], J. Sullivan[3], H.F. Willard[1], L.P. Svetkey[4], G.S. Ginsburg[1].* 1) Inst Genome Sci & Policy, Duke University, Durham, NC; 2) Department of Biostatistics and Bioinformatics, Duke University Medical Center; 3) Department of Pediatrics, Div Medical Genetics, Duke University Medical Center; 4) Department of Medicine, Div Nephrology, Duke University Medical Center.

With the advent of direct-to-consumer testing, online communication has increased as a mode of delivery of genetic test results. However, the degree to which the public is able to comprehend their results without the assistance of a trained professional and the opportunity to discuss the meaning of the results is uncertain. We are conducting a randomized study to assess the impact of the method of delivery of genetic risk results for Type 2 diabetes mellitus (T2DM) on risk comprehension, risk perceptions, and health behavior. Three hundred participants recruited from the general public in Durham, NC were randomized to undergo testing provided by deCode Genetics of several polymorphisms associated with T2DM and receive their test result in-person from a genetic counselor or online through the company's website; 246 participants have completed the 1-week follow-up. Overall, 60% of individuals self-identified as White and 29% as African-American. Seventy percent of participants are female, and 65% have a Bachelor's degree or higher. A total of 38% of participants indicated that they completely trusted the genetic test result and 50% somewhat trusted the result. Overall, 73% of participants correctly reported their genetic risk for T2DM as compared to the general population (increased, decreased, or equal to). Participants who received their results in-person from the genetic counselor were significantly more likely to correctly indicate their comparative risk (85%) than those who reviewed their results on-line (61%) ($p < 0.0001$). A smaller proportion of respondents (58%) correctly reported their actual genetic risk (relative risk of developing T2DM based solely on genotype) based on their test report. Participants who received their result in-person from the genetic counselor were also more likely to correctly report their actual genetic risk (69%) as compared to those who reviewed their results on-line (48%) ($p = 0.001$). However, there was no statistically significant difference in the rate of correct response about their overall risk (lifetime risk and genetic risk) between the counseling group (65%) and online group (54%) ($p = 0.11$). In summary, participants who received their genetic risk results in-person from a genetic counselor were more likely to correctly comprehend the different risks included in their test report compared to reviewing their test result online.

Knowledge and attitudes regarding genomic medicine and research in South Florida's Hispanic and Black communities. *S. Hahn, K. Czape, A. Rupchock, M. Gavier, C. Jean, LD. Adams, J. Lee, MA. Pericak-Vance.* Hussman Institute for Human Genomics, University of Miami, Miami, FL.

While participation of minority groups in genetic and translational research is crucial, it has been historically low. Focus group research among Hispanics and Blacks in South Florida shows they may have unique attitudes and barriers to research participation. An anonymous paper survey was administered in South Florida to assess knowledge and attitudes about genetic testing and research. The survey, comprised primarily of previously published questions and available in English, Spanish, and Creole, was offered at public locations and events. Preliminary data shows a completion rate of 78% (n=242), with 51% and 27% self-identifying as Hispanic and Black, respectively. Average age was 40; 71% were female and 50% completed college. Most appreciated the concept of inheritance and the significant role of genetics in health. 77% were aware that family history influences disease risk; 80% were aware we each have genetic variations that put us at risk; and 89% knew most health problems result from a combination of genetic and other factors. Fewer knew that specific disorders have known genetic contributions such as diabetes (71%), cancer (62%), heart disease (54%), and autism (28%). Only 57% (76% of Blacks) knew sickle cell has a known genetic component. 72% answered genetic tests are used frequently to predict who will get common diseases such as heart disease and Alzheimer disease indicating misconceptions about current utility. While most were receptive to genetic testing, 48% were very or somewhat worried people will be able to learn their results. 37% thought they could be denied health insurance based on genetic information even if they didn't have the disorder. Views about genetic research were generally favorable. 78% indicated genetic research is very good and 82% would be very likely or somewhat likely to participate. While 46% said nothing would keep them from participating in genetic research, many indicated reasons that would, including worry about being harmed (20%), lack of time (19%), and worry about misuse of private information (15%). 52% answered incorrectly that all ethnic groups benefit equally from research even if a group does not participate. Overall, South Florida communities have comparable levels of knowledge of genetics to other US areas, and have a positive attitude towards genetics and genetic research. Gaps in knowledge and awareness identified may be used to improve educational initiatives, and increase minority involvement.

1355W

Recorded Interviews with Human Geneticists; an International Web-based Historical Resource. *P.S. Harper.* Institute of Medical Genetics, Cardiff University, Cardiff, United Kingdom.

A series of 80 recorded interviews with older human and medical geneticists has been undertaken by the author over the past 8 years, 62 of which have transcripts accessible on the website of the Genetics and Medicine Historical Network (www.genmedhist.org). Both laboratory and clinical workers are included in the series, which is international and principally European orientated, complementing a separate American series.(www.socgen.-ucla.edu/ hap/). These interviews form a valuable resource as part of the documentation of the history of human and medical genetics world-wide (see Harper PS, A Short History of Medical Genetics, OUP, 2008), giving information that often does not appear in written documents, in additon to providing a personal picture of the individuals involved and often of their older colleagues and teachers. There is an urgent need for extension of this work by both geneticists and historians; 10 subjects in the current series are already deceased since interview. Of particular importance will be interviews with the founders of `newer' fields such as human molecular genetics.

Managing ethical, legal, and social issues in cancer genome sequencing projects: a survey of current practices. *C. Allen[1,2], W.D. Foulkes[2].* 1) Biomedical Ethics Unit, McGill University, Montreal, Quebec, Canada; 2) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Quebec, Canada.

Background: Large-scale whole genome sequencing (WGS) studies promise to revolutionize cancer research by identifying targets for therapy and discovering molecular biomarkers to aid in early detection, diagnosis, prognosis, and prediction of treatment response. Such projects raise a number of ethical, legal, and social (ELS) issues that must be examined. This study analyses informed consent (IC) forms from cancer genome sequencing research to determine how investigators currently engaged in such studies are managing these issues. Methods: Thirty IC forms were collected from the US, Canada, Australia, Belgium, and the Netherlands. A thematic analysis examined (1) stated purpose of sample collection, (2) scope of consent requested, (3) data sharing protocols (4) privacy protection measures, (5) described risks of participation, (6) subject re-contacting, and (7) protocol for withdrawal. Results: Seventeen of the forms collected were seeking samples for the purpose of discovering the genetic basis of a particular cancer type. Five stated the purpose of broader medical research. Three forms were seeking consent only for the study described, while six intended to use samples for related research, and sixteen for any type of future research. Three forms did not discuss data sharing, while eleven stated the intention to share data with affiliated researchers, and sixteen with the public in general, though in the latter case gaining access to sensitive data would require authorization. All but one of the forms stated that samples and data would be de-identified, though twenty-one described re-identification as a risk. Participant re-contacting practices varied but could occur to obtain additional information, to suggest additional research participation, or in five instances, to return individual research results. Twenty-nine forms discussed withdrawal, though the described consequences of this for existing samples and data varied. Conclusion: Examining IC forms from WGS research elucidates how investigators are handling some of the ELS challenges that this research poses. This information is important for ensuring that while the public benefits of research are maximized, the rights of participants are also being appropriately respected. Acknowledgements: Funding for this article was provided by the APOGEE-Net/CanGèneTest Research Network and by Susan G. Komen for the Cure.

1357W

Parents' Preferences for Return of Results in Pediatric Genomic Research. *J.G. Amatruda[1], S.I. Ziniel[2,3], E.D. Harris[1], C.M. Clinton[1], S.K. Savage[4], N.L. Huntington[2,5], R.C. Green[6,7], I.A. Holm[1,2,8].* 1) Division of Genetics and Program in Genomics, Children's Hospital Boston, Boston, MA; 2) Department of Pediatrics, Harvard Medical School, Boston, MA; 3) Clinical Research Program, Children's Hospital Boston, Boston, MA; 4) Children's Hospital Informatics Program, Children's Hospital Boston, Boston, MA; 5) Division of General Pediatrics, Children's Hospital Boston, Boston, MA; 6) Partners Center for Personalized Genetic Medicine, Boston, MA; 7) Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 8) The Manton Center for Orphan Disease Research, Children's Hospital Boston, Boston, MA.

Objectives: Current guidelines for returning individual research results (IRR) from genomic studies focus on criteria including analytic and clinical validity, actionability, and severity of the outcome. However, many argue that the personal meaning of genomic information and participant preferences should play a role in return of IRR. Children's Hospital Boston (CHB) has taken the latter approach by initiating a large pediatric genetic repository, The Gene Partnership, in which IRR are returned in accordance with participant preferences. Recognizing that there is skepticism that participants truly understand the implications of their preferences for IRR to receive, the goal of this study was to explore parents' preferences for return of IRR on themselves and their children. We hypothesized that although most parents will report a desire to receive all IRR on themselves and their children, once presented with specific types of IRR, many would choose only a subset of possible results. **Methods:** We designed a survey to assess the interest of parent in enrolling themselves and their children in a hypothetical genetic research repository, and their preferences for return of return of IRR. The survey was mailed to 6872 parents of patients at CHB. **Results:** Preliminary analysis of data on over 800 respondents showed that 83% wanted to receive IRR on themselves and 85% wanted to receive IRR on their children. When asked if they wanted to receive all IRR as opposed to choosing which IRR to receive, 77% of respondents wanted to receive all results on themselves and 83% on children. However, when later asked about specific categories of results (based on analytic validity, clinical validity, actionability, and severity of the outcome) only 54% of respondents who initially wanted all IRR, wanted to receive results in all categories on themselves; the percentage was 57% for results on their children. Further, those respondents who wished to choose which IRR to receive were significantly more likely to be concerned about the impact of receiving IRR on various aspects of their lives (e.g., worry, insurance status, job status, discrimination) ($p < 0.001$). **Conclusions:** These results suggest that although participants may not understand the implications of receiving all IRR arising from genomic research, education on the types of results that may arise will enable participants to set preferences that better reflect their desires for return of results.

"It's really good judgment on their part not to tell people the stuff they can't control": Experience of whole exome sequencing among breast cancer survivors. *B. Bernhardt[1, 2], H. Pang[2], J. Powers[3], J. Stopfer[3], S. Domchek[3], K. Nathanson[1].* 1) Dept Med Gen, Univ Pennsylvania, Philadelphia, PA; 2) Center for the Integration of Genetic Health Care Technologies, Univ Pennsylvania, Philadelphia, PA; 3) Abramson Cancer Center, Univ Pennsylvania, Philadelphia, PA.

Although whole exome sequencing (WES) provides a powerful tool for gene discovery, there is considerable debate about the obligations of clinicians and researchers to disclose incidental findings. In an ongoing study, we are offering WES for identification of novel cancer susceptibility genes to women from "high risk BRCA1/2 negative" families recruited from a research registry. As a part of the informed consent process, participants are told that a multidisciplinary expert panel will review all results and determine which are both medically actionable and significant. Participants would be given the option of choosing to learn those results only. Participants were consented for WES by telephone or at a clinic visit by a study genetic counselor, and all acceptors and decliners subsequently were offered an opportunity to participate in a telephone interview to describe motivations for participation in the WES research, assess participant understanding of WES, and to assess attitudes towards returning of results. Interviews were recorded, transcribed and coded. Of the 53 women offered WES to date, 35 consented to WES, 3 declined and 17 did not respond to the offer. From the 13 interview transcripts that have been analyzed, all women correctly understood that the study's purpose is to find "new cancer genes." All women participated for altruistic reasons or to obtain information that could provide medical benefit to themselves or family members, primarily their children. Few women identified risks to participation, but when probed, some mentioned hypothetical risks of insurance discrimination or anxiety. With the exception of one woman, all participants understood "medically actionable" as meaning some intervention could modify health outcomes. If given the option to receive results for non-actionable diseases, the majority of the women would want such results so they could keep abreast of treatment advancements, or be prepared. However, all participants accepted the limitations placed on the types of results they could receive, either because they trusted the researchers to make decisions in their best interests, or they found the research design acceptable. These preliminary findings suggest that after a 30 minute consenting process, women can understand the purpose of WES research, agree with researchers on the interpretation of medically-actionable results and accept that all findings will not be returned to them.

1359W

Citizens' values regarding expanded newborn screening and the role of parental consent: A public engagement study. *Y. Bombard[1], F.A. Miller[1], R.Z. Hayeems[1], J.C. Carroll[2], D. Avard[3], J. Allanson[4], R. Axler[1], J. Bytautas[1], P. Chakraborty[4], Y. Giguere[5], J. Little[6], B.J. Wilson[6].* 1) Department of Health Policy, Management and Evaluation, University of Toronto, Toronto, ON, Canada; 2) Department of Family and Community Medicine, Mount Sinai Hospital, University of Toronto, Canada; 3) Centre for Genomics and Policy, Department of Human Genetics, McGill University, Montreal, Canada; 4) Department of Genetics, Children's Hospital of Eastern Ontario, and Department of Pediatrics, University of Ottawa, Canada; 5) Department of Medical Biology, Centre Hospitalier Universitaire de Quebec (CHUQ), University of Laval, Canada; 6) Department of Epidemiology and Community Medicine, University of Ottawa, Canada.

Introduction: Historically, newborn screening (NBS) programs identified serious conditions where early detection and pre-symptomatic treatment were necessary to avert clinical harm. Today NBS has expanded to screen for disorders for which there is limited evidence of health benefits for infants, yet many continue to operate on a mandatory or implied-consent model. The expansion of NBS has produced policy dilemmas about the scope of NBS and the role of parental consent. Continued debate about expanded NBS has led to calls for stakeholder engagement to inform policy. We investigated citizens' values regarding the scope of NBS and the type of consent parents should provide for NBS. Methods: We conducted eight focus groups (FG; n=60), and one Citizens' Panel (CP) with a subset of the participants (n=16). Recruitment was designed to ensure socio-economic, ethnic, age and family life diversity. FG and CP approaches included an educational component, deliberative discussion and pre- and post-questionnaires. Data were analyzed with descriptive statistics and qualitative content analysis. Results: Knowledge about NBS significantly improved (mean `knowledge scores': FG: pre=6.87 (SD:2.68) vs. post=7.8(SD:2.12) $p<0.0001$ & CP: pre=7.53(SD:1.25) vs. post=8.50 (SD:0.83) $p=0.018$). The majority (>94%) supported NBS that identifies serious treatable disorders; a majority (>69%) also supported NBS for untreatable conditions. Participants valued newborns' rights to open futures and informational benefits for family, such as avoiding the diagnostic odyssey, preparation and reproductive risk information. Potential harms, such as learning false positive results, were minimized, but some identified risks from stigma and unwanted knowledge. A majority endorsed having parents either required or strongly encouraged to have their infants screened. Finally, the CP recommendation was to screen for CF (16/16 in favour) while 12 were in favour and 4 against NBS for DMD. Conclusions: Most participants anticipated benefits from early identification of treatable and untreatable disorders through NBS. Participants' general endorsement of broad-scoped panels stemmed from their value-based trade-offs that prioritized benefits (e.g., newborns' open futures and informational benefits for affected infants and family) over considered harms. Further research is warranted to better understand the sources of these value-based trade-offs and their generalizability across different populations.

1360W

Legislation on direct-to-consumer genetic testing in seven European countries. *P. Borry[1,9], R.E. van Hellemondt[2], D. Sprumont[3], C. Fittipaldi Duarte Jale[4], E. Rial-Sebbag[5], T. Matthias Spranger[6], L. Curren[7], J. Kaye[7], H. Nys[1], H. Howard[8].* 1) Biomedical Ethics and Law, University of Leuven, Leuven, Belgium; 2) Leiden University Medical Centre, Leiden, the Netherlands; 3) Institute of Health Law, University of Neuchâtel, Switzerland; 4) Portuguese Catholic University, Portugal; 5) Inserm U558, University of Toulouse III, France; 6) Institute for Public Law, University of Bonn, Germany; 7) HeLEX Centre for Health, Law and Emerging Technologies, University of Oxford, U.K; 8) Inst. of Biomedical Ethics, University of Basel, Switzerland; 9) Dept. Clinical Genetics and Medical Humanities, VU University Medical Centre Amsterdam, The Netherlands.

An increasing number of private companies are now offering direct-to-consumer (DTC) genetic testing services. The tests offered range from tests for single gene, highly penetrant disorders to susceptibility tests for genetic variants associated with common complex diseases or with particular non-health-related traits. Although a lot of attention has been devoted to the regulatory framework of DTC genetic testing services in the U.S.A., only limited information about the regulatory framework in Europe is available. We will report on the situation with regard to the national legislation on direct-to-consumer (DTC) genetic testing in seven European countries (Belgium, the Netherlands, Switzerland, Portugal, France, Germany, United Kingdom). The paper will address whether these countries have legislation that specifically address the issue of DTC genetic testing or have relevant laws that is pertinent to the regulatory control of these services in their countries. The findings show that France, Germany, Portugal, Switzerland have specific legislation that defines that genetic tests can only be carried out by a medical doctor after the provision of sufficient information concerning the nature, meaning and consequences of the genetic test and after the consent of the person concerned. In the Netherlands, some DTC genetic tests could fall under legislation that provides the Minister the right to refuse to provide a license to operate if a test is scientifically unsound, not in accordance with the professional medical practice standards or if the expected benefit is not in balance with the (potential) health risks. Belgium and the United Kingdom allow the provision of DTC genetic tests. Although relevant legislation that bind DTC companies exists at the European level (E.g. the in vitro medical diagnostic devices, consumer protection legislation, data protection legislation), the lack of a harmonized (European) approach at all levels is problematic in a context where services are offered through the internet.

PGD and PGS, between practice and ethics, what happens in Quebec? *C. Bouffard[1], S.L. Tan[2], A.K. Maglo[1], M.A. Dubois[1], R. Drouin[1].* 1) Sherbrooke University, Dept Ped, Fac Med Hlth Sci, Sherbrooke, PQ, Canada; 2) McGill University, Health Centre Royal Victoria Hospital ,687 Pine Avenue West Women's Pavilion 6th floor Montreal, Quebec 687 Pine Avenue West Women's Pavilion 6th floor Montreal, Quebec.

In August 2010, the Quebec government made a landmark decision to publicly fund in vitro fertilization and other related assisted procreation services, including preimplantation genetic diagnosis (PGD) and but not preimplantation genetic screening (PGS). According to the new Quebec regulations, PGD will be funded publicly if performed by a licensed hospital for the purpose of detecting specific chromosomal or single-gene defects. Under these conditions, Quebec's policy will likely impact the provision of assisted reproductive technologies in the rest of Canada. However, despite the political will, the legal battles between federal and provincial governments and the needs of patients, the infrastructures are not ready to absorb the demand. Under these conditions, a little over a year after the announcement of the supervision of PGD and PGS by the Quebec government, what is the situation? Has the system kept its promises? What are the opinions of practitioners? Can we consider that the conditions of delivery of reprogenetic services are ethical? Methodology - Qualitative Research Design: Phase I) Online questionnaires for 10 obstetricians working in fertility clinics and laboratories, 10 geneticists engaging in activities related to PGD and PGS, and 05 genetic counselors working within a Quebec context. Data analysis: Quantitative and qualitative analyses (open and closed questions). Result: The preliminary results presented here are part of a vaster research on the conditions of delivery of PGD in Canada, but they apply only to Quebec. Several reasons are such that waiting lists are growing and services are being delivered in dribs and drabs. It seems that the current conditions of delivery of reprogenetic services covered by the Quebec government and the desire to keep these within the public system, promote the expansion of private enterprise, reprogenetic tourism and the exile of specialists. Conclusion: The current conditions of delivery of reprogenetic services in Quebec can bring about ethical issues as to accessibility and equity which mainly affect people who cannot afford to offer themselves these services through the private system, as well as issues related to the underutilization of expertise in place.

Parental Perspectives on Pediatric Genetic Research. *T. Brazg[1], H.K. Tabor[1,2], J. Crouch[1], S.M. Fullerton[3], B.S. Wilfond[1, 2].* 1) Center for Pediatric Bioethics, Seattle Children's Research Institute, Seattle, WA; 2) Department of Pediatrics, University of Washington, Seattle, WA; 3) Department of Bioethics and Humanities, University of Washington, Seattle, WA.

Increasingly, parents of children with both Mendelian and complex diseases, as well as parents of healthy children, are being asked to enroll their offspring in genetic research studies. Limited data exist about how parents decide whether or not to have their children participate in these kinds of studies, or their perspectives on the possibility of receiving individual or aggregate research results. We interviewed 23 parents whose children with autism or diabetes were enrolled in one of three genetic research studies. These interviews were conducted as part of a larger study on genotype-driven research recruitment. The interviews were transcribed and analyzed using thematic qualitative analyses. The specific research question addressed in this analysis was what are parents' perspectives on research participation and return of research results for genetic studies in which their children are enrolled? Parents discussed a wide range of people for whom their child's participation in genetic research could have implications. They made reference to the impact on themselves as parents and care-takers, their family more broadly, their affected and unaffected children, grandchildren, future generations, others with the disease and society at large. The most frequently cited concepts that influenced parents' decisions to enroll their children in genetic studies were: time and convenience; “helping” themselves, their children, or others; the relevance of the research to their family; and weighing burdens and benefits of participation. When asked about the possibility for the return of research results, parents explained that receiving both individual and aggregate results would be an incentive for further research participation. They also described potential positive and negative psychological impacts of receiving genetic research results, ranging from providing an explanation for their child's disease to possible guilt and anxiety. Parents of children in autism research also cited reproductive planning - for themselves or in the future for their unaffected children - as a specific potential benefit of receiving their children's individual genetic research results. By better understanding how parents make decisions about enrolling their children in genetic research and how they feel about the possibility of receiving individual genetic research results, we can develop the most effective and appropriate ways to design pediatric genetic research.

ELSI challenges encountered when integrating population-based and clinical biobanks into a national biobank infrastructure: The case of Biobank Norway. *I. Budin-Ljøsne[1], B. Solberg[2], J.R. Harris[1].* 1) The Norwegian Institute of Public Health, Oslo, Norway; 2) Norwegian University of Science and Technology, Trondheim, Norway.

Norway hosts a rich collection of population-based biobanks, clinical biobanks and national health registries. Biobank Norway is a recently funded infrastructure project that aims to integrate these biobanks into a national platform in order to enhance the use of these data and biological samples in genomic and health research and innovation. In addition to building interoperability at a national level, Biobank Norway will be optimally coordinated with international biobanking initiatives. Establishing a platform that spans clinical and population-based biobanks requires streamlined and secure procedures for the handling and sharing of data and biospecimens. Furthermore, consideration of diverse stakeholders in the development of policies regarding a host of issues is essential for maximizing the success and sustainability of biobanks. Most of the ethical, legal and social implications (ELSI) that are encountered in the development of a national biobank platform are universal, though some are country-specific depending on national ethical-legal frameworks. This presentation describes the most challenging ELSI issues confronting Biobank Norway and discusses approaches being used to address these issues in Norway and internationally. Examples of these ELSI challenges include the ELSI implications associated with the “blurring” of traditional boundaries between research biobanks and disease biobanks, between clinic and research and between predictive and diagnostic testing. Further issues include determining which human biological samples and associated data can be stored in a national biobank infrastructure and can be shared internationally knowing that informed consent may not have been collected or is restricted, implementing procedures to guarantee the respect for privacy and confidentiality of stored data as well as the development of policies related to the return of results and incidental findings.

The role of the human growth receptor exon 3 polymorphism (hGHRd3) in maternal glycemia and neonate size. *E.S. Ingersoll[1], H. Weis[1], C.M. Ackerman[1], L.P. Lowe[2], M.G. Hayes[1], B.E. Metzger[1], W.L. Lowe[1], M. Urbanek[1], HAPO Study Cooperative Research Group.* 1) Division of Endocrinology, Metabolism, and Molecular Medicine, Northwestern University, Feinberg School of Medicine, Chicago, IL; 2) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL.

Background: The GH/IGF-1 axis plays a role in both longitudinal bone growth and glucose homeostasis. A common polymorphism in the human growth hormone receptor (hGHR) is a complete deletion of exon 3. The truncated receptor (hGHRd3) shows greater sensitivity to growth hormone therapy in patients and this may be due to increased downstream signaling rather than increased binding affinity for GH. The hGHRd3 allele has also been associated with short stature and protection against type 2 diabetes and insulin resistance. Our objective was to investigate the contribution of the hGHRd3 allele to neonatal size and glycemia. **Methods:** We genotyped 3300 European ancestry mothers and neonates (2056 mothers, 1238 neonates) and 1594 Mexican-American mothers and neonates (795 mothers, 788 neonates) from Bellflower, CA from the Hyperglycemia and Adverse Pregnancy Outcome Study cohort. We used a previously established multiplex PCR method. The hGHRd3 (minor) allele frequency observed for this study was 0.279 and 0.248 for European ancestry and Mexican-Americans respectively and genotypes were in Hardy Weinberg equilibrium. We analyzed association of several neonatal size and metabolic parameters (birth weight, length, head circumference, sum of skin folds, cord glucose and C-peptide, 2 hour glucose) and maternal height with hGHR allele using a previously established model, fully adjusted for confounding variables. **Results:** There was a negative association between the GHRd3 allele and birth length in mothers and babies. This effect was significant (-0.12cm per d3 allele, CI:-0.24cm, -0.003; p=<0.05) for the effect of mother's genotype on birth length and approached significance for the effect of neonatal genotype on birth length. None of the other outcomes showed significant association with genotype, including maternal height which can impact fetal growth. **Discussion:** This study is the largest evaluation of the impact of the hGHRd3 polymorphism on fetal growth to date and confirms previous reports that hGRd3 allele is associated with shorter birth length, although this effect is modest. The role of interaction of maternal and neonatal genotype in this association will require further study. There was no evidence for an appreciable effect of hGHRd3 on other common measures of birth size or newborn glycemic control.

Chromosomal prenatal diagnosis: Study of 250 cases. *C. Albu[1,2], D. Albu[1,2], E. Severin[1], M. Dumitrescu[2,3].* 1) University of Medicine and Pharmacy Carol Davila, Bucharest, Romania; 2) Alco San Clinic, Bucharest, Romania; 3) Marius Nasta Hospital, Bucharest, Romania.

Antenatal cytogenetic diagnosis is an accepted component of prenatal care for women at increased risk for chromosomally abnormal offspring. Objective: to investigate the frequency of the different types of chromosomal abnormalities in order to highlight the importance of prenatal cytogenetic test. Patients and Methods:This study included 250 prenatal karyotypes carried out in the last year. The age of the caucasian pregnant women was between 24 and 46 years, caucasian womens. The study included karyotypes performed by cultivation of amniocytes and trophoblastic cells obtained by amniocentesis and chorionic villus sampling. Results: 92,78% from a total of the karyotypes were normal and 4,1% presented a chromosomal abnormalities. Sex chromosome aberrations were present in 8,49% of the abnormal karyotypes. Autosomal aneuploidies represented the highest percent of the chromosomal abnormalities, respectively 50,99%. Translocations were the second most frequent, with a total of 14,32%. Lower rates were found in inversions (2,66%), duplications (5,20%), deletions (3,49%) and marker chromosomes (2,65%). Conclusions: The necessity of the prenatal detection of fetal chromosomal abnormalities to all pregnancies and especially for the risk categories.

Prenatal molecular diagnosis of Down syndrome: a comparison between molecular and traditional karyotyping. *D. Chu[1], J. Liou[2].* 1) Graduate Inst Med Biotech, Chang Gung Univ, Dept Med Biotech, Tao-Yuan, Taiwan; 2) Department of OB/GYN, Chang Gung Memorial Hospital, Taipei , Taiwan.

Trisomy 21, a.k.a. Down syndrome, is the most commonly seen chromosome aneuploidy in live births. The incidence is estimated to be around 1 in 900 to 1 in 1000 worldwide. Currently, multiple maternal serum markers screening test (MMST) in the second trimester plus karyotyping as the confirmation test are still standard procedures to identify fetal Down syndrome. However, due to the limitations associated with these methods, molecular approaches using chromosome 21-specific short Tandem repeats (STR) markers are suggested to be a rapid and accurate alternative for this purpose. In this study, we performed our previously established STR analysis on 602 amniotic fluid samples which were collected for traditional karyotyping due to increased risk for trisomy 21 based on MMST positive results or advanced maternal age. Data indicated that 2 of the 602 were positive for trisomy 21 and the rest 600 cases were negative. These results were consistent with those of traditional karyotyping. It is concluded that prenatal molecular diagnosis of chromosome aneuploidy is a rapid yet reliable alternative of karyotying. It is also practical for clinical application.

RAPID PRENATAL DIAGNOSIS OF COMMON CHROMOSOME ANEUPLOIDIES BY QF-PCR: EAST-SLOVENIAN EXPERIENCES. *a. erjavec skerget[1], s. stangler herodez[1], a. zagorac[1], b. zagradisnik[1], n. kokalj vokac[1,2].* 1) Laboratory of Medical Genetics, University Clinical Centre Maribor, Maribor, maribor, Slovenia; 2) Medical Faculty Maribor, Department of Molecular Biology, SI - 2000 Maribor.

INTRODUCTION Quantitative-fluorescence polymerase chain reaction (QF-PCR) was used to detect common foetal aneuploidies in the Slovenian population. The results were obtained within 48 - 72 hours after sample collection in order to alleviate parental anxiety in cases with only raised risk of trisomy (maternal age) and in cases with high risk for foetal aneuploidy (positive serum screening tests, nuchal translucency measurements, ultrasound abnormalities or others). METHODS The QF-PCR tests were performed on 265 prenatal samples (73.3 % amniotic fluids, 26.7% chorionic villus) which were analysed blind, without knowledge of the results obtained using conventional cytogenetic analysis. DNA from prenatal samples were analysed using on in-house-developed method with 20 micro-satellite markers located on the chromosomes 13, 18, 21, X and Y. The QF-PCR results of 61.8% samples were compared with their respective karyotypes. RESULTS 262 samples were successfully analysed. In 7.2% of cases a numerical chromosome abnormalities with QF-PCR were detected: 18 autosomal trisomies and 1 triploidy. Results of QF-PCR and karyotyping were compared in 162 cases. In a group with raised risk of fetal trisomy the specificity and sensitivity of QF-PCR method was 100%. Among cases with high risk for fetal aneuploidy sensitivity was 100% but specificity was lower, 91% to 95%, depending up on referral reason. CONCLUSIONS Our results demonstrates that QF-PCR is a reliable and rapid method for detection of common numerical chromosome disorders. In a group of older woman with raised risk for foetal aneuploidy the results of QF-PCR can be used alone without karyotyping. In cases with higher risk, especially those with pathological ultrasound, analysis only with QF-PCR method isn't enough. However, karyotyping is still required for all prenatal samples in Slovenia.

1368W

A comparison of emerging technologies for aneuploidy detection in spontaneous pregnancy loss. *C.N. Paxton[1], S. South[1,2,3], A. Brothman[1,2], K. Geiersbach[1,3].* 1) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT, USA; 2) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT, USA; 3) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT, USA.

Background: An estimated 15% of clinically recognized pregnancies are spontaneously lost in the first trimester, and of these, up to 50% are chromosomally abnormal. Genetic testing permits identification of the cause of pregnancy loss and facilitates genetic counseling and future pregnancy planning. Cytogenetic cell culture is the historic standard method for analyzing products of conception (POCs), but due to the poor viability of many of such samples, the failure rate is approximately 10-20%. Several molecular methods have recently been introduced for detection of genomic abnormalities in POCs. We have compared three hybridization based technologies for accuracy, ease of use, and analytic sensitivity.

Methods: All samples were previously characterized by cytogenetics or oligonucleotide array platform. The samples included 65 POCs with abnormal karyotype and 5 POCs without karyotype due to growth failure in culture. DNA was extracted from backup flasks or directly from residual cleaned villi or fetal somatic tissue. Testing was performed according to manufacturer instructions using the Affymetrix SNP6.0 array, Perkin Elmer Karyolite BACs-on-Beads (BoBs), and NanoString Karyotype CodeSet.

Results: Results were 100% concordant between methods for SNP6.0 array and BoBs, and 90% concordant for Nanostring. All 5 culture failure samples yielded results by at least one method, with 100% concordance between methods. 5 samples with an abnormal karyotype showed normal female results with 100% concordance between methods, consistent with maternal cell contamination (MCC) of the backup flask used for DNA extraction in these cases. 3 samples showed evidence of placental mosaicism. As expected, BoBs and Nanostring did not detect polyploidy and neither method reliably detected segmental aneusomies.

Conclusions: The Affymetrix SNP6.0 method had the highest analytic sensitivity and was superior to karyotype for characterizing segmental aneusomies. MCC in cultured cells and placental mosaicism in uncultured cells can contribute to discrepant results by any of the three methods tested. Novel lower resolution methods (PE BoBs and Nanostring) show an overall lower analytic sensitivity but are attractive solutions for lower cost and secondary testing on samples for which a karyotype cannot be obtained.

Rapid prenatal diagnosis of common chromosome aneuploidies using quantitative fluorescent (QF)-PCR: 10 years experience in a center from the Republic of Macedonia. *D. Plaseska-Karanfilska, S. Madjunkova, I. Maleva, S. Kiprijanovska.* Research Center for Genetic Engineering and Biotechnology “Georgi D. Efremov”, Macedonian Academy of Sciences and Arts, Skopje, Macedonia.

The quantitative fluorescent (QF) PCR of selected small tandem repeat (STR) markers enables rapid and accurate prenatal diagnosis of the aneuploidies of chromosomes 21, 18, 13, X and Y. Here, we present our results of the use of QF-PCR for prenatal detection of common chromosomal aneuploidies in 2200 pregnancies at risk performed in a period of 10 years. It was also used in the prenatal cases for monogenic diseases to control for maternal contamination of the fetal material. The prenatal diagnosis was performed on genomic DNA isolated from fetal cells collected by amniocentesis or chorionic villus samples. All samples were analyzed by at least four STR markers on each of chromosomes 21, 18 and 13. In addition, amelogenin, TAF9, SRY and STR markers on X chromosome were used for the determination of the gender and sex chromosome aneuploidies. Maternal blood samples were analyzed in all blood contaminated amniotic samples and in most chorionic villi samples. In most instances the QF-PCR analysis was performed as a stand-alone test. No discordant results were obtained when cytogenetic analysis was performed in addition to QF-PCR. In one case the discordant sex between ultrasonography and QF-PCR was due to sex reversal subsequently confirmed by cytogenetic analysis. Forty seven (2.1%) samples could not be analyzed due to maternal contamination of fetal material. We have detected 46 trisomy 21 fetuses, 18 trisomy 18, five trisomy 13, five monosomy X, four XXY, two triploidy, one XYY, one triple X and one double trisomy 21 and XXY fetus. Polymorphic duplications involving STR markers D13S631, D21S1441, D18S978 or D18S535 were detected in seven fetuses; in all fetuses the duplications were inherited from one of the parents. The parental origin of the aneuploidy was determined in 64 cases; trisomy 21 (n=39), trisomy 18 (n=13), trisomy 13 (n=3), monosomy X (n=5) and XXY syndrome (n=4). The origin was maternal in the majority of the autosomal trisomies (all except one trisomy 21) and paternal in most of the sex chromosome aneuploidies (four of the five monosomies X and three of the four XXY syndrome cases). Triple X syndrome was detected in one woman with a fetus with trisomy 18. In conclusion, the QF-PCR method is an efficient, rapid and reliable method for prenatal diagnosis of the most common chromosome aneuploidies. In addition, it can provide information about the origin of the aneuploidy and maternal contamination of the fetal material.

1370W

Bac on Beads technology a rapid and reliable screening for Chromosomal Aneuploidies: One year experience. *G. Queipo[1,2], J. Duran[2], Z. Najera[2], N. Najera[2], R. García- Cavazos[3].* 1) Human Genetics, Hospital General de Mexico, Mexico City, Mexico; 2) NanoLab, Next Generation Diagnosis Mexico City, Mexico; 3) Perinatal Genetics Medicine, Mexico City, Mexico.

There have been significant advances in antenatal screening for fetal aneuploidy. Prenatal screening is a world wide tool used to detect those high risk aneuploidies pregnancies in the first o second gestational trimester with non invasive technique as ultrasound and biomarkers. However invasive studies are necessary in positive cases. Chromosome abnormalities are a well-established cause of pregnancy loss and birth defects. The most common are autosomal aneuploidy (~75%), followed by polyploidy (~13%), sex chromosome abnormalities (~8%) and structural imbalance (~4%). Trisomy of chromosome 21, 13, or 18 as well as sex chromosome aneuploidy account for 60-80% of abnormal fetal karyotypes detected in cultured amniotic fluid cells. For non-mosaic standard trisomy, cultured karyotype analysis has been considered a reliable detector of fetal abnormality. Nevertheless, the sensitivity of karyotyping depends on the number of cells established in a particular culture, and results are usually not available for 3-4 days or more. Furthermore, it is very difficult to identify chromosome microdeletions. In addition to karyotype analysis, fluorescence in situ hybridization (FISH), is an easy-to-handle, rapid, and highly sensitive tool for genetic analysis, it has been developed in the past two decades for prenatal assay. However, that detection power depends on the probes included in the analysis. Recently molecular and genomic technology development has been improved rapid detection of chromosomal gain or loses in one assay with the CGH-array strategy. BACs-on-Beads™ based multiplex assay designed to detect the 5 most common aneuploidies and gains and losses in 9 well characterized target regions in 24 hr. Constitutional BoBs is a simple, robust assay that offers significant benefits in terms of ease of handling, minute sample volumes, reduced time-to result and improved pick-up rates for today's cytogenetics and molecular genetics. Here we present our successful experience using this strategy in prenatal analysis and discuss the possibilities in reproductive genetics diagnosis as Preimplantational (PGD), pregnancy lost analysis using Bac on beads analysis.

1371W

Female infant with t(X;Y), including *SRY*. *S. Ramanathan[1], M.D. Maxwell Lutz[2], H.S Brar[2], R.D. Clark[1].* 1) Pediatric Genetics, Loma Linda University Health Care, 2195 Club Ctr Dr, Ste A Loma Linda, CA; 2) Maternal Fetal Medicine and Genetics, 4000 14th St, Ste 502, Riverside, CA.

We report a 6-week-old female, the product of an uncomplicated pregnancy, who was diagnosed prenatally with a *de novo* sex chromosome abnormality. Amniocentesis done for advanced maternal age detected 46,X,add(X)(p11.4) on routine chromosome analysis. There was a terminal deletion of 22 megabases from Xpter→p22.11 and addition of 5 megabases from Ypter →Yp11.2 on SNP microarray analysis. The baby was inferred to have an unbalanced t(X;Y) with Yp material translocated onto the deleted Xp. The pseudoautosomal region common to both Xp and Yp was present in two copies, one from the normal X and one, presumably, from the Y chromosome on the derivative X. There were two copies of the *SHOX* gene and one copy of the *SRY* gene. The presence of the *SRY* gene was also confirmed by FISH analysis. The gene implicated in the development of gonadoblastomas, *TSPY*, localized to distal Yq, was absent. The baby was born at term by normal vaginal delivery to a 36-year-old G7P4SAb2 mother. Birth weight was 5lb 11oz and length was 18”. An echocardiogram detected a trivial muscular ventricular septal defect (VSD). A normal uterus and normal endometrium were seen on pelvic ultrasound. The ovaries were not visualized; the exam will be repeated at 6 months. At 6 weeks, the baby is healthy, with no stigmata of Turner syndrome and normal external female genitalia on physical examination. Translocations between the X and Y chromosomes are rare. When *SRY* is present, it usually results in phenotypic males or true hermaphrodites, with rare exceptions. The *SRY* gene is typically deleted in females with X/Y translocations (Burnside *et al*., 2008). One possible explanation for the phenotype in our patient could be skewed X-inactivation of the derivative X-chromosome, silencing the *SRY* gene; X-inactivation studies are underway. Alternately, position effect, disrupting *SRY* gene expression due to the chromosome rearrangement could be another explanation (Sharp A *et al*., 2004). The large deletion on the X-chromosome in our patient predisposes to variable features of Turner syndrome. She is, however, expected to have normal stature and to be at negligible risk for gonadobastomas. Other than the trivial VSD, she appears to be a normal female, although the risk for gonadal dysgenesis remains. To our knowledge, this is the first report of prenatal diagnosis of t(X;Y) in a female, with the *SRY* gene being present.

1372W

Detection of identical unbalanced karyotype in two consequent fetuses due to a maternal pericentric inversion of chromosome 18. *F.I. Sahin[1], O. Ozer[1], E. Tarim[2], Z. Yilmaz[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Obstetrics and Gynecology, Baskent University Faculty of Medicine, Ankara, Turkey.

Amniocentesis is the most preferred diagnostic method for detection of chromosomal abnormalities in the prenatal period. Rapid and correct diagnosis for chromosome abnormalities is important during the prenatal diagnostic process. Different diagnostic approaches could be use for prenatal diagnosis but conventional cytogenetic analysis is always accepted as the gold standard. QF PCR is a method for using rapid diagnosis of numerical chromosome abnormalities, enabling rapid diagnosis of numerical and to some extent structural abnormalities such as partial trisomy. During prenatal diagnosis, diagnostic tools need to be used in time and situation. Recombinant chromosome 18 due to familial inherited pericentric inversion chromosome 18 was detected previously in prenatal and postnatal cases. In the current case, we report a recurrent partial trisomy 18 due to a maternally inherited inversion 18 karyotype. Amniotic fluid sample of a 29 years old 17 weeks pregnant woman was sent to our department due to an increased nuchal fold and risk for trisomy 18 in second trimester maternal serum screening. QF-PCR resulted in partial trisomy 18, confirmed by culture results. Parental blood karyotypes were studied revealing a 46,XX,inv(18)(p11.31q21.1) karyotype of the mother and a normal karyotype of the father. The karyotpe of the fetus was reported as 46,XX,der(18)ish rec(18)dup(18q)inv(18)(p11.31q21.1)(18qter++)mat. The parents decided to terminate the pregnancy after genetic counseling and a new spontaneous pregnancy came up 5 months after termination revealing a karyotype similar to the first pregnancy. The mother did not give her decision on to terminate or continue the pregnancy yet. As experiencing two repetitive unbalanced fetuses was so annoying to the parents, during the genetic counseling session after the second unbalanced pregnancy, preimplantation genetic diagnosis was suggested to the parents to prevent another unbalanced fetus. Partial trisomy 18q and monosomy 18p are uncommon chromosomal abnormalities with variable phenotypic expressions. Using prenatal and preimplantation diagnostic tools to prevent liveborn unbalanced infants is important in such cases enabling to take home a healthy baby.

1373W

Limitations of quantitative fluorescent polimerase chain reaction (QF-PCR) method on detection of common chromosome aneuploidies. *Y.K. Terzi[1], O. Ozer[1], Z. Yilmaz[1], E. Tarim[2], F. Yanik[2], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Obstetrics and Gynecology, Baskent University Faculty of Medicine, Ankara, Turkey.

The quantitative fluorescent polymerase chain reaction (QF-PCR) assay is one of the rapid aneuploidy detection (RAD) tests. It allows detection of common chromosome aneuploidies prior to full karyotype analysis. Besides its' advantages, QF-PCR results have some technical limitations. Analysis of QF-PCR results is very difficult and sometimes impossible in case of maternal cell contamination, low levels of mosaicism, absence of informative marker for one chromosome, and partially trisomies or monosomies. In this study we aimed to discuss limitations of QF-PCR in our cohort. Genomic DNA was extracted from amniotic fluid or chorionic villi samples and QF-PCR was performed by a commercially available diagnostic kit including a set of STR markers for chromosomes 13, 18, 21, X and Y (Devyser, Sweden). In addition, our kit provided us to make a comparison of X chromosome copy number with an autosomal chromosome (Chromosome 7). PCR products were analyzed with ABI310 Genetic Analyzer (Applied Biosystems, Foster City, CA) and GenescanV3.7 software. In this study, a retrospective analysis was performed on 538 prenatal samples which have been analyzed with QF-PCR for chromosomes 13, 18, 21, X and Y. Five hundred and nineteen samples were reported as normal or abnormal accurately, however, results of the 19 samples were not assessed because of maternal cell contamination (2.42%). Absence of adequate copy of informative markers was detected for chromosomes 13, 21, X/Y and 7/X (1.11%). Absence of PCR products was observed in one patient (0.19%). As a conclusion, although QF-PCR is a rapid and useful diagnostic tool for prenatal diagnosis for common chromosomal aneuploidies, it is insufficient or makes it hard to evaluate in some circumstances due to its own limitations. Because of this, we believe that QF-PCR should be an adjunct to conventional karyotype analysis.

1374W

A recurrent familial L410R mutation in the TSC2 gene associated with isolated cardiac rhabdomyomas. *R. Teitelbaum[1], F. Golding[2], G. Ryan[4], D. Myles-Reid[1], R.K. Basran[5], A. Milunsky[5], D. Chitayat[1,3].* 1) The Prenatal Diagnosis & Medical Genetics Program, Mount Sinai Hospital, Toronto, ON, Canada; 2) Division of Cardiology, Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 4) The Fetal Medicine Unit (SPP), Mount Sinai Hospital, Toronto, ON, Canada; 5) Center for Human Genetics, Department of Pediatrics, Boston University School of Medicine.

The tuberous sclerosis complex (TSC) is an autosomal dominant condition with clinical and genetic heterogeneity. Many cases are caused by de novo mutations in the TSC2 gene and the penetrance is 100%. We report a family with an L410R mutation in exon11 of the TSC2 gene with isolated cardiac rhabdomyomas. The first pregnancy of a non-consanguineous Caucasian couple initially presented with cardiac rhabdomyomas on fetal ultrasound. The pregnancy was interrupted and the autopsy showed a female fetus (46,XX) with isolated multiple rhabdomyomas. Mutation analysis of TSC1 and TSC2 showed a heterozygous L410R mutation in exon 11 of the TSC2 gene. This change had not been previously reported in the literature and its clinical significance was not known. It was predicted to be possibly damaging by Poly Phen analysis and not tolerated by SIFT analysis. Parental physical examination including Wood's lamp skin examination, brain CT scan, echocardiography and eye examination was normal. The L410R gene mutation was detected in the father. It was not detected in the paternal grandmother. The paternal grandfather was lost to follow-up. A subsequent pregnancy was again complicated with isolated fetal rhabdomyomas. The pregnancy continued and the multiple cardiac rhabdomyomas were confirmed postnatally and decreased in size. Mutation analysis detected the familial L410R TSC2 mutation in the female newborn. At the age of 3-years, no other findings associated with TSC have been identified and her development is normal. Physical examination including Wood's lamp skin examination, brain CT scan, and eye examination have been normal. This family raises the possibility that the L410R mutation in the TSC2 gene may be associated with isolated cardiac rhabdomyomas. Longer follow-up is needed to confirm this observation.

1375W

Mutations in the planar cell polarity gene CELSR1 associated with neural tube defects in humans. *R. Allache[1,2], P. De Marco[3], E. Merello[3], V. Capra[3], Z. Kibar[1,2].* 1) Pathology and Cell Biology, University of Montreal, Montreal, Quebec, Canada; 2) Department of Obstetrics and Gynecology, CHU Sainte Justine Research Center, Montreal, Quebec, Canada; 3) U.O. Neurochirurgia, Instituto G. Gaslini, Genova, Italy.

Neural tube defects (NTDs) represent a group of very common congenital malformations in humans, affecting 1-2 infants per 1000 births and represent a major cause of perinatal mortality. They are caused by a partial or complete failure of the spinal column to close during early development of the embryo. The causes of NTDs are complex involving both genetic and environmental factors. The most common forms of NTDs are anencephaly and spina bifida. Animal models have proven to be a powerful approach in dissecting the complexity underlying these traits. Studies from these models have provided strong evidence for the involvement of a signaling pathway called the non-canonical Frizzled (Fz) /Dishevelled (Dvl) or the planar cell polarity (PCP) pathway in NTDs. This pathway controls an important morphogenetic process of convergent extension (CE) which is essential during formation of the neural tube. Mutations in genes of this pathway cause NTDs in mouse models, and, importantly, recent studies have shown that mutations in two PCP genes, VANGL1 and VANGL2, were associated with human NTDs. These studies strongly implicate the Fz/Dvl pathway in the causation of NTDs. Our study aims at molecular and genetic analyses of another gene of this pathway, CELSR1, in human NTDs. The open reading frame and exon-intron junctions of CELSR1 were amplified by PCR and the products were sequenced in a large cohort of 471 non-syndromic NTD patients. We have identified 31 novel and rare missense mutations which were absent in 637 ethnically-matched controls. Ten of these mutations affect highly conserved amino acid residues. Our findings implicate CELSR1 as a risk factor for NTDs in a subset of patients and provide additional evidence for a pathogenic role of PCP signaling in these malformations.

Association of A80G polymorphism in the RFC1 gene with the risk for having spina bifida-affected offspring in Southeast Mexico and interaction with C677T-MTHFR. *L. Gonzalez-Herrera, O. Vargas-Sierra, S. Contreras-Capetillo, G. Perez-Mendoza, I. Castillo-Zapata, D. Pinto-Escalante, T. Canto-Cetina.* Dept Genetica, Univ Autonoma de Yucatan, Meridal, Yucatan, Mexico.

Spina bifida (SB) is the most prevalent neural tube defect (NTD) in Yucatan, at Southeast Mexico. Polymorphisms in folate metabolism genes have been suggested as susceptibility candidates for SB. Ingested folate is hydrolyzed into monoglutamate forms in the intestine by the reduced-folate carrier (RFC-1). RFC1 carrier transports folate across the placenta. The polymorphism A80G of the RFC-1 gene could impair folate transport from maternal blood to the fetus; and has been demonstrated as a genetic risk factor for NTD. Additionally this variant may interact with low folate status and MTHFR mutations to increase NTDs risk. This study analyzed the association of A80G polymorphism in the RFC1 gene with the risk for having spina bifida affected-offspring and its interaction with C677T-MTHFR polymorphism. A case-control association study was performed with 119 mothers and 64 fathers of children with open-dorsolumbar SB as cases. The control group was 140 mothers and 55 fathers with healthy offspring. Genotyping for A80G polymorphism in the RFC1 gene was performed by PCR-RFLP. Statistical standard X2 analysis was calculated using STATA 10.2 software. Genotype frequencies were distributed according to Hardy-Weinberg expectations ($p>0.05$). Distribution of allele G was significantly higher in cases than controls ($p= 0.04$), suggesting that the allele G is associated with the parental risk of having an SB-affected child. Comparison of genotypes GG vs AA+AG supported this significant finding: OR=1.763, IC 1.15-2.70, $p= 0.009$. Stratification by gender showed that risk was only significant in mothers (OR=1.63, IC 0.968-2.75, $p= 0.04$). The interaction of A80G-RFC1/C677T-MTHFR, did not show significant differences between case and control parents ($p>0.05$). However, stratification by gender showed differences for the genotype combinations AG/CT and GG/CT in mothers ($p=0.039$). In fathers, the genotype combination with both mutants GG/TT was significantly associated with the risk for having SB-affected offspring ($p= 0.043$). Our findings suggested the association of allele G of A80G-RFC-1 with the genetic risk for having an SB-child, which might be controlled maternally. There might be an interaction between A80G-RFC1 and C677T-MTHFR, since the genotype combinations GG/CT in mothers and GG/TT in fathers were associated with the higher risk to have a child with SB in Southeast, Mexico.

Spectrum and frequency of pathogenic chromosomal structural variants detected among foetuses with increased nuchal translucency and have a normal karyotype. *K. CHOY, H.K. WONG, W. CHONG, K.Y. KWOK, K.W. SUEN, C.C. WANG, T.K. LAU, T.Y. LEUNG.* The Chinese University of Hong Kong, Shatin, Hong Kong.

Large nuchal translucency (NT) has been known to be associated with chromosomal disorders. To determine the prevalence of submicroscopic chromosomal abnormalities of fetuses that had increased nuchal translucency and an apparently normal karyotype, DNA was extracted from a cohort of 97 stored CVS samples retrieved from a database of fetuses with increased first trimester nuchal translucency >3.5mm and normal karyotype result during first trimester screening. These samples were examined by microarray based comparative genomic hybridization (aCGH) using a 44K custom designed oligonucleotide array specifically constructed for prenatal screening with an average genome-wide resolution <100kb across the genome. Variations in copy number (CNVs) were reported after excluding known non-pathogenic variants. Nine of the 97 (9.3%) cases that were tested had abnormal aCGH results with known pathogenic micro-deletions or micro-duplications ranging from 269kb to 8 Mb size. Our data indicate that most of the pathogenic CNVs identified (7/9) were known to be associated with neurodevelopmental delay and/or mental retardations phenotype. There was also a significant association between the severity of increased NT and an abnormal aCGH result (NT>4mm; $p<0.05$). Fetuses with morphological anomalies or normal morphology respectively had an abnormal aCGH result indicating pathogenic CNVs are not restricted to fetuses that have other morphological anomalies visible by ultrasound scan. This finding indicates that the incidence of submicroscopic chromosomal abnormalities in the group of fetuses with increased NT but normal karyotypes is substantial. Chromosome microarray analysis may improve clinical recognition of chromosomal abnormalities that are currently not identified prenatally.

1378W

Diagnostic utility of array-based comparative genomic hybridization (aCGH) in a prenatal setting- our experience of 502 cases. *i. maya[1], b. Davidov[1], e. taub[1], y. Zalzstein[1], m. shohat[1,2].* 1) genetic institute, rabin medical center, petah tikva, Jordan; 2) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Objective: Array-based comparative genomic hybridization (aCGH) is a technique for detecting submicroscopic deletions and duplications. There is limited information regarding its use in the prenatal setting. Here, we present our experience of 502 prenatal aCGHs between 2006 and 2011. Materials and Methods: We reviewed the medical files of 502 prenatal cases seen in the Recanati Genetic Institute between 2006 and 2011 on whom prenatal aCGH was carried out. Results: The indications for testing were fetal anomalies on ultrasound (U/S) (41%), advanced maternal age (AMA)(18%), family history of a disorder of unknown etiology (17%), parental concern (13%), Abnormal routine karyotype (9%) and abnormal serum biochemical screening for common fetal aneuploidies (1%). Of 45 cases with a known abnormal karyotype, 35 (80%) had a normal aCGH. This enabled us to reassure the families and the pregnancies were continued. The remaining 10 (20%) showed an abnormal aCGH, confirming the chromosomes were unbalanced, and after proper genetic counsling they were terminated. Of 457 cases with a normal karyotype, 7 had an abnormal aCGH with known clinical significant and additional 4 cases with unclear clinical significance. Overall, new clinically relevant results were detected by aCGH in 52 cases, providing additional information for prenatal genetic counseling and risk assessment (detection rate of 1: 10). Conclusion: Our results suggest that prenatal aCGH should be offered particularly in cases with abnormal U/S (detection rate was 1:52). We found the rate of detecting an abnormality by aCGH in low-risk pregnancies (normal fetal U/S) was 1:83, but larger studies will be needed to expand our knowledge and validate our conclusions.

1379W

Cockayne Syndrome and prinatal diagnosis. *B. Bozorgmehr, F. Afroozan, A. Kariminejad.* Dept Clinical Genetics, K-N Pathology & Genetics Ctr, Tehran, Iran.

Cockayne Syndrome is a rare autosomal recessive disorder characterized by profound postnatal growth deficiency with loss of adipose tissue, microcephaly, mental retardation, unsteady gait and peripheral neuropathy. We are reporting a 6-year-old girl with severe growth and developmental delay, microcephaly, mental retardation, sunken eyes and photosensitive dermatitis.Her parents are related and had a history of death of their first daughter 3 years ago.Her diagnosis confirmed by a defect in DNA repair in fibroblast followed exposure to ultraviolet light.we performed prenatal diagnosis for their next pregnancy and they have normal child now.

1380W

Prenatal Noonan and aCGH testing for increased nuchal translucency/thickness and cystic hygroma. *C. Coffeen[1], N. Nakata[1], S. Bhatt[2], V. Watiker[2].* 1) Esoterix Genetic Laboratories, LLC, Los Angeles, CA; 2) G-Path Medical Associates, Inc., Los Angeles, CA.

Increased nuchal translucency/thickness (NT) and cystic hygroma confer an increased risk for chromosome abnormalities as well as Noonan syndrome. Genetic counselors at Genzyme Genetics[SM1] offer counseling for Noonan syndrome evaluation and array CGH to patients with increased NT or cystic hygroma and normal prenatal karyotype. A retrospective analysis was performed to evaluate the utility of this testing. Patients who were referred to Genzyme Genetics for genetic counseling from April 2010 through January 2011, and had an abnormal ultrasound finding of increased NT or cystic hygroma and subsequent normal fetal karyotype were included in the review. A total of 393 patients met the inclusion criteria, 82% (322/393) had increased NT and 18% (71/393) had cystic hygroma. All patients were counseled regarding the ultrasound findings, possible impact, and were offered prenatal Noonan testing and aCGH. Fifty-seven (15%) patients elected further testing, 6 had only Noonan testing, 35 had only aCGH, and 16 had both tests. Among the 22 patients who had Noonan testing, 4 (18.2%) were found to be mutation positive. Among the 51 who had aCGH testing, 4 (7.8%) had an abnormal aCGH result. Forty of the 57 patients who underwent further testing (70%) had an ultrasound finding of increased NT; 3/40 (7.5%) were mutation positive for Noonan and 3/40 (7.5%) had abnormal aCGH results. Among the 17/57 (30%) with a cystic hygroma; 1/17 (5.9%) was mutation positive for Noonan and another one had a variant of unknown clinical significance. Overall, 14.0% (8/57) of patients who had Noonan or aCGH testing were found to be mutation positive for Noonan syndrome or had an abnormal aCGH result. These findings support the importance of offering Noonan and aCGH testing to patients with increased NT or cystic hygroma and normal fetal karyotype.

1381W

Diagnosis and clinical presentation of 20 patients referred for antenatal hyperechogenic kidneys with renal cysts and diabetes syndrome (RCAD). *K. Dahan[1], K. Lolin[2], K. Ismaili[2], L. Collard[3], B. Grisart[1], N. Godefroid[4], V. Benoit[1].* 1) Ctr Human Gen, Institut de Pathologie et de Génétique, Gosselies, Belgium; 2) Department of Pediatric Nephrology, Hôpital Universitaire des Enfants-Reine Fabiola, Université Libre de Bruxelles (ULB), Brussels, Belgium; 3) CHC, clinique de l'Espérance, CHU Sart-Tilman, rue Saint-Nicolas, 4420 Montegnée, 4000 Liège 1; 4) Department of Pediatrics, Cliniques Universitaires St-Luc, Université Catholique de Louvain, Brussels, Belgium.

Hepatocyte nuclear factor 1beta (HNF1beta) mutations have been recognized to cause renal cysts and diabetes syndrome (RCAD), also referred to as maturity-onset diabetes of the young, type 5 (MODY5). We performed mutational analyses including cytogenomic array analysis and we found HNF1B abnormalities in 20 patients, all referred for antenatal hyperechogenic kidneys with renal hypodysplasia (n =11), kidney enlargement (n=2), unilateral multicystic dysplastic kidney (MCDK; n = 3) and bilateral MCKD (n = 1). The recurrent 1.4 Mb deletion at 17q12 comprising HNF1B gene was detected in 11/20 while a single exon deletion/duplication was found in 2/20, missense changes in 5/20, nonsense change in 1/20 and a single-nucleotide deletion in one of them. Compound heterozygosity was observed in one girl who is carrier for a paternally inherited missense mutation and a de novo HNF1B deletion. HNF1B anomalies were responsible for severe oligohydramnios and termination of pregnancy in 1/20. In the remaining patients, the GFR decreased with longer follow-up and was lower in patients with solitary functioning dysplastic kidney (3/20). Extrarenal manifestations are frequent especially among the carriers of HNF1B deletion including mild facial dysmorphic features with macrocephaly in 5, jejunum atresia in one, elevated liver enzyme levels in 5, short stature in 2 while no one had presented autistic features. Additionally, regular ultrasound examination had revealed a Wilms tumor in an asymptomatic girl (2 years-old), raising the question on hypothetical relationship between HNF1B germline mutation and increased risk for neoplasia. Therefore, prenatal counseling and follow-up should be multidisciplinary.

1382W

Difficulty in Prenatal Diagnosis of Short Ribs with Polydactyly. *C. Hills[1,2], M.E. Pierpont[2,3].* 1) Children's Heart Clinic, Minneapolis, MN; 2) Children's Hospitals and Clinics of Minnesota, Minneapolis, MN; 3) University of Minnesota, Minneapolis, MN.

At 20 weeks gestation, a fetal ultrasound demonstrated a very narrow thoracic cage, shortened ribs, polydactyly, and reduced long bone growth. These results were consistent with Short Rib Polydactyly Syndrome (SRPS) type III, frequently a lethal condition. Parents declined amniocentesis. Minimal intervention was planned at delivery based on the poor prognosis. The parents are consanguineous (first cousins once removed). A paternal aunt had a stillborn infant with short limbs. After term delivery, the female infant was vigorous. The weight was 3400 g (50th centile), length 48 cm (20th centile) and OFC 36 cm (75th centile). Key physical findings included lack of respiratory distress, mild frontal bossing, depressed nasal bridge and hypertelorism. There was a central raphe from the nose to the lips. The upper lip gum was attached closely to the anterior alveolar ridge. The chest was narrow and appeared wider at the lower end of the thorax. Lungs were clear. A systolic murmur was heard. There were short limbs bilaterally with more proximal shortening than distal shortening and polydactyly of all 4 limbs. There were hypoplastic, dysplastic fingernails and toenails. An echocardiogram demonstrated a complete atrioventricular septal defect. A bone survey showed a skeletal dysplasia with narrowed thorax, shortened ribs, rounded metaphyses and lateral spikes associated with the distal aspect of the femurs and humeri. There was polydactyly and shortening of the long bones including the tubular bones of the hands and feet. The patient's clinical course and physical findings including her respiratory status, nail hypoplasia, appearance of the anterior alveolar ridge and the type of cardiac malformation were more consistent with Ellis-van Creveld syndrome (EVCS), but the patient's bone survey was interpreted as consistent with SRPS, type III. Mutations in the DYNC2H1 gene on chromosome 11q cause both SRPS type III and asphyxiating thoracic dystrophy (Jeune syndrome). EVCS is associated with mutations in the EVC1 and EVC2 genes on chromosome 4p. Cytogenetic testing showed a normal 46,XX karyotype. DNA analysis showed a homozygous deletion, c.1108delT in exon 10 of the EVC2 gene consistent with a diagnosis of EVCS. The clinical and radiological phenotypes of SRPS type III and EVCS have many similarities. This case illustrates the difficulty in making a definitive diagnosis prenatally and reviews the findings that led to the diagnosis of EVCS in this patient.

1383W

Fryns-like multiple congenital anomalies syndrome with 1,13 Mb chromosome 16p13.11 deletion detected by array-comparative genomic hybridization. *J. Martinovic[1,2], C. Fallet-Bianco[3], B. Simon-Bouy[4], J. Michel[5], E. Alix[5], D. Sanlaville[5].* 1) Unit of Fetal Pathology, Hosp Antoine Beclere, Clamart, France; 2) Unit of Fetal Pathology, Department of Pathology, Laboratoire Cerba, St Ouen L'Aumone, France; 3) AP-HP, Department of Neuropathology, Hôpital Saint-Anne, Paris, France; 4) Cytogenetics Laboratory, Centre Hospitalier de Versailles, Le Chesnay, France; 5) Cytogenetics Department, Hospices Civils de Lyon and UCBL1, Lyon, France.

We present a 27-week fetus with Fryns Syndrome (FS)-like phenotype who had submicroscopic chromosome 16p13.11 deletion of 1,13Mb detected by array-comparative genomic hybridization (CGH) after normal karyotyping with G-banded chromosome analysis. Fetal phenotype on fetopathological examination disclosed growth restriction, dysmorphic features including flat, coarse facies, depressed nasal bridge, long philtrum, retrognathia, hypoplastic ears, unilateral renal agenesis, uterine hemi-agenesis, costo-vertebral malsegmentation/fusion defects, hypoplastic terminal phalanges of fingers, pachygyria, hypoplastic corpus callosum and cerebellum. A 180,000-oligonucleotide microarray (Agilent Technologies, Santa Clara, CA) was used to analyze the fetal DNA. Array CGH revealed a 1.16 Mb 16p13.11 deletion in the fetus between genomic positions 15,039,244-16,174,807 (hg18). This deletion was confirmed by FISH using the RP11-368O18 BAC clone. This deletion occurred de novo, and should be presumed as a cause of this multiple congenital anomalies syndrome. This deletion includes several genes, in particular NDE1. Recurrent deletions in 16p13.11chromosomal region have been previously reported and have been associated with epilepsy, multiple congenital anomalies, and cognitive impairment. Recently, based on Nde1-null mice experiment, it was proposed that NDE1 have an essential role in human cerebral cortical neurogenesis. Moreover NDE1 deficiency causes both a severe failure of neurogenesis and a deficiency in cortical lamination. So, NDE1 haploinsuffiancy could explain cerebral malformation observed in the fetus. Nevertheless other malformations described in the fetus have not been previously reported in patients with this 16p13.11 deletion. We conclude that phenotypes similar to FS, however without diaphragmatic hernia, can be caused by a new clinically identifiable chromosome deletion syndrome at 16p13.11 including growth retardation, genito-urinary malformations, skeletal anomalies with costo-vertebral malseglmentation defects and terminal phalangeal hypoplasia, as well as cerebral anomalies with pachygyria, hypoplastic corpus callosum and cerebellum. This case expands the clinical phenotype described in patient with 16p13.11 microdeletion. We also conclude that array CGH should be performed prior to the definite diagnosis of FS in order to provide a causal explanation and an accurate genetic counselling to the family.

1384W

Retrospective study of 1,094,807 newborns showed the national average rate of preterm birth in China is 5.5%, which has been increased 14% from 2005 to 2009. *N. Zhong[1, 2], X-L. Zhao[2], China Preterm Clinical Research Consortium.* 1) Human Genetics, New York State Institute for Basic Research in DD, Staten Island, NY; 2) Peking University Center of Medical Genetics, Beijing, China.

Preterm birth (PTB), accounting for 5-12% newborns world-wide, is recognized as the leading cause for the neonatal death. However, the PTB rate in China was unknown. To determine the Chinese PTB rate, a retrospective study was performed by the China Preterm Clinical Research Consortium (CPCRC) headed by the Peking University Center of Medical Genetics. A total number of 1,094,807 newborns, delivered from January 2005 to December 2009 among 132 hospitals from 23 provinces, were studied based on hospital records. Our results showed that The PTB rate in each year is: 5.18% for year 2005, 5.36% for year 2006, 5.29% for year 2007, 5.74% for year 2008, and 5.92% for year 2009, giving rise to an increase of 14% from 2005 to 2009. The rates are noticed highly varied by geographic regions. The highest rate of 11.4% occurred at Henan province, which is located at center of China in the year of 2006. To assess the risk factors associated with PTB, environmental factors including education background, economic incomes, air pollutions, and geographical location were analyzed. Underdeveloped area was selected to compare to the advanced industrial area. Through our birth defect surveillance network, 40,000 newborns were crossed with 30,000 prenatal screenings, by which 1,919 pregnancies including 189 deliveries with twins were extracted. Our data showed that among 1,730 singletons, 8.5% was delivered before 37 weeks as the PTB in the industrial area, which is higher than the national average rate; 4.80% with weight less than 2,500 grams, as the low weight births (LBW), 1.67% had one or more structural dysmorphology, which were 13.6% (20/147) among PTBs but only 0.58% (9/1,558) in full-term births; and 1.67% stillbirths. To correlate to the prenatal screening, PTB at <32 weeks had 2.94%, 32-36 weeks had 6.19%, and >37 weeks had 3.47% of AFP>2MoM; <32 weeks had 11.76%, 32-36 weeks had 4.42%, and >37 weeks had 4.30.47% of HCG>3MoM; and <32 weeks had 44.1%, 32-36 weeks had 2.65%, and >37 weeks had 0.57% of dysmorphology. Among 189 twin-pregnancies, 46.5% had PTB and 5.29% had stillbirth. In addition, 32.39% had AFP>2MoM (compared to 26.73% in full-term birth), 21.02% had HCG>3MoM (compared to 13.37% in full-term birth), and 2.27% (compared to 0.5% in full-term birth) had physical abnormalities. Our study clearly provided significant evidence that increased level of mid-term prenatal screening of maternal AFP and HCG could be applied as a genetic signature for PTB.

Fetal hydrotorax - case report. *D. Albu[1, 2], C. Albu[1,2], E. Severin[1], M. Dumitrescu[3].* 1) University of Medicine and Pharmacy Carol Davila, Bucharest, Romania; 2) Alco San Clinic, Bucharest, Romania; 3) Marius Nasta Hospital, Bucharest, Romania.

Objective: To determine wether or not a fetus with hydrothorax has Down syndrome. Background: Fetal hydrothorax refers to a collection of fluid within the fetal thoracic cavity as a result of leakage or generalized fluid retention from a variety of causes. Case report: A 27-year-old Caucasian female, pregnant for the first time, was referred at 27 weeks' gestation for a routine prenatal ultrasound. The couple had normal general health and was not consanguineous. There was no family history of genetic disorders. Routine ultrasonography, triple test (AFP,uE3, hCG), selective ultrasonography for detection of fetal abnormalities, thoracocentesis and amniocentesis were performed. Results: Ultrasound examination at 27 weeks of gestation revealed a single fetus with a large hydrothorax (~200ccm) on the left side compressing the lung and pushing down the driaphragm. A sample of 70ccm pleural fluid was obtained at 28 weeks of gestation through fetal thoracocentesis by ultrasound guided puncture. Post procedural ultrasound examination revealed positive lung expansion. A sample of 40cmc amniotic fluid was also obtained for further analysis. The cesarean section was scheduled at 33 weeks of gestation after treatment with dexamethasone. Triple test was not sensitive to the presence of a possible trisomy. Genetic investigations were recommended because fetal hydrothorax is frequently associated with Down Syndrome. Karyotype and QF-PCR from both amniotic fluid and thoracic fluid indicated the presence of Trisomy 21. Conclusion: Prenatal diagnosis was useful in management, prognosis and detection of Down Syndrome through analysis of thoracic and amniotic fluid, in a fetus with hydrothorax.

1386W

Prenatal Ultrasound and Autopsy Findings in Costello Syndrome. *K. Chong[1], J. Jessen[1], K. Fong[2], S. Keating[3], P. Shannon[3].* 1) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, Mount Sinai Hospital, University of Toronto; Toronto, ON, Canada; 2) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital, University of Toronto; Toronto, ON, Canada; 3) Department of Medical Imaging, Mount Sinai Hospital, University of Toronto; Toronto, ON, Canada.

Costello syndrome is an autosomal dominant genetic condition characterized by postnatal growth deficiency, dysmorphic facial features, mental retardation and cardiac defects including hypertrophic cardiomyopathy and arrhythmia. Prenatally, the phenotype for Costello syndrome has not been well recognized in pregnancy as the condition itself is rare; most of the published literature has been via case reports and studies compiled from parental surveys of liveborn children. We report a 37 year old G4P0SA3 woman who presented at 18 weeks gestation with a positive screen for Down syndrome. Amniocentesis revealed a normal male karyotype. Detailed fetal ultrasound at 25 weeks showed polyhydramnios, increased nuchal fold and discrepant limb/ head measurements. Fetal echocardiogram confirmed biventricular hypertrophy and possible hypoplastic aortic arch. Follow up fetal ultrasound at 30+weeks gestation showed large head and abdomen, bilateral pleural effusions, hepatomegaly, enlarged kidneys and generalized edema. Given the severity and poor prognosis of the cardiomyopathy, the pregnancy was induced and the baby died. Autopsy revealed hydrops fetalis, craniofacial dysmorphic features, hypertrophic cardiomyopathy and skeletal muscle changes suggestive of a congenital myopathy. Genetic testing revealed a common mutation in the HRAS gene confirming the diagnosis of Costello syndrome. The importance of fetal autopsy in pursuing a rare diagnosis like Costello syndrome in the setting of prenatal cardiomyopathy is discussed.

Interaction within the 10q24.2 region with in utero tobacco smoke exposure on asthma risk in Latino children. *S.S. Oh[1], D. Hu[1], C. Gignoux[1], L. Roth[1], L. Borrell[2], S. Sen[1], H. Farber[3], R. Kumar[4], F. Lurmann[5], P. Avila[6], D. Serebrisky[7], S. Thyne[8], W. Rodriguez-Cintron[9], J. Rodriguez-Santana[10], E. Gonzalez-Burchard[1].* 1) UC San Francisco, San Francisco, CA; 2) CUNY, New York, NY; 3) Texas Children's Hospital, Houston, TX; 4) Children's Memorial Hospital, Chicago, IL; 5) Sonoma Technologies Inc., Sonoma, CA; 6) Northwestern University, Chicago, IL; 7) Jacobi Medical Center, New York, NY; 8) San Francisco General Hospital, San Francisco, CA; 9) VA Medical Center, San Juan, Puerto Rico; 10) Centro de Neumologia Pediatrica, San Juan, Puerto Rico.

BACKGROUND Asthma is a complex disease with a multifactorial etiology. Asthma morbidity and mortality in U.S. Latinos is widely disparate (Puerto Rican children are among the most affected while Mexican American children are among the least affected), suggesting environmental and genetic influences. Smoking during pregnancy (i.e., in utero tobacco exposure) places the unborn child at risk for developing impaired lung function and asthma. We hypothesized that the joint exposure of in utero tobacco smoke and polymorphisms of asthma-related genes would synergistically increase asthma risk. **METHODS** We used a multi-center case-control study of Latinos aged 8-21 sampled nation-wide to investigate the association of asthma with top hits of SNPs identified from a meta-analysis of 9 GWA studies of asthma risk, 5 of which were conducted among Latinos. Allelic associations were assessed with a logistic regression model assuming additive inheritance. We also estimated the SNPs' interaction effects with in utero smoking on asthma risk by including interaction terms between in utero exposure and SNP genotype in logistic regression models. DNA from our sample of 1,049 asthmatic and 1,058 asthma-free Latino children was genotyped on an Infinium iSelect chip. **RESULTS** After adjusting for postnatal smoke exposure, Latino sub-ethnicity, global ancestry, age, and gender, we observed an enrichment of allelic association p-values from a 109kb region in 10q24.2, but only among children with in utero exposure to tobacco smoke. Among the 24 SNPs genotyped from this region, 24, 19, and 12 SNPs were significant at alpha levels of 0.05, 0.01, and 0.005, respectively. The SNP minor allele frequencies were not significantly different between cases and controls unexposed to in utero tobacco smoke, but among subjects exposed to in utero tobacco smoke, the minor alleles were present two to three times more frequently among cases than among controls, suggesting SNP-smoking interactions. In our adjusted logistic regression model, interaction terms for 24, 21, and 12 SNPs were significant at alpha levels of 0.05, 0.01, and 0.005, respectively. **CONCLUSION** Association of the 10q24.2 region with asthma is strongly modified by in utero tobacco smoke exposure, independent of postnatal tobacco smoke exposure. Future studies to replicate and extend these results will help identify mechanisms underlying the interactions.

1388W

Immune and fibrosis pathway genes are important in anti-SSA/Ro exposed neonates with congenital heart block and/or cardiomyopathy. *R.M. Clancy[1], P.S. Ramos[2], M.C. Marion[2], J.P. Buyon[1], C.D. Langefeld[2].* 1) New York University Langone School of Medicine, New York, NY; 2) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC.

Fetuses exposed to maternal anti-Ro/SSA antibodies can develop congenital heart block and/or fibrotic cardiomyopathy (cardiac manifestations of neonatal lupus), which carry substantial mortality. Several lines of evidence support a fetal genetic risk, including increased recurrence rates, concordance in a third of monozygotic twins, and results from the first published genome-wide association study (GWAS). Since there may be a global enrichment of specific pathways overlooked if only the most significant associations are considered, enrichment of associations in specific pathway-related genes was herein further evaluated. Based on the proposed pathogenesis which invokes an injury cascade initiated by antibody binding to apoptotic cardiocytes and subsequent inflammation and tissue fibrosis, we posit that immune and fibrotic responses may promote cardiac injury in these children. To test this hypothesis, we used Ingenuity Pathway Analysis to compile a list of all genes genes with immune (n=1,993 genes) and fibrotic (n=327 genes) functions. We then tested for an enrichment of admixture and genomic control adjusted significant P-values (at alpha=0.001) in SNPs that met quality control criteria. We observed a strong enrichment of significant SNPs (P<1x10-7) in both immune and fibrosis-related pathways; the enrichment existed whether including (n=12,782 immune, 2,417 fibrotic SNPs) or excluding (n=12,472 immune, 2,387 fibrotic SNPs) the extended HLA region. As a control, genes with bone functions (n=568 genes) did not exhibit enrichment (P=0.08; 4,355 SNPs outside of the HLA). To narrow down the specific immune-related pathways, we tested for enrichment in specific candidate immune pathways: apoptosis (2,283 genes), T cell function (980 genes), cell infiltration (311 genes), innate immune cell function (1,381 genes), interferon (102 genes), TLRs (10 genes) and calcium channels (13 genes). Excluding the extended HLA region, the apoptosis- (P<1x107; 15,935 SNPs), T cell- (P=1.2x10-4; 5,768 SNPs), innate immune cell- (P<1x10-7; 8,730 SNPs), interferon- (P=6.4x10-5 5; 417 SNPs) and TLRs- (P=8.7x10-6; 46 SNPs) related pathways continued to show an enrichment of significance. These results suggest that immune- and fibrosis-related genes are likely involved in predisposing to cardiac manifestations of neonatal lupus.

Phenotype-Specific Adverse Effects of *XPD* Mutations on Human Prenatal Development Implicate Transcription Factor (TF)IIH in Regulation of Cellular Metabolism in Placenta. *R. Moslehi[1], A. Kumar[1], J.L. Mills[2], X. Ambroggio[3], C. Signore[2], A. Dzutsev[4].* 1) Epidemiology & Biostatistics, School of Public Health, and Cancer Research Center, University at Albany, Rensselaer, NY; 2) National Institute of Child Health and Human Development (NICHD), NIH; 3) National Institute of Allergy and Infectious Disease (NIAID), NIH; 4) National Cancer Institute (NCI), NIH.

Background Mutations in *XPD* (*ERCC2*), *XPB* (*ERCC3*) and *TTD-A* (*GTF2H5*), genes involved in nucleotide excision repair (NER) and transcription, can cause trichothiodystrophy (TTD). *XPD* mutations can also cause other DNA repair disorders such as xeroderma pigmentosum (XP). We hypothesize that abnormalities in TTD NER/transcription genes affect normal placental development and that fetal genotype and exact genetic abnormality are both relevant to the postulated mechanism. **Methods** We conducted a comparison of all reported XPD-associated TTD (n=43) and XP (n=37) cases with respect to frequencies of pregnancy complications including preeclampsia. We also mapped preeclampsia-associated mutations onto the available XPD crystal structures in order to delineate their biologic impact. Furthermore, we analyzed gene expression microarrays in placenta in order to decipher common biologic pathways of involvement of all TTD NER/transcription genes in normal human placental development. **Results** Compared to XP, TTD-affected pregnancies were associated with significantly higher incidence of preeclampsia (P=0.003), preterm delivery (<37 weeks gestation) (P<0.0001), low birth weight (<2500 grams) (P<0.0001), small for gestational age (SGA)<10thpercentile (P=0.006), SGA<3rd (P=0.003) and NICU admission (P<0.0001). Structural mapping localized the preeclampsia-associated mutations to a C-terminal motif and the helicase surfaces of XPD, regions implicated in binding of XPD with cdk-activating (CAK) and p44 subunits of Transcription Factor (TF)IIH. Time course, gene-gene correlation and pathway analyses suggested important functions for all TTD NER/transcription genes throughout gestation (from 1st to 3rd trimester) and implicated their involvement in regulation of cellular metabolism (via regulation of several nuclear receptors by CAK domain of TFIIH) in placenta. **Conclusion** Our results revealed that a specific subset of *XPD* mutations which lead to TTD, but are unrelated to XP, result in higher risk of preeclampsia and other gestational complications, possibly due to their adverse effects on binding of XPD with CAK and p44 subunits of TFIIH leading to impairment of TFIIH-mediated functions in placenta. Overall, our epidemiologic, molecular and microarray analyses implicated dysregulation of cellular metabolism in addition to transcription pathways, caused by abnormalities in TTD NER/transcription genes, in preeclampsia and other placental vascular complications noted in our study.

The fetal RHD genotyping and gender determination from cell-free fetal DNA circulating in maternal blood. *A. Stan[1], C. Dragomir[1], L. Savu[1], E. Severin[2].* 1) Genetic Lab , Bucharest, Romania; 2) Carol Davila Univ Med Pharm, Bucharest, Romania.

Background: The NIPD (non-invasive prenatal diagnosis) approach is of greatest interest to the researchers in the prenatal diagnosis field. We report the non-invasive fetal RHD genotyping and fetal gender determination performed in Romania. Objective: Although the prenatal diagnosis procedures currently employed in Romania are based exclusively on invasive sampling procedures of fetal cells our aim was to introduce a NIPD protocol in our country. Patients and Methods: We tested 68 pregnant RhD negative women with RhD positive partners who referred to our laboratory for prenatal diagnosis tests. For the cell-free total DNA extraction from maternal plasma we used the QIAamp® DSP Virus kit. The standard working protocol was modified. We developed two different PCR multiplex based reactions. The first included specific primers for two sequences in the exon 5 and respectively exon 7 of the RHD gene. To the second PCR reaction we added specific primers for fetal gender determination. Both reactions included the) -globin sequence detection as internal control. The PCR products were automated analyzed on the QIAxcel instrument using the QIAxcel DNA High Resolution Kit, QIAGEN. Results: We detected 48 fetuses with RHD positive genotype and 20 fetuses with RHD negative genotype. All 68 cases were analyzed in triplicate. For the last 12 samples we determined the fetal gender along with the RHD genotype; the results were confirmed by the QF-PCR method for aneuploidies detection from CVS or amniotic fluid. Conclusion: Our results confirm that this non-invasive approach is feasible and accurate and will improve the management of mother-fetus RhD incompatibility and avoid the unnecessary administration of anti-D immunoglobulin to mothers that does not undergo amniocentesis.

Non-Invasive Prenatal Detection of a novel 12p12.1-p11.22 Microdeletion in a Fetus By Next Generation Sequencing of Maternal Plasma DNA. *D. Peters, T. Chu, S. Yatsenko, N. Hendrix, W. Allen Hogge, U. Surti, K. Bunce, M. Dunkel, P. Shaw, A. Rajkovic.* Magee-Womens Res Inst, Univ Pittsburgh, Pittsburgh, PA.

Prenatal diagnosis of aneuploidies and genomic imbalances requires a pure sample of fetal genomic material, which must be obtained via invasive means such as chorionic villus sampling (CVS) or amniocentesis. Unfortunately, these invasive procedures carry a significant risk of fetal loss and parental anxiety. Alternative, risk-free, methods for the non-invasive analysis of fetal DNA in maternal plasma have shown promise for the detection of fetal aneuploidy. However, the non-invasive prenatal detection of chromosomal microdeletions and microduplications remains elusive. The goal of this study therefore is to demonstrate proof of concept for non-invasive detection of a chromosomal abnormality in a fetus with a novel 12p microdeletion. Having previously given birth to a daughter with a paternally inherited 4.2Mb deletion on chromosome 12p12.1-p11.22, a couple expecting their second child presented to the Center for Medical Genetics at the Magee-Womens Hospital of UPMC for genetic counseling. Amniocentesis performed at 21 weeks of gestation showed a normal male chromosome complement, but microarray analysis performed on DNA extracted from cultured amniocytes identified single-copy 12p12.1-p11.22 loss, the same deletion as identified in sibling and father. FISH analysis confirmed the interstitial deletion in the fetus. A maternal blood sample was drawn at 35 gestational weeks and DNA extracted from the plasma was then used as a substrate for single end read (35bp) Illumina DNA sequencing, which generated a total of 243,340,714 reads of which 75% (182,691,185) could be mapped uniquely and perfectly to the latest version of human reference genome, GRCh37. In addition, we obtained 7 maternal plasma libraries, where both the mother and fetus are known to be diploid for both chromosomes 12 and 14 as reference libraries for sequencing. When comparing the sequencing reads from the known 12p deletion library with those from the reference libraries, we were able to detect the single copy fetal loss of the 12p region in DNA from maternal plasma, achieving 100% sensitivity, with the test for the chr12.del region resulting in highly significant adjusted p values (<=0.05) in all 7 comparisons, and 100% specificity resulting in non-significant adjusted p values (>= 0.05) in all 7 comparisons. In summary, we have demonstrated proof of concept for non-invasive detection of a chromosomal abnormality in a fetus with a novel 12p microdeletion.

Runs of Homozygosity (ROH) analysis from GWAS data for Preterm Birth. *A. Uzun[2,3,4], B. Feenstra[5], ML. Marazita[6], M. Melby[5], JC. Murray[1], J. Padbury[2,4].* 1) University of Iowa, Department of Pediatrics,Iowa City, Iowa; 2) Women and Infants Hospital, Pediatrics, , Providence, RI; 3) Brown University, Center for Computational Molecular Biology, Providence, RI; 4) Brown Alpert Medical School, Providence, RI; 5) Statens Serum Institute, Department of Epidemiology, Copenhagen, Denmark; 6) University of Pittsburgh, Division of Oral Biology, School of Dental Medicine, Pittsburgh, PA.

Runs of consecutive homozygous markers may identify recessive traits/rare variants for complex diseases. This form of homozygosity mapping can be identified from polymorphic variance used for Genome Wide Association (GWAS) studies. We present an approach to identify patterns of homozygosity from GWAS data. We compare the outputs from cases and the controls from a large GWAS of preterm birth. The data was derived from the Gene Environment Association Studies initiative (GENEVA) funded by the trans-NIH Genes, Environment, and Health Initiative (GEI). The data from GENEVA consists of nearly 4000 Danish women and children. Genotype data from 1929 control and preterm women were studied. The gestational age at delivery varied from 20 to 40 weeks. We divided the patients into four groups. Group A: 40 weeks, group B: 37 and less weeks, group C: 34 and less weeks, group D: 30 and less weeks. We identified runs of homozygosity (ROHs) in whole genome by the ROH program implemented in PLINK version 1.07. In order to exclude short and very common ROHs that may occur in all individuals, the minimum length for an ROH was set at 1000kb, minimum number of consecutive SNP number was 100, density (kb/SNP) was 50 and largest gap was 1000kb. SNP data from each chromosome of each woman were used. We further defined the boundaries of shared regions of RoH using a custom program using Perl scripts and mapped these to the UCSC Genome Browser. We compared the block frequency and gene location between each gestational group. Mean number of blocks per patient did not differ, but the mean length of RoH is significantly greater in each of the younger gestational age groups, p<0.001. We found several RoH blocks covering preterm birth related genes (ASHG2010, Abstract # 1711). These regions were used to compare the abundance of RoH blocks in each gestational age group. For example on chromosome (chr) 1, RoH covering the MTF2, TMEM206, NENF, on chr 2 IL1R2, on chr 4 IL15, on chr 7 PON1, on chr 8 TRAM1, on chr 14 CKB, on chr 17 LLGL1 genes were significantly higher in group B than group A. We found 121 SNPs from preterm related genes which overlap between single gene variant association tests and the ROH block regions. Higher density coverage from GWAS data will increase the resolution and further define blocks. In combination with single variant association testing and haplotype analysis, RoH mapping may identify fruitful regions for targeted resequencing in specific groups.

1393W

Novel loci associated with birth weight provide biological links between intrauterine growth, postnatal growth and metabolic traits. *H. Yaghootkar[1], M. Horikoshi[2], D.O. Mook-Kanamori[3], U. The genetic loci influencing birth weight (BW) and its relationship to postnatal growth and adult disease are poorly characterized. Two loci have been reported, CCNL1 and ADCY5, which contain variants associated with BW. To identify additional loci associated with BW we performed a genome-wide association study using 26,864 European descent individuals from 18 studies and followed up 17 loci in up to 37,120 individuals. In each study, we analyzed the association between BW Z-score and SNP using linear regression, with sex and gestational age (when available) as covariates. We excluded multiple and premature births. We performed fixed-effects inverse-variance meta-analyses to combine results from all studies. We identified four novel and confirmed two loci containing variants associated with BW at p<9x10-8. These loci fell into three broad categories. First, two of the four strongest associations represented the same signals as known type 2 diabetes (T2D) signals - in or near ADCY5 (p=3.5x10-15, previously reported) and CDKAL1 (p=9x10-17). In both loci, the BW-lowering allele is also associated with greater T2D risk. This is consistent with the fetal insulin hypothesis, which proposes that common genetic variation influencing insulin secretion is a key link between lower BW and later life T2D risk. Second, three associations represented the same signals as known adult height signals, in or near HMGA2 (p=3x10-19), LCORL (p=1x10-8) and HHIP (p=9x10-8) genes. For all three loci, the height-increasing allele represented the same signal as the BW-increasing allele. Third, the previously reported association near the CCNL1 gene (p=2.9x10-28), represents the strongest association with BW (with percent effect sizes equivalent to the effect of the FTO locus on BMI). This locus has no known overlap with other traits and likely represents an effect specific to intrauterine growth. Of the 32 known adult-BMI loci, there was no evidence of association or enrichment of effects on BW. In a subset of studies (n= 8780), newborns with 9-12 BW-lowering alleles weighed 150g (95% CI: 116-185g) less than those with 5 or fewer BW-lowering alleles at 6 loci. This effect is equivalent to that of 5-6 cigarettes/day smoked in the 3rd trimester of pregnancy, or roughly half the effect reported for extreme maternal starvation. Our analysis of the genetic component contributing to BW highlights genetic loci contributing to growth processes and to metabolic trait regulation.

1394W

Noninvasive prenatal diagnosis of multiple fetal aneuploidies using massively parallel sequencing. *A.J. Sehnert[1], D.W. Bianchi[2], R.P. Rava[1].* 1) Research and Development, Verinata Health, San Carlos, CA; 2) Pediatrics, Obstetrics & Gynecology, Tufts University School of Medicine, Boston, MA.

Background: Recent advances in noninvasive prenatal diagnosis show that massively parallel sequencing of cell free fetal DNA in maternal blood detects fetal trisomy 21 (T21). We wished to determine whether techniques focused on T21 diagnosis would also detect other aneuploidies. Methods: Blood samples were collected from 1,014 pregnant women prior to prenatal procedure at 13 US clinics. DNA extracted from 119 samples underwent massively parallel sequencing. A training set of 71 samples was selected from the first 435 samples collected (Apr-Dec 2009). All subjects with an affected fetus in this series were included (26 abnormal karyotypes) and a random selection of non-affected samples. Utilizing normalized chromosome values (NCVs) from the sequencing data an algorithm was developed. The classification process was then evaluated on an independent test set of 48 samples (27 abnormal karyotypes) randomly selected from 575 samples (Jan-Jun 2010). Laboratory personnel were blinded to karyotype. Mapped sites for chromosomes of interest in the sequencing data from the training set were normalized individually by calculating the ratio of number of sites on a specified chromosome to number of sites on an optimized normalizing chromosome (or chromosome set). Threshold values for trisomy or sex chromosome classification were then established and a classification scheme was defined including a `no call' zone for each. Results: Sequencing of the independent test set lead to 100% correct classification of T21 (13/13) as well as T18 (8/8). One case of T13 was `no call' for Chr 13. In five samples with other complex karyotypes, 4 were correctly classified including 45,X (2/3) and a fetus with karyotype; 46,XY,+unidentified marker. The third 45,X sample was `no call' for sex. A rare Chr 9 abnormality was also unexpectedly detected. The sample, mosaic karyotype; 47,XX+9[9]/46,XX[6] was correctly classified for sex, and a relatively low NCV was observed for Chr 21. Since Chr 9 is in the denominator of our algorithm for calculating Chr 21 ratio, this lowered the overall NCV. Conclusions: Massively parallel sequencing is capable of detecting multiple fetal chromosomal abnormalities from maternal plasma. This may provide an advantage over serum analytes, which at present provide only indirect risk for T21 and T18.

1395W

Ancestral origins of African American women in the Healthy Pregnancy, Healthy Baby cohort. *M.L. Miranda[1, 2], M.E. Garrett[3], K.S. Quinn[3], G.K. Swamy[4], A.E. Ashley-Koch[3].* 1) Nicholas School of the Environment, Duke University, Durham, NC; 2) Department of Pediatrics, Duke University Medical Center, Durham, NC; 3) Center for Human Genetics, Duke University Medical Center, Durham, NC; 4) Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC.

African American women have greater risk than Caucasian women for adverse birth outcomes, even when controlling for social and demographic differences. However, many African American women have excellent birth outcomes, and a possible contributor to differential risk is the percentage of European admixture. The Healthy Pregnancy, Healthy Baby Study is a prospective cohort of pregnant women aimed at identifying genetic, social and environmental contributors to disparities in pregnancy outcomes in the US South. Clinical and genetic data were available for 848 non-Hispanic Black (NHB) women. Clinical outcomes analyzed included infant birth weight, pre-term birth (gestation < 37 weeks), birth weight less than 5th percentile for gestational age (SGA5), birth weight less than 10th percentile for gestational age (SGA10), and preeclampsia. 1509 SNPs were genotyped using the Illumina African American admixture panel. Six mitochondrial DNA (mtDNA) SNPs were genotyped via Taqman assays in order to construct ancestral mtDNA haplogroup (L0, L1, L2, L3, N, or R) for each subject. Among our NHB women, the genome-wide average percentage of European admixture was 17.9%. None of the clinical outcomes were associated with this estimate of European admixture. The distribution of subjects in each mtDNA haplogroup was: L0 (3.7%), L1 (18.5%), L2 (28.0%), L3 (39.9%), N (0.7%), R (9.3%). European admixture did not significantly differ among the 4 African mtDNA haplogroups (L0=17.3%, L1=17.4%, L2=17.6%, L3=16.7%). However, European admixture was higher among the women with mtDNA haplogroup R (24.4%, p<0.0001) compared with the African haplogroups. Clinical outcomes were also tested for association with African haplogroups. Women in the L3 haplogroup were more likely to deliver low birth weight (<1500g) babies than women in the L2 haplogroup (p=0.004). Women in the L3 haplogroup were also more likely to deliver SGA10 than women in the L2 haplogroup (p=0.016). These data suggest that NHB women in the L3 haplogroup, which originated in east Africa, are at greater risk for adverse birth outcomes than NHB women with the L2 haplogroup, which originated in western and sub-Saharan Africa. Thus, some measures of ancestral origin in African American women are correlated with differential risk for adverse birth outcomes. Additional analyses will be needed to determine whether the mtDNA haplogroups are a surrogate for mitochondrial function.

Differential impact of mtDNA mutations on the mtDNA copy number during human oogenesis and embryofetal development. *J. Steffann[1], S. Monnot[1], D.C. Samuels[2], N. Gigarel[1], P. Vachin[1], L. Hesters[3], P. Burlet[1], Y. Ville[4], M. Rio[1], A. Benachi[3], R. Frydman[3], AS. Lebre[1], A. Munnich[1], A. Rotig[1], N. Frydman[3], JP. Bonnefont[1].* 1) Paris Descartes University, Inserm unit U781, and Genetics Department, Necker Hospital, Paris, France; 2) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, USA; 3) Department of Obstetrics and Reproductive Medicine, and Inserm unit U782, A Béclère Hospital, Clamart, France; 4) Obstetrics Department and Paris Descartes University, Necker Hospital, Paris, France.

Mitochondrial DNA (mtDNA) mutations cause serious disorders with maternal inheritance and a high transmission risk, resulting in common requests for preimplantation (PGD) or prenatal diagnoses (PND). These procedures are hampered by the lack of data on the pathophysiological impact of mtDNA mutations during human development. We previously showed in the frame of our PGD/PND activities that mtDNA mutations differentially modulate the bottleneck size in humans, and segregate according to a random genetic drift throughout the whole embryofetal development. There are however no available data regarding the putative impact of mtDNA mutations on the overall amount of mtDNA during human oogenesis and embryofetogenesis as well. In order to get an insight into this point, we collected oocytes (controls, n:19; m.3243A>G, n:12; m.8344A>G, n:5), preimplantation embryos (controls, n:9; m.3243A>G, n:12; m.8344A>G, n:12), and chorionic villi samples (CVS) at 11 GW (controls, n:7; m.3243A>G, n:14) and at delivery (controls, n:3; m.3243A>G, n:4). We devised a test enabling the simultaneous assessment of the mtDNA copy number (CN) and mutant load at the single cell level. The analysis of oocytes and embryos showed that the mtDNA CN i) is identical in control and mutant oocytes, suggesting that mtDNA mutations do not influence mtDNA replication during oogenesis, ii) is significantly increased in m.3243A>G vs control peimplantation embryos ($p<0.01$), suggestive of a mutation-dependent induction of mtDNA replication during early embryogenesis, iii) strongly correlates with the mutant load (range 0-80%) in m.3243A>G embryos ($R2=0.42$, $p<0.0013$), suggesting some process of compensation for the respiratory chain dysfunction, iiii) is identical in m.8344A>G vs control preimplantation embryos, indicating that the mtDNA replication induction observed in the m.3243A>G embryos is mutation-specific. The analysis of CVS showed that the mtDNA CN i) is significantly increased in m.3243A>G vs control CVS at 11-GW ($p<0.01$), ii) does not correlate with the mutant load (range 0-80%) at this gestation stage, iii) strongly decreases from 11 to 37-39 GW in both control (-50 %) and m.3243A>G CVS (-65%), and iiii) becomes then identical in both control and m.3243A>G CVS (heteroplasmy range: 5-45%). These data highlight the complex relationships between mtDNA mutations and the overall amount of mtDNA, depending on mutation types, mutant load values, cell types and human development stages.

1397W

Novel *NEB* mutation in an Ashkenazi Jewish infant with severe congenital Nemaline Myopathy. *A. Ludtke[1], R. Kornreich[1], T. Winder[2], L. Mehta[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Prevention Genetics Laboratory, Marshfield, WI.

Nemaline myopathy (NM) is a heterogeneous neuromuscular disorder characterized by variable onset and severity of muscle weakness. So far, mutations in 6 different genes encoding thin filament muscle proteins have been associated with NM. Mutations in the *NEB* gene cause autosomal recessive disease, including congenital forms of NM. The only known recurrent mutation in this gene is a 2502 bp deletion spanning exon 55, present in an estimated 1:108 individuals of Ashkenazi Jewish descent in the orthodox community. We report the case of a female infant who presented with severe muscle weakness, contractures, dysmorphic features and long bone fractures, consistent with fetal akinesia. The infant passed away at 3 days of age from respiratory failure. The pregnancy was complicated by polyhydramnios and bilateral club feet on fetal ultrasound at 20 weeks gestation. The parents were Ashkenazi Jewish, non-consanguineous, and with no relevant family history. The couple had been screened for Jewish genetic disorders through the Dor Yeshorim organization. The infant had normal blood chromosome analysis and array CGH. Due to the phenotype of a severe neuromuscular disorder, the parents underwent carrier screening for two common recessive, neuromuscular disorders, NM and spinal muscular atrophy. The mother was found to carry the common Ashkenazi Jewish NEB mutation R2478_D2512del, which was also present in the deceased baby's DNA. The father was negative for the mutation. Sequencing of all 183 exons including exon-intron junctions of the *NEB* gene in the father identified a novel heterozygous mutation c.9619-2A>G at the junction of intron 66 and exon 67. The same mutation was then identified in the child's DNA. Since the mutation is predicted to disrupt the intron 66 splice acceptor site, it is expected to be causative for NM in homozygous or compound heterozygous individuals. This case illustrates the phenotype of severe congenital NM which should be included in the differential diagnosis of fetal akinesia. Further, it highlights the limitations of targeted mutation panels for screening of recessive diseases - an important aspect of genetic counseling, where one member of a couple is identified to be a carrier and the other is negative for common mutations. Knowledge of the causative mutations in this setting helps to provide accurate genetic counseling and reproductive options, such as prenatal or preimplantation genetic diagnosis in future pregnancies.

1398W

Prenatal diagnosis of) -thalassemia using polymorphic marker revealed DNA recombination 5' to) -globin gene. *z. kainimoghaddam, M. Karimipour, A. Amiriyan, M. Taghavi, A. Sanjari, M. Chobini, S. Zeinali.* Molecular Medicine, Pasteur, Tehran, Tehran, Iran.

Introduction:) -thalassemia is an inherited autosomal blood disease and the most frequent single gene disorder in Iran. The prenatal diagnosis (PND) is an effective option for preventing the birth of an affected child Methods used for PND are direct mutations analysis and indirect method using DNA polymorphisms at B-globin gene cluster. There is always the possibility of error due to meiotic recombination between the polymorphic markers and the mutation in) -globin gene. In this study we report a family was referred to our clinic for PND with a major thalassemia child. Material and Methods: From each individuals (parents and affected child) 5ml of blood was collected in EDTA and DNA extracted by using sulting out method.CVS(chorionic wily sample) was obtained 10-12 weeks of gestation age.DNA was prepared from CVS by using standard methods. ARMS/PCR and PCR-RFLP were exploited for prenatal diagnosis in parallel. Results: In this study we found the mutation (-25bp deletion) for this family and five polymorphisc sites ((Hind III/. G, ,HincII/3'?) , AvaII/) , HinfI/)) were investigated .The fetus was normal for this mutation. AvaII/) polymorphic site was not informative but HinfI/) (-/-) showed the fetus was normal.The polymorphic sites (Hind III/ . G, ,HincII/3'?)) were similar each othe r(+/-) that indicated the fetus was heterozygous carrier. Discussion: These results show the fetus is normal for the mutation(-25bp deletion) associated the polymorphic site HinfI/) ,and other polymorphic sites are conversed .The finding of a recombination) -globin haplotype has important implication in the prenatal diagnosis of) -thalassemia disorder .Therefore for the PND of) -thalassemia by linkage RFLPs, it is important to carry out complete haplotype analysis of each chromosome in the family and to use polymorphic markers from both the 5' and 3' group whenever possible.

Preimplantation Genetic Diagnosis Based Detection of Uniparental Disomy on Embryos Undergoing IVF. *G. Ozgon[1], A. Fejzullahu[1,2], K. Senvardar[1,3], A. Biricik[4], F. Fiorentino[4].* 1) Nesiller Genetics Diagnosis Centre and R&D, Istanbul, Turkey; 2) Molecular Biology Genetics and Biotechnology Graduate Program, Institute of Science and Technology, Istanbul Technical University, Istanbul, Turkey; 3) Gebze Institute of Technology, Faculty of Science, Department of Molecular Biology and Genetics, Kocaeli, Turkey; 4) GENOMA, Molecular Genetics Laboratory, Rome, Italy.

In recent years, the clinical application of preimplantation genetic diagnosis (PGD) has provided an alternative approach for the prevention of affected pregnancies in couples at high reproductive risk. The main indications are advanced maternal age, repeated implantation failure, repeated miscarriage and severe male factor infertility. Therefore, the selection of euploid embryos for transfer by the help of preimplantation genetic screening (PGS) of chromosomally normal embryos from subfertile patients, has a strong impact in IVF efficiency as aneuploidies are the main cause of spontaneous abortions and implantation failures. Moreover, the technique diagnosis not only aneuploidies or unbalanced inheritance but also it allows the diagnosis of uniparental disomy (UPD). Although UPD, where both chromosomes are inherited from one parent and no chromosomes are inherited from the other, is exoterically a rare event, it was mentioned to be detected in higher proportion rate in chromosome 14. In view of these findings, the aim of this study is to investigate the association of UPD analyzed in aneuploidy and inv(9) conditions. In this study preimplantation genetic screening (PGS) was performed in 46 cycles for aneuploidy diagnosis subsequently in chromosomes 13, 18, 21 and XY. 365 blastomeres were analyzed by polymerase chain reaction (PCR) and nested polymerase chain reaction (Nested PCR) with specific markers used in aneuploidy screening. Couples with advanced maternal age, repeated implantation failure, repeated miscarriage and inv(9) indications were analyzed for aneuploidy screening (13, 18, 21 and XY). After PCR and Nested PCR reaction all products were analysed by fragman analysis on ABI 3100 Genetic Analyzer. The obtained results showed that the rate of UPD in couples with aneuploidy indication was approximately 3.6% (335 blastomere). More interestingly the rate of UPD in 35 blastomeres screened in couples with inv(9) indication was detected to be 34%. Inv(9) is a common (1-3%) heteromorphism in the general polulation categorized as a minor chromosomal rearrangement without abnormal phenotypes, however, it is correlated to be associated with subfertility and recurrent abortions. Although the UPD is a rare event, it is observed that there is a strong association between inv(9) and UPD in couples undergoing IVF. As a conclusion, further studies are needed to understand the cause of these genetic abnormalities in couples at high reproductive risk.

Pre-implantation genetic diagnosis offers a fair chance of having unaffected offspring for mitochondrial DNA disorders. *H.J.M. Smeets[1,2], D.M.E.I. Hellebrekers[1], R. Wolfe[3], A.T.M. Hendrickx[1], J.P.M. Geraedts[1,2], P.F. Chinnery[4], C.E. De Die[1,2], I.F.M. De Coo[5].* 1) Dept Clinical Genetics, Maastricht UMC, Maastricht, Netherlands; 2) Research School GROW, Maastricht UMC, Maastricht, Netherlands; 3) School of Public Health and Preventive Medicine, Monash University, Melbourne, Australia; 4) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, UK; 5) Dept of Pediatric Neurology, Erasmus MC-Sophia Children's Hospital, Rotterdam, Netherlands.

Mitochondrial disorders are often fatal multisystem disorders, for a significant part caused by heteroplasmic mtDNA point mutations. Prenatal diagnosis is in general not possible for these maternally inherited mutations due to extensive variation in mutation load among embryos and the inability to accurately predict the clinical expression. We hypothesized that preimplantation genetic diagnosis (PGD) should be a better alternative, if a minimal mutant level existed below which the chance for an embryo of being affected was acceptably low, irrespective of the mtDNA point mutation. We performed a systematic review of muscle mutant levels, evaluating 159 different heteroplasmic mtDNA point mutations derived from 327 unrelated patients or pedigrees, but excluding three overrepresented mtDNA mutations. Mutation levels were included for familial mtDNA point mutations only, covering all affected (n=195) and unaffected maternal relatives (n=19) from 137 pedigrees. Mean muscle mutant levels were comparable between probands and affected maternal relatives and between affected individuals with tRNA- versus protein-coding mutations. Using an estimated a-priori prevalence of being affected in pedigrees of 0.477, we calculated the risk of being affected at varying mutant levels. A 95% or higher chance of being unaffected was associated with a muscle mutant level of 18% or less. Most mtDNA mutation carriers will have oocytes below this threshold. Our data provide for the first time carriers of all heteroplasmic mtDNA point mutations a fair chance of having healthy offspring, by applying PGD.

Monosomy 18p presenting prenatally as mild ventriculomegaly-case report and review of the literature. *K. Bajaj[1,2,3], M. Rosner[1,3], T. Goldwaser[1,3], J. Gebb[1,3], P. Dar[1,3], S. Klugman[1,3].* 1) Department of Obstetrics & Gynecology and Women's Health, Montefiore Medical Center, Bronx, NY; 2) Department of Obstetrics & Gynecology, North Bronx Health Network, Bronx, NY; 3) Albert Einstein College of Medicine, Bronx, NY.

BACKGROUND: Mild ventriculomegaly occurs in approximately 0.1% of pregnancies. Common causes include genetic aberrations, central nervous system (CNS) malformations, hemorrhage, or fibrosis due to infection. Aneuploidy is reported in 5-10% of cases. Most cases of isolated mild ventriculomegaly have normal developmental outcomes. CASE: 22 year-old nullipara with no significant family history presented for amniocentesis after anatomy sonogram at 20 weeks gestational age revealed a female fetus with mild bilateral ventriculomegaly (right ventricle = 11.2mm, left ventricle 10.5mm). Until then, the pregnancy had been uncomplicated, including a negative second trimester aneuploidy screen. The patient denied any fevers or infectious exposures. Fetal karyotype revealed a de-novo 46, XX, del(18)(p11.2); prenatal microarray confirmed this finding. Amniotic fluid was negative for toxoplasmosis and cytomegalovirus. Subsequent sonogram revealed low set gallbladder and right kidney and abnormally curved toes with overlapping 3rd and 4th digits in feet. After extensive counseling the patient decided to continue with the pregnancy DISCUSSION: Prenatal diagnosis of monosomy 18p was previously reported in association with increased nuchal translucency and holoprosencephaly. A critical region for holoprosencephaly, HPE4, is located on the distal portion of 18p. To our knowledge, this is the first report of monosomy 18p presenting prenatally with a subtle findings of mild ventriculomegaly. We review the cytogenetic/clinical features and management of isolated ventriculomegaly and monosomy 18p syndrome.

1402W

PRENATAL SCREENING OF SMN1 DELETION OR DUPLICATION SHOWED PREGNANCIES IN THE HIGH-RISK WOMEN HAD A HIGHER ABNORMAL COPY NUMBERS OF SMN1 ALLELES THAN THAT IN THE GENERAL PREGNANCIES. *Y. Chen, MJ. Liu, HB. Li, J. Mao, H. Li.* Center of Reproduction and Genetics, Suzhou Municipal Hospital, Suzhou, Jiangsu, China.

Because of the severity of spinal muscular atrophy (SMA) and the lack of effective treatment, a population-based screening of SMN1 deletion is promising for disease prevention. A TagMan probe-based real-time PCR assay, followed by multiplex ligation-dependent polymerase amplification (MLPA) as confirmation, was used to determine SMN1 gene deletion. 541 subjects including 458 pregnant women and 83 amniotic fluid samples that had been collected previously from a group of high-risk population for prenatal screening of trisomy 21, trisomy 18 or neural tube defect were studied. Our results showed that among the pregnant women, SMA carrier accounts for 2.18% (10/458=1/46). In addition, 1.75% (8/458) were identified having three copies of SMN1 allele and 0.22% (1/458) with 4 copies of SMN1allele, which brought the abnormal copy number up to 4.1%. The corresponding data with 1 copy and 3 copies in the amniotic fluid samples were 7.23% (6/83) and 1.20% (1/83), respectively, showing the abnormal copy number is 8.4% in the high-risk population that is significantly higher than the general population.

1403W

Early Delivery of Infants for Treatment of Retinoblastoma Diagnosed by Prenatal *RB1* Mutation Identification. *H. Dimaras[1, 2], E. Heon[3], J. Sutherland[3], M. Day[3], V. Khetan[3,4], J. Gardniner[5], H.S.L. Chan[1], B.L. Gallie[3].* 1) Hematology/Oncology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Ophthalmology & Vision Sciences, The University of Toronto, Toronto, ON, Canada; 3) Ophthalmology & Vision Sciences, The Hospital for Sick Children, Toronto, ON, Canada; 4) Sankara Nethralaya Hospital, Chennai, India; 5) Ophthalmology & Vision Sciences, University of British Columbia, Vancouver, BC, Canada.

Purpose: To determine ocular outcomes of infants confirmed prenatally to carry their family's *RB1* mutation who underwent pre-term delivery to initiate treatment. **Methods:** A retrospective study of Sickkids medical records documented children born between 1 June 1996 and 31 May 2011, seen at Sickkids because of relation to a retinoblastoma proband. Information was collected on: relation to proband; sex; timing of and result of prenatal ultrasound (if performed); gestational age at birth; pregnancy or delivery complications; date of *RB1* molecular testing, type of sample tested and result; timing and location of first and all subsequent tumor appearance(s) in each eye; treatment history; International Intraocular Retinoblastoma Classification of each eye; laterality; Tumour Node Metastasis staging; date of last follow-up; and visual outcome. **Results:** Of 15 infants shown to carry their parent's *RB1* mutation, 9 were tested prenatally and 6 after birth. Of the infants tested prenatally, 7 were delivered at 36-37 weeks gestation and 2 were spontaneously premature. The infants that were not tested prenatally were born at full term. After birth, daily/weekly examination for tumors occurred. Vision-threatening tumors were present at birth in 22% (2/9) of infants delivered early or born prematurely, and 50% (3/6) of full-term infants; posterior tumors appeared age 1 to 6 months in 9 infants. All patients eventually developed tumors in both eyes. Good vision was maintained in all children delivered early; treatments included focal therapy (all); later chemotherapy (4). Full-term infants received focal therapy (6), chemotherapy (5), stereotactic radiation (2), and enucleation of one eye (2). **Conclusion:** Expedient intervention and optimal outcomes were facilitated by prenatal molecular detection coupled with early delivery.

1404W

Detection of aneuploidies from microdissected amniotic cells by quantitative fluorescent-polymerase chain reaction (QF-PCR). *R. Drouin[1], J. Lamoureux[1], A. Emad[1], E. BenDavid[1], K. Chun[2], C. Bouffard[1].* 1) Div Genetics, Dept Ped, Faculty Medicine & Health Sciences, Univ Sherbrooke, Sherbrooke, Quebec, Canada; 2) Genetics Program, North York General Hospital, Toronto, Ontario, Canada.

QF-PCR (Quantitative Fluorescent-Polymerase Chain Reaction) allows for the targeted detection of aneuploidies using fluorescently labelled PCR primers. In prenatal diagnosis, QF-PCR is an excellent alternative to fluorescence in situ hybridization (FISH) for rapid aneuploidy diagnosis (RAD) of chromosomes 13, 18, 21, X and Y, particularly in terms of cost and rapid turnaround time. In this project, we show that QF-PCR can be performed using the DNA of five laser-microdissected amniotic cells. To do so, cultured fetal cells from amniotic liquid sampling were split in two: one large aliquot for standard DNA extraction and another small one for laser microdissection. The fetal cells from the smaller aliquot were spread on membrane-mounted metal frame slides and five cells were isolated by laser microdissection. Then, whole genome amplification (WGA) was performed using extracted DNA from these microdissected cells. In parallel, DNA was extracted from the larger aliquot of cultured amniotic cells; these samples were used as controls for validation. PCR amplification of short tandem repeats (STR) specific for chromosomes 13, 18 and 21 as well as the sex chromosomes was performed on DNA from both the microdissected cells and the control amniotic cells using QF-PCR. Amplicons were separated by capillary electrophoresis and quantitatively analyzed to determine allele dosage and sexing. Results with control samples showed that QF-PCR is a very sensitive and specific technique for allele dosage and sexing. Results of QF-PCR on WGA-DNA from microdissected cells showed weaker signals of amplification as compared to that of control samples. However, allele dosage and sexing of samples correlated between control and WGA-DNA samples. To date, we have carried out studies on 20 samples with various chromosome constitutions, including 46,XX; 46,XY; 47,XY,+21; 47,XX,+21; 45,X; and 47,XXY. These results confirm that QF-PCR can be performed successfully on a small number of fetal cells (five cells). In addition to giving rapid, inexpensive and accurate results on amniotic fluid cells, QF-PCR is an efficient technique that could be used in non-invasive prenatal diagnosis for rapid detection of aneuploidies where a very small number of fetal cells would be available.

Clinical study of chorionic villous sampling for 10 years. *K. Lee[1], S. Kim[1], S. Shim[2], J. Baek[3], D. Cha[1,2].* 1) Dept OB/GYN, Kangnam-Gu, CHA General Hosp, CHA university, Seoul, Korea; 2) Genetics Laboratory, Fertility Center of CHA Gangnam Medical Center, CHA university, Seoul, Korea; 3) Department of Obstetrics and Gynecology, Bundang CHA Hospital, CHA university, Seoul, Korea.

Purpose : The purpose of this study was to evaluate the indications of chorionic villous sampling(CVS), the positive predictive value for fetal chromosomal abnormalities, the fetal loss rate of CVS at CHA medical center. Materials and methods : We reviewed medical records of 511 cases in whom the CVS for prenatal cytogenetic diagnosis were performed between 67 days and 120 days of gestation for the period of April 2000 to April 2010 in CHA medical center. Fetal karyotyping was obtained by direct and indirect culture methods. Results : The most common indications of CVS were abnormal ultrasonic findings including increased nuchal translucency (294/511, 57.5%). The positive predictive value of abnormal karyotyping according to the indication of CVS was highest in the cases showing parent abnormal karyotyping (14/21, 66.7%). Fetal loss rate was 1.2% (6/511). Conclusion : In our study, the complication rate of CVS was not much higher than second trimester amniocentesis. If CVS is performed by an expert operator, CVS is feasible and reliable procedure for prenatal genetic diagnosis.

Distribution of Fetal Skeletal Dysplasias in a Tertiary Care Centre: Genetic, Pathologic, and Radiological Findings in 91 cases. *U. Mohan[1], S. Keating[2], D. Chitayat[3,4], A. Toi[3,5], K. Chong[3,4], G. Tomlinson[6], P. Glanc[7].* 1) Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada; 2) Department of Pathology, Mount Sinai Hospital, Toronto, Ontario, Canada; 3) Center for Excellence in Obstetric Ultrasound, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Division of Clinical Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 5) Department of Medical Imaging, Mount Sinai Hospital, Toronto, Ontario, Canada; 6) Centre for Innovation in Complex Care, Toronto General Hosptial, Toronto, Ontario, Canada; 7) Department of Medical Imaging, Sunnybrook Health Sciences, Toronto, Ontario, Canada.

PURPOSE: The purpose of this study was to determine the distribution of various fetal skeletal disorders in a tertiary care centre, based on the 2006 Nosology and Classification of Genetic Skeletal Disorders[1]. The study provides additional information on rare skeletal disorders and further characterizes pathologic features of these disorders. **METHOD AND MATERIALS:** A retrospective review of 1806 perinatal autopsies from 2002-2009 at Mount Sinai Hospital, Toronto, ON was performed. The study population consisted of stillborns and terminated fetuses in their second and third trimesters as well as live born infants who died shortly after birth. The reports were reviewed for cases with a final diagnosis of a skeletal disorder, based on the 2006 Nosology[1]. Pathological, genetic, clinical and radiological information were gathered from the reports **RESULTS:** Of the 1806 perinatal autopsies performed, 91 (5.0%) received a diagnosis of a skeletal disorder. The 91 cases encompassed 15/37 groups according to the 2006 Nosology[1]. Out of the 91 cases, 75 (82.5%) had a complete autopsy (photos, x-rays, gross physical and histopathological analysis with or without biopsy) while limited autopsy (external exam, photos and x-rays) was performed in 16 (17.6%) cases. There was a slightly increased ratio of males to females (1.33:1). Prenatal screening was done in 14/91 (15.4%) cases and 7 had abnormal results. A diagnosis could be reached in 77/91 (84.6%) cases. The most common skeletal dysplasia was Thanatophoric dysplasia type 1 (17/91, 18.7%) followed by Osteogenesis imperfecta type 2 (15/91, 16.5%). **CONCLUSION:** Skeletal dysplasias comprised 5% of all perinatal autopsies at our tertiary referral centre. The most common skeletal dysplasias were Thanatophoric dysplasia type 1 and Osteogenesis imperfecta type 2. A combination of radiographic features, gross morphology, histopathology and DNA analysis provided a diagnosis in 77/91 (84.6%) cases while in 14/91(15.4%) cases a final diagnosis could not be determined. **CLINICAL RELEVANCE:** Familiarity with genetic and imaging findings and the distribution and lethality of various perinatal skeletal dysplasias is crucial in order to provide appropriate counselling for current and future pregnancies. 1. Nosology and Classification of Genetic Skeletal Disorders: 2006 Revision. A. Superti-Furga, S. Unger and the Nosology Group of the International Skeletal Dysplasia Society. SNP array analysis in Prenatal Diagnosis: what do pregnant couples want to know? *G. Oudesluijs[1], S.R. Riedijk[1], M.I. Srebniak[1], A.M. Joosten[1], L.C.P. Govaerts[1], K.E.M. Diderich[1], M. Boter[1], D. Van Opstal[1], A. Tibben[1,2], R-J.H. Galjaard[1].* 1) Department of Clinical Genetics, Erasmus Medical Center, P.O. Box 2040, Rotterdam 3000 CA, The Netherlands; 2) Center for Human and Clinical Genetics, Leiden University Medical Center, P.O. Box 9600, NL-2300 RC Leiden, The Netherlands.

PND after detection of fetal abnormalities must be fast and accurate in case there is a limited legal time frame for TOP. Prenatal SNP array testing is faster (reporting time within a week) and detects much smaller aberrations (~0.15 Mb) compared to karyotyping (~ >5 Mb). However, CNVs leading to an (increased risk for) known disorders not related to the fetal anomalies could be encountered. These so-called incidental findings could lead to unsolicited knowledge about hereditary predispositions and carriership of all kinds of diseases at any age, apart from findings of uncertain clinical significance. Unexpected confrontation with unsolicited knowledge in a prenatal setting might be harmful for the decision process in the course of pregnancy. This has led to much debate concerning the use of microarrays in PND. Therefore pregnant couples need to be informed about the possible outcomes. We introduced a questionnaire that categorizes the kind of clinical information obtained from SNP array analysis. Pregnant couples can choose which clinical information they would like to receive about their unborn child. This was introduced during pre-test genetic counselling in 2009 in a selection of pregnant couples with fetal anomalies, which were referred to a clinical geneticist. Of all pregnant couples 25% indicated they only wished to be informed about results that (most probably) cause the fetal abnormalities. Another 25% also wanted to be informed about disorders that most probably affect health at childhood age. However, 50% chose to be informed of health problems at any age. Especially the latter choice does not comply with the generally accepted view that PST of children is not performed in general. This is because it is at odds with the future child's right to decide for her or himself whether or not to be informed of a (predisposition) of a genetic disorder. It also raises the question whether or not the prospective parents are truly able to make informed choices. Alternatively, a more general consent model could be more applicable in these situations. It is also questionable whether parents are fully entitled to choose not to be informed of a serious treatable genetic condition of their future child. We will present more data on these issues. These data are important to guide us in future proper genetic pre-test counselling in prospect of the higher chance of incidental findings when next generation sequencing is introduced as a diagnostic tool in PND.

1408W

Non-invasive Prenatal Diagnosis (NIPD) of Multiple Trisomic Chromosomes in a Triploid Fetus Using a Novel Single Nucleotide Polymorphism (SNP) Based Bioinformatics Approach. *M. Rabinowitz[1], G. Gemelos[1], M. Banjevic[1], J. Baner[1], B. Levy[1,2], M. Hill[1].* 1) Gene Security Network, Redwood City, CA; 2) Columbia University Medical Center, NY, NY.

Objective: Determine if trisomy is non-invasively detectable with high confidence on a triploid fetus, using novel informatics to analyze SNP loci of free floating fetal DNA in maternal plasma.

Design: Retrospective case study.

Materials and Methods: 20ML of blood was drawn from a pregnant patient following an abnormal ultrasound. After centrifugation, maternal DNA was extracted from the buffy coat (DNEasy, Qiagen); cell-free DNA was extracting from plasma (QIAamp, Qiagen). Targeted sequencing was applied to SNP loci on chromosomes 2 and 21 in both DNA samples. Maximum-Likelihood Bayesian estimation selected the most likely hypothesis from the set of all possible ploidy states. The method determines fetal DNA fraction, ploidy state and explicit confidences in the ploidy determination. No assumptions are made about the ploidy of a reference chromosome. The diagnostic uses a test statistic that is independent of sequence read counts, which is the recent state of the art.

Results: We accurately diagnosed trisomy of chromosomes 2 and 21. Child fraction was estimated at 11.9% [CI 11.7-12.1]. The fetus was found to have one maternal and two paternal copies of chromosomes 2 and 21 with confidence of effectively 1 (error probability<10^{-30}). This was achieved with 92,600 and 258,100 reads on chromosomes 2 and 21 respectively.

Conclusions: This is the first demonstration of non-invasive prenatal diagnosis of trisomic chromosomes from maternal blood where the fetus was triploid, as confirmed by karyotype. Extant methods of non-invasive diagnosis would not detect aneuploidy in this sample. Current methods rely on a surplus of sequence reads on a trisomic chromosome relative to disomic reference chromosomes; but a triploid fetus has no disomic reference. Furthermore, extant methods would not achieve similarly high-confidence ploidy determination with this fraction of fetal DNA and number of sequence reads. It is straightforward to extend the approach to all 24 chromosomes.

1409W

A Novel Method to Detect Fetal Trisomy in Pregnant Women Using a Selective Analysis of Cell-free DNA in Maternal Blood. *K. Song[1], A. Sparks[1], C. Struble[1], E. Wang[1], W. Barrett[1], R. Stokowski[1], C. McBride[1], J. Zahn[1], D. Hollemon[1], K. Lee[1], N. Shen[1], J. Sandler[1], J. Doshi[1], M. Sun[1], J. Garrison[1], P. Pattee[1], J. Stuelpnagel[1], A. Tomita-Mitchell[2], M. Mitchell[2], A. Oliphant[1].* 1) Tandem Diagnostics, San Jose, CA; 2) Medical College of Wisconsin, Milwaukee, WI.

We have developed a novel, highly accurate, cost-effective, high throughput method for non-invasive detection of fetal aneuploidy and sub-chromosomal copy number variation. Current prenatal testing for fetal aneuploidies such as Trisomy 21 (Down syndrome) is suboptimal in that screening blood tests and imaging are imprecise, and invasive testing, while diagnostic, carries the risk of fetal demise. To overcome these challenges, several groups have demonstrated that non-invasive analysis of cell free DNA (cfDNA) from maternal blood may be highly accurate for fetal aneuploidy detection. One approach utilizes next generation sequencing in which cfDNA from all chromosomes are analyzed. Because this method involves analysis of DNA from the entire genome, next generation sequencing costs and throughput constrain its efficiency and scalability. By contrast, our alternative approach utilizes specific assays developed against chromosomes or genomic regions of interest, thereby enabling sequencing of DNA from up to 96 different patient samples per Illumina HiSeq lane or up to 1500 patient samples per sequencing run. Our initial evaluation of selective cfDNA analysis involved 301 pregnant patient samples, including 39 confirmed Trisomy 21 and 7 confirmed Trisomy 18 pregnancies. Using 5-fold cross validation, we correctly classified 39/39 (100%) Trisomy 21 and 7/7 (100%) Trisomy 18 cases. One of 255 (0.4%) low to average risk samples was classified as Trisomy 21. We are currently conducting a larger study analyzing samples from pregnant women with Trisomy 13, Trisomy 18, and Trisomy 21 fetuses, and will present our findings. In addition to detection of chromosomal aneuploidies, our selective analysis of cfDNA in maternal blood has future use for analysis of sub-chromosomal region copy number changes in the fetus.

1410W

Impact of prenatal diagnosis on livebirth prevalence of infants with Down syndrome. *C. Stoll, Y. Alembik, B. Dott, M.P. Roth.* Genetique Medicale, Faculte de Medecine, Strasbourg, France.

Objectives: Down syndrome (DS) constitutes 8% of cases of registered congenital anomalies in Europe. The objectives of this study were to examine trends in the live birth prevalence of DS during 30 years in a well defined population in the light of trends in maternal age and prenatal diagnosis. Methods: The material for this study came from multiple sources on births and terminations of pregnancy (TOP) after prenatal diagnosis of DS in 402,532 consecutive pregnancies of known outcome. The study period was divided into 3 subgroups 1979-1988, 1989-1996 and 1997-2008.In the area under study prenatal diagnosis of DS is offered to all women more than 38 years. Maternal serum screening (triple test) is offered to all pregnant women since 1997 and fetal ultrasonographic scanning is routine practice. Results: Between 1979-1988, 1989-1996 and 1997-2008 TOP for DS was 16.2%, 46.8% and 72.3%, respectively. During the 3 time periods the livebirth prevalence per 10,000 of DS was 9.79, 10.26, and 6.08, respectively. The total prevalence of Down syndrome was 11.69, 19.31 and 23.10, respectively. The livebirth prevalence of DS has since 1997 increasingly diverged from the rising total prevalence. The main reason for these observations is the increase in maternal age, from 24.8 to 30.1 year. Conclusion: The rise of maternal age has brought with it an increase in the number of pregnancies affected by DS. The widespread practice of routine prenatal diagnosis and TOP has counteract the effect of maternal age in its effect on livebirth prevalence of DS. However the high total prevalence of fetal DS shows that more efforts on the primary prevention of chromosomal abnormalities are needed.

1411W

Future choices in prenatal diagnosis - How will women decide? *M.R. Susman[1], J. Halliday[1], J. Bayer[3], D. Amor[2].* 1) Public Health Genetics, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Genetic Health Services Victoria, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 3) Centre for Community Child Health, Murdoch Childrens Research Institute, Parkville, Victoria, Australia.

Purpose: With the introduction of non-invasive prenatal diagnosis (NIPD) for Down syndrome and the simultaneous offer of arrays for molecular karyotyping, the complexity of women's choices will increase. There is considerable research into women's attitudes about testing for Down syndrome, but little information about other chromosome conditions. This study explores how women decide whether to have a hypothetical diagnostic prenatal blood test for four chromosome conditions, ranging from moderately severe to extremely mild, when given a short description of the outcome. **Methods:**Pregnant women, less than 20 weeks, recruited through ultrasound clinics, were sent a questionnaire based on the Theory of Planned Behaviour, encompassing measures of attitude (eg. believing that having the information is a good thing), subjective norm (eg. a partner influencing their decision) and perceived behavioural control (eg. wanting to test but it being too expensive). Each questionnaire included a description of one of the four conditions and each woman responded to only that condition. **Results:**Analysis of 230 questionnaires (62, 60, 51 and 57 respectively for each of the four conditions) showed that 73% of participants had a positive intention to test. There were no significant differences in demographics between the four groups, with 73% having a university education, 38% being in their first pregnancy, 90% having had prenatal screening for Down syndrome, and 11% utilising IVF or ICSI. Women's attitudes, subjective norms, and perceived behavioural control contributed 70% (R=0.84) of the variation in their intention to have a test. Attitude and subjective norm were both significant contributors to intention, with attitude being the best predictor () = 0.6). Significant differences between the four conditions were evident for attitudes, but not for subjective norms or perceived behavioural control. Women intending to test had significantly different attitudes from those not intending to test. **Conclusion:**This is the first quantitative study to explore women's attitudes to prenatal testing for less severe and milder chromosome conditions. A small, but important group of women differentiated between, but most wanted testing for all four conditions. This finding should be taken into account when developing policy and planning services related to NIPD.

1412W

Fractional DNA quantification by massively parallel shotgun sequencing — implications for fetal fraction measurement in maternal plasma. *J. Tynan[1], G. Hogg[1], M. Tang[1], L. Cagasan[1], J. Clemens[1], D. van den Boom[2], P. Oeth[1].* 1) Sequenom Center for Molecular Medicine, San Diego, CA; 2) Sequenom, Inc., San Diego, CA.

BACKGROUND: Presence of circulating cell free (ccf) fetal DNA in maternal plasma can be confirmed by detection of paternally inherited alleles in maternal plasma DNA, or alternatively, by detection of fetal specific methylation patterns in maternal plasma DNA. The fractional concentration of ccf fetal DNA in maternal plasma has been measured by paternal Y-chromosomal allele detection using digital PCR, and fetal specific methylation patterns of ccf fetal DNA in maternal plasma can be used to quantify the fetal fraction. Here, we demonstrate the ability to detect and quantify low fractional concentration single nucleotide polymorphism (SNP) alleles in mixed DNA samples using multiplexed PCR enrichment of SNP loci with simultaneous incorporation of sequences required for subsequent massively parallel shotgun sequencing (MPSS) in the absence of library generation. METHOD: We tested a high-level multiplexed SNP panel to amplify genomic loci of high minor allele frequency using a model system of genomic DNAs. Each of the forward and reverse PCR primers was within 36 base pairs of the SNP site and contained additional sequences to allow capture of the PCR product directly onto the flow cell surface for sequencing on the Illumina GAIIx or HiSeq2000. After cluster generation by bridge PCR, sequencing primers corresponding to the forward PCR primer sites were hybridized to the clusters for sequencing. The resulting clusters were sequenced for 36 cycles. The observed reads were compared to the expected 36 base reads based upon the amplicon PCR design, and the number of observed reads exactly matching the expected reads was determined. The number of matched reads for each of the expected SNP alleles was used to calculate the allele frequency of each SNP allele. RESULTS: In these initial experiments, each of the amplicon products was detected by sequencing. Based on observed allele counts, allele ratios matched genotypes of the DNAs used. Results of DNA mixtures at 2%, 6% and 20% fractions showed the ability to distinguish low fractional concentration alleles even in the 2% DNA mixture. CONCLUSION: This method demonstrates a proof-of-concept to apply MPSS of enriched targeted alleles to noninvasive prenatal diagnostics. Increased numbers of targets in such an assay are predicted to provide universal population coverage, and inclusion of molecular index sequences into the amplicon will allow multiplexing of samples into a single flow cell lane.

Discovery of the serum biomarker proteins in severe preeclampsia by Proteomic Analysis. *D.H. Cha[1], J.s. Park[2], S.J. Lee[2], Y.N. Kim[3], K.P. Kim[2].* 1) Dept OB/GYN, Kangnam CHA Hosp, Seoul, Korea; 2) Department of Molecular Biotechnology and Institute of Biomedical Science and Technology, Konkuk University, Seoul 143-701, Korea; 3) Department of Obstetrics and Gynecology, Inje University, Pusan Paik Hospital, Korea.

Preeclapsia (PE) is a severe disorder that occurs during pregnancy, leading to maternal and fetal morbidity and mortality. PE affects about 3~8% of all pregnancies. In this study, we conducted LC-MS/MS to analyze serum samples depleted of the six most abundant proteins from normal and PE-affected pregnancies to profile serum proteins. A total of 237 proteins were confidently identified with <1% FDR from the two groups of duplicate analysis. The expression levels of those identified proteins were compared semi-quantitatively by spectral counting. To further validate the candidate proteins with a quantitative mass spectrometric method, selective reaction monitoring (SRM) and enzyme linked immune assay (ELISA) of serum samples collected from pregnant women with severe PE (n=8) or normal pregnant women (n=5) was conducted. Alpha2-HS-glycoprotein (AHSG), Retinol binding protein4 (RBP4) and alpha-1-microglobulin/bikunin (AMBP) and Insulin like growth factor binding protein, acid labile subunit (IGFBP-ALS) were confirmed to be differentially expressed in PE using SRM ($p<0.05$). Among these proteins, AHSG was verified by ELISA and showed a statistically significant increase in PE samples when compared to controls.

Analysis of the relative contribution of genetic, developmental and environmental causes to the origin of birth defects. *R. Elespuru.* FDA/CDRH Div Biol, FDA Federal Labs at White Oak, Silver Spring, MD 20993.

Heritable damage to the genome is a concern along with cancer risk when considering the safety profile of radiation or chemotherapy, medical devices, drugs, and other products subject to regulatory risk/benefit analysis. Birth defects are a major adverse event monitored world-wide and could, potentially, be useful for assessing the extent of heritable effects. However, because information about the causes of birth defects is limited, these events generally have not been useful as genetic endpoints of environmental effects in humans. New genetic analyses and recent epidemiological studies are expected to provide a better understanding of these causes. In order to aid in prevention and risk assessment, the eleven most common birth defects (for the US listed on the Center for Disease Control web site; similar to the March of Dimes global listing) have been analyzed for likely causation. The categories include: developmental, mendelian genetic, multi-genic, and gene-environment - based alterations. Genetic causes are differentiated according to likely inherited or de novo alteration. All but the inherited genetic origins could be affected by external environmental exposures or by the combination of genetics and environment. Birth defects occur generally at an incidence of ~3-4% world-wide. The common anomalies analyzed represent ~one third of the total (i.e. ~1% of births). Those birth defects that are caused at relatively high frequency by inherited recessive alleles (cystic fibrosis, metabolic disorders), viruses (some eye defects), or developmental (gestational) effects (fetal alcohol syndrome, neural tube defects) are not likely to be informative as endpoints for heritable genetic alterations. Some birth defects appear to be caused by female based (Down Syndrome and other triploidies) or male based (Achondroplasia) deficiencies affected by germ cell age; these should be considered as target endpoints only when mechanistically appropriate. There is considerable evidence that some birth defects (e.g. cleft palate) have multiple contributing causes - developmental, mendelian genetic, multi-genic, and gene-environment. The causes of other major classes of birth defects (e.g. cardiovascular defects) remain largely unknown. However, emerging information may be added to a framework of categories representing different types of causes, some of which are informative and relevant to a given risk assessment perspective, and some of which are not.

Prenatal Onset of Neonatal Hemochromatosis and Infantile Cortical Hyperostosis: A Possible Mechanism for Disease Association. *N. Martin[1], G. Taylor[2], P. Whitington[3], H. Melin-Aldana[4], RS. Lachman[5], WR. Wilcox[5], A. Toi[6], R. Windrim[7], D. Chitayat[1,8], K. Chong[1]*. 1) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 2) Division of Pathology and Laboratory Medicine, Hospital for Sick Children, Toronto, ON, Canada; 3) Children's Memorial Research Center, Feinberg School of Medicine, Northwestern University, Chicago IL; 4) Dept of Pathology and Laboratory Medicine, Feinberg School of Medicine, Northwestern University, Chicago IL; 5) Medical Genetics Institute, Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, Los Angeles, California; 6) Dept of Medical Imaging, Mount Sinai Hospital and University Health Network, University of Toronto, Toronto, ON, Canada; 7) Dept of Obstetrics and Gynecology, Mount Sinia Hospital, Toronto, ON, Canada; 8) Division of Clincal and Metabolic Genetics, Dept of Pediatrics, Hospital for Sick Children, Toronto, ON, Canada.

Neonatal hemochromatosis (NH) is characterized by hepatic failure in the newborn period with marked siderosis of extrahepatic tissues, including the heart, pancreas and mucosal glands of the respiratory system. Recent evidence suggests a congenital alloimmune disease between the maternal and fetal immune systems as a novel mechanism for NH. Infantile cortical hyperostosis (ICH) or Caffey disease consists of benign cortical thickening of affected bones and swelling of the contiguous soft tissues usually presenting in young infants. Prenatal onset is presumed to be autosomal recessive and associated with a high mortality rate. We present a fetus with ultrasound findings in the third trimester of marked polyhydramnios, deformed long bones with a small chest, possible brain abnormalities, and facial dysmorphisms. At birth, the baby had hypoglycemia, coagulopathy, and multisystem organ failure, which resulted in his death on day 18. Autopsy showed NH with liver damage. Immunostaining of the liver confirmed that the NH was alloimmune in origin. Skeletal findings were consistent with ICH. The pathogenesis of prenatal ICH is unclear, however, it has been hypothesized that myeloid hyperplasia in the fetal liver may be a cause for the lethality in these cases. Given the clinical and pathological findings of NH in this case, we suggest that prenatal ICH may be alloimmune in origin and that the inheritance pattern of this lethal condition may in some cases, not be the result of autosomal recessive inheritance.

Brest, Hôpital Morvan, Service de Gynécologie-Obstétrique, Brest, F-29200, France; 6) C.H.R.U. Rennes, Laboratoire de Génétique Moléculaire, Rennes, F-35000, France; 7) C.H.R.U. Nantes, Laboratoire de Génétique Moléculaire, Nantes, F-44000, France; 8) C.H.R.U. Poitiers, Laboratoire de Génétique Moléculaire, Poitiers, F-86000, France; 9) A.P.H.P. Hôpital R. Debré, Laboratoire de Biochimie-Hormonologie, Paris, F-75019, France.

Objectives: Ultrasonographic examinations allow the detection of signs that may indicate abnormalities in the foetus. Among them, non-visualization of foetal gallbladder (NVFGB) or foetal echogenic bowel (FEB), may be possible clues for cystic fibrosis (CF). Cystic fibrosis is an autosomal recessive disease caused by mutations in the CFTR gene which lead, in its classic form, to severe chronic pulmonary infections and pancreatic insufficiency. The aim of our study was to evaluate the incidence of CF in cases referred for genetic diagnosis when the foetal gallbladder was not seen at ultrasonographic examination and correlate CF diagnosis with presence of echogenic bowel. Methods: We reviewed all consecutive cases of NVFGB diagnosed in Western France and referred for analysis of the gene responsible for CF over the 2002-2009 period. Results: Over the 8-year period, 37 foetuses with NVFGB had CFTR gene analysis. CF was diagnosed in five cases, leading to a CF incidence of 13.5%. All the CF foetuses had NVFGB associated with foetal echogenic bowel (FEB), and the risk of CF was still increased in foetuses with both these signs (5/11, 45.5%). The risk of CF was also 11.6-fold higher in foetuses with both these signs than in foetuses with FEB alone (45.5% vs. 3.9%; RR=11.6, 95% CI: [4.7; 28.8], p=0.0001]. Using Bayesian calculations, we estimated that the residual risk of CF was less than 1 in 68 (1.5%) when one mutation was identified by our molecular protocol. Nine of the non-CF foetuses had another disease evidenced (i.e. 28.1%) Conclusion: This study highlights the need to properly investigate the foetal gallbladder, especially when associated with FEB. Although it is not possible to accurately gauge the importance of NVFGB, it should be considered as an additional pointer to the need to conduct a CFTR gene analysis, especially when FEB is detected simultaneously.

1417W

Screening for the gr/gr Y chromosome Microdeletion in infertile Tunisian men. *A. HTIRA, M. GRIBAA, O. Mamay, I. Ben Charfeddine, A. AMARA, D. Hmida, M. AJINA, H. BEN ALI, S. TRABELSI, A. SAAD.* Laboratory of human cytogenetics, molecular genetics and reproductive biology in Farhat Hached University hospital, Street Ibn El Jazzar, 4000, Sousse, Tunisia.

As a common variation in the azoospermia factor c (AZFc) region of Y chromosome, the gr/gr deletion is regarded as a significant risk factor for spermatogenic impairment. But, no definitive conclusion has been established for its exact role. This deletion is caused by intra-chromosomal homologous recombination and removes half of the AZFc region genes. In our study we investigate the role of gr/gr subdeletion in spermatogenic failure. For this, a total of 82 idiopathic infertile Tunisian men referred to our laboratory for genetic investigations. They are affected by azoospermia or severe oligozoospermia which normal or elevated FSH level. All these patients have normal karyotype (46,XY) and show no subchromosomal microdeletions on Yq11 (AZFa, AZFb, AZFc). Analysis of gr/gr region on AZFc locus with specific STSs (sY1291, sY1161, sY1191 and sY1201) was performed on genomic DNA by multiplex PCR. Thirty two healthy fertile men with normal sperm were selected for control data. We identified four patients with gr/gr deletion (4.87%) and three in the group of control men (8.23%). No significant difference was found (P= 0,7). Our results showed that gr/gr deletion is a simple polymorphism and cannot be responsible of the spermatogenic failure in our patients. Otherwise, other studies found that this deletion can be responsible for a male infertility. By the way, the relationship between gr/gr deletion and male infertility can be related to the ethnicity and geographic region of the patients.

1418W

Role of genetic factors and oxidative stress in of idiopathic male infertility. *V. Sundararajan, T. Jayapalraja, R. Kumar, R. Dada.* All India Institute of Medical Sciences, New Delhi, New Delhi, India.

Introduction: Infertility is the major concern among the married couples and in atleast 50% of them; the male partner is the sole contributor to the problem. Majority of these men are diagnosed with no aetiology and hence they are idiopathic cases. Aim: The current study was planned to evaluate the role of genetic and molecular factors in 200 men with idiopathic infertility. Methods: The work involved cytogenetic and Y chromosome micro-deletion analysis. Patients with cytogenetic and Yq micro-deletion anomalies were excluded for further studies and screened for sperm mtDNA ATPase and NADH gene mutations. Seminal oxidative stress was estimated by chemiluminescence assay. Results: Out of 200 infertile men screened, 13% harbored cytogenetic abnormalities. This frequency is higher when compared to the previous report from Indian population. Azoospermia factor (AZF) microdeletions were detected in 9.5% infertile men, where AZFc deletion was predominant (6%) followed by AZFb (2%) and AZFa (1.5%) deletions. This is in accordance to the range reported in the world wide population. Level of ROS in both washed and neat semen was found to be significantly ($P<0.0001$) higher in infertile men compared to controls. However, no correlation between ROS level and the sperm parameters was observed. The ROS levels in raw semen showed a strong positive correlation ($r=0.842$, $p<0.0001$) with ROS levels in washed semen. Significantly higher frequency of nucleotide changes in mitochondrial ATPase6, ND4 and ND5 gene was observed in infertile OA men, who had significantly ($P<0.001$) higher ROS levels, compared controls. Majority of the mitochondrial nucleotide changes observed were found to be pathogenic by polyphen computational analysis. Conclusion: In conclusion, screening for cytogenetic and Yq anomalies are highly recommended in patients opting for ARTs as there is increased incidence of these anomalies in Indian population. Increased mitochondrial DNA mutations in infertile men may have better diagnostic and prognostic value in ART, as there is no paternal transmission of paternal mtDNA. It is also important to distinguish the genetic cause of male infertility, whether it is nuclear or mitochondrial, to counsel such couples prior to undergoing assisted reproduction.

1419W

High level of expression and rapid purification of recombinant human FSH in CHO cells. *S. Teimourain[1], M.H Modarresi[1], M.H Hedayati[2].* 1) Tehran University of medical sciences, Tehran, Tehran, Iran; 2) Pasteur Institute of Iran Research and Production complex 25 km west of Tehran Tehran-Karaj Autobahn Tehran,Iran Postal code:31599.

FSH is a glycoprotein which is clinically used for treatment of anovulation and in assisted reproduction technologies such as invitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI). In this study,the genes encoding apha and beta-subunits of human FSH were sequense optimized by site directed mutagenesis and cloned in Pvitro-2- neo vector. After amplification of plasmid in Ecoli top 10 starin, plasmid was purified and then transfected into Chinese hamster ovary (CHO-K1) cells. In selective mediunm containing 800μg/ml G418, a CHO clone was isolated capable of secreting intact glycosylated FSH in the amount of 20pg/cell/48 hours. Roller bottel monolayer cells were incubated in DMEM medium containing 10μg/ml insulin. After three days, the supernatant harvested and purified by dye affinity chromatography(orange 1).The overal recovery was 55% as tested by Elisa and the purity was 90% as tested by SDS-PAGE .

Study of GTn-repeat expansion in Heme oxygenase-1 gene promoter as genetic cause of male infertility. *A. Aleyasin[1], E. Siasi[2], J. Mowla[3].* 1) Medicin genetic, National institute of genetic and biotechnology, Tehran, Iran; 2) Molecular and madicin genetic, Tarbiat modares university, Tehran, Iran; 3) Molecular genetic, Tarbiat modares university, Tehran, Iran.

Abstract Objective- The length of GT-repeats polymorphic region in the promoter of human Heme oxygenase-1 gene (HO-1) alters the level of its transcriptional activity in response to oxidative stresses. Decreased level of HO-1 protein in the seminal plasma has been reported to be associated with oligospermia and azoospermia in male infertility. This is the first study to investigate the association between GT-repeats expansion in promoter of HO-1 and male infertility. Methods- The allelic frequencies for different GT-repeats in the promoter of HO-1 gene were determined in 100 case and 100 normal control groups using PCR-PAGE, ABI fragment analysis genotyping and sequencing analysis. Results- All alleles were classified into S and L alleles. S alleles with < 27 specified as allele number 0 to 3 and L alleles > 27 repeats were specified as 4 to 6 alleles. The L allele frequency was significantly higher (54.5%) among case group than that in the normal controls (37.5%). Statistical analysis provide significant relationship between L alleles and male infertility ($P<0.001$). Conclusions- This study shows for the first time that GT-repeats expansion in promoter of the HO-1 gene is associated with oligospermia and azoospermia in male infertility among Iranian infertile cases.

Maternal smoking, gene variants of xenobiotic-metabolizing enzymes, and risk for anorectal atresia and stenosis. *M.M. Jenkins[1], J. Reefhuis[1], M.L. Gallagher[1], S.A. Rasmussen[1], D.A. Koontz[1], C. Sturchio[2], E.J. Lammer[3], M.A. Honein[1], National Birth Defects Prevention Study*. 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Battelle, Columbus, OH; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Maternal smoking during pregnancy has been suggested as a risk factor for anorectal atresia and stenosis in infants, but modest effect estimates might reflect an interaction between genetic risk factors and smoking. We analyzed 5 polymorphisms in 3 genes that code for enzymes involved in metabolism of chemicals in cigarette smoke (*CYP1A1*, *CYP1A2*, and *NAT2*) in mothers and their infants to assess their modifying effect on anorectal atresia and stenosis risk and the potential interaction with maternal smoking. Exposure assessment was based on maternal interviews, and DNA was extracted from cytobrush-derived buccal cells collected from infants and their parents as part of a multi-site, population-based, case-control study of major birth defects. Case families had infants with anorectal atresia or stenosis, and control families had live born infants with no major structural birth defects. Infants had estimated due dates between Oct 1, 1997 and Dec 31, 2003. Nineteen and one-half percent of mothers who completed the interview reported smoking in the month before pregnancy or during the first trimester. Whole genome amplification (WGA) was completed on samples with sufficient DNA (⁄ 5µg) using Sigma's GenomePlex® kit. Genotyping was completed on either genomic DNA or WGA products using Pyrosequencing® technology. Genotyping call rates were 99.4 to 99.6%. Data from 173 case families and 1706 control families with successful genotype results for ⁄ 4 variants from the infant, mother, or both, were included in these analyses. Independent effects of *CYP1A1*2A*, *CYP1A2*1C*, and *CYP1A2*1F* rapid oxidizer variants on anorectal atresia and stenosis risk were not observed in non-Hispanic White, non-Hispanic Black, or Hispanic mothers and their infants. Independent effects of *NAT2*5* and *NAT2*6* slow acetylator variants on anorectal atresia and stenosis risk were observed in Hispanic infants (odds ratio (OR)=2.7, 95% confidence interval (CI) 1.0-7.4 and OR=6.2, 95% CI 1.4-26.4, respectively); no significant effects were observed for non-Hispanic White (OR=0.7, 95% CI 0.4-1.3 and OR=1.4, 95% CI 0.7-2.9) and non-Hispanic Black (OR=1.4, 95% CI 0.2-12.3 and OR=3.6, 95% CI 0.6-20.5) infants; no significant effects were observed in their mothers. Further analyses stratified by periconceptional smoking status and adjusted for confounders will assess the interaction of maternal smoking and these xenobiotic-metabolizing enzyme gene variants on anorectal atresia and stenosis risk.

1422W

G5508A polymorphism of the *Sept12* gene may be associated with idiopathic male infertility. *M. Shahhoseini[1], M. Azad[1], M. Sabbaghian[2], K. Anisi Hemaseh[1], A. Amiri Yekta[1], M.H. Sanati[3], M.A. Sadighi Gilani[2], H. Gourabi[1]*. 1) Department of Genetics, Royan Institute for Reproductive Medicine, ACECR, Tehran, Iran; 2) Department of Andrology, Royan Institute for Reproductive Medicine, ACECR, Tehran, Iran; 3) National Institute for Genetic Engineering and Biotechnology, Tehran, Iran.

Introduction: Male infertility is a multifactorial disorder, which affects approximately 10% of couples at childbearing age with substantial clinical and social impact. Genetic factors are associated with the susceptibility to spermatogenic impairment in humans. Recently, *Sept12* is reported as a critical gene for spermatogenesis. This gene encodes a testis specific member of Septin proteins which belong to a family of polymerizing GTP-binding proteins. Septin 12 in association with other septins is an essential annulus component in mature sperm. **Material & Methods:** Seventy infertile men and thirty six normal controls referred to the Royan Institute were analyzed for 5 reported SNPs in the active site coding region of Sept12. Genomic DNA was extracted from periphery blood samples using standard techniques, and a 341bp DNA sequence was amplified by PCR and analyzed by sequencing. **Results:** Genotype analyses indicated that G5508A polymorphic *Sept12* alleles were distributed in three peaks of frequency in both control and diseases groups .Categorization of the alleles into (GG), (GA), (AA) types revealed a significant difference between azoo, asthenospermia and controls (*P* values less than 0.05 by chi-squre test). **Conclusion:** According to our finding we suggest that G5508A polymorphism in *Sept12* gene can affect on spermatogenesis in men, the opinion needs more investigation in different populations.

1423W

Association study of C109869T SNP in SLC6A14 gene with azoospermia and olidospermia in idiopathic infertile men. *E. Siasi[1], A. Aleyasin[2], J. Mowla[3]*. 1) Molecular and medicin genetic, Tarbiat modares university, Trhran, Iran; 2) medicin genetic, national institute of genetic and biotechnology, Trhran, Iran; 3) Molecular genetic, Tarbiat modares university, Trhran, Iran.

Back ground- C109869T polymorphism in SLC6A14 gene has been suggested to be associated with male infertility using Genome Wide SNP Association Study (GWAS). This SNP is an intergenic SNP located on the X chromosome 200 Kb from solute carrier family 6, member 14 (that is member of sodium and chloride dependent neurotransmitter transporters family). This SNP is functional variant responsible for the oligospermia phenotype by a regulatory capacity. Objective- This is the first study to evaluated association between C109869T SNP and idiopathic male infertilility in Iranian population. Methods- This relationship has been studied in 96 idiopathic infertile men with azoospermia and oligospermia and 100 normal control men. Primer pairs were designed to amplify 183bp fragment containing this polymorphism. Analysis of SNP was performed by PCR-RFLP and High Resolution Melt (real time PCR-HRM Corbett analysis). Amplified fragment was sequenced to determine the PCR product and allelic identify. Results- Genotype frequencies of the CC, CT and TT were as 85.5%, 5.2% and 9.3%, in the case group and 90%, 4% and 6% in the control group respectively. The prevalence of tested SNP was approximately similar in both infertile patients and fertile control groups. Statistical analysis showed significant relationship between C109869T SNP and idiopathic male infertility. Conclusion- This result indicated the (C109869T) SNP play role in infertile Iranian with oligospermia and azoospermia similar to that observed is Europian population.

Gene Expression Profiling of Uterine Prolapses. *H. Ak Celik[1], H.H. Aydin[1], B. Zeybek[2], N. Askar[2]*. 1) Dept. of Medical Biochemistry, School of Medicine, Ege University Bornova, Izmir, Turkey; 2) Dept. of Obstetrics & Gynecology, School of Medicine, Ege University Bornova, Izmir, Turkey.

Prolapses of the pelvic organs are a common disease affecting the live qualities of women. Age, menaupose, pregnancy, vaginal delivery, obesity, chronic constipancy, pelvic bone structure and hysterectomy are important risk factors. Additionally, population studies are shown that genetic factors play important role in prolapses of pelvis organs. Despite the high prevalence of the disease, very little is known its pathophysiology. In this study, discovery of new candidate genes which have role on developing of the disease in uterosacral ligaments of patients with uterus prolapses is aimed. For this purpose, whole genome gene expression profiling were carried out by using Affymetrix U133 2.0 plus GeneChip® in 10 controls and 15 uterine prolapses samples of uterosacral ligament. Statistical analyses were conducted by using Partek Genomic Suite (Partek Inc., MO, USA) and Ingenuity Pathway Analysis 8.7 (Ingenuity Systems Inc. CA, USA). Differences were considered statistically significant at P-value <0.05 and 2 fold change in gene expression between patient population and control subjects. There was a relationship between the uterine prolapses and increased expression of genes which are associated with biological adhesion, immune system and stimuli response processes. Among the genes; expressions of CREB5, FNDC1, HMCN1, VCAN, COMP, CTHRC1, DUSP10, THY1, CD44, ADAMTS16, SERPINE1, MLLT10, PAMR1, SYNC, GOLIM4 and PI16 were most significantly increased in uterine prolapses compared to the controls. However, ERAP2, HLA-DQA1, LOC572558 gene expressions were found decreased in the patients. Obtaining results provides to develop new strategies for new diagnostic and prognostic markers and understanding pathophysiology of uterine prolapses.

1425W

Exploration the tissue specific promoter of aromatase gene (*CYP19*) to SNP analysis in infertile men. *P. Afsharian, M. Khosravi, K. Fallah-Zadeh, M. Shahhoseini.* Department of Genetics, Royan Ins. for Reproductive Medicine, Tehran, Iran.

Aromatase is the key enzyme in biosynthesis of estrogens from androgens. It is encoded by the *CYP19* gene which is located in the chromosome 15q21.2 in human genome. Aromatase is expressed under different tissue specific promoters (TSPs) as an un-translated exon in mammals. In most mammals, *CYP19* expression is under the control of gonad- and brain-specific promoters, PII and PI.f respectively. In the human, however, there are at least eight additional promoters (totally 10 TSPs with the 93 kb in length) that seemed to have been recruited throughout the evolution possibly via alterations in DNA. One of the key mechanisms that permit the recruitment of such a large number of promoters seems to be the extremely promiscuous nature of the common splice acceptor site, since activation of each promoter gives rise splicing of an un-translated first exon onto this common junction immediately upstream of the translation start site in the coding region. These partially tissue-specific promoters are used in the gonads, bone, brain, vascular tissue, adipose tissue, skin, fetal liver and placenta for physiologic estrogen biosynthesis. PII is introduced as the specific promoter in human ovary tissue, although, it hasn't been directly launched as the main promoter in human testis, while there are some information about the aromatase promoter in rat testis (PII, PI.f & PI.tr). Since aromatase plays an important role in human reproductive endocrine system, genetic alterations of *CYP19* would be the critical parameter in fertility/sterility. Based on the recent studies that aromatase expression is declined through spermatogenesis failure; we study the promoter SNPs in infertile men referred to our institute. As the first step, we tried to screen the regulatory region of *CYP19* in order to find the testis-specific promoter in human testicular cell line (NT2). To achieve this purpose, the presence of RNApol-II in different candidate promoters (located in un-translated exon) was checked by the use of Chromatin Immunoprecipitation (ChIP) technique. Our results showed that among all known *CYP19* promoters, PII is the main promoter to study the aromatase SNPs in our patients.

1426W

Spontaneous pregnancies in patients with Turner syndrome **G. Bergvall MD, E. Stattin MD PhD Clinical Genetics, Umeå, Sweden.** *G. Bergvall, E. Stattin.* Laboratorymedicine, Clinical genetics, Umeå, UMEÅ, Sweden.

Introduction: Patients with Turner syndrome are in the majority of cases infertile and do not menstruate. Their ovaries degenerate and by birth or early childhood there is complete follicle depletion in the majority of cases, although in 5-20% of cases sufficient follicles survive to allow spontaneous menarche, followed by premature menopause. Spontaneous pregnancies in patients with Turner syndrome is uncommon, and completed pregnancies is rare. It has been suggested that it could be explained by a gonadal mosaicism, with presence of a normal celline. Here we want to report two cases with Turner syndrome who have completed four normal pregnancies without assisted reproduction. Methods We have in our laboratory and outpatient clinic investigated two women with Turner syndrome who have completed spontaneous pregnancies. Case 1 have completed one spontaneous pregnancy, while case 2 have completed three dito. All four children are healthy. We have performed a conventional cytogenetic analysis by G-banding on peripheral blood lymphocytes. We have done FISH-analysis on 200 cultured lymphocytes, as well as FISH-analysis on 500 imprinted oral buccal cells, obtained with brushpin. Results

	Karyotype	FISH/lymphocytes	FISH/ buccal cells	Age at childbirth
Case 1	45,X[24]	X/XX 198/2	X/XX/XXX 434/20/36	33
Case 2	45,X[24]/ 47,XXX[1]	X/XX/XXX 183/8/9	waiting for results	27, 29, 31

Conclusion: This casereport want to focus on the rare, yet possible situation where a women with Turner syndrome have regular menstruations and become spontaneously pregnant. Our investigations show normal sex chromosomes in 2%-4% of lymphocytes and 4%- ? of oral buccal cells. There is signs of low-grade mosaicims for normal cellines in these cases. Whether this is the situation in the gonads we can only speculate on.

PGD via array comparative genomic hybridization (aCGH) can be used for any translocation to simultaneously detect unbalanced embryos and aneuploidy. *P. Colls, T. Escudero, J. Fischer, G. Harton, S. Munné.* Reprogenetics, Livingston, NJ.

Objectives: 1) Determine the resolution of aCGH in detecting translocations; 2) Determine how many cases previously analyzed by FISH could be analyzed by aCGH; and 3) Validate aCGH for use in translocations in combination with aneuploidy testing. **Design:** Prospective validation of the technique and retrospective comparison with FISH. **Material and Methods:** Consenting translocation carriers underwent PGD via embryo biopsy with aCGH using 24sure-Plus microarrays. Embryos determined by aCGH to be abnormal were fixed and all cells analyzed by FISH with up to 15 probes to determine the error rate and resolution. Once the lower detection limit of aCGH was determined, we consulted our database of all previous PGD cases to determine how many would be analyzable by aCGH. **Results:** Nineteen (19) procedures of PGD for reciprocal translocations and 15 for Robertsonian translocations were performed with aCGH. ArrayCGH has the ability to detect fragments 4 Mb or greater, similar to the limit of conventional G-banded karyotyping. A total of 1317 procedures of PGD for reciprocal (n=931) or Robertsonian translocations (n=351), and inversions (n=35) previously analyzed by FISH were reviewed to determine if they could be diagnosed using aCGH based on the above resolution. 196 reciprocal translocations had one fragment smaller than 4 Mb, but none had two fragments smaller than 4 Mb. By detecting 3 fragments larger than 4 Mb, these cases are analyzable by aCGH. Similarly all Robertsonian translocations can be analyzed since whole q arms of acrocentric chromosomes are translocated. All inversions had a sufficient number of fragments large enough to be analyzed by aCGH. Twenty three embryos determined by aCGH to be unbalanced were reanalyzed by FISH and all (100 %) were found to be consistent with the aCGH diagnosis. To date, from 54 PGD procedures studied with aCGH, 22.7 % of embryos were normal or balanced, 19.9 % were unbalanced, 31.9 % were unbalanced and aneuploid, and 23.1 % were only aneuploid. **Conclusions:** Present results indicate that aCGH can simultaneously analyze any translocation detectable by regular karyotyping and any aneuploidy, even in cases in which one of the four chromosome fragments is below aCGH resolution. Using this method, the present error rate is 0 % for translocations, and 2 % for aneuploidy (see Gutierrez-Mateo et al. 2011). aCGH can detect 23 % more abnormalities than FISH performed only with probes for the translocation.

1428W

Familial X-Autosome translocation associated with Infertility. *L. Martelli[1,2], M.L.C. Moreira[2], R.M. Scarparo[2], C.G. Picanço[2], C.S. Pereira[1], C.H.P. Grangeiro[2], W.A.R. Baratela[2], J.M. Pina Neto[1,2], S.A. Santos[1], J. Huber[2], E.S. Ramos[1,2].* 1) Dept. Genetics, University of Sao Paulo, School of Medicine- Ribeirao Preto, SP, Brazil; 2) Medical Genetics Division, University Hospital, Ribeirao Preto, SP, Brazil.

Numerical and structural chromosomal aberrations are strongly correlated to infertility. Translocations involving the X chromosome and autosomes are rare rearrangements with an estimated occurrence of 1 to 3 per 10,000 live births. These translocations, although extremely rare, may affect reproductive capacity depending upon the location of breakpoints of the X chromosome. We report a 27 years old man, referred to the Medical Genetics Division (HCFMRP-USP) for male infertility. Familial history revealed one brother and two uncles on the maternal side with infertility. The patient is the second child of healthy, unrelated parents, with no history of miscarriages. He was born at term by Cesarean section after an uneventful pregnancy. He showed adequate psychomotor development and physical examination was normal with no dysmorphic features. After marriage and 3 years trying to have children without success, the couple was evaluated by the Human Reproduction Department, with final diagnosis of male factor infertility. Espermogram demonstrated azoospermy. Testicular biopsy showed that general architecture of testicles was preserved, with edematous stroma, and regular number of Leydig cells with mild thickening of seminiferous tubules. Conventional cytogenetic analysis by GTG high resolution banding revealed an apparently balanced translocation between X and 22 chromosomes with karyotype 46,Y,t(X;22)(p22.3;q11.2). Maternal karyotype showed the same translocation between Xp;22q. She presented a normal phenotype and three pregnancies: her first son (also diagnosed as azoospermic) and her daughter (22yo) also showed the same translocation. Infertility in X-autosome translocation carriers is more likely to arise because of meiotic disturbances leading to spermatogenic failure. Meiotic arrest is considered to result from a disturbance of the X chromosome condensation and inactivation process during male meiosis. This finding also has implications in female meiosis with increased risk of infertility. Therefore X inactivation studies were performed to predict premature ovarian failure in apparently unaffected sister who carries the same translocation.

1429W

Molecular genetics and cytogenetics investigation in a man with infertility and azoospermia. *H. Shabanloo[1], N. Khazamipour[2], E. Bagherizadeh[1], F. Behjati[1,3], M. Noruzinia[4].* 1) Genetic Department, Sarem Women Hospital, Tehran, Iran; 2) Sarem Cell Research Center, Sarem Women Hospital, Tehran, Iran; 3) Genetics Research Center, University of Social Welfare and Rehabilitation Science, Tehran,Iran; 4) Department of Medical Genetics, Tarbiatmodares university, Tehran, Iran.

Yq- microdeletions are the common cause of infertility. Three different loci (AZFa, AZFb, AZFc) involve the genes responsible for spermatogenesis mapped to these regions referred to as `azoospermia factors'. So molecular genetic analysis of Y-microdeletions is important in diagnostic procedure for nonobstructive infertile men. A 26 year old male with infertility was referred for genetic counseling. Paraclinical examination showed hypogonadotropic-hypogonadism. TESE confirms showed maturation arrest, leidig cell atrophy, tubular hyalinization and absence of spermatozoa. Chromosomal study was carried out using standard GTG banding technique. Molecular analysis performed by two multiplex PCR with the primer sets for ZFX/ZFY and SRY genes as internal control and primers for STSs in each AZF regions. (sY84 and sY86 in AZFa, sY127, sY134 in AZFb and sY254 and sY255 in AZFc regions). PCR products were electrophoresed on 1.8% agarose gel. Cytogenetic analysis showed that the patient was mosaic with a deletion of chromosome Yq described as45,X[8]/46,X,del(Y)(q11.23)[92]. Microdeletion analysis revealed no amplification in AZFb and AZFc STSs. But AZFa STSs as well as ZFX/ZFY and SRY regions are amplified. Deletion of any of `azoospermia factors' associated with spermatogenic arrest at a particular stage of germ cell development showed a characteristic testicular phenotype. The molecular and cytogenetic analysis for this patient confirm a microdeletion expanding AZFb and AZFc regions which can be the cause of his infertility.

1430W

Incidence of fra (16) (q22) and its Probable Consequences in a Worker of a Place with Extreme Chemical Pollution. *H. Pour-Jafari[1,2], K. Hasrak[1], B. Pourjafari[2], S. Ghahramani[3], E. Kamrani Saleh[3].* 1) Mol Med & Genetics, School of Medicine, Hamadan Un Med Sci, Hamadan, Iran; 2) Research Center for Molecular Medicine, Hamadan University of Medical Sciences, Hamadan, Iran; 3) Genetic Lab., Sh. Beheshti Hospital, Hamadan, Iran.

The rare autosomal fragile site, fra (16) (q22), is the most common of all rare autosomal fragile sites and has a heterozygote frequency of about 5%. In some cases its familial types are reported. Also it is possible to experimentally induce fragile site on chromosome number 16 at q22 point treating with some chemicals in cell culture. Further studies on this fragile site indicate that fra(16)(q22) is a region with AT-rich and late replicating DNA. We report a family with two spontaneous abortions. Proband was a simple worker and clinically normal but fra(16)(q22) carrier. Also study of his sperm analysis has showed that majority of sperms were morphologically abnormal. We drew the pedigree, and studied his parent karyotypes. The karyotype of his father was normal but his mother was carrier for the mentioned fragile site. His wife had normal karyotype (46, XX) too. The important and notable point in their family history was that the proband has worked in a high risk work place with industrial chemical pollution in recent five years. The hazardous effects of such envivonmental work places are proved. Also the mutagenic and/or clustogenic effects of chemicals are shown in numerous research works. Sometime in genetic counseling at the first glance, it seems that the incidence of fragile site is direct result of environmental hazards. Although different evidence suggest that such polluted work place, without using special mask, as our case, could increase the risk of fetal deaths in progenies, but in our case the existence of fra (16) (q22) was from the mother side (familial) and probably the fetal deaths were its consequences . However genetic counselors have to consider the life style and work place situations of the families in their counseling procedures, paying attention to genetic factors, such as karyotyping, has its remarkable significance.

1431W

Identification of a hotspot for non-allelic homologous recombination (NAHR) centred on an Alusq sequence at the DPY19L2 locus. *C. Coutton[1, 2], F. Abada[1, 2], R. Harbuz[1, 2], D. Escalier[3], R. Zouari[4], R. Merdassi[5], M. Ben Khelifa[1, 2], F. Vialard[6], C. Triki[7], S. Hennebicq[8], P.S. Jouk[8], V. Satre[8], C. Arnoult[1], J. Lunardi[2], P.F. Globozoospermia is a rare syndrome of male infertility characterized by the presence of 100% round, acrosomeless spermatozoa in the patient's ejaculate. We demonstrated previously that a large majority of globobozoospermia patients had a 200 Kb deletion removing the totality of *DPY19L2,* a gene likely involved in spermatid polarization, and that the deletion probably occurred by Non Allelic Homologous Recombination (NAHR) between two homologous 28 Kb low Copy Number (LCR) located on each side of the gene. We have now analyzed 18 patients presenting with a homozygous *DPY19L2* deletion and 450 control subjects. One control subject was heterozygous for the deletion. Detailed analysis was carried out by DNA amplification and sequencing of the 37 deleted alleles identified. We demonstrate that the recombination always took place within a 1 Kb minimal region roughly located in the middle of the 28 Kb LCR. This region shows the highest sequence identity between the two LCRs (99% vs 97% for the rest of the sequence) and contains a canonical AluSq sequence located in the centre of the 1 Kb region. We observed three distinct breakpoints within this region indicating that the studied alleles (n=37) derived from at least three separate recombination events and not a single ancestral founding allele. These results thus show that the AluSq sequence might provide a favoured target site for homologous recombination within the LCRs. We also screened the 450 control subjects with inverted LCR PCR primers designed to amplify the recombined duplicated alleles. Three subjects carried a duplicated allele. Sequence analysis illustrated that the identified duplications corresponded to the reciprocal allele of two of the characterised deletions, thus confirming that these genetics events were indeed caused by homologous interchromatid or interchromosomal strand exchange. Overall this study shows that all recombination events identified at the *DPY19L2* locus occurred within a few hundred nucleotides of a canonical AluSq sequence indicating its likely involvement in the process, furthermore identification of perfect-match reciprocal deleted and duplicated alleles provide a textbook example of interchromatid or interchromosomal NAHR.

1432W

Screening for Copy Number Variations (CNVs) in Couples with Recurrent Pregnancy Loss (RPL). *J. Wen[1], M. Stephenson[3], W. Robinson[2], S. Martell[1], K. Calli[1], E. Rajcan-Separovic[1].* 1) Dept of Pathology, University of British Columbia, Vancouver, BC, Canada; 2) Dept of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 3) Dept of Obstetrics & Gynecology, the University of Chicago Medical Center, Chicago, IL, USA.

Background: Our recent whole genome array based studies of sporadic and recurrent miscarriages identified unique CNVs in ~50% of miscarriages with normal chromosome results. The majority of the CNVs were small (<250kb) in size and inherited from either partner. In addition, we identified CNVs in couples with RPL, which may predispose them to miscarriage. In order to determine if these candidate “miscarriage” CNVs are associated with RPL we screened 98 additional RPL couples and 90 fertile controls using Quantitative Multiplex PCR of Short fluorescent Fragment (QMPSF). Material and methods: 12 genes located within 12 “miscarriage” CNVs were selected for copy number assessment in RPL couples and in fertile controls. These genes included CTNNA3, TIMP2, RALA, PNPLA4, STX8, STX6, WDR37, NPAS3, CETN2, NSDHL, OFD1 and GPR180 . Results: Recurrence of copy number change was detected for 2/12 tested “miscarriage” genes so far. RALA (v-ral simian leukemia viral oncogene homolog A -ras related) gene copy number change was found in 13 subjects (9%) from 9 couples with RPL and in none of the controls. Interestingly, 4/9 couples had RALA gene copy number change detected in both partners. Duplications of RALA were more prevalent than deletions and occurred in 11/13 subjects. STX8 (Syntaxin 8) gene deletions occurred in 4 subjects (male and female) with RPL (3%) and in one control (1%). Conclusions: We identified two genes with higher frequency of copy number change in RPL subjects than controls. RALA is a multifunctional GTPase involved in a variety of cellular processes including cell migration, proliferation, and membrane trafficking. STX8 is a vesicle trafficking protein involved in cell cycle regulation. Transmission of copy number changes for these two genes from carriers to their miscarriages is under investigation to determine their role in recurrent pregnancy loss. In addition, frequency studies of all 12 “miscarriage” genes in 100 additional RPL couples and 100 additional idiopathic miscarriages using QMPSF is ongoing.

Genetic thrombophilic mutations among Iranian couples with recurrent spontaneous abortion. *A. Poursadegh Zonouzi[1], E. Sakhinia[2,3], A. Firozi[3], N. Karimi Ansari[3], N. Chaparzadeh[1], Y. Heshmat[3], M. Nouri[4], M. Sadaghian[4], L. Farzadi[4], A. Ghasemzadeh[4].* 1) Faculty of science Azarbaijan University of Tarbiat Moallem, Department of Cellular and Molecular Biology, Tabriz, Iran; 2) Faculty of Medicine Tabriz university of Medical Science, Department of Biochemistry Molecular Medicine Division, Tabriz, Iran; 3) Tabriz Medical Sciences University, Tabriz Genetic Analysis Centre (TGAC), Tabriz, Iran; 4) Tabriz University of Medical Science, Department of Obstetrics and Gynecology and women's reproductive health research center, Tabriz, Iran.

Introduction: Recurrent spontaneous abortion (RSA) is a frequent obstetric complication that affects 1-5% of couples. The pathophysiology of RSA is complex and remains largely unclear. Various investigations examined the prevalence of thrombophilic gene mutations in women with miscarriages. However, the role of these in RSA is still controversial. In order to determine the association of specific inherited thrombophilias and recurrent spontaneous abortion; 10 most common thrombophilic genes were investigated. Material & methods: A total of 139 women were included in this study: 89 women with a history of recurrent miscarriages and 50 fertile women with at least two live births from many different regions of North West of Iran. Genomic DNA was extracted from whole blood samples by a standard salting-out protocol. Two molecular genetics methods, Amplification Refractory Mutation System (ARMS-PCR) and restriction fragment length polymorphisms (PCR-RFLP) were then used for the identification of MTHFR (677C/T and 1298A/C), Factor V (1691G/A and 4070A/G), Prothrombin (20210G/A), PAI-1 (-675 I/D, 5G/4G), Factor XIII (Val34Leu), Beta-fibrinogen (-455G/A), ACE (intron 16 I/D), Factor VII (Gln353Arg), Glycoprotein Ia (807C/T), tPA (intron h D/I) gene mutations. Results: Between the two groups, no differences in the frequency of specific gene mutations were detected. However, the prevalence of homozygous mutations for MTHFR (677C/T and 1298A/C), Prothrombin (20210G/A), PAI-1 (-675 I/D, 5G/4G), Factor XIII (Val34Leu), Beta-fibrinogen (-455G/A), ACE (intron 16 I/D) and total gene mutations among patients with RSA was significantly higher than among controls. Conclusions: Compound thromboplilic gene mutations rather than a specific gene mutation can be a risk factor for first trimester RSA. However, further studies on a larger series are needed for a better understanding of the role of these gene mutations in this clinical setting.

Replication Study of 72 Single Nucleotide Polymorphisms Associated with Spontaneous Very Preterm Birth Using a State-Based Biobank. *D. Williamson[1], M. Pearl[2], J. Yang[2], GN. DeLorenze[3], CJ. Bean[4], WM. Callaghan[1], A. Grant[4], E. Lackritz[1], R. Romero[5], GA. Satten[1], H. Simhan[6], AR. Torres[7], J. Westover[7], R. Yolken[8], M. Kharrazi[9].* 1) Division of Reproductive Health, Centers for Disease Control and Prevention, Atlanta, GA; 2) Sequoia Foundation, La Jolla, CA; 3) Kaiser Permanente Division of Research, Oakland, CA; 4) Division of Blood Disorders, Centers for Disease Control and Prevention, Atlanta, GA; 5) Perinatology Research Branch, Eunice Kennedy Shriver National Institute of Child Health & Human Development, National Institutes of Health; 6) University of Pittsburgh School of Medicine, Pittsburgh, PA; 7) Center for Persons with Disabilities,UtahStateUniversity, Logan, UT; 8) School of Medicine, Johns HopkinsUniversity, Baltimore, MD; 9) Genetic Disease Screening Program, California Department of Public Health, Richmond, CA.

Background Preterm birth (birth < 37 weeks gestation) is one of the leading causes of infant mortality and morbidity. There are striking disparities in the rates and consequences of preterm birth across racial and ethnic groups. Research indicates that preterm birth is a multifactorial disease caused by genetic, social, and environmental factors, which most likely interact to increase risk. Identification of risk alleles may allow for early detection of women at high risk of preterm birth. Methods We identified 72 single nucleotide polymorphisms (SNPs) from manuscripts in the published literature that reported an association with preterm birth. We attempted to confirm these associations using data from 601 spontaneous very preterm births (<32 weeks for 207 whites and 217 Hispanics and <34 weeks for 177 blacks) and 796 controls identified from singleton live births born in southern California between 2000- 2007. Maternal blood specimens leftover from mid-pregnancy screening were genotyped using a Sequenom platform. Results We confirmed the association between 13 SNPs and spontaneous very preterm birth ($p < 0.05$). These included 5 among blacks (IFNG rs2430561, IL6R rs4845374, MMP1 rs1799750, TGFB1 rs1800469, TNFRSF1A rs740841), 2 among whites (IL10RA rs17121510, IL6R rs4845374), and 6 among Hispanics (IL10 rs1800896, IL15 rs10833, IL1B rs1143627, IL2RB rs228947, rs228954, rs3218315). Only one SNP was significant in two race-ethnicity groups (IL6R rs4845374) and no single SNP was significant across all three race-ethnicity groups. Conclusions: While the association between 13 previously-reported SNPs and very preterm birth were confirmed, we found differences in the genetic risk among each race-ethnic group.

1435W

Novel *FTO* locus Associated with polycystic ovary syndrome. *O.A. Garcia[1], P. Mutharasan[1], R.S. Legro[2], A. Dunaif[1], M. Urbanek[1].* 1) Division of Endocrinology, Metabolism and Molecular Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois, United States of America; 2) Department of Obstetrics and Gynecology, Penn State Hershey College of Medicine, Hershey, Pennsylvania, United States of America.

Background: Polycystic ovary syndrome (PCOS) is a complex polygenic endocrine disorder that is the leading cause of infertility among women. PCOS not only affects the reproductive phenotype but is also associated with increased risk of obesity, insulin resistance and type 2 diabetes. Therefore the fat mass and obesity-associated *(FTO)* gene has been proposed as a candidate gene for PCOS. Recent studies have failed to demonstrate a strong association at traditional loci in the *FTO* gene. We tested the hypothesis that *FTO* contributes to the etiology of PCOS by tagging the entire *FTO* region and testing for association with PCOS. **Methods:** We genotyped 88 single nucleotide polymorphisms (SNPs) within *FTO* using the Infinium iSelect Beadchip technology (Illumina, San Diego, CA). The majority were haplotype-tagging SNPs (r^2>0.8 and minor allele frequency (MAF)γ 0.05); the remainder were known nonsynonymous coding SNPs. We tested for association in a European-derived cohort of 931 cases fulfilling NIH criteria and 961 minimally phenotyped controls. We adjusted for population stratification with 253 ancestry informative markers. Genetic analyses were carried out in PLINK using three models. Model 1 adjusted for population stratification using the first two principal components. Model 2 adjusted for population stratification and BMI. Model 3 adjusted for population stratification, BMI and age. **Results:** We found evidence for association at two regions of the gene. The first region maps to intron 1, encompassing the region previously found to be strongly associated with obesity and potentially associated with PCOS. The strongest association was observed at rs9939609 with Model 1 (OR=1.29, p=0.00021) but loses significance with Models 2 and 3. The second region maps to intron 8, an area not in linkage disequilibrium with region 1, with the strongest association at rs8056199. This marker was significantly associated with PCOS under all models tested but shows the strongest association with Model 3 (OR=1.29, p=0.00014). rs8056199 was not associated with BMI in the PCOS cases or in the complete cohort. **Discussion:** Previous studies have found evidence for association between variants within *FTO* and PCOS. However, these analyses have been limited to the region of *FTO* that is strongly associated with BMI, and this association was further weakened in PCOS cohorts after adjustment for BMI. Here we have identified a second region of *FTO* that is associated with PCOS but not BMI.

1436W

Maternal genetic variation in inflammatory response genes interact with a measure of air pollution exposure to influence infant birthweight in non-Hispanic black women. *A.E. Ashley-Koch[1], M.E. Garrett[1], K.S. Quinn[1], A.C. Buskwofie[1], S. Edwards[2], G.K. Swamy[3], M.L. Miranda[2, 4].* 1) Center for Human Genetics, Duke University Medical Center, Durham, NC; 2) Nicholas School of the Environment, Duke University, Durham, NC; 3) Department of Obstetrics and Gynecology, Duke University Medical Center, Durham, NC; 4) Department of Pediatrics, Duke University Medical Center, Durham, NC.

OBJECTIVE: To evaluate the contribution of maternal genetic variation and a measure of air pollution exposure to infant birthweight (BWT) among non-Hispanic black (NHB) women. **METHODS:** Healthy Pregnancy, Healthy Baby is a prospective cohort of pregnant women aimed at identifying genetic, social, and environmental contributors to racial disparities in pregnancy outcomes. English-literate women >18 yrs with a normal singleton pregnancy residing within Durham County, NC were enrolled prior to 28 weeks gestation. 673 NHB women were examined for BWT in this analysis. Maternal samples collected during inpatient admission for delivery were genotyped. Maternal residential address at enrollment was georeferenced and the distance to the nearest major roadway was calculated as a proxy for exposure to traffic-related air pollution. Haplotype tagging single nucleotide polymorphisms (htSNPs) were genotyped for 105 SNPs in 20 candidate genes using Taqman assays from Applied Biosystems Incorporated. Linear regression was used to examine the relationship between htSNPs and infant BWT, adjusting for parity, infant sex, maternal age, education, insurance, and smoking status. We also examined potential interactions between htSNPs and roadway proximity. **RESULTS:** Mean infant BWT was 3025 g (sd=653 g). Nominal evidence for main effects on infant BWT was detected with *CR1* (rs17047661, p=0.006), *IL10* (rs1518111, p=0.008), 2 SNPs in *IL8* (rs2227538, p=0.01; rs2227306, p=0.02), *IL12B* (rs2853694, p=0.03), *IL6* (rs2069840, p=0.03) and *IL12A* (rs568408, p=0.04). Evidence for SNPs interacting with roadway proximity to influence BWT was detected with two SNPs in *TLR4* (rs12344353, p=0.01; rs5030725, p=0.03), two SNPs in *IL4* (rs2227282, p=0.008; rs2243283, p=0.03) and one SNP in *INFG* (rs2069714, p=0.04). **CONCLUSIONS:** Similar to previous reports, genetic variation in inflammatory response genes provided evidence for main effects on infant BWT among NHB women in our study. Moreover, we provide the first evidence that some of these genes interact with air pollution exposure to influence infant BWT. Thus, maternal inflammatory response may be exacerbated by oxidative stress and particulate contamination due to exposure to air pollution during pregnancy.

1437W

***Hormad1*-deficiency causes azoospermia in males and pregnancy loss in females.** *H. Kogo, M. Tsutsumi, T. Ohye, H. Inagaki, H. Kurahashi.* Division of Molecular Genetics, ICMS, Fujita Health University, Toyoake, Aichi, Japan.

Infertility and pregnancy loss are commonly observed clinical problems in humans. Dynamic chromosome segregation processes, including meiotic recombination, synapsis and chiasma formation, are essential in meiotic prophase I. Genetic defects in the genes involved in these processes consistently cause reproduction failure in mice, suggesting that infertility in humans may be caused by defects in meiotic genes. To date, however, the molecular mechanism of mammalian meiosis is still insufficiently understood. In the present study, we investigated a hitherto uncharacterized meiotic gene, mouse *Hormad1* by gene targeting. *Hormad1*-deficient mice are infertile both in males and females. The mutant testes are hypoplastic due to the apoptosis of spermatocytes at the pachytene stage. The *Hormad1*-deficient spermatocytes show an extensive failure of homologous pairing and synapsis, which causes apoptosis due to the pachytene checkpoint. In contrast, unexpectedly, *Hormad1*-deficient ovaries contain a normal number of oocytes, despite extensive synapsis failure as in spermatocytes, and consequently produce aneuploid oocytes, indicating a failure of pachytene checkpoint function by the *Hormad1*-deficiency. The *Hormad1*-deficient oocytes can be fertilized, and the conceptus can occasionally survive after implantation, but fetal loss eventually results from aneuploidy. By analysis of *Hormad1*/*Spo11* double mutant female mice, the *Hormad1*-deficiency was found to completely abrogate the massive oocyte loss in the *Spo11*-deficient ovary. This result clearly demonstrates that HORMAD1 is required for a DNA damage-independent synapsis checkpoint. The double mutant spermatocytes also evade the arrest at the zygotene/pachytene transition caused by the *Spo11*-deficiency, although these cells are eventually eliminated at the pachytene stage due to the failure of meiotic sex chromosome inactivation, that is a male-specific phenomenon caused by extensive asynapsis. This additional male-specific surveillance mechanism for asynapsis will explain the sexually dimorphic consequence of meiocytes harboring extensive asynapsis in mammalian meiosis. Collectively, HORMAD1 is a key molecule required for multiple functions including homologous pairing, synapsis, and synapsis checkpoint in mammalian meiosis. Our results suggest that genetic defects affecting the HORMAD1-dependent function could be a candidate cause of azoospermia in males and pregnancy loss in females in human reproduction.

Association of overweight and obesity with diminished reproductive potential through change of sperm parameters; a pilot study. *M. najafi.* Zoology, University of Mysore, Mysore, karnataka, India.

Najafi M1, Yousefi A2, Sharath Kumar C3, Ravi Kumar S3 and Malini S.S1 1. Human Genetics Laboratory, Department of Studies in Zoology, University of Mysore, Manasagangothri, Mysore, Karnataka, India. 2. M.Sc Nutrition 3. Medivawe IVF and Fertility Research Hospital, Mysore, Karnataka, India. Corresponding authors; 1. Mohsen Najafi PhD. student, Human Genetics lab, Departemnt of studies in Zoology University of Mysore Email: mohsen.genomics@gmail.com 2. Dr. Suttur.S. Malini Assistant Professor DOS in Zoology, University of Mysore. Telephone: 08212419784 (O) E-mail: ssmalinisri@yahoo.co.in mohsen.najafi78@yahoo.com To investigate the link between increased BMI in overweight and obese men and diminished reproductive potential compare to control group in Karnataka, South India. In this pilot study a total 65 overweight and obese men (BMI⁄ 25), aged 25 to 45 years, were enrolled from different obesity clinics, infertility hospitals and gyms of Mysore city. Out of this number, 15 subjects were excluded from the study since either they were not convinced to donate semen sample or suffered from diabetes and other diseases. All cases and controls were evaluated for different semen parameters according to World Health Organization (WHO) standards. Statistical analysis was performed using the SPSS software, version 16.0. P-values less than 0.05 were considered statistically significant. Different conditions of infertility are observed among overweight and obese individuals enrolled in this study. Although sperm function test does not show statistical significant values in overweight and obese men when compared with control group but, variations in the semen parameters are significant in obese men compared to controls .In case of oligoasthenospermic subjects pH shows a significant increase compared to controls. Also the levels of Fructose show a significant decline in both azoospermic and oligoasthenosermic groups when compared to control group. Data obtained from this pilot study suggest a potential link between increased BMI in men and the semen quality which may ultimately diminish the chance of paternity. Key words: Obesity; BMI; Male Infertility.

1439W

Lessons from Chernobyl: Low dose irradiation at conception leads to a highly increased (epi) genetic risk. *K. Sperling[1], A. Koerblein[2], H. Neitzel[1].* 1) Inst Med & Human Gen, Charite - CVK, Berlin, Germany; 2) Untere Soeldnersgasse 8, D-90403 Nuernberg.

The international guidelines for radiological safety are primarily based on (a) studies of high doses of acute, external irradiation received by the Japanese atomic bomb survivors and (b) large-scale animal experiments, especially with mice. The genetic risk of low dose irradiation is generally estimated from high doses under the assumption of a linear model with no threshold. However, this model does not adequately consider the Chernobyl effect of internal exposure to radionuclides and, as outlined here, neglects the extreme sensitivity to ionizing radiation around conception. From an epidemiological point of view, the Chernobyl accident in April 1986 was unique, leading to a low dose radiological exposure of large parts of Europe, first due to the intake of short lived radionuclides. Exactly 9 months after the accident, there was a significant increase in the prevalence of Down syndrome (DS) in West-Berlin and Belarus. As more than 90% of DS cases are due to maternal meiotic nondisjunction, which takes place around conception, there is a highly distinct temporal relationship between exposure and the effect. This finding is paralleled by a significant increase in the sex ratio of newborn, beginning in January 1987 (Bavaria) and confined in 1987 to the exposed countries. This is explained by a loss of female embryos due to the extensive epigenetic modifications of the paternal genome, especially the paternal X, immediately after fertilization. Among the newborn with DS in West-Berlin, there was also a significant increase in the sex ratio. Since bias and relevant confounders could be excluded, a causal relationship between exposure and the increase both in the sex ratio and trisomy 21 remains the only explanation. In man, but not in mice, the maternal meiotic divisions around conception are extremely error prone and, perhaps, also the extreme epigenetic modifications of the paternal genome, explaining that even under optimal conditions more than 70% of all conceptuses are lost, mostly before clinical recognition of pregnancy. It is logical to assume that these naturally error prone processes can be easily disturbed by environmental factors, e.g. ionizing radiation. In this respect, extrapolation from mouse to human is of limited value and consequently there is an urgent need for analytical epidemiological studies with respect to other environmental hazards. Moreover, the International guidelines for radiological safety should be revised accordingly.

Outcomes of over 400 cycles of `transport' PGD for single gene disorders. *G. Harton[1], S. Jaroudi[2], M. Konstantinidis[3], J. Sanchez[1], S. Tormasi[1], R. Prates[1], N. Goodall[1], D. Wells[3].* 1) Reprogenetics, Livingston, NJ; 2) Reprogenetics UK, Oxford, UK; 3) University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Women's Centre, John Radcliffe Hospital, Oxford, UK.

Introduction: Preimplantation genetic diagnosis (PGD) is offered to individuals at high risk of transmitting an inherited disorder to their offspring. PGD entails genetic testing of blastomeres biopsied from cleavage stage embryos from in vitro fertilization (IVF), and aims to ensure that embryos selected for transfer are unaffected by the familial disorder. The diagnosis should be sensitive, accurate and fast to allow for the greatest chance of pregnancy with the lowest risk of misdiagnosis. **Aim:** Evaluate the diagnostic and clinical outcomes of PGD cycles carried out for patients at high risk of transmitting a single gene disorder (e.g. cystic fibrosis). **Material & Methods:** A retrospective review of 405 cases of PGD performed between September 2008 and December 2010 was carried out. The maternal age ranged between 20 and 45 years (mean 33.28). IVF and embryo biopsy took place in more than 60 different fertility clinics, with blastomeres sent to a single specialist PGD laboratory for analysis. The majority of protocols involved a multiplex polymerase chain reaction (PCR) step to amplify the mutation site as well as linked short tandem repeat (STR) polymorphisms, followed by fragment size analysis. Further amplification of the mutation site was usually preformed by a nested PCR prior to minisequencing or other forms of DNA analysis. **Results:** PGD was performed for a total of 3376 embryos, with over 50 different disorders diagnosed. A diagnosis was obtained for 85% of cells tested. Amplification failure was observed for 10% of cells tested and allele dropout (ADO) was seen in approximately 11% of cells. The accuracy of the diagnosis was predicted to be greater than 98% in most cases. No misdiagnoses were recorded to date. The pregnancy rate (positive hCG) per embryo transfer was 59.7% and the implantation rate (number of gestational sacs/number of embryos replaced) was 48%. The pregnancy rate per transfer showed an influence of maternal age: 60% for patients under 35 years of age and 52.6% for patients over 35. **Conclusion:** Transport PGD allows patients to receive treatment in their local area, avoiding the need to travel to IVF clinics that have in-house PGD capability. This will reduce the financial burden and stress felt by patients and allows local clinics to retain cycles. The results of this large study showed good rates of diagnosis, accuracy and pregnancy, indicating that transport PGD is an effective treatment option for patients.

`No thanks'- why pregnant women choose not to have cystic fibrosis carrier screening. *L. Ioannou[1,2], J. Massie[3,4], S. Lewis[5], B. McClaren[6], V. Collins[1], M. Delatycki[1,2,4,7].* 1) Bruce Lefroy Centre , Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 2) Department of Medicine, Monash University, Melbourne, Victoria, Australia; 3) Department of Respiratory Medicine, Royal Children's Hospital, Melbourne, Victoria, Australia; 4) Department of Paediatrics, University of Melbourne, Melbourne, Victoria, Australia; 5) Public Health Genetics, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 6) Genetics Education and Health Research, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 7) Clinical Genetics, Austin Health, Melbourne, Victoria, Australia.

Introduction: A population-based cystic fibrosis (CF) carrier screening program was introduced in Victoria, Australia in 2006. It is offered for a fee by doctors to couples planning a pregnancy or in early pregnancy. The aim of this study was to assess the attitudes and opinions of women declining screening and compare these to those of individuals who accepted screening. Methods: Between December 2009 and May 2011, women who declined a direct offer of CF carrier screening by their obstetrician were invited to participate. The questionnaire explored knowledge, reasons for declining screening, decision making, attitude towards screening and satisfaction with information provided. Results: A total of 50 completed questionnaires were received. The majority of participants were aged 30-34 (54%), had a university qualification (78%) and earned a household income of more than $100,000AUD per annum (78%). Twenty-five participants (51%) answered 6 to 10 of the 15 knowledge questions correctly; however 29 (59%) incorrectly believed that couples who have a child with CF usually have a family history. Knowledge level was significantly lower in participants who declined screening, compared to those who accepted screening, for 9 of the 15 knowledge questions. The main reasons for declining screening were having no family history of CF and would not consider a termination of pregnancy for CF. Having a family history of CF (χ^2=54.86, p<0.01) or other genetic conditions (χ^2=53.68, p<0.01) had a significantly greater influence on the decision whether to have screening, for those who declined screening, compared to those who accepted it. Almost all of the women whom participated (96%) believe that CF carrier screening should be available to those who wish to be screened. Conclusion: There is no significant demographic difference between those who accepted screening and those who declined it. The main reason for declining screening is having no family history of CF, with those who declined screening stating that it had a greater influence on their decision compared to those who accepted screening.

1442W

Search for autosomal recessive prenatal lethal or semi-lethal mutations by genome-wide association study (GWAS) of reproductive traits. *J.X. Chong[1], G. Kosova[1], C. Ober[1,2].* 1) Human Genetics, The University of Chicago, Chicago, IL; 2) Obstetrics and Gynecology, The University of Chicago, Chicago, IL.

Spontaneous miscarriage is relatively common, with only ~25% of conceptuses surviving to term. Although most of these pregnancy losses are due to chromosomal abnormalities, some may be due to recessive lethal (or semi-lethal) mutations. Although many such mutations are known in mice, few autosomal recessive prenatal lethal mutations have been reported in humans. The Hutterites, a North American founder population, proscribe contraception and uniformly desire large families, making them particularly suitable for studies on the genetics of reproductive traits. In this study, we sought to identify recessive mutations that cause prenatal lethality in homozygotes by conducting a couple-based GWAS of family size and birth rate in ~260 Hutterite couples who had been genotyped for ~300,000 SNPs. Parental genotypes were used to calculate each couple's “risk” of having children homozygous for the minor allele at each SNP, based on Mendelian probabilities. Linear regression was performed to determine if risk at each SNP was a significant predictor of family size or birth rate. Two filters were then applied in series to all SNPs with p-values $\leq 10^{-4}$ with either phenotype. First, transmission disequilibrium tests were used to further select SNPs at which there was undertransmission of the minor allele (p<0.1) to children of heterozygous parents. Then, to look for deficiences of living homozygous offspring, genotype segregation ratios were examined among the offspring of couples in which both parents were heterozygous for the minor allele. We report a 154 kb region on chromosome 1 in which the minor alleles at multiple SNPs are associated with reduced family sizes (smallest p=8.3x10^{-5}) and under-transmitted in families of carrier parents (transmission:non-transmission ratio=282:333; p=0.04). Moreover, segregation ratios in 258 offspring of carrier couples were 85:118:55, significantly different than the expected 64.5:129:64.5 (p=0.01). This locus includes two candidate genes: *CNN3*, which regulates actin cytoskeleton remodeling that is required for trophoblast cell fusion during placenta formation; and *ALG14*, which is involved in the regulation of protein folding and stabilization and is required for growth in yeast. This is the first GWAS for prenatal lethal mutations, the results of which will add to our knowledge of genetic causes of pregnancy loss.

1443W

Determining the mutation underlying a novel 46, XY Disorder of Sexual Development (DSD) using next-generation sequencing strategies. *R.L. Hood[1,2,3], S. Douglas[3], C. Goldsmith[3], D.E. Bulman[2], K.M. Boycott[3].* 1) Department of Biochemistry, Microbiology and Immunology, Faculty of Medicine, University of Ottawa, Ottawa, Ontario, Canada; 2) Regenerative Medicine, Ottawa Hospital Research Institute, Ottawa, Ontario, Canada; 3) Children's Hospital of Eastern Ontario Research Institute, University of Ottawa, Ottawa, Ontario, Canada.

The development of next-generation sequencing technologies has revolutionized modern genetics and enabled researchers to elucidate novel biological applications at unprecedented speeds. Through this technology one can experimentally determine the causative gene(s) or variants underlying a particular disease. We describe a family with a novel 46, XY disorder of sexual development (DSD) inherited in an autosomal dominant manner. Intrafamilial variability was evident with clinical presentations ranging from normal male (obligate carrier) to varying degrees of hypospadias to female external genitalia in the 7 affected male family members. The genetic cause of this disorder is currently unknown as mutations in genes known to be involved in the sexual development pathway, including SRY, NR5A1, DHH, NROB1, SOX9, WT1, and MAP3K1, were excluded via clinical testing and segregation analysis with linked markers. Association of the disorder in this family with a 1p31-p35 duplication encompassing WNT4 could not be excluded by linkage; however, normal copy number data using the Affymetrix 6.0 array made this very unlikely. Therefore, we plan on utilizing next-generation sequencing to experimentally identify the DSD gene and its causative mutation. It will then be possible to determine the biological significance this gene has in human sexual development. This study will elucidate additional molecular components and mechanisms underlying secondary sex-characteristics, thereby contributing to our overall understanding of sex differentiation and determination.

1444W

No evidence for aberrant placental DNA methylation in karyotypically normal recurrent miscarriage. *CW. Hanna[1], DE. McFadden[2], WP. Robinson[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pathology, University of British Columbia, Vancouver, BC, Canada.

Recurrent miscarriage, 3 or more consecutive spontaneous abortions of pregnancy before 20 weeks gestation, occurs in 1-2% of couples trying to conceive. Chromosomal errors are observed in over 50% of miscarriages; however causes of karyotypically normal losses are less understood. Imprinted genes are expressed in a parent-of-origin specific manner and are particularly important in placental function. The mono-allelic expression of these genes is often associated with differential DNA methylation, alterations of which have been suggested to be a cause of pregnancy loss. We hypothesize that placental villi of karyotypically normal miscarriages from women with recurrent miscarriage will exhibit aberrant DNA methylation at imprinted loci and globally throughout the genome. DNA was extracted from placental villi of karyotypically normal miscarriages from women experiencing recurrent miscarriage (N=33) and chromosomally normal first trimester controls (N=16). Bisulfite pyrosequencing allowed the targeted interrogation of DNA methylation at the imprinted loci *PLAGL1*, *H19* ICR, *SGCE*, *TP73*, and *SNRPN*, as well as at LINE-1 elements, used as a surrogate measure of global methylation. Two of 33 (6.1%) recurrent miscarriage placentae showed a loss of methylation (defined as values greater than 1.5x the interquartile range) at any of the 5 imprinted loci, as did 1 of 16 (6.3%) control placentae. There was also no significant difference in average methylation at any of these imprinted genes after correcting for multiple comparisons. Genome-wide DNA methylation was also assessed in 20 samples (10 cases, 10 controls) using the Illumina Infinium HumanMethylation27 BeadChip, which interrogates 27,578 CpG sites. Significance Analysis of Microarrays was utilized to identify candidate genes, using a <1% False Discovery Rate and >10% absolute difference between groups. Fourteen candidate CpG sites were identified; however methylation at these sites was found to vary with gestational age of the pregnancy and therefore likely represents subtle differences in gestational age between the case and control groups. Finally, we found no difference in global methylation as measured by LINE-1 elements (p=0.61) or as an average of the 27,578 CpG sites (p=0.21). This study suggests that epigenetic errors in the placenta associated with imprinting or global DNA methylation do not represent a common contribution to karyotypically normal pregnancy loss in women with recurrent miscarriage.

1445W

A familial case of macrozoospermia caused by an abnormal splicing of *AURKC*. *M. Ben Khelifa[1,2], R. Zouari[3], R. Harbuz[1,2], L. Halouani[3], C. Arnoult[1], J. Lunardi[2], P.F. Ray[1,2].* 1) Laboratoire AGIM, FRE 3405 CNRS - UJF, Equipe Génétique Infertilité et Thérapeutique (GIT), campus santé de Grenoble, 38 700 La Tronche, France; 2) UM de Biochimie et Génétique , CHU Grenoble, Grenoble, France; 3) CPSR les Jasmins, 23, Av. Louis BRAILLE, 1002 Tunis, Tunisia.

The presence of close to 100% large headed multi-tailed spermatozoa in the ejaculate has been described as a rare phenotype of male infertility with a very poor prognosis. We demonstrated previously that most cases were caused by a homozygous mutation (c.144delC) in the Aurora Kinase C gene (*AURKC*) leading to the absence or the production of a non-functional protein. *AURKC* deficiency in these patients blocked meiosis and resulted in the production of tetraploid spermatozoa unsuitable for fertilization. We describe here the study of two brothers presenting with large-headed spermatozoa. Standard sperm analysis and molecular analysis of *AURKC* was carried out in two brothers presenting with a typical large headed spermatozoa phenotype. Both affected brothers were heterozygous for the c.144delC mutation. After complete sequencing of the gene, a new heterozygous variant, c.436-2A>G, was identified in both patients. This mutation is located in the acceptor consensus splice site of exon 5. AURKC transcripts were extracted from one of the patient's leukocytes and Reverse Transcription Polymerase Chain Reaction (RT-PCR) was realized showing 1) the presence of a truncated transcript indicating that c.436-2A>G leaded to the skipping of exon 5 ; 2) the absence of a normal size's band indicating that transcripts with c.144delC were subject to mRNA decay. We identified a new *AURKC* mutation in two affected brothers who were also carrying the recurrent c.144delC mutation. There was no phenotypic difference observed between the sperm of these patients compared with patients homozygous for the previously described mutation. RT-PCR analysis confirmed that the newly identified mutation altered the splicing of the mRNA, inducing the skipping of exon 5, thus confirming the pathogenicity of the mutation. These results indicate that *AURKC* molecular analysis of patients with large headed spermatozoa should not be stopped in the absence of a homozygous recurrent mutation on exon 3 but complete sequence analysis should be performed. This diagnosis is important since the identification of *AURKC* mutations in patients is strongly correlated with sperm chromosomal abnormality, precluding any attempt of intra-conjugal treatment by intra cytoplasmic sperm injection (ICSI).

Chromosomal segregation in spermatozoa of five Robertsonian Translocation carriers t(13;14). *S. Brahem, M. Mehdi, M. Mahjoub, M. Gribaa, S. Ibala, A. Saad.* Laboratoire de Cytogénétique, Biologie Moléculaire et Biologie de la Reproduction Humaines, Tunisia.

Purpose: To analyse the segregation of a Robertsonian translocation t(13;14) in five male carriers, and to verify a possible inter-chromosomal effect (ICE) of the Robertsonian translocation on chromosomes 18, X, and Y. Methods: The spermatozoa of these patients (n = 5) and of fifteen donors with normal semen parameters and 46,XY karyotype were analysed using triple colour FISH with locus specific probes for chromosomes 13, 14, and 21 and by triple colour FISH for chromosomes X, Y, and 18. Results: The frequency of balanced spermatozoa resulting from alternate segregation varied between 62.16 and 81.70% with a mean of 71.5%. The rates of unbalanced spermatozoa resulting from adjacent segregation varied between 13.4 and 25.1% with a mean of 18.26%. Triple colour FISH X-Y-18 showed a significant increase in disomy frequencies of these chromosomes in comparison with controls, indicating an ICE. Conclusion: In spite of the high number of normal/ balanced frequencies, there is still much unbalanced spermatozoa resulting from adjacent mode of segregation. This raises the question of the unbalanced chromosomal risk for the offspring of 45,XY, t(13;14) males and the importance of the genetic counselling prior to ICSI or IVF treatment for couples where the male is a Robertsonian translocation carrier.

1447W

Molecular diagnosis of male factor infertility using APEX microarrays. *E. Oitmaa[1,2], A. Tammiste[1], S. Suvi[2], M. Punab[3], M. Saare[4], M. Remm[1], A. Metspalu[1,5], A. Salumets[4,6].* 1) Institute of Molecular and Cell Biology, University of Tartu, Estonia; 2) Asper Biotech Ltd., Estonia; 3) Andrology Centre, Tartu University Hospital, Estonia; 4) Competence Centre on Reproductive Medicine and Biology, Estonia; 5) The Estonian Genome Center of University of Tartu, Estonia; 6) Department of Obstetrics and Gynecology, University of Tartu, Estonia.

Objective: Male factor infertility (MFI) issues are causative in approximately 15-20% of infertile couples. The unfavourable genetic background is thought to cause for 15-30% of male factor infertility cases. Therefore, the correct determination of genetic basis of infertility is very important for further treatment of patients. Here, we demonstrate a single-step Arrayed Primer Extension (APEX) based microarray assay for the MFI diagnosis. Design & Method: The MFI-APEX assay enables analysis of numerous genetic factors simultaneously, like AZF-microdeletions; Klinefelter syndrome (47,XXY); 270 mutations in cystic fibrosis transmembrane conductance regulator (CFTR) gene; 42 mutations/variations in genes involved in cryptorchidism, hypogonadism, spermatogenic failure and 6 polymorphisms in androgen receptor gene. MFI-APEX assay validation was performed in blinded study using 62 DNA samples. Ten DNA samples were obtained from men without infertility issues and 52 DNA samples obtained from MFI patients. Seven out of 52 DNA samples have microdeletions in the AZFc region, 2 DNA samples have microdeletions in the AZFb+c region, 14 DNA samples have 47,XXY and 29 DNA samples obtained from idiopathic infertile men. Analysis of the APEX genotyping data were performed with PicDBAutoScan 5.0 program of the Genorama Genotyping Software™ (Asper Biotech Ltd). Results: We developed MFI-APEX microarray assay for the detection of genetic factor of the male infertility. Analysis of the APEX results revealed that 1 idiopathic infertile patient was homozygous for p.Thr121ins (c.364_365ins3) in USP26 gene; AZFc microdeletion was correctly identified in 7 DNA samples; AZFb+c microdeletion was correctly identified in 2 DNA samples; 47,XXY was correctly identified in 13 DNA samples. Overall, the assay call rate was 99%, accuracy 95%, specificity 93% and sensitivity 97%. Conclusion: Our experiments demonstrated that MFI-APEX assay is suitable for the rapid single-step, robust, reliable and cost-effective detection of possible genetic cause for male infertility problem. Furthermore, MFI-APEX testing is recommended before the couple undergoes assisted reproduction in order to prevent the possible inheritance of the genetic lesion to the next generation.

1448W

***TP53* PIN3 and PEX4 polymorphisms are associated with recurrent in vitro fertilization failure and endometriosis.** *D.D. Paskulin[1,2], C.A.B. Souza[3], J.S. Cunha-Filho[3], P. Ashton-Prolla[1,2,4].* 1) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil; 2) Genomic Medicine Laboratory, Experimental Research Center, Hospital de Clínicas de Porto Alegre, Brazil; 3) Department of Obstetrics and Gynecology, Hospital de Clínicas de Porto Alegre, Brazil; 4) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Brazil.

Objective: p53 plays a crucial role in human fertility as it regulates leukemia inhibitory factor expression, a secreted cytokine that is critical for blastocyst implantation. Several polymorphisms in the *TP53* Pathway are thought to have significant effects on human fertility. We hypothesized that polymorphisms in the *TP53* Pathway that alter p53 function may be involved with recurrent *in vitro* fertilization (IVF) failure and endometriosis, and therefore, tested the association of functional polymorphisms in the *TP53* gene (PIN2, PIN3 and PEX4) as well as SNPs in *MDM2*, *MDM4*, *HAUSP* and *LIF* in women with these phenotypes. **Patients and Methods**: A total of 115 IVF patients with recurrent implantation failure (IVF Group), 98 infertile patients with endometriosis (END Group) and 130 fertile women (CON Group) were included in the study. DNA was obtained from leukocytes and ARMS-PCR or allelic discrimination using TaqMan Assays were performed for genotyping. Patients and controls were categorized according to genotype of each SNP and evaluated for baseline characteristics and pregnancy outcomes. *TP53* haplotype frequencies were calculated by direct count. **Results**: Baseline characteristics demonstrated that both IVF and END patients were younger and had reduced number of pregnancies, live births, cesarean and abortions when compared with the control group (all P<0.01). The prevalence of the *TP53* PIN3 A2 allele (P=0.042 for IVF and P=0.004 for END) and *TP53* PEX4 Pro allele (P=0.007 for IVF and P=0.009 for END) were increased in our IVF and END patients when compared with the control group. Haplotypes C-A2-Pro, C-A1-Pro were associate with high risk for IVF (P=0.038, OR= 1.6; P=0.004, OR=3.5 respectively) and END (P=0.018, OR=1.8; P=0.02, OR=4.11 respectively). No association was found between *MDM2*, *MDM4*, *HAUSP* and *LIF* SNPs and endometriosis or IVF. **Conclusion**: Our data confirms that the *TP53* PEX4 Pro allele is enriched in infertile women less than 35 years of age, and demonstrates that the Pro allele is also enriched in infertile women with endometriosis. In addition, the *TP53* PIN3 A2 allele was found, for the first time, to be associated with risk for these two clinical entities. Our results reinforce that *TP53* is crucial for human fertility and that polymorphisms that alter p53 expression patterns may be good biomarkers for infertility and endometriosis.

1449W

Genome-wide association study identifies novel candidate genes for male fertility in humans. *G. Kosova[1], N. Scott[1], C. Niederberger[2], G.S. Prins[2], C. Ober[1,3].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Urology, University of Illinois at Chicago, Chicago, IL; 3) Department of Obstetrics and Gynecology, University of Chicago, Chicago, IL.

Despite the fact that hundreds of genes have been identified that affect fertility in animal models, relatively little is known about genes that influence natural fertility in humans. To broadly survey genetic variation affecting male fertility, we utilized a two-stage approach. First, we conducted a genome-wide association study (GWAS) for two measures of fertility, family size and birth rate, in 269 married men who are members of a founder population of European descent that proscribes contraception and desires large families. Associations between ~250,000 autosomal SNPs and the fertility traits were tested using a regression-based test, designed for large, complex families. Eighty two SNPs at 41 independent loci showed association at $P \leq 1x10^{-4}$ for either trait. At the second stage, the most significantly associated SNP at each of these 41 loci were taken forward to a validation study in 123 ethnically diverse men from Chicago who had previously undergone semen analysis. Nine SNPs that were associated with reduced fertility measures in the Hutterites were also associated with at least one of the 10 parameters of sperm quantity and/or motility. Overall, we observed 24 associations with *P*-values < 0.05, based on 5,000 permutations. The fraction of permutations yielding a higher number of significant associations in this data set was 0.0041, reflecting a significant enrichment for small *P*-values. Among the nine associated loci are outstanding candidates for male fertility genes, including *USP8*, an essential deubiquitinating enzyme that has a function in acrosome assembly, and genes with potential roles in regulation of innate immunity, such as cytokine induced *UBD* and *EPSTI1*, and the latent TGF-) receptor, *LRRC32*. We suggest that more severe mutations in some of these genes may account for some cases of unexplained infertility (or subfertility) in general population. Supported by NIH grant HD21244.

Successful application of preimplantation genetic diagnosis for aromatic L-amino acid decarboxylase deficiency by a combination of molecular approaches. *S.P. Chang[1,2], S.H. Wu[2], G.C. Ma[1,3], H.H. Wu[4,5], C.H. Wu[4,5], T.M. Chang[6], F.P. Tsai[7], M. Chen[1,2,4,8,9].* 1) Center for Medical Genetics, Changhua Christian Hosp, Changhua City, Taiwan; 2) Department of Life Sciences, National Chung-Hsing University, Taichung, Taiwan; 3) Institute of Biochemistry and Biotechnology, Chung Shan Medical University, Taichung, Taiwan; 4) Department of Obstetrics and Gynecology, Chung Shan Medical University, Taichung, Taiwan; 5) Department of Obstetrics and Gynecology, Changhua Christian Hospital, Changhua, Taiwan; 6) Department of Pediatrics, Changhua Christian Hospital, Changhua, Taiwan; 7) Poyuan Women's Clinic, IVF Center, Changhua, Taiwan; 8) Department of Life Sciences, Tunghai University, Taichung, Taiwan; 9) Department of Obstetrics and Gynecology and Department of Medical Genetics, College of Medicine and Hospital, National Taiwan University, Taipei, Taiwan.

Aromatic L-amino acid decarboxylase (AADC) deficiency is an autosomal recessive disorder, resulting in inborn error of neurotransmitter metabolism. Defects in the DDC gene, located in7p12.1p12.3, are known to be responsible for this condition. So far, less than 20 DDC mutants have been described in no more than 50 cases with clinical association worldwide. A Twainese couple experienced three neonatal deaths and two induced abortions because of AADC deficiency was referred to us and requested in vitro fertilization (IVF) treatment together with preimplantation genetic diagnosis (PGD) for an unaffected pregnancy. In a preliminary molecular evaluation, the couple was shown to carry the same heterozygous mutation in DDC, IVS6+4A>T, which has been reported as a hotspot in more than 80% of Taiwanese patients. Therefore, we designed and utilized a novel combination of amplification refractory mutation system and quantitative polymerase chain reaction (ARMS-qPCR), to screen and exclude the affected embryos from transfer. Preliminary testing showed that the ARMS-qPCR amplification rate of 60 single lymphocytes and 15 single blastomeres was 100% (60/60) and 93% (14/15), respectively. Direct sequencing of the PCR products proved that the accuracy was 100% (74/74). These results revealed that the protocol we used is feasible in both of blastomeres and lymphocytes. In PGD, five single cells obtained by blastomere biopsy in day-3 embryos were tested by means of ARMS-qPCR to detect the presence of the disease-causing mutation, and two of them were determined to be unaffected: one was homozygous wide-type and the other one was heterozygous carrier. Then, the two unaffected embryos were transferred in day 5. After 38 weeks of uneventful gestation, a healthy male baby was born successfully. Postnatal genotyping confirmed the baby to be a carrier with healthy phenotype. We concluded that ARMS-qPCR is a simplified and feasible technique for PGD. To our knowledge, this is the first successful application of PGD in AADC.

Thrombophilic Mutations and Susceptibility to Preeclampsia in a Population from Western Iran. *Z. Rahimi[1], Z. Rahimi[1], A. Vaisi-Raygani[1], A. Parsian[2].* 1) Biochemistry, Kermanshah University of Medical Sciences, Kermanshah, Kermanshah, Iran; 2) Division of Neuroscience & Behavior, NIAAA, National Institutes of Health, Rockville, Maryland, USA.

Aim. Preeclampsia is one of the most common and most serious complications of pregnancy. Inherited thrombophilias might be involved in the increased susceptibility to adverse pregnancy outcomes including preeclampsia. The aim of present study was to determine the possible association between factor V Leiden (FVL) mutation (G1691A) and prothrombin G20210A polymorphism with susceptibility to preeclampsia. Methods. We studied 198 women with preeclampsia including 128 women with mild and 70 women with severe forms and 101 age and parity matched healthy pregnant women with uncomplicated pregnancy from Western Iran. The sample was genotyped was done by polymerase chain reaction-restriction fragment-length polymorphism (PCR-RFLP) using MnI I and Hind III for FVL and prothrombin G20210A, respectively. Results. Among cases there were 23 women (19 with severe and 4 with mild preeclampsia) of early-onset pre-eclampsia (before 34 weeks gestation) and 175 cases of later-onset pre-eclampsia (after 34 weeks gestation). The frequency of heterozygous FVL mutation was 7.6% among all preecalmptic women (8.6% in mild and 5.7% in severe preeclamptic women) and 7.9% in healthy pregnant women (P>0.05). However, the prevalence of FV G1691A were 10.5 and 3.9% among severe preeclamptic women of early-onset and late-onset pre-eclampsia, respectively (P>0.05). The prevalence of prothrombin G20210A were 1.6, 2.9, and 3% among women with mild preeclamsia, severe pre-eclampsia and controls, respectively (P>0.05). The level of triglycerides (TG) was significantly higher among women with severe preeclampsia compared to mild preeclampsia that was not associated with the two thrombophilic mutations. Conclusions. Our results indicate that neither FVL nor prothrombin G20210A might be a risk factor for preeclampsia in our population. Key words. Thrombophilic mutations, FV Leiden, Prothrombin G20210A, Preeclampsia.

1452W

MTHFR genotype and haplotype analysis in couples with multiple miscarriages. *S. Stangler Herodez[1], B. Zagradisnik[1], A. Erjavec Skerget[1], V. Vlaisavljevic[3], N. Kokalj Vokac[1, 2].* 1) Laboratory of Medical Genetics, University Clinical Centre Maribor, Maribor, Slovenia; 2) Medical Faculty, University of Maribor, Maribor, Slovenia; 3) Department of Reproductive Medicine and Gynecologic Endocrinology, University Clinical Centre Maribor, Maribor, Slovenia.

INTRODUCTION. Multiple miscarriages may have adverse effects on the emotional and social aspects of infertile couples' life that wish to have a child. Infertility affects approximately 15% of married couples and is a worldwide reproductive health problem. Methylenetetrahydrofolate reductase (MTHFR) gene C677T and A1298C polymorphisms influence homocysteine metabolism which in turn may contribute to the unexplained embryo losses in early pregnancy and may be overrepresented in couples who have fertility problems or have experienced recurrent miscarriages. In this study we have performed the MTHFR genotype and haplotype analysis in couples with multiple miscarriages and healthy controls. METHODS. DNA was extracted from peripheral blood samples and allele specific PCR was performed for the detection of each mutation. Statistical analysis was performed with JavaStat software system. RESULTS. All possible MTHFR C677T/A1298C genotype combinations were represented in both tested groups. Combined MTHFR C677T/A1298C genotype distributions showed statistically significant differences between: couples with multiple miscarriages and controls ($p < 0.001$), and male probands with fertility problems and male controls without an infertility history ($p < 0.001$). The distributions of MTHFR C677T polymorphisms of couples with multiple miscarriages exhibited a significantly low frequency of the MTHFR 677CC genotype, compared to the control group, respectively, whereas no significant change in the couples MTHFR A1298C genotype frequency was observed. Further, only male probands with fertility problems exhibited significantly low frequency of the MTHFR 677CC genotype. Haplotype analysis of the two MTHFR polymorphisms showed a moderate difference in the distribution of the TC haplotype between couples group and controls. CONCLUSIONS. Significant difference in the prevalence of the combined MTHFR C677T/A1298C genotype distributions was observed in couples with multiple miscarriages when compared to controls without an infertility history. We found out that only male probands contributed to the association indicating that MTHFR mutation may be a gender specific factor which affects fertility of grown adults. The presence of combined MTHFR C677T/A1298C genotypes highly increased the risk of men infertility. Our presented data highlight the importance of MTHFR mutation screening in couples with multiple miscarriages, especially in male adults.

Higher clinical pregnancy rates are seen when performing 23-chromosome single nucleotide polymorphism (SNP) microarray preimplantation genetic screening (PGS) on blastocysts, versus Day-3 embryos. *A.T. Benner[1], P.R. Brezina[2], L. Du[1], M.C. Gunn[1], W.G. Kearns[3].* 1) Genetics, Center for Preimplantation Genetics, LabCorp, Rockville, MD; 2) Gynecology and Obstetrics Johns Hopkins Medical Institutions Division of Reproductive Endocrinology and Infertility, Baltimore, MD, United States; 3) Gynecology and Obstetrics, Genetics, Johns Hopkins Medical Institutions, Center for Preimplantation Genetics, LabCorp Rockville, MD, United States.

Background: We determined the clinical pregnancy rate using SNP PGS in women with recurrent pregnancy loss (RPL) undergoing in vitro fertilization (IVF). **Materials and Methods:** A retrospective review was conducted of all embryos that underwent PGS by 23 chromosome SNP microarrays from 1/1/2010 to 1/25/2011. Patients underwent standard in vitro fertilization (IVF) and preimplantation genetic screening (PGS) due to primarily a history of > 2 spontaneous miscarriages. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using HumanCytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Parental DNA was analyzed and compared to embryonic cells to determine the presence of benign copy number variations. Embryos derived from parents with known translocations or inversions were excluded from the study. Binomial confidence intervals for proportions were calculated. **Results:** 2,976 embryos from 317 clinical IVF cycles were tested. 2,704 (90.8 percent) of these embryos, derived from 249 (78.5 percent) IVF cycles, were at Day-3 of development (D3 group) when biopsy was performed. Conversely, 272 (9.2 percent) of embryos, derived from 68 (21.5 percent) IVF cycles, were at the blastocyst stage (D5 group) when biopsy was performed. On Day-3, per IVF cycle, an average of 8 total embryos were obtained of which an average of 3.1 were euploid and available for uterine transfer. At the blastocyst stage, per IVF cycle, an average of 4 total embryos were obtained of which an average of 1.9 were euploid. Of all embryos, 59 percent were aneuploid on Day-3 biopsy versus 41 percent aneuploidy in blastocyst biopsies. The clinical pregnancy rates were significantly higher (86 percent, $p<.05$) in the D5 group compared to the D3 group (65 percent). The miscarriage rate in the D3 and D5 groups were 6 percent and 9 percent respectively (not statistically different). However, both the D3 and D5 groups had miscarriage rates that were significantly lower than the background pregnancy loss rates seen in non PGS pregnancies from women undergoing IVF with a history of documented RPL (internal data). **Conclusion:** PGS using 23-chromosome SNP microarrays is practical in improving clinical pregnancy rates in couples with RPL. In addition, PGS performed on blastocysts, versus Day-3 embryos, results in significantly higher clinical pregnancy rates in similar patient populations.

1454W

23-chromosome single nucleotide polymorphism microarray (SNP) in embryos generated from parents with known chromosomal translocations also identifies a high rate of aneuploidy. *L. Du[1], P.R. Brezina[2], A.T. Benner[1], M.C. Gunn[1], W.G. Kearns[3].* 1) Genetics, Center for Preimplantation Genetics, LabCorp, Rockville, MD, U.S.A; 2) Gynecology and Obstetrics Johns Hopkins Medical Institutions Division of Reproductive Endocrinology and Infertility, Baltimore, MD, U.S.A; 3) Gynecology and Obstetrics, Genetics, Johns Hopkins Medical Institutions, Center for Preimplantation Genetics, LabCorp Rockville, MD, U.S.A.

Background: We determined the rate of aneuploidy in embryos from couples with balanced translocations or pericentric inversions undergoing in vitro fertilization (IVF) with preimplantation genetic diagnosis (PGD) and preimplantation genetic screening (PGS). **Materials and Methods:** A retrospective review was conducted of all embryos derived from parents with balanced reciprocal or Robertsonian translocations or pericentric inversions that were evaluated for PGD and PGS from 1/1/2010 to 1/25/2011. Patients underwent IVF and PGD/PGS. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using HumanCytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Parental DNA was analyzed and compared to embryonic cells to determine the presence of benign copy number variations. Binomial confidence intervals for proportions were calculated. **Results:** A total of 64 IVF cycles were evaluated of which the translocation or inversion was present in either the mother (43 percent) or the father (57 percent). 80 percent were reciprocal tranlocations, 18 percent were Robertsonian translocations, and 2 percent were pericentric inversions. These cycles generated 466 total embryos. Surprisingly, only 80 embryos (17 percent) were diagnosed with molecular karyotypes showing unbalanced translocations that were a result of segregation of known parental translocations. Of all the embryos evaluated, 174 (37 percent) were chromosomally normal for the translocation chromosomes and aneuploidy, while 149 (32 percent) were genetically balanced for the translocation chromosomes but possessed other aneuploidies. Sixty three (14 percent) of the samples evaluated were from highly fragmented embryos and resulted in failed amplification and no diagnosis. The average clinical pregnancy rate per IVF cycle was 58 percent and did not statistically differ regardless of if the parental translocation was of maternal or paternal origin, or if the translocation was of Robertsonian or reciprocal origin. **Conclusions:** Diagnosing viable embryos through 23 chromosome PGD/PGS is a promising strategy to maximize the pregnancy potential of patients with known genetic translocations or inversions. Aneuploidy on chromosomes unrelated to parental translocations or inversions was observed in 32 percent of embryos. Therefore, such parental chromosomal aberrations are likely an independent risk factor for aneuploidy.

1455W

In developing human embryos, chromosomal duplications (⁄ 200 kilobases (kb)) are more common than deletions ⁄ 200 kb as identified by 23 chromosome single nucleotide polymorphism (SNP) microarrays. *M.C. Gunn[1], P.R. Brezina[2], A.T. Benner[1], L. Du[1], W.G. Kearns[3].* 1) Genetics, Center for Preimplantation Genetics, LabCorp, Rockville, MD; 2) Gynecology and Obstetrics Johns Hopkins Medical Institutions Division of Reproductive Endocrinology and Infertility Baltimore, MD, United States; 3) Gynecology and Obstetrics, Genetics, Johns Hopkins Medical Institutions, Center for Preimplantation Genetics, LabCorp Rockville, MD, United States.

Background: We determined if, in the developing human embryo, the frequency of clinically significant chromosomal deletions (DEL) and duplications (DUP) ⁄ 200 Kilobases are similar as determined by SNP microarrays. **Materials and Methods:** A retrospective review was conducted of all embryos that underwent PGS by 23 chromosome SNP microarrays from 1/1/2010 to 1/25/2011. Patients underwent standard in vitro fertilization (IVF) and preimplantation genetic screening (PGS) due to primarily a history of > 2 spontaneous miscarriages. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using HumanCytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Parental DNA was analyzed and compared to embryonic cells to determine the presence of benign copy number variations. DELs and DUPs ⁄ 200 Kilobases were considered clinically significant. Embryos derived from parents with known translocations or inversions were excluded from the study. Molecular karyotypic interpretations were performed with the reader, the laboratory director, blinded to the identity of each sample. Binomial confidence intervals for proportions were calculated. **Results:** 1,902 embryos from 236 clinical IVF cycles were tested. 37.2 percent (707/1902) of all embryos were euploid without DUP or DEL. There was a high rate of morphologic fragmentation on some embryos which led to 9.8 percent (186/1902) embryos with no molecular diagnosis obtained. Of the remaining 1009 abnormal embryos, 5.7 percent (58/1009) had DUP or DEL with no aneuploidy and 27.4 percent (277/1009) had DUP or DEL coupled with aneuploidy. 66.8 percent (674/1009) had aneuploidy without DUP or DEL. In total, there were 470 DUP, 175 involving the p arm and 295 involving the q arm. In contrast, there were only 95 DEL, 35 involving the p arm and 60 involving the q arm. DUP and q arm abnormalities were significantly more commonly observed compared to DEL or p arm abnormalities ($p<.05$). **Conclusions:** DUP seem to be much more common than DEL in the developing embryo. Additionally, these DUP and DEL are more commonly found in the q rather than the p arm. All embryos survived to cleavage stage for PGS biopsy. Therefore, duplications or structural aberrations in the q arm might be more compatible with early embryo development than deletions or errors in the p arm.

1456W

Aneuploidy in human embryos is associated with clinically significant deletions and duplications identified by 23 chromosome single nucleotide polymorphism (SNP) microarrays. *W.G. Kearns[1], P.R. Brezina[2], L. Du[3], M.C. Gunn[3], A.T. Benner[3].* 1) Gynecology and Obstetrics, Genetics, Johns Hopkins Medical Institutions, Center for Preimplantation Genetics, LabCorp Rockville, MD; 2) Gynecology and Obstetrics Johns Hopkins Medical Institutions Division of Reproductive Endocrinology and Infertility, Baltimore, MD, United States; 3) Genetics Center for Preimplantation Genetics, LabCorp Rockville, MD, United States.

Background: We determined if clinically significant chromosomal deletions (DEL) and duplications (DUP)／ 200 kilobases in size are associated with aneuploidy. **Materials and Methods:** A retrospective review was conducted of all embryos that underwent PGS by 23 chromosome SNP microarrays from 1/1/2010 to 1/25/2011. Patients underwent standard in vitro fertilization (IVF) and preimplantation genetic screening (PGS) due to primarily a history of > 2 spontaneous miscarriages. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using HumanCytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Parental DNA was analyzed and compared to embryonic cells to determine the presence of benign copy number variations. DELs and DUPs／ 200 Kilobases were considered clinically significant. Embryos derived from parents with known translocations or inversions were excluded from the study. Positive predictive value and binomial confidence intervals for proportions were calculated. **Results:** 1,902 embryos from 236 clinical IVF cycles were tested. 37.2 percent (707/1902) of all embryos were euploid without DUP or DEL. There was a high rate of morphologic fragmentation on some embryos which led to 9.8 percent (186/1902) embryos with no molecular diagnosis obtained. Of the remaining 1009 abnormal embryos, 5.7 percent (58/1009) had DUP or DEL with no aneuploidy and 27.4 percent (277/1009) had DUP or DEL coupled with aneuploidy. 66.8 percent (674/1009) had aneuploidy without DUP or DEL. The presence of DEL or DUP was predictive of the presence of aneuploidy with a positive predictive value of 83 percent [95 percent CI = 76 percent -86 percent]. In only 3 embryos was a DUP or DEL found in the same chromosome as aneuploidy. The distribution of DEL and DUP was not normally distributed among all chromosomes, with 20.7 percent of all DEL and DUP occurring on either chromosomes 9 or 19 and only 1.9 percent of all DEL and DUP occurring on either chromosomes 15 or 21. **Conclusions:** The presence of DEL and DUP in developing embryos seems to be predictive of the presence of aneuploidy. These structural aberrations may disrupt normal cell cycle checkpoint mechanisms. This finding may further the understanding of developmental biology.

Preimplantation genetic diagnosis for recurrent pregnancy loss using array CGH. *S. Munne, r. prates, s. tormasi, n. goodal, g. harton, p. colls.* Reprogenetics, Livington, NJ.

Objective: To use single cell analysis by array CGH and screen the in-vitro fertilization generated embryos of patients suffering from recurrent pregnancy loss (RPL). The pregnancy results of this preimplantation genetic diagnosis (PGD) approach will be compared to the expected loss rate in the same patients. The error rate of the technique will be determined by reanalysis of the remainder cells of cleavage stage embryos determined by PGD to be abnormal. Material and Methods: 161 in vitro fertilization and PGD procedures of couples with idiopathic RPL (3 or more miscarriages) were included in the study. PGD was done using single cell biopsy at embryo cleavage stage followed by whole DNA amplification, and analysis by array CGH using a Bluegnome array. Each PGD patient was matched with their expected loss rate for RPL patients (Brigham et al. 1999). An ongoing pregnancy was defined as past second trimester. Some embryos classified as abnormal were later fixed for FISH analysis using probes for 12 chromosomes (X, Y, 8, 13, 14, 15, 16, 18, 19, 20, 21, 22) plus any other found abnormal in the PGD analysis. In addition, a small fraction of embryos had two cells analyzed by aCGH and that information was also used for validation purposes to determine the error rate of the technique. Results: In total 1520 embryos were analyzed, of which 33% were normal, 63% were abnormal, 3% had no nucleus in the cell biopsied or the DNA did not amplify, and 1% of cells had a chaotic profile that could not be analyzed. Of the abnormal embryos, FISH reanalysis of 108 embryos showed a discordance (error) rate with PGD results of 2.6%, and 102 embryos had 2 cells analyzed of which in 2.9% embryos one cell was normal and the other abnormal and thus considered discordant (errors). Of the 161 IVF procedures with PGD, pregnancy data was available for 138 procedures, of which 58 (42%) became pregnant and 53 cycles (38%) are ongoing past second trimester or delivered. We would expect a 34.3% miscarriage rate in this specific group of patients, but the miscarriage rate found was only 8.6% (5/58) ($p<0.001$). Conclusions: Current PGD results with single cell analysis of embryos indicate a very low discordance rate after reanalysis of the same embryos. In addition, PGD achieved a significant decrease in the miscarriage rate for idiopathic RPL patients. These results confirm that RPL is mostly caused by chromosome abnormalities in the embryos produced by these patients.

1458W

In women with a history of recurrent pregnancy loss (RPL) under 40 years of age, the rate of aneuploidy seen in embryos is relatively constant with advancing maternal age. *K. Richter[3], P. R. Brezina[1], A. T. Benner[2], L. Du[2], M.C. Gunn[2], B. Boyd[2], W.G. Kearns[4].* 1) Gynecology and Obstetrics, Division of Reproductive Endocrinology and Infertility, Johns Hopkins Medical Institutions , Baltimore, MD. U.S.A; 2) Genetics, Center for Preimplantation Genetics, LabCorp. Rockville, MD, U.S.A; 3) Research, Shady Grove Fertility Reproductive Science Center, Rockville, MD, U.S.A; 4) Gynecology and Obstetrics, Genetics, Johns Hopkins Medical Institutions, Center for Preimplantation Genetics, LabCorp Rockville, MD. U.S.A.

Background: We determined if patients undergoing in vitro fertilization (IVF) and preimplantation genetic screening (PGS) for RPL experienced increased rates of aneuploidy with increasing maternal age. **Materials and Methods:** A retrospective review was conducted of all embryos that underwent PGS by 23 chromosome SNP microarrays from 1/1/2010 to 1/25/2011. Patients underwent standard in vitro fertilization (IVF) and preimplantation genetic screening (PGS) due to primarily a history of > 2 spontaneous miscarriages. Embryo biopsy was performed at either the cleavage or blastocyst stage. Sample DNA was amplified and analyzed using HumanCytoSNP-12 DNA beadchips and GenomeStudio and KaryoStudio software. Parental DNA was analyzed and compared to embryonic cells to determine the presence of benign copy number variations. Embryos derived from parents with known translocations or inversions were excluded from the study. Data was split into four patient groups based on maternal age (<35, 35-37, 38-40, and >40). Binomial confidence intervals for proportions were calculated. **Results:** 1,902 embryos from 236 clinical IVF cycles were tested. Of embryos from women <35 years (N=594), 287 (48%) were aneuploid. Of embryos from women 35-37 years (N=268), 130 (49%) were aneuploid. Of embryos from women 38-40 years (N=626), 299 (48%) were aneuploid. Of embryos from women >40 years (N=414), 235 (57%) were aneuploid. No differences were observed among the rates of aneuploidy in the <35, 35-37, and 38-40 groups and these groups together had an average rate of aneuploidy of 48.1% [95% CI: 45.6%-50.7%]. The >40 group had an average rate of aneuploidy of 57% [95% CI: 52.0%-61.5%], significantly ($p=0.002$) higher than the pooled results of the <35, 35-37, and 38-40 groups. There was a high rate of morphologic fragmentation on some embryos which led to an approximate 9% of embryos with no molecular diagnosis obtained and this did not statistically differ between groups. **Conclusions:** Pregnancy loss rates increase steadily with advancing maternal age in the general population. Our data suggests that the underlying mechanisms that cause recurrent pregnancy loss may overshadow the gradual increasing rate of aneuploidy that accompanies increasing maternal age up to 40 years. After the maternal age of 40, age related aneuploidy begins to represent an additional pregnancy challenge for couples suffering from RPL.

1459W

Single nucleotide polymorphisms in angiogenesis regulating genes and the risk of preeclampsia and small for gestational age infants: evidence from parent-infant trios. *P.H. Andraweera[1,2], G.A. Dekker[1,3], S.D. Thompson[1], L.M.E. McCowan[4], R.A. North[5], C.T. Roberts[1] on behalf of the SCOPE consortium.* 1) Discipline of Obstetrics and Gynaecology, Research Centre for Reproductive Health, University of Adelaide, Adelaide, South Australia, Australia; 2) Human Genetics Unit, Faculty of Medicine, University of Colombo, Sri-Lanka; 3) Women's and Children's Division, Lyell McEwin Hospital, Elizabeth Vale, South Australia; 4) Department of Obstetrics and Gynaecology, University of Auckland, New Zealand; 5) Division of Women's Health, King's College London, London, UK.

Introduction: Altered endothelial integrity is demonstrated in pregnancies complicated by preeclampsia and small for gestational age infants (SGA). Both complications increase the risk of later life coronary artery disease and stroke. Angiopoietin-1(AGP1) is a pro-angiogenic growth factor and thrombospondin-1(TSP1) is an anti-angiogenic molecule. Two functional single nucleotide polymorphisms (AGP1 A1414T and TSP1 A2210G) are known to alter plasma AGP1 and TSP1 levels and also associate with stroke and coronary artery disease, respectively. We aimed to investigate these SNPs in preeclampsia and in SGA, in parent-infant trios. Method: We recruited 3234 nulliparous pregnant women, their partners and babies to a prospective multicenter cohort study in Adelaide and Auckland. Preeclampsia was defined as blood pressure／ 140/90 mmHg after 20 weeks gestation with proteinuria or any multisystem complication. SGA was defined as birthweight <10th customised centile adjusted for maternal height, weight, parity, ethnicity, gestational age at delivery and infant sex. Uterine and umbilical artery Doppler was performed at 20 weeks gestation. Average uterine artery resistance index >90th centile and the presence of bilateral notching of the uterine arteries were considered abnormal. DNA extracted from peripheral blood, buccal swabs, saliva or cord blood was genotyped using Sequenom MassARRAY. Logistic regression was used to compare the odds of preeclampsia and SGA between the genotype groups adjusting for potential confounders. Results: Amongst 2123 Caucasian pregnancies, 1185 (55.8%) were uncomplicated, 123 (5.8%) developed preeclampsia and 216 (10.2%) had SGA infants. Maternal AGP1 A1414T was associated with preeclampsia (aOR 3.2, 95% CI 1.5-6.4), increased mean uterine artery resistance index (p=0.029) and the presence of bilateral notching of the uterine arteries (p=0.017). Paternal (aOR 1.4, 95% CI 1.0-2.0) and neonatal TSP1 A2210G was associated with SGA (aOR 1.5, 95% CI 1.0-2.2). Maternal TSP1 A2210G approached significance for an association with SGA (p= 0.06, OR 1.3, 95% CI 0.9-1.9) and was associated with reduced maternal birthweight adjusted for gestational age at delivery (p=0.032). Conclusion: The SNPs previously shown as contributing to the risk of coronary artery disease and stroke are associated with preeclampsia and SGA infants. Inherited susceptibility to impaired endothelial integrity may underlie vascular disorders across the life course.

1460W

DNA Methylation Profile of Trisomy 22 Placentas. *J.D. Blair[1], D. Diego-Alvarez[1], M.S. Peñaherrara[1], D.E. McFadden[2], W.P. Robinson[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Department of Pathology, University of British Columbia, Vancouver, British Columbia.

Trisomy 22 (T22) is among the most common aneuploidies in clinically recognized pregnancies. All complete T22 end in miscarriage. The presence of an extra chromosome may affect gene expression directly through a dosage effect or indirectly through alterations in the epigenome such as DNA methylation. The placenta is the interface between the mother and fetus, thus changes in placental gene expression could have serious adverse effects upon the pregnancy. This study's intention is to investigate differences in DNA methylation in the placenta caused by the presence of T22. Genome-wide DNA methylation was assessed using the Illumina Infinium HumanMethylation27 BeadChip array, which analyzes 27, 578 CpG sites genome-wide. The samples tested were: first trimester T22 chorionic villi samples (n=5) and gestational age-matched chromosomally normal villi (n=7) as controls. Data analysis by Significance Analysis of Microarrays identified 48 differentially methylated candidate CpG sites, with a false discovery rate (FDR) of <10% and a Delta-) (absolute difference in average methylation) of >15%. Four of the top candidates (greatest Delta-) and 0% FDR) were chosen for follow up (SLC25A22, OR7A5, SLC6A11, CYP1A2). Pyrosequencing was used to validate the chip results in these genes using a larger sample size, (T22, n=6; FTC, n=24) while also surveying adjacent CpGs. Of the four sites examined, three, SLC25A22 (+12.9% greater average methylation in T22, p<0.001), SLC6A11 (-13.1%, p<0.001), and CYP1A2 (-28.1%, p<0.001) were all determined to have significant methylation differences between T22 samples and FTC samples. OR7A5 showed no significant methylation differences (p=0.52). The biological significance of these genes in miscarriage vary: The two SLC genes produce membrane-based ion transporters that are most prominent in the brain, while CYP1A2 is an estrogen metabolizer of particular interest to this project due to the complex hormonal regulation required for maintaining pregnancies. This study is important to gain insight into the specific epigenetic changes of T22 pregnancies, and more important, to develop T22 as a model to gain further insight into the genetic causes underlying a variety of pregnancy complications, including pregnancy loss.

1461W

Genomewide genetic analysis of spermatogenic failure. *D. Conrad[1], K.I. Aston[2], C. Ober[3], P.N. Schlegel[4], D.T. Carrell[2].* 1) Department of Genetics, Washington University School of Medicine, St Louis, MO, 63110, USA; 2) Andrology and IVF Laboratories, University of Utah School of Medicine, 675 Arapeen Drive, Ste 205, Salt Lake City, Utah, 84117, USA; 3) Department of Human Genetics, The University of Chicago, 920 E. 58th St. CLSC 425 Chicago, IL 60637, USA; 4) Department of Urology, Weill Cornell Medical College, New York Presbyterian/Weill Cornell Hospital, Starr 900, 525 East 68th Street, New York, NY 10065, USA.

The identification of multiple Y-linked loci responsible for spermatogenic failure is a canonical result of human genetics. Beyond these so-called Azoospermia Factor loci (AZF1 and AZF2) few convincing studies have shown a reproducible genetic basis for the disease elsewhere in the genome, despite the fact that spermatogenic failure has been observed in over 100 mouse knockout lines involving autosomal sequence. Here, we have used whole-genome SNP arrays to screen for evidence of dominant and recessive genetic factors influencing spermatogenic success in carefully selected individuals diagnosed with idiopathic non-obstructive azoospermia (n = 47) and severe oligozoospermia (n = 50), as well as normospermic individuals (n = 65) . We find reproducible signs of an increase in the amount of aneuploid sequence due to large (>100kb), rare CNVs on the X chromosome (204 total kb / sample vs 89 total kb / sample, p = 0.03) and autosomes (deletions only; 117 total kb / sample vs 56 total kb / sample, p = 0.02) in men with spermatogenic failure compared to normospermic individuals. A second signature, an enrichment of large chromosome segments apparently homozygous-by-descent (HBD), was identified in cases, supporting the existence of a recessive component to fertility, with as many as 5%-15% of cases showing patterns of HBD consistent with recent consanguinity. These genetic signatures of CNV burden and homozygosity are qualitatively similar between azoospermic and oligozoospermic samples, suggesting that it is useful to consider the two phenotypes as two regions along a continuous quantitative trait distribution, which has a polygenic basis waiting to be documented and integrated into clinical practice.

Self-Reported Reproductive Pathology in Women with Tuberous Sclerosis Complex. *E. Gabitzsch[1], M. Raia[1], M.K. Koenig[2], V.H. Whittemore[3], H. Northrup[1], S. Nader-Eftekhari[4], M.J. Gambello[1].* 1) Dept of Pediatrics, Division of Medical Genetics, University of Texas Health Science Center, Houston, TX; 2) Dept of Pediatrics, Division of Child and Adolescent Neurology, University of Texas Health Science Center, Houston, TX; 3) The Tuberous Sclerosis Alliance, Silver Spring, MD; 4) Dept of Obstetrics and Gynecology, Division of Reproductive Endocrinology, University of Texas Health Science Center, Houston, TX.

Tuberous Sclerosis Complex (TSC) is an autosomal dominant tumor suppressor disorder characterized by hamartomas in various organ systems. Inactivating mutations in either the TSC1 or the TSC2 gene cause most cases of TSC. Recently, the use of ovarian specific conditional knock-out mouse models has demonstrated a crucial role of the TSC genes in ovarian function. Mice with complete deletion of Tsc1 or Tsc2 showed accelerated ovarian follicle activation and subsequent premature follicular depletion, consistent with the human condition premature ovarian failure (POF). POF is defined in women as the cessation of menses before the age of 40 and elevated levels of follicle stimulating hormone (FSH). The prevalence of POF is estimated to be 1%, affecting a substantial number of women in the general population. Nonetheless, the etiology of most cases of POF remains unknown. Based on the mouse model results, we hypothesized that the human TSC1 and TSC2 genes are likely to be crucial for ovarian development and function. Moreover, since women with TSC already have one inactivated TSC gene, we further hypothesized that they may show a higher prevalence of POF or other reproductive pathology. To test this hypothesis, we surveyed 1000 women with TSC belonging to the Tuberous Sclerosis Alliance, a national support organization. We analyzed 182 questionnaires for information on menstrual and reproductive function, as well as TSC. This self-reported data revealed 8 women (4.4%) with possible POF, as determined by menstrual history report and additional supportive data in some of the respondents. This prevalence is much higher than 1% in the general population. Data from all women suggested other reproductive pathology associated with TSC such as a high rate of miscarriage (41.2%) and menstrual irregularity of any kind (31.2%). These results establish a previously unappreciated effect of TSC on women's reproductive health. Moreover, these data suggest that perturbations in the cellular pathways regulated by the TSC genes may play an important role in reproductive function.

Polymorphisms in LEP, LEPR, and PPAR. are associated with age at menarche and menopause in Korean women. *KZ. Kim[1], A. Shin[1], YS. Lee[2], SY. Kim[2], YJ. Kim[3], ES. Lee[4].* 1) Cancer Epidemiology Branch, National Cancer Center, Goyang-si, Korea; 2) Functional Genomics Branch, National Cancer Center, Goyang-si, Korea; 3) Cancer Early Detection Branch, National Cancer Center, Goyang-si, Korea; 4) Department of Breast and Endocrine Surgery, College of Medicine, Korea University, Seoul, Korea.

Purpose In this study, we explored the genetic effects of adiposity-related genes on timing of menarche and menopause, and total menstruation duration in lifespan among Korean women. Methods Ten single nucleotide polymorphisms (SNPs) in LEP, LEPR, and PPAR. genes were investigated to evaluate the genetic effects on menstruation among 400 breast cancer patients and 452 cancer-free healthy participants, from National Cancer Center in Korea. Associations between SNPs and age at menarche, age at menopause, and total menstruation duration were evaluated. Results Four SNPs (rs2167270 of LEP, rs7602 of LEPR, rs4684846, and rs3856806 of PPAR.) were associated with late menarche (⁄ 17 years old). Four SNPs (rs2167270, rs1801282 and rs2120825 of PPAR. , and rs3856806) were associated with early menopause (<40 years old) among postmenopausal women. In logistic regression model with covariate adjustment, subjects with GG genotype of rs7602 (LEPR) showed higher risk for late menarche (OR=1.91, 95% CI=1.07-3.40) compared to their counterpart with GA or AA genotypes. Although rs2167270 (LEP) was not associated with late menarche or early menopause, it was associated with total menstruation duration (<30 years; OR=0.56, 95% CI=0.31-0.99 for GG genotype) compared to GA or AA genotypes). Conclusion Our results propose that adiposity-related genes, LEP, LEPR, and PPAR. , might have a role in onset and cessation of menstruation, and total menstruation duration.

Risk assessment of ART and its related factors in the development of Prader-Willi syndrome. *K. Matsubara[1,2], N. Murakami[2], S. Sakazume[2], Y. Oto[2], T. Nagai[2], T. Ogata[1,3].* 1) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan; 2) Department of Pediatrics, Dokkyo Medical University Koshigaya Hospital, Koshigaya, Japan; 3) Department of Pediatrics, Hamamatsu University School of Medicine, Department of Pediatrics, Hamamatsu University School of Medicine, Hamamatsu, Japan.

To examine whether assisted reproductive technology (ART) and its related factors can be a risk factor for the development of Prader-Willi syndrome (PWS), we studied 74 Japanese PWS patients who were born during the years 1997-2008 when statistical data on ART are available in Japan. Of the 74 patients, seven were born after ART (six after ICSI and one after IVF). Molecular studies revealed underlying genetic causes in all patients, including the seven patients born after ART of whom two had deletion of the paternally derived 15q imprinted region and five had trisomy rescue type upd(15)mat (TR-upd(15)mat). The maternal ages at birth were increased in PWS patients conceived after ART (36-45 years), especially in those with TR-upd(15)mat (38-45 years), consistent with the notion that the advanced maternal age is a risk factor for the development of TR-upd(15)mat. The frequency of births after ART was significantly higher in PWS patients than in the general population ($P=2.2\times10^{-9}$), even after adjusting maternal ages (⁄ 35 years) ($P=5.4\times10^{-6}$). Among PWS patients, however, although the relative frequency of TR-upd(15)mat was significantly higher in patients conceived after ART than in those conceived naturally ($P=0.008$), it became non-significant after adjusting maternal ages (⁄ 35 years) between the two groups (P=0.22). The results imply that ART and/or ART-related parental and environmental factors can be a risk factor for PWS in general. In addition, the relative predominance of TR-upd(15)mat in patients born after ART is primarily ascribed to an ART-related maternal age factor rather than ART itself.

1465W

Apoptosis is not the mechanism for embryo self correction of aneuploidy at the blastocyst stage. *B.R. McCallie[1], R. Loper[2], H. Buttermore[2], W.B. Schoolcraft[1,2], M.G. Katz-Jaffe[1,2].* 1) National Foundation for Fertility Research, Lone Tree, CO; 2) Fertility Laboratories of Colorado, Lone Tree CO.

Meiotic and mitotic errors are both responsible for chromosomal abnormalities observed during the preimplantation stages of embryo development. Studies comparing the chromosome constitution of early human embryos across developmental days have indicated the potential for “self-correction”, especially in the cases of trisomic embryos during development to the blastocyst stage. On average 50% of cleavage stage aneuploid embryos on day 3 are re-evaluated as euploid blastocysts on day 5 of embryonic development. One proposed mechanism of “self correction” is the extrusion of the trisomic chromosome, which would be expected to result in uniparental disomy (UPD). However, studies have shown that 0% of “corrected” chromosomes displayed UPD. An alternative mechanism for “self correction” is apoptosis of aneuploid cells within the embryo, as it is already known that apoptosis is an active pathway in human blastocysts. The aim of this study was to evaluate the function of apoptosis in association with chromosome aneuploidy of the day 5 human blastocyst. Surplus cryopreserved human blastocysts were donated with consent and IRB approval by infertile couples for research. Individual blastocysts underwent a trophectoderm biopsy after thawing to remove 4-6 cells for comprehensive chromosome screening of all 23 pairs of chromosomes using quantitative real-time PCR. Total RNA was isolated from individual euploid (n=8) and aneuploid (n=8) blastocysts using the Arcturus PicoPure RNA isolation kit (Applied Biosystems) followed by reverse transcription prior to pre-amplification with Taqman assays (Applied Biosystems). Quantitative real-time PCR was performed in triplicate for pro-apoptotic genes (BAX, BAD, BAK and BID), as well as for anti-apoptotic genes (BCL-2, BCL-W, BCL-XL and MCL-1), relative to two constant internal housekeeping genes; PPIA and ACTB. Results showed that all pro-apoptotic and anti-apoptotic genes were expressed in each of these 16 human blastocysts. Using GeneSpring GX11 software (Agilent Technologies) for statistical analysis, no significant differences in gene expression were observed for any of the pro-apoptotic or anti-apoptotic genes between euploid and aneuploid blastocysts. In conclusion, apoptosis is an active pathway at the blastocyst stage in human embryos. However, this pathway does not appear to be responsible for degradation of aneuploid cells on day 5 of embryonic development or embryo “self correction”.

1466W

PARP-3 polymorphism of an ADP-ribosyltransferase 3 (ART3) is associated with reduced sperm count in Czech dysfertile men. *P. Norambuena, P. Krenkova, A. Stambergova, M. Macek Jr., M. Macek Sr.* Dept. Biology and Medical Genetics , Charles Univ Prague- UH Motol, Prague, Czech Republic.

Poly(ADP-ribose) polymerase 3 (PARP-3) is a newly characterized PARP interacting with DNA damage response proteins, suggesting its contribution to the DNA damage response and epigenetic modification leading to gene silencing (1). The ART3 protein is expressed in testes in particular in spermatocytes, indicating that it exerts specific function only required at a particular stage of spermatogenesis (2). PARP-2 gene polymorphism T>A (SNP1-SNP4) is significantly associated with azoospermia secondary to meiotic arrest in Japanese men (3). The aim of our study was ascertainment of association of the G>A SNP rs6836703 polymorphism with impairment of spermatogenesis in Czech males. We genotyped DNA samples of 257 fertile men with proven paternity and 98 dysfertile men with the azoospermia, 29 with severe oligospermia (sperm count <5x106/ml) and with oligospermia (5-15.106/ml). The G>A polymorphism (rs6836703) was examined by high resolution melting of small amplicons. PCR was performed using the LightCycler480 Real-time PCR system. Melting profiles “G/G”, “G/A” and “G/A” were determined. Association studies were analyzed by odds ratio and chi-square test, where p-values >95 were considered significant. The “G”allele frequency in fertile males was 442/514 (86%), while for allele “A” 72/514 (14%). Azoospermic males did not differ from controls (31/36 - 86% of “G” alleles, 14% for “A” alleles in 5/36). In males with severe oligospermia only a tendency towards higher frequency of the “A” allele was observed (p=0.08; 22.4% versus 14% in controls). Highly significant increased frequency of allele “A” was revealed in oligospermia (p=0.004; 25.5% versus 14% in controls). Our original results suggest that PARP-3 gene polymorphism is associated with milder impairment of spermatogenesis in contrast to PARP-2 polymorphism associated with azoospermia (3). Our finding might also reflect the different sensitivity to epigenetic influences, due to the presumed PARP-3 impact on respective epigenetic modifications (1). In conclusion, the increased frequency of the “A” and of the “AA” genotype of the rs6836703 G>A PARP-3 polymorphism is associated with milder impairment of spermiogenesis in Czech dysfertile men. (1) Rouleau M et al. J Histochem Cytochem 2009; 57(7):675-685; 2) Friedrich M et al. Asian J Androl 2006; 8(3):281-287; (3) Sakugawa N et al. J Assist Reprod Genet 2009; 26(9-10):545-552. 1467W

Differential expression of NELF splice variants in human and mouse immortalized GnRH neurons. *S.D. Quaynor[1,2], L.Y. Goldberg[1,2], H.G. Kim[1,2,3], L.P. Chorich[1,2,3], L.C. Layman[1,2,3].* 1) Institute of Molecular Medicine; 2) Section of Reproductive Endocrinology, Infertility, & Genetics, Department of Obstetrics & Gynecology, and; 3) Neuroscience Program, Georgia Health Sciences University, Augusta, GA.

Idiopathic hypogonadotropic hypogonadism (IHH) results from deficient gonadotropin-releasing hormone (GnRH) secretion or action. Kallmann Syndrome (KS) is due to migration failure of GnRH and olfactory neurons during development, resulting in IHH with anosmia. Nasal embryonic LHRH factor (NELF) is a nuclear protein that was differentially isolated from migratory GnRH neurons and mutations have been identified in IHH/KS. We previously found that although Nelf mRNA expression did not differ in mouse immortalized GnRH neuronal cells, NELF protein expression was greater in migratory compared with postmigratory cells. The goal of this study was to determine if mRNA/protein expression discordance was due to differential expression of splice variants (sv). We hypothesize that migratory GnRH neuronal cell lines (mouse GN11 and NLT; human FNCB4-hTERT) will have a different expression pattern of sv than postmigratory GT1-7 cells. PCR products from RT-PCR were cloned and individual colonies were analyzed by denaturing gradient gel electrophoresis (DGGE) and DNA sequencing. Preliminary results indicate five splice variants in mouse cells, and two splice variants in human cells. Human FNCB4-hTERT and all three immortalized mouse GnRH cells predominantly express variant 2 ranging from 72-78% in the cell lines. In addition, DGGE findings showed the presence of splice variants, which differed in specific cell types (pre-migratory and post migratory immortalized mouse GnRH neurons). Finally , we identified 3 novel splice variants in the immortalized mouse GnRH neuronal cells lines which have not been reported. Differential Nelf mRNA splice variant expression could play a role in GnRH neuron migration and/or function as well as in the human phenotype of IHH/KS.

High genetic heterogeneity in the causation of moles in patients with no NLRP7 mutations. *R. Reddy[1], J. Qian[1,2], R. Bagga[3], M.C Addor[4], J. Majewski[1,5], R. Slim[1].* 1) Department of Human Genetics and Obstetrics Gynecology, McGill University Health Centre, Montreal, Quebec, Canada; 2) Women's Reproductive Health Laboratory, Women's Hospital, Zhejiang University School of Medicine, Hangzhou, China; 3) Dept of Obstetrics & Gynecology, Post Graduate Institute of Medical Education and Research (PGIMER), Chandigarh, India; 4) Division autonome de Genetique Medicale CHUV - 1011 Lausanne / Switzerland; 5) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada.

Background : Molar pregnancies are characterized by the absence of embryo and hydropic degeneration and proliferation of chorionic villi (OMIM 231090). Molar pregnancies affect 1 in 1000 pregnancies in North America and their incidences are much higher in Asia. To date, NLRP7 is the only known gene for hydatidiform moles (Murdoch et al., 2006). Genetic heterogeneity in the causation of recurrent moles has been documented based on the absence of linkage to 19q13.4, the region containing NLRP7, in one family (Slim et al., 2005) and the absence of mutations in this gene in several families. Therefore, more than one gene are involved in the causation of molar pregnancies. **Objective:** The goal of this study is to identify a second gene responsible for the causation of recurrent moles in cases with no NLRP7 mutations. **Methodology and Results:** To achieve this goal, a microarray SNP (Illumina 610 Quad) analysis had been performed on 8 affected patients and their unaffected relatives from 6 cases with no mutations in NLRP7. The Illumina data didn't show a common halpotype or homozygosity for the same chromosomal region in more than two patients indicating the high genetic heterogeneity in the causation of moles in these patients. Mutations in NLRP7 can explain 80-90% of the genetic cause of familial molar pregnancies, a situation analogous to Breast cancer where mutations in BRCA1 and BRCA2 explain 90% of the genetic heritability of Breast cancer while several other genes such as ATM, PTEN, CDH1, CHEK2 and p53 explain only 10% of the genetic heritability. Our Illumina data indicate the presence of more than one gene responsible for molar pregnancies in the small number of analyzed cases. Next generation Exome sequencing is ongoing on these patients and this approach may overcome the high genetic heterogeneity in patients with no NLRP7 mutations and lead to the identification of one or several new genes for recurrent moles.

Molecular study and familial pattern of internal apoptotic pathway BAX and BCL2 genes and mitochondrial genome in idiopathic repeated pregnancy loss. *S.M. Seyedhassani[1,2], M. Houshmand[1], A. Aflatoonian[2], S.M. Kalantar[2], G. Modabber[1].* 1) National institute of genetic engineering and biotechnology, Tehran, Iran; 2) Research and clinical center for infertility, Yazd, Iran.

Introduction: About 1 in 300 couples and 0.5-2% of women are involved in repeated pregnancy loss (RPL). Various etiological factors involve in RPL and the main part of them remains unknown. Among them the genetic factors are important. The apoptotic changes and the aberrant expression of many genes including apoptotic related genes were seen in RPL. Material and methods: Familial pedigrees of 335 consecutive couples suffering from RPL were initially evaluated at a primary stage. Among them, 96 women were screened as idiopathic at reproductive age. Molecular genetic variations in internal apoptotic related genes BAX, BCL2 and mitochondrial genome were investigated in comparison to control group. Results: The evaluation of familial pedigree of 335 RPL couples showed 120 cases of RPL in female relatives and 76 cases in male relatives. Other families with RPL were seen in two or three consecutive generations in 15.6% of female relatives. At least two cases of RPL in other consanguineous marriages were observed in 4.2%. There were familial marriages in 51.6% of RPL women and 21.8% of control group (P=0.0003). The mean of the D-loop mutations was 8.79 and 4.90 in RPL and control group respectively (ANOVA=0.0001). Among them, 22 mutations were significant in RPL group and the insertion of C in nucleotide 114 was novel. The G90C variation of BAX gene and the mean of mtDNA mutations were significant in second familial pattern consisted of familial marriages with RPL. Discussion: The high frequency of RPL in maternal pedigree implicates the maternal background of the disorder. On the other hand, there were higher rate of familial repeats of abortion, RPL repeats and consanguineous marriage in RPL pedigrees. Such evidences show the genetic background. However, pedigree analysis has critical role in the approach of RPL women. Our result indicates a supportive role of RPL for A(-179)G mutation in Bax gene, but two polymorphisms, G90C and G95A found in exon 1, provide a susceptible background for promoting miscarriages. These variations can have important roles in RPL, independently or as a part of haplogroups. An obvious role of inheritance and genetic background are detected by analysis of familial patterns.

1470W

Are ABO & Rh Blood Groups New Genetics Risk Factors for Endometriosis? *SMB. Tabei[1], K. Daliri[1], P. Rostami[2], A. Nariman[1].* 1) Department of Medical Genetics, Medical School, Shiraz University of Medical Sciences, Zand Street, Shiraz, Iran; 2) Dr. Rostami Infertility Center, Shiraz, Iran.

BACKGROUND: Endometriosis is a complex gynecologic disorder with a particular genetic background with recurrence risk 5-7% for first-degree relatives. It has been estimated that endometriosis occurs in roughly 5-10% of women in reproductive age and up to 50% of women with infertility. Up to now, associations between different malignancies and main blood groups are documented in the literature but, explanation for these associations is still unknown. A current hypothesis is increasing and facilitation of tumor cellular mobility by these antigens. ABO and Rh genes are located on 9q34and 1p36 chromosome respectively, therefore, these main blood groups may be assumed as important genetic risk factors for tumor or tumor-like diseases. Endometriosis shows some malignancy behaviors such as local invasion and genetic changes. Motivated by evidence that, ABO and Rh distribution in patients of United States, Turkey and South Korea have been revealed a controversial results we designed a case-control study in Southern population of Iran. Women with endometriosis also were divided into two groups fertile an infertile. METHODS: This case- control study was carried out, retrospectively. We used donor database of Shiraz Blood Transfusion Organization as control and medical records of 470 patients who have been diagnosed as endometriosis by laparoscopy and confirmed by pathology analysis who have been referred to Zeinab Hospital and Dr Rostami Infertility Center, Shiraz, Iran as cases. Statistical methods included chi square by Medcalc software. RESULTS And DISCUSSION: Our population is neighbor to Turkey (an Asian country) therefore, as we expected our results were similar to Demir et al in Turkish population, though Rh positivity in Turkish patients showed a significant difference compared with control. No significant difference was revealed between patients and control groups (ABO blood groups $P > 0.05$, Rh blood groups $P > 0.05$, 95% CI). Moreover, no significant difference was detected in ABO and Rh blood groups in women with endometriosis according to reproductive status (fertility or infertility). In conclusion, based on our results in Southern population of Iran and Demir et al from Turkey, ABO blood groups are not new genetics risk factors for endometriosis though Matalliotakis et al and Kim et al found significant relationship in USA and South Korea population, respectively.

Mutation in the *SYCP3* gene identified in a woman with recurrent pregnancy loss affect the synaptonemal complex conformation at meiotic prophase I. *M. Tsutsumi, H. Kogo, H. Inagaki, T. Ohye, H. Kurahashi.* Fujita Health University, Toyoake, Japan.

Meiotic chromosomal nondisjunction causes aneuploid conceptuses, and most of them result in early pregnancy loss. Events occurring in prophase during meiosis I are important for proper chromosome segregation. SYCP3 is one of the essential components of the chromosomal axes in the synaptonemal complex that is central to the interaction of homologous chromosomes called synapsis during prophase I. We had previously identified a heterozygous mutation in the *SYCP3* gene from a woman with recurrent pregnancy loss. This mutation was predicted to produce C-terminally truncated mutant SYCP3 protein that inhibited fiber formation by normal SYCP3 in a dominant negative manner when coexpressed in COS-7 cells. However, the behavior of the mutant protein in meiotic cells had been unclear.

In this study, we examined the effects of the mutant protein to meiotic chromosomes using a gene transfer system into mouse oocytes at prophase I combined with *in vitro* organ culture of ovaries. In brief, fetal mouse ovaries at 13 to 15 dpp were injected with a plasmid DNA carrying an epitope-tagged normal or mutant cDNA of the *Sycp3* gene with meiosis-specific promoter. The plasmids were introduced into oocytes by electroporation, and ovaries were *in vitro* cultured on the membrane insert for two to four days and analyzed by immunofluorescence. Chromosomal spreads of oocytes were prepared to analyze chromosomal axes and synapsis. When normal SYCP3 was expressed, the localization of the epitope-tagged SYCP3 was similar to that of endogenous SYCP3, and synapsis between homologous chromosomes marked with SYCP1 was normal at pachytene stage. When mutant was expressed, the epitope-tagged mutant SYCP3 also colocalized with endogenous SYCP3 along the chromosome axis, in some instances, intermittently. The chromosomal axes incorporated with more mutant SYCP3 appeared thicker and tended to show less synapsed. These data suggest that the mutant SYCP3 may disturb or delay the formation of synapsis. It is possible that, in the presence of mutant SYCP3, chromosomal axes alters its fine conformation and formation of synapsis or its robustness might be affected. Defects in synapsis may impair crossover events, which will cause nondisjunction in meiosis I and produce oocytes with aneuploidy leading to recurrent pregnancy loss.

1472W

ASSOCIATION OF CYTOKINE GENE POLYMORPHISMS AND RECURRENT MISCARRIAGES. *A. Kaur, N. Sudhir, A. Kaur.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Cytokine gene polymorphisms in the promoter regions of TNF-(and IL-10 are associated with recurrent miscarriages (RM). The aim of present study was to investigate the association of the IL-10 -592C/A and TNF-(-308 G/A, promoter polymorphisms among women with at least three consecutive miscarriages. Among 80 couples studied, chromosomal anomalies were seen in 4 subjects (3 males and 1 female). Infections with TORCH test followed by structural uterine anomalies, endocrine defects and blood group incompatibility in couples emerged as important factors in the miscarriage cases. After cytogenetic investigations and analysis of clinical reports, genotyping was done in 50 women with RM and 50 controls for IL-10-592C/A and TNF-(-308G/A promoter polymorphism to see the association of these loci with miscarriages. Patients having anatomical abnormalities, hormonal disorders, hyperprolactinemia, erythroblastosis fetalis, chromosomal aberrations and TORCH infections were excluded from the polymorphism study. Allele frequencies were calculated for each genotype and the difference in allele frequencies between recurrent miscarriage and control women by using a Pearson $\chi 2$ test (SPSS Inc.10, Chicago, IL, USA) and expected genotype frequencies were calculated from the allele frequencies under the assumption of Hardy-Weinberg equilibrium. The mean maternal age was 25.9 years and that of controls was 26.4 years, mean miscarriages were 3.39 and mean gestational age was 3.6 months. IL-10-592C/A promoter polymorphism in the present case-control study did not show any association with the recurrent miscarriages (Chi-square value for genotypes = 0.491 and for alleles = 0.021 and $P > 0.05$). Statistical analysis further revealed that TNF-(-308G/A promoter polymorphism in the present sample was not associated with recurrent miscarriages (Chi-square value for genotypes = 1.413 and for alleles = 1.070 and $P > 0.05$). The results indicated absence of any association of a particular genotype or allele of IL-10-592C/A and TNF-(-308G/A promoter polymorphism with the recurrent miscarriages. The study is being carried out on a larger sample in our region.

Analysis of sperm telomeric length in idiopathic infertile men. *J. Thilagavathi, S. Venkatesh, M. Kumar, R. Kumar, R. Dada.* All India Institute of Medical Sciences, New Delhi, India.

Introduction: Telomeres are non-coding repeat hexanucleotide sequences that protect the ends of chromosomes and preserve the genome integrity within the cells. Telomeres shorten during each cell division in the absence of telomerase. When telomere length becomes critically short, cell senescence occurs. Telomeres in germline cells are balanced with each cell division and very less is known about its length in sperm and its association in male reproduction. Aim: The current study was aimed to estimate telomere length in the sperm from both infertile and control (fertile) men. Methods: Both infertile men (n=17) and controls (n=12) were evaluated for standard semen analysis and sperm DNA were isolated by separating the sperm from the semen by gradient separation technique. The average telomere length from the sperm DNA was quantified using a validated quantitative (Q-PCR) based assay. This method measures the average ratio of telomere repeat copy number to a standard single copy gene (36B4) copy number (T/S ratio) in each sample. Results: Infertile men had significantly ($P<0.0001$) lower sperm count and sperm motility compared to controls. Similarly normal morphology was also found to be significantly ($P<0.001$) lower in infertile men compared to controls. Relative quantification analysis showed that T/S ratio was significantly ($p<0.05$) lower in sperm samples from infertile men compared to controls (0.637 (0.617, 0.684) Vs 0.653 (0.631, 0.657). Conclusion: Altered telomere length is associated with many diseases however its role in male infertility is not explored. Our study for the first time confirms shortened telomere length in the sperm of infertile men. Therefore sperm telomere has functional role in fertilization apart from other disorders (cancer, and ageing) and needs to be confirmed with large number of samples.

Genetic architecture of carotid artery intima-media thickness in Mexican Americans. *P.E. Melton, J.E. Curran, M. Carless, M.P. Johnson, T.D. Dyer, J.W. MacCluer, E.K. Moses, H.H. Goring, J. Blangero, L.A. Almasy.* Texas Biomedical Research Institute, San Antonio, TX.

Intima-media thickness (IMT) of the common and internal carotid arteries is a well established heritable risk factor for atherosclerosis and stroke. Often IMT is measured as the average of these two arteries yet they are believed to result from separate underlying biological mechanisms. The aim of this study was to conduct a family-based genome-association study (GWAS) in Mexican Americans to identify genetic polymorphisms influencing IMT and to determine if different carotid artery segments are influenced by different genetic components. IMT for the common and internal carotid arteries was determined through B-mode ultrasound in participants from the longitudinal San Antonio Family Heart Study (SAFHS). A GWAS utilizing 931,219 single nucleotide polymorphisms (SNPs) from Illumina (San Diego, CA) microarrays was undertaken with carotid artery IMT phenotypes utilizing an additive measured genotype model after adjustment for non-independence of families using kinship variance components. Among 29 families, 763 participants had IMT measured. Heritability estimates were 0.26 (±0.08) for average common carotid IMT and 0.45 (±0.07) for average internal carotid IMT. The genetic correlation between the common and internal carotid artery IMT was 0.51, indicative of some shared genetic components but also may suggest the potential for different contributing underlying biological pathways. The most robust association was detected for two SNPs (rs16983261, rs6113474, p=1.60x10-7) in complete linkage disequilibrium on chromosome 20p11 for the internal carotid artery near wall. The nearest gene to these SNPs is paired box 1 (PAX1). Heterozygotes with the minor allele (T) for these SNPS had significantly lower average (Δ=0.23 mm) internal carotid artery IMT. We also identify suggestive associations near genes (NAP5, EXOC3L2) that have shown genetic relationship with neurodegenerative disorders, including Alzheimers Disease, and schizophrenia. Further analysis of these results is being undertaken with full-genome sequencing in SAFHS participants. This study represents the first large scale GWAS of IMT in a non-European population and identified several novel loci. We also do not detect any common GWAS signals between common and internal carotid arterial segments indicating that they may not be completely influenced by shared biological components.

326T

New SLC10 mutations found in a Japanese patient with arterial tortuosity syndrome. *T. Morisaki[1,2], Y. Honda[3], A. Yoshida[1], K. Fujii[3], Y. Kohno[3], H. Morisaki[1].* 1) Dept Bioscience & Genetics, Natl Cerebr Cardiovasc Ctr Res Inst, Suita, Osaka, Japan; 2) Dept Mol Pathophysiol, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan; 3) Dept Pediatircs, Chiba Univ Grad Sch Med, Chiba, Japan.

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive connective tissue disorder characterized by tortuosity and elongation of the large and medium-size arteries, aneurysms or vascular dissection. ATS is caused by mutations in SLC2A10 gene, encoding for the facilitative glucose transporter 10 (GLUT10). So far, more than 30 families were reported to have SLC2A10 mutations world-wide, whereas no Japanese patient was reported. Here, we present the clinical and molecular characterization of a novel Japanese ATS patient. A 2 year-old boy was referred for virus infection and noticed to have symptoms for connective tissue disorders as well as annuloaortic dilatation and aortic tortuosity. There was no family history for similar symptoms nor parental consanguinity. Inguinal and diaphragmatic hernias and funnel chest were noted during his neonatal period. No developmental abnormality was observed so far. His skin was found to be loose and hyperextensible. Echocardiography showed normal aortic valve with three leaflets without stenosis or regurgitation, along with annular dilatation (the valve ring diameter:17 mm; sinus Valsalva diameter:27 mm; ST junction diameter: 16 mm). Also, he was found to have prominent tortuosity and elongation in both aorta and medium-sized arteries including cervical, intracranial, abdominal and iliac arteries. Based on his hyperextensible skin and arterial tortuosity, genetic analysis for SLC2A10 was performed and revealed that he has 2 novel point mutations in the exon 2 of this gene (p.Arg231Gln(c.692G>A) and p.Tyr239X(c.417T>A)). Genetic study of his parents revealed that the p.Arg231Gln mutation was derived from his father and the p.Tyr239X mutation from his mother and he was a compound heterozygote of these mutations. No mutation was identified in FBN1, TGFBR2, TGFBR1, ACTA2, or COL3A1 gene. This is the first report of a Japanese patient for ATS with compound heterozygotes of new SLC2A10 mutations.

327T

Distinct phenotypic differences between *TGFBR1* and *TGFBR2* gene mutation carriers in Loeys-Dietz syndrome. *H. Morisaki[1], A. Yoshida[1], H. Ogino[2], T. Morisaki[1,3], LDS clinical research group in Japan.* 1) Dept Bioscience & Genetics, NCVC Res Inst, Suita, Osaka, Japan; 2) Dept Cardiovascular Surgery, Natl Cerebr & Cardiovasc Ctr,Suita, Osaka, Japan; 3) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci, Suita, Osaka, Japan.

Loeys-Dietz syndrome (LDS) is a systemic connective tissue disorder characterized by vascular and skeletal manifestations caused by mutations in *TGFBR1* or *TGFBR2* genes. It is generally considered that there are no phenotypic differences between patients with mutations in *TGFBR1* and those in *TGFBR2*, and the majority of LDS patients harbor mutations in *TGFBR2* gene. The nationwide research program to study clinical spectra of LDS in Japan started in 2009. Patients were recruited for genetic testing when their dysmorphic features or cardiovascular manifestations suggested of LDS. Fifty genetically-diagnosed patients are currently registered and complete clinical records were available from 40 of them. Using this cohort, we analyzed the phenotype-genotype correlations in Japanese LDS patients. The study cohort consisted of 18 *TGFBR1* mutation carriers (14 probands) and 22 *TGFBR2* mutation carriers (18 probands). Significant differences between patients with *TGFBR1* mutations and those with *TGFBR2* mutations were observed in regard to age at initial diagnosis of probands (31.2y vs. 10.1y, p=0.0001), first recognizable manifestation (skeletal / cardiovascular)(1/17 vs. 14/8, p=0.0002), cleft palate/abnormal uvula (22% vs. 73%, p=0.0015), hypertelorism (61% vs. 91%, p=0.02), strabismus (6% vs. 36%, p=0.039), positive wrist- & thumb sign (11% vs. 45%, p= 0.018), pectus deformity (6% vs. 32%, p=0.04), talipes equinovarus (0% vs. 23% , p=0.03), joint laxity (17% vs.73%, p=0.0004), and fulfillment of former Ghent MFS diagnostic criteria(11% vs.50%, p=0.009). Aortic involvement (83% vs. 91%, p=0.47) and tortuosity of cervical arteries (56% vs. 59%, p=0.82) were observed equally. In general, patients with *TGFBR2* mutations were diagnosed at younger age, usually suspected of Marfan-related disorders, showed more distinct dysmorphic features. In contrast, those with *TGFBR1* mutations are diagnosed at older age by cardiovascular event like AAE or TAAD, presenting less skeletal features. In this study, we found higher percentage of *TGFBR1* mutation probands (44%) compared to previous report (2-25%). This discrepancy may be explained by the difference in patient recruitment procedure, since initial diagnoses those with *TGFBR1* mutations were young-onset TAAD or familial TAAD in most of the cases. Since the risk of aortic involvement was similar between both genotypic groups, LDS should be considered as differential diagnosis of all familial TAAD patients.

Coronary artery disease is associated with altered gene expression in human left ventricular myocardium. *J.D. Muehlschlegel[1], D. Christodoulou[2], K.Y. Kiu[1], J. Gorham[2], G. Lee[1], S.K. Shernan[1], S.F. Aranki[3], C.E. Seidman[2], J.G. Seidman[2], S.C. Body[1].* 1) Anesthesiology, Perioperative and Pain Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA. 75 Francis St, CWN L1 Boston, MA 02115; 2) Department of Genetics Harvard Medical School NRB, 77 Avenue Louis Pasteur Boston, MA 02115; 3) Department of Surgery Division of Cardiac surgery Brigham and Women's Hospital 75 Francis St Boston, MA 02115.

Introduction: Cardiopulmonary bypass (CPB) with cardioplegic arrest is associated with ischemia leading to metabolic substrate depletion, reperfusion injury, apoptosis and necrosis. We assessed differences in gene expression in left ventricular (LV) tissue samples from patients with and without coronary artery disease (CAD) undergoing aortic valve replacement (AVR) with CPB prior to, and after cardioplegic arrest using whole-genome transcriptional profiling. Methods: Apical punch biopsies from the LV vent placement site were taken from 14 patients (8 with CAD, 6 controls without CAD) undergoing AVR with CPB at two time points; immediately after aortic cross clamping (pre-ischemia), and immediately before aortic cross clamp removal (post-ischemia). The Illumina HiSeq Analysis platform was used to quantify genome-wide mRNA expression. Lists of genes expressed differently in pre- vs. post ischemic tissue from patients with and without CAD were identified. These gene lists were subjected to Ingenuity Pathway Analysis 9.0 (IPA; Ingenuity Systems) to identify regulatory networks operant in these hearts. Multivariate modeling was used to adjust for age, sex and aortic cross clamp duration. Results: Median duration of aortic cross clamping was 119 mins and 80 mins for patients with and without CAD respectively. The top network represented genes involved in cellular growth and proliferation, cell death, and cancer. The majority of these genes were significantly up-regulated in CAD patients compared to no-change or down-regulated in non-CAD controls. Discussion: The human LV exhibits significant, yet variable changes in gene expression in response to ischemia during CPB depending on the presence of or absence of CAD. Variations in these pathways represent important contributors to the pathophysiology of ventricular ischemia, and thus, may have help guide efforts to reduce myocardial damage during surgery as well as to serve as potential biomarkers of injury.

329T

Identification of a new chromosomal locus for a mutation causing Left ventricular non-compaction with ventricular tachycardia cardiopathology. *E. Muhammad[1], A. Levitas[2], V.C. Sheffield[3], R. Parvari[1,4].* 1) Developmental Genetics, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 2) Soroka Medcal Center, Ben Gurion University of the Negev, Beer Sheva, Israel; 3) University of Iowa, Iowa City, IA, United States; 4) National Institute of Biotechnology Negev, Beer Sheva, Israel.

Structural and functional disorders of the heart are important causes of morbidity and mortality. Three Bedouin patients at ages 14-18 years of a single large consanguineous Bedouin family presented with Left ventricular non-compaction and sustained Ventricular Tachycardia. They were evaluated by Echocardiography which showed severe left side enlargement, severely depressed left ventricular (LV) function with focal lacunas in the LV free wall, but normal origin of the coronary artery. The 2 older patients were treated with recurrent electrical cardio version and intravenous administration of amiodarone and on discharge have undergone implantable cardioverter-defibrillator (ICD) implantation. The recessive pattern of inheritance in the consanguineous family suggested homozygosity of the mutation inherited from a common founder. We have performed homozygosity mapping using the affymetrix SNP 5 array on the patients and found a single large chromosomal block of homozygosity on chromosome 11q24 shared by all of them. Verification of this block with VNTR markers in all available family members proved linkage. The Lod score analysis, under the model of a recessive trait with full penetrance, using the PedTool server, was 2.46 for 2 point and 4.59 for the multipoint analysis. This chromosomal locus does not contain any of the known genes causing this disease; efforts are now being done to identify the mutated gene.

330T

Association of MTHFR C677T Gene Polymophism in Children with Congenital Heart Defects. *H.P. Mundluru[1], S. Sunayana Begum[1], K. Srujana[1], K. Nageswar Rao[2], V. Sreedevi[1], G. Sandhya Devi[3], K. Vasudevan[2], K. Manohar[1], A. Jyothy[1].* 1) Genetic Toxicology, Institute of Genetics, Hyderabad, Andhra Pradesh, India; 2) Department of Pediatric Cardiology, Care Hospital, Banjara hills, Hyderabad; 3) Indo- American Cancer Hospital, Banjara Hills, Hyderabad.

Congenital heart defects (CHD) are the most common type of birth defects affecting 1% of new born children and results from incomplete development of the heart during the first 6 weeks of pregnancy. Shortness of breath, cyanosis, heart murmur, respiratory infections and stunted growth are the symptoms of congenital heart defects. The human body needs folate to synthesize, repair, and methylate DNA as well as to act as a cofactor in biological reactions. Maternal multivitamin supplementation containing folic acid reduces the risk of neural tube defects, and evidence suggests that it may be associated with other reproductive outcomes, including congenital heart defects. Methylenetetrahydrofolate reductase (MTHFR) catalyses the reduction of 5,10-methylenetetrahydrofolate into 5-methyltetrahydrofolate, which is the circulating form of folate. 5-Methyltetrahydrofolate donates its methyl group to homocysteine, forming methionine and tetrahydrofolate. In the MTHFR enzyme, a common C→T substitution at position 677 (referred to as 677T) exists, resulting in a substitution of alanine to valine, causing impaired folate binding and reduces the activity of MTHFR enzyme. In the present investigation 45 children with congenital heart defects and 45 subjects belonging to the same age, sex and socio economic status were studied. The prevalence of heterozygotes were observed to be higher in patients when compared to controls. The study indicated that the heterozygous condition of MTHFR gene may be associated with the disease condition.

The contribution of biogeographical ancestry and polymorphisms in the *CETP* and *LIPC* genes to dyslipidemia in HIV positive men receiving highly active anti-retorviral therapy. *M. Nicholaou, J. Martinson, L. Kingsley, Multicenter AIDS Cohort Study (MACS).* Infectious Diseases & Microbiology, University of Pittsburgh, Pittsburgh, PA.

Highly active anti-retroviral therapy (HAART) has been successful in delaying the progression to AIDS in HIV infected individuals. Exposure to HAART can result in metabolic side effects such as dyslipidemia in a subset of treated patients. We used a custom designed Illumina GoldenGate Genotyping assay to investigate the genetic susceptibility to dyslipidemia attributed to HIV infection and HAART treatment. We performed a literature search to identify SNPs that had been previously associated with dyslipidemia and/or cardiovascular disease (CVD) in the general population. 280 clinically relevant SNPs and 1,132 TagSNPs covering 75 gene regions were included on the GoldenGate array. 1,945 men were selected from the Multicenter AIDS Cohort Study (MACS) for genotyping and phenotypic analysis of serum lipid levels. This population was stratified by HIV/HAART status and biogeographical ancestry using a panel of 124 Ancestry Informative Markers (AIMs). Among men of European ancestry, those who were infected with HIV and receiving HAART had significantly lower serum low-density lipoprotein cholesterol (LDL, $P = 1.90 \times 10^{-4}$) and high-density lipoprotein cholesterol levels (HDL, $P < 1.00 \times 10^{-7}$), with significantly higher serum triglyceride (TRIG, $P < 1.00 \times 10^{-7}$) levels compared to HIV/HAART (-/-) controls. Among men of mixed African and European ancestry, those who were HIV/HAART (+/+) had significantly lower LDL ($P = 1.80 \times 10^{-4}$) levels compared to HIV/HAART (-/-) controls. Four SNPs; rs1532624 ($P = 1.66 \times 10^{-5}$), rs1532625 ($P = 2.36 \times 10^{-5}$), rs711752 ($P = 4.48 \times 10^{-5}$), and rs708272 ($P = 4.59 \times 10^{-5}$), located in the *CETP* gene region on chromosome 16 had statistically significant associations with serum HDL levels in HIV/HAART (+/+) European men. One SNP, rs261334 ($P = 6.53 \times 10^{-6}$), located in the *LIPC* gene region on chromosome 15 was associated with serum LDL levels and another SNP, rs4783961 ($P = 9.83 \times 10^{-6}$) located in the *CETP* gene region, was associated with HDL levels in HIV/HAART (+/+) men of mixed African and European ancestry. These results show that HAART-associated dyslipidemia varies depending on biogeographical ancestry and implicates two genes associated with serum lipid levels in these patients.

***Il-6* and *TNF* variants interact with air pollution in modulating inflammatory blood markers and MI risk.** *F. Nyberg[1,2], S. Panasevich[1], K. Leander[1], P. Ljungman[1,3], T. Bellander[1], U. de Faire[1,4], G. Pershagen[1,5].* 1) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) AstraZeneca R&D Mölndal, Mölndal, Sweden; 3) Department of Cardiology, South Hospital, Stockholm, Sweden; 4) Department of Cardiology, Karolinska Hospital, Stockholm, Sweden; 5) Department of Community Medicine, Karolinska Hospital, Stockholm, Sweden.

Background: Air pollution exposure induces cardiovascular effects, possibly via systemic inflammation and coagulation misbalance. Genetic variation may determine individual susceptibility. **Objectives:** To investigate effect modification by inflammation (*IL6*, *TNF*) and coagulation (*fibrinogen B*) , *PAI-1)* gene variants on the effect of long- or short-term air pollution exposure on both blood marker levels and myocardial infarction (MI) risk. **Methods:** We studied 1192 MI cases and 1506 population controls aged 45-70 years from Stockholm. Selected *IL6*, *TNF*, *FGB* and *PAI1* SNPs/variants were genotyped. Retrospective emission inventories and spatial dispersion modelling was used to assess long-term air pollution exposure to traffic-NO2 and heating-SO2 emissions at home addresses up to 30 years back in time. Urban background NO_2, SO_2, PM_{10} and O_3 measurements were used to estimate variation in short-term air pollution exposure from hours up to 5 days back in time. Gene-environment interactions for short- and long-term air pollution on blood marker levels were studied in the population control sample, for long-term exposure on MI risk by comparing cases and controls, and for short-term exposure on MI onset, comparing the case onset time with control time points (case-crossover design). **Results:** We observed gene-environment interaction for several *IL6* and *TNF* SNPs in relation to inflammation blood marker levels. For example, for long-term air pollution, 1-year traffic-NO_2 exposure was associated with higher IL-6 levels with each additional *IL6-174C* allele, and 1-year heating-SO_2 exposure was associated with higher levels of TNF-(in *TNF-308AA* homozygotes vs. *-308G* carriers, with comparable findings for 5- and 30-year exposure metrics. Similarly for short-term air pollution exposure, we saw interaction with some *IL6* and *TNF* SNPs in relation to blood marker levels, most obviously for averaging over last 12-24 hours or 2 days. For each of these associations, the pattern of long-term MI risk or risk of acute MI onset followed closely the corresponding pattern of effect on blood markers across genotype groups. We observed no interactions for *FGB* or *PAI1*. **Conclusions:** Genetic variants in *IL6* and *TNF* may modify effects of both long- and short-term air pollution exposure on inflammatory marker levels, with a corresponding pattern of association with both long-term MI risk and acute MI onset.

333T

Cytokine (IFN-. , IL-6, TNF-(, TGF-) 1 and IL-10) genotyping in Turkish Children with cardiomyopathy. *S. Oguzkan Balci[1], N. Col Araz[2], O. Baspinar[3], T. Sever[1], A. Balat[4], S. Pehlivan[1].* 1) University of Gaziantep,Faculty of Medicine, Department of Medical Biology and Genetics, Gaziantep, Turkey; 2) University of Gaziantep, Faculty of Medicine, Department of Pediatrics, Gaziantep, Turkey; 3) University of Gaziantep, Faculty of Medicine, Department of Pediatric Cardiology, Gaziantep, Turkey; 4) University of Gaziantep, Faculty of Medicine,Department of Pediatric Nephrology, Gaziantep, Turkey.

Objectives of Study:Cardiomyopathy (CMP) is a cardiac muscle disease of an unknown etiology and defined by World Health Organization (WHO) as “diseases of the myocardium associated with cardiac disfonction”. Considering the role of cytokines in pathogenesis of CMP, and that cytokine gene polymorphism may affect the cytokine production, we investigated the association of CMP with IFN-. , IL-6, TNF-(, TGF-) 1 and IL-10 genes. Method: Twenty children with CMP, and 21 age-and sex-matched healthy controls were tested for 8 polymorphisms in 5 different genes. DNA was extracted from whole blood by standard salting out method. Cytokine genotyping was performed by polymerase chain reaction sequence-specific primer methods. The polymorphisms analyzed in the present study were IFN-. (+874), IL-6 (-174), TNF-((-308), TGF-) 1 (+10, +25) and IL-10 (-1082 , -819 , -592). The results were statistically analyzed by calculating odds ratios (OR) and 95% confidence intervals (CI) using chi-square test. Results: CMP patients had significantly higher frequencies of IFN-. (+874) polymorphism in both TT genotype (p=0.002, OR:11.6 [95 % CI:2.11-63.75]) and T allele (p=0.004, OR:3.34, CI: [1.35-8.27]). Our data also indicated a significant difference in C allele frequencies of IL-6 (-174) polymorphism between CMP patients and the controls (p=0.035, OR:2.36 [95 % CI:0.91-6.10]). In addition, GG genotype and G allele frequencies of TNF-((-308) polymorphism were lower in CMP patients than the controls (p=0.033, OR:0.20 [95 % CI:0.45-1.91], p=0.047, OR:0.26 [95 % CI:0.06-1.06], respectively). The haplotypes of TGF-) 1 and IL-10 were compared in terms of their expressions, and we found that the TT/GG, TC/GG haplotypes of TGF-) 1 had significantly decreased in the CMP (p=0.008, OR:0.16 [95 % CI:0.04-0.64]), whereas there were no statistically significant differences in the haplotypes of IL-10. Conclusion: The present study showed that TT/GG, TC/GG haplotypes of TGF-) 1, IFN-. (+874), IL-6 (-174) and TNF-((-308) polymorphisms were associated with CMP in Turkish children.We suggest that high expressions of IFN-. (+874) and TNF-((-308), and low or intermediate expressions of TGF-) 1 may be related to the pathogenesis of CMP. However, our results allow for only preliminary conclusions due to small sample size, therefore, further studies with larger samples are needed to address the exact role of this cytokines in childhood CMP.

334T

Down-regulation of Casz1 by siRNA injection into mouse tail-vein. *B. Oh, S.M. Ji, Y-B. Shin, S. Park, H. Lee, J-E. Lim.* Biomedical Engineering, Sch Med, Kyung Hee Univ, Seoul, Korea.

Blood pressure is regulated by many genetic and environmental factors. To identify genes that mediate this regulation, genome-wide association studies (GWASs) have been performed using large samples from various ethnicities. The Wellcome Trust Case Control Consortium (WTCCC), Amish study, KORA, KARE, the Global BPgen consortium, and the CHARGE consortium have conducted GWASs on hypertension and blood pressure, identifying 14 independent loci that govern blood pressure that reached genome-wide significance: 6 enzymes, 2 solutes channels, 2 transcription factors, 1 growth factor, 1 cell signaling protein, 1 structural protein, and 1 hypothetical gene. CASZ1, castor zinc finger 1, gene was found to be associated with blood pressure in both European descents and Japanese. CASZ1 was also known as survival-related gene (SRG). This gene encodes a putative protein of 172 amino acids, mainly located in the perinuclear region, and SRG is highly expressed in many human cancer cell lines although it is low in most tissues except liver and placenta. Also it was found that SRG-transfected cells are resistant to apoptosis induced by cytokine/serum deprivation, suggesting its role in controlling apoptosis and tumor formation. To attempt the down-regulation of Casz1 gene in mouse, we synthesized siRNA against mouse Casz1 and tested its efficiency in mouse NIH 3T3 cell lines. The siRNA reduced the transcript level by 58.53% in cells, and then the siRNA was injected into mouse tail-vein to reduce the expression of Casz1 in vivo, and the several tissues such as liver, kidney, heart, skeletal muscle, smooth muscle, spinal cord and brains were examined the level of Casz1 transcript 24 hours after the siRNA injection. The Casz1 transcripts in most tissues were seldom reduced but in kidney reduction upto 46% was repeatedly found. The reduction efficiency was at peak after 24 hours and the reduction seems to be decreased following 24 hours. Therefore we injected Casz1 siRNA everyday for three days to examine the phenotype change such as blood pressure, however the change of blood pressure could not be found.

335T

Functional consequences of heterozygous *ACTA2* mutations. *C.L. Papke[1], J. Cao[1], S. Lim[2], M. Rees[1], J. Chandra[3], A. Trache[2], W. Zimmer[2], D.M. Milewicz[1].* 1) Department of Internal Medicine, The University of Texas Health Science Center, Houston, TX; 2) Department of Systems Biology and Translational Medicine and Medical Physiology, Texas A&M Health Science Center College of Medicine, College Station, TX; 3) Department of Pediatrics - Research, Division of Pediatrics, The University of Texas MD Anderson Cancer Center, Houston, TX.

Mutations in ACTA2 (smooth muscle cell (SMC)-specific (-actin) cause a diffuse vasculopathy characterized by both thoracic aortic aneurysms leading to aortic dissections and occlusive vascular diseases, including early onset coronary artery disease and strokes. Occlusive lesions are characterized by medial and intimal SMC hyperplasia. *Acta2*$^{-/-}$ mice were used a model system to investigate the cellular pathways responsible for arterial dilatation and occlusion. These mice have normal vascular development but decreased arterial contractility. We found that *Acta2*$^{-/-}$ mice develop ascending aortic dilatation by 4 weeks of age, and the dilatation progresses with age. Aortic pathology in the *Acta2*$^{-/-}$ mice was characterized by thickening of the medial layer, increased number of elastic lamellae and SMCs and increased Mmp2 and proteoglycan expression (P<0.01). *Acta2*$^{-/-}$ aortic SMCs proliferated and migrated more rapidly than wildtype (WT) *in vitro* (P<0.05). *Acta2*$^{-/-}$ mice had greater neointimal formation with carotid injury (intima/media ratio of 2.19 vs 0.32 in WT; P<0.001). The MRTF:SRF axis was not responsible for the increased SMC proliferation. Assessment of focal adhesions (FAs) using quantitative Total Internal Reflection Fluorescence microscopy identified increased vinculin and activated focal adhesion kinase (pFAK) in FAs, and increased FA size in *Acta2*$^{-/-}$ SMCs compared to WT (P<0.01). Activation of FAs leads to increased expression of platelet-derived growth factor receptor-) (Pdgfr)), and increased expression and activation of Pdgfr) was confirmed in *Acta2*$^{-/-}$ SMCs compared to WT. SMC proliferation *in vitro* and neointimal formation *in vivo* in *Acta2*$^{-/-}$ mice was inhibited with imatinib mesylate (P<0.05). Media switching and PDGF-BB neutralizing antibody experiments demonstrated that Pdgfr) activation in *Acta2*$^{-/-}$ SMCs was ligand-independent. *Acta2*$^{-/-}$ SMCs had increased reactive oxygen species (ROS) compared to WT by flow cytometry, and treatment with either antioxidants or mitochondrial respiratory chain inhibitors decreased Pdgfr) activation. Thus, in *Acta2*$^{-/-}$ SMCs, loss of (-actin induces FA rearrangement with FAK activation and increased Pdgfr) expression, in addition to ligand-independent Pdgfr) activation due to increased ROS production. In summary, these data suggest that hyperplasia of SMCs contributes to occlusive lesions resulting from *ACTA2* mutations, and that imatinib could potentially be used to prevent these occlusive lesions.

Lipoproteins are highly heritable and risk factors for cardiovascular outcomes such as coronary artery disease, myocardial infarction, and stroke. So far, genome-wide association studies (GWAS) have revealed 95 lipid-associated loci when analyzing more than 100,000 samples. These 95 loci explain 10-12% of the interindividual variance of high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG) and total cholesterol (TC). To discover more genes associated with a phenotype and thus explain more of the heritability of this phenotype, usually the sample size was increased. Instead of further raising the sample size, more refined phenotypes, namely lipoprotein subfractions, can be analyzed. We measured the concentration of 15 lipoprotein subfractions, termed L1-L15, in 1,791 plasma samples of the KORA study using diffusion-weighted NMR-spectroscopy and analyzed their association with the 95 known lipid loci. In addition, we conducted a cluster analysis to investigate the interrelationship of the lipoprotein subfractions in fasting samples as well as in samples during a lipid tolerance test. We found that eight loci (*LIPC*, *CETP*, *PLTP*, *FADS1-2-3*, *SORT1*, *GCKR*, *APOB*, *APOA1*) are associated with at least one of the 15 NMR-measured lipoprotein subfractions whereas only four loci (*CETP*, *SORT1*, *GCKR*, *APOA1*) are associated with serum lipid levels in the study. Statistical power analyses of the eight loci revealed a strengthening in association when analyzing lipoprotein subfractions. Accordingly, we also observed an increase in the variance explained by our regression models. The cluster analysis in fasting samples revealed five different groups of lipoprotein subfractions of which one only consisted of lipoprotein subfraction L1, which is only marginally captured by serum lipids. In conclusion, NMR-based fine mapping of lipoprotein subfractions strengthens the association with genetic loci and provides novel information on their biological nature.

337T

Lipoprotein lipase gene (*LPL*) resequencing and plasma lipid profile. *D. Pirim[1], F.Y. Demirci[1], S.C. Hughes[1], M. Irfan[1], Y. Wang[1], J.E. Hokanson[2], R.F. Hamman[2], C.M. Kammerer[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO.

In the U.S., coronary heart disease (CHD) is the most common cause of death in both males and females. Epidemiological studies have identified several risk factors for CHD, including low high-density lipoprotein cholesterol (HDL-C) and elevated total cholesterol, low-density lipoprotein cholesterol (LDL-C), and triglycerides (TG), but the genetic variations that cause predisposition to dyslipidemia still remain to be further explored. Lipoprotein lipase (*LPL*) is one of the major genes involved in lipid metabolism and its sequence variation has already been reported to be associated with the risk of CHD and other complex traits such as dyslipidemia, type 2 diabetes, essential hypertension, and Alzheimer's disease. In this study, we investigated the common and rare variation in *LPL* (located at 8p22) by resequencing individuals with HDL-C levels in the upper 5th percentile (n=47) and the lower 5th percentile (n=48) selected from a population-based non-Hispanic White (NHW) sample of 623 individuals. A total of 179 variants (substitutions or indels) plus one microsatellite were identified in 95 individuals by resequencing the entire *LPL* gene and flanking regions (about 30 kb), including 91 variants with minor allele frequency (MAF) <0.05 and 88 common variants with MAF ⁄ 0.05. Of the 91 relatively uncommon or rare variants, 21 were present only in the low HDL-C group and 25 were present only in the high HDL-C group. Overall, the prevalence of uncommon or rare variants was higher in the high HDL-C than the low HDL-C group. Thirty two common variants showed significant (p-value <0.05) allele frequency differences between the high and low HDL-C groups. Of the 12 common variants analyzed to date in the entire NHW sample, 7 showed significant association with the lipid levels. Our results suggest that both common and rare variants of this gene are associated with inter-individual variation in plasma lipid profile. The genotyping of remaining tag SNPs and relevant rare variants in the entire sample is about to be completed and their analysis will unravel the extent to which *LPL* genetic variation affects the regulation of plasma HDL-C levels and other lipids.

338T

Vestibular symptoms in long QT syndrome. *G. Poke, J. McGaughran.* Genetic Health Queensland, Brisbane, Australia.

This small case control study details self- and family-reported vestibular and auditory symptoms in a group of patients with LQTS 1 and 2 (both disorders of potassium channels). Their responses are compared with those of a control group with LQTS 3 (caused by a sodium channel defect). Potassium channels are vital for normal hearing, which depends on maintenance of a high endolymphatic potassium concentration. They are also necessary for normal cardiac conduction. Some disorders can affect both systems: for instance, in the heterozygous state, mutations in *KCNQ1* can cause Romano-Ward syndrome (nonsyndromic LQTS). Homozygous mutations in the same gene may result in Jervell and Lange-Nielsen syndrome (the combination of sensorineural hearing loss and LQTS). It is increasingly recognised that potassium channels may also be involved in vestibular function. This study was prompted by a number of LQTS patients in the cardiac clinic complaining of dizziness. We show that vestibular symptoms may be a hallmark of potassium-channel related LQTS, independent of cardiac rhythm disturbances.

339T

Familial Mutation In Kozak Sequence Of GATA4 Associated With ASD Type 2; GATA4 L325V Associated With Atrial Fibrillation. *A.V. Postma, R. Mohan, K. van Engelen, A. Ilgun, V.M. Christoffels, P. Barnett.* Academic Medical Center, Amsterdam, Netherlands.

The Gata family of transcription factors are critical in embryonic development, cell growth, and differentiation. They are defined by an evolutionarily conserved DNA-binding domain consisting of two zinc finger motifs. Gata4 is one of the earliest genes expressed by specified cardiac precursors at the cardiac crescent stage of mouse development. Missense mutations in GATA4 are associated with ASD type 2 and recently with atrial fibrillation. We screened 33 familial patients with ASD type2 and 17 with familial atrial fibrillation for mutations in GATA4 (all negative for Nkx2.5 and Tbx5 mutations). This led to the identification of a mutation at -6bp from the ATG start site, which co-segregates in a family with ASD type 2. This position is part of the strongly conserved Kozak consensus sequence which serves to initiate translation. Expression analysis showed that this mutation leads to a 50% decrease in the amount of protein, in effect a hypomorph, indicating that the -6bp is an essential part of the Kozak sequence. In a patient with familial atrial fibrillation without structural anomalies, we identified a L325V aminoacid change. The L325V mutant does not show a difference in activation of the ANF-luciferase reporter assays. However, qPCR analysis on H10 cells transfected with the mutant GATA4 gene, shows a significant increase in Cx40 and Cx43 expression and a decrease in Tbx3, in comparison to wildtype GATA4. Nuclear trafficking was normal for the L325V mutant. We are currently investigating the mechanism by which the L325V GATA4 mutation causes atrial fibrillation.

Long QT Syndrome: A Preliminary Study. *N. Pratibha[1], A. Ali[1], FQ. Sameera[1], K. Thangaraj[2], A. Venkateshwari[3], C. Narsimhan[4].* 1) Department of Genetics, Osmania University, Hyderabad, India; 2) Center for Cellular and Molecular Biology, Habsiguda, Hyderabad; 3) Institute of Genetics and Hospital for Genetic Disorders, Ameerpet, Hyderabad; 4) Care Hospitals, Hyderabad.

Long QT Syndrome, a rare arrythmogenic disorder is characterized by delayed repolarization of the heart following a heartbeat, leading to the prolongation of the QT interval. Inherited LQTS is the prototype of the “primary cardiac arrhythmias” or “cardiac ion channelopathy”. LQTS is caused by mutations in genes encoding cardiac ion channels. One such disorder; “Jervell-Lange Nielsen Syndrome” is the outcome of mutations in KCNQ1 or KCNE1 genes resulting in defective IKs channels. PCR based SSCP analysis of KCNQ1 revealed band pattern variation in a proband. On sequencing a 4bp insertion was identified in the patient and his first degree relatives. This led to changes in the secondary structure of the mRNA. Insilco analysis revealed changes in splice site and binding sites of the SR and hnRNP proteins in the spliceosome complex. This change in binding sites could lead to alteration in processing of the mRNA during the maturation process which will be further discussed.

Prenatal diagnosis for cardiomyopathy: genotype may not predict phenotype. *N. Quercia[1], S. Baxter[2], B.H. Funke[2,3], A. Dipchand[4], S. Bowdin[1].* 1) Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, ON, Canada; 2) Laboratory for Molecular Medicine, Partners Healthcare Center for Personalized Genetic Medicine, Cambridge, MA; 3) Department of Pathology, Massachusetts General Hospital, Boston, MA; 4) Division of Cardiology, Hospital for Sick Children, Toronto, ON, Canada.

Our understanding of the natural history of hypertrophic cardiomyopathy (HCM) and dilated cardiomyopathy (DCM) predisposing gene mutations is still emerging. Some genotype-phenotype correlations can be made however, caution must be used when using this data to counsel prenatal cases. In our experience, prenatal genetic diagnosis is rarely requested or available for isolated DCM/HCM. We present an infant female, diagnosed with DCM in infancy, the product of a first cousin Sri Lankan mating and prenatally predicted to be unaffected with DCM. Amniocentesis revealed a parentally inherited heterozygous MYBPC3 c.3628-41_3628-17del mutation that was predicted to result in mild or moderate HCM with later onset. Prenatal diagnosis was requested by her parents after genetic testing in their son, also diagnosed with DCM in infancy, was found to be homozygous for the MYBPC3 mutation. This deletion is common (2-8% of individuals) in the heterozygous form in the South Asian population. It is known to affect splicing and leads to exon skipping. It has been associated with mild hypertrophy in heterozygotes and has been reported to show severe and early presentation in homozygous individuals. Parental studies revealed they were both heterozygous for the mutation; both had normal echocardiograms and ECGs at 30 (mother) and 38 (father) years. Family history is remarkable only for a shared parental uncle who died suddenly at 30 years of suspected drowning. Prenatally, the couple was counselled that the presence of MYBPC3 mutation in the heterozygous state would likely result in mild to moderate HCM with later onset. Fetal echocardiograms at 15 and 20 weeks gestation were normal. The pregnancy and delivery were unremarkable. A postnatal screening echocardiogram at 3 weeks revealed DCM with a left ventricular ejection fraction of 36%. Postnatal sequencing of 19 DCM related genes, metabolic studies and karyotype were normal, aside from the known MYBPC3 heterozygous mutation. This case highlights that caution is needed when predicting the phenotype using prenatal genotype. Given that both heterozygous and homozygous individuals in this family presented with DCM in infancy, it is unlikely that the MYBPC3 familial mutation is the sole cause of DCM in this family; other modifying genes may play a role. Future genetic testing may reveal other currently unknown DCM predisposing gene mutation(s) that either alone or in conjunction with the MYBPC3 variant causes DCM.

Effects of common and rare genetic variants of *APOC4* on HDL-cholesterol levels. *Z.H. Radwan[1], F.Y. Demirci[1], J.E. Hokanson[2], R.F. Hamman[2], C.H. Bunker[3], C.M. Kammerer[1], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, Univ Colorado Denver, Aurora, CO; 3) Epidemiology, GSPH, Univ Pittsburgh, Pittsburgh, PA.

Coronary heart disease (CHD) is a major public health problem in Western countries as it continues to be a leading cause of premature mortality and morbidity. Dyslipidemia with low high-density lipoprotein cholesterol (HDL-C) and high low-density lipoprotein cholesterol (LDL-C) is one of the CHD risk factors. *APOC4* belongs to the *APOE/C1/C4/C2* gene cluster on chromosome 19q13 that has been implicated in regulation of different lipid traits in several studies. As compared to other members of this cluster, *APOC4* received relatively little attention in those studies. The primary aim of this study was to identify both common and rare variants in *APOC4* and flanking regions by resequencing about 5 kb-long genomic fragment in U.S. non-Hispanic White (NHW) and African Black individuals with HDL-C levels in the upper and lower 5th percentiles and examine their effects on HDL-C and other lipid levels. The analysis of sequencing data from individuals with HDL-C levels in the upper 5th percentile (47 NHWs and 48 African Blacks) and those with HDL-C levels in the lower 5th percentile (48 NHWs and 47 African Blacks) identified a total of 64 variants (substitutions or indels) plus one microsatellite, of which 13 were shared by both populations. Of 26 variants observed in NHWs, 12% were located in exons, 12% were indels, and 50% had ⁄ 5% minor allele frequency (MAF). Of 51 variants observed in African Blacks, 12% were in exons, 8% were indels, and 41% had ⁄ 5% MAF. All 3 exonic variants in NHWs and 4 out of 6 exonic variants in African Blacks were predicted to cause non-synonymous amino acid changes. Among NHWs, 31% of the individuals in the low HDL-C group had rare or relatively less common variants (MAF<5%) versus only 10% of those in the high HDL-C group. On the other hand, a reverse trend was observed in the Black sample (46% in the low HDL-C group versus 54% in the high HDL-C group). Screening of common variants in the entire sample set (623 NHWs and 788 Blacks) revealed significant or borderline associations with various lipid traits.

343T

G protein coupled Receptor Kinase 5 protein polymorphism and expression in Indian patients with Cardiac failure. *S. Ramalingam[1], T. Sairam[1], S. Ranjani[1], S. Narayanan[2], G. Rajendiran[2], J.S. Bhuvaneswaran[2], R. Sankaran[1].* 1) PSG Center for Molecular Medicine and Therapeutics , PSGInstitute of Medical Sciences and Research,Avanashi Road, Coimbatore, Tamilnadu, India; 2) Department of Cardiology,PSG Institute of Medical Sciences and Research,Avanashi Road, Coimbatore,Tamilnadu,India.

Purpose: Cardiovascular diseases are increasingly recognized as a major cause of mortality and morbidity globally and more so in the developing countries. Heart failure is a common consequence of coronary heart disease and with the increasing prevalence of heart diseases in India, cardiac failure has become one of the most important public health problems. Recent evidences reveal a protective effect of the GRK5Leu41 polymorphism in patients with cardiac failure. Studies have also shown that the expression of GRK5 in peripheral leucocytes is higher in mice models with cardiac failure and can be a surrogate marker to estimate the cardiac GRK expression. There are no studies in Indian population till date which looks at GRK5 polymorphism or its expression in cardiac failure patients. We studied the association of severity of cardiac failure with GRK5Leu41polymorphism and expression of GRK5 in peripheral blood in patients with cardiac failure. **Methods:** In this ongoing study we have recruited 32 patients with cardiac failure with class III or IV according to the New York Heart Association criteria. All patients were evaluated by a cardiologist and blood was collected for RNA and DNA isolation. Amplification was done using tetra primers and the SNP was detected using RFLP method. RNA (DNAase treated) was quantified using NANODROP 2000 and 500ng of RNA was used to synthesize cDNA using USB First strand cDNA Synthesis Kit (USB, USA) for Real Time PCR. **Results:** We present our interim results of this ongoing study. Of the 32 patients with cardiac failure, one patient had a homozygous GRK5Leu41 polymorphism and three had a heterozygous polymorphism respectively. The homozygous variant and two heterozygous variants presented with class III disease and one patient with heterozygous variant had class IV disease. The expression studies were carried out in 14 patients and there was an up regulation of GRK5 in 12 patients and down regulation in two patients. Those with downregulation had Class III symptoms with a mean duration of illness of 6 months, while those with upregulation had Class III (4patients) and class IV (8 patients), and a mean duration of illness of 2.6 years. The results of this study are consistent with physiological mechanisms operational in cardiac failure, and represent a study first of its kind in India.

344T

Genome-wide analysis of variability in normal cardiac conduction across multiple electronic medical record systems. *M.D. Ritchie[1], R.L. Zuvich[1], J.C. Denny[2, 3], D.C. Crawford[1], J.S. Schildcrout[4], A.H. Ramirez[2], J.M. Pulley[5], M.A. Basford[5], C.G. Chute[6], I.J. Kullo[6], C.A. McCarty[7], R.L. Chisholm[8], A.N. Kho[8], E.B. Larson[9, 10], G.P. Jarvik[9, 11], CHARGE. QRS GWAS Consortium[12], R. Li[13], D.R. Masys[3], J.L. Haines[1], D.M. Roden[2, 5].* 1) Molec Physiology & Biophysics, Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 2) Department of Medicine, Vanderbilt Univ, Nashville TN; 3) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 4) Department of Biostatistics, Vanderbilt Univ, Nashville, TN; 5) Office of Personalized Medicine, Vanderbilt Univ, Nashville, TN; 6) Department of Medical Informatics, Mayo Clinic, Rochester, MN; 7) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, Wisconsin; 8) Department of Medicine, Northwestern University, Chicago, IL; 9) Group Health Research Institute, Seattle WA; 10) Department of Medicine, University of Washington, Seattle, WA; 11) Department of Genome Sciences, University of Washington, Seattle, WA; 12) International Consortium; 13) NHGRI, NIH, Bethesda, MD.

The duration of the QRS interval, an index of conduction in the cardiac ventricle, varies ~2-fold in normal adults without cardiac disease. We used electronic medical records (EMRs) coupled to DNA samples to identify the genomic determinants of normal QRS duration in the electronic MEdical Records & GEnomics (eMERGE) network. The electronic phenotyping algorithm for normal QRS duration identified 6126 individuals of European-descent in five EMR systems across the network. These individuals had a first recorded ECG read as normal with no confounding heart disease, medications, or electrolyte abnormality at that time. After quality control, genome-wide association (GWA) analysis on 5272 individuals identified 108 QRS-associated SNPs with P values <10-5. Each of these were examined in the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) QRS GWAS consortium meta-analysis, and 23 replicated with P values <1.1x10-11, while the remaining 85 had P values >0.003. Eighteen of the 23 replicating SNPs were in the chromosome 3 SCN5A-10A locus. The top SNPs/loci included rs6800541 in SCN10A with pE<8.54x10-6 (eMERGE) and pC<1.88x10-27 (CHARGE), rs2207790 in NFIA with pE< 8.70x10-5 and pC<6.31x10-18, and rs1321313 near CDKN1A with pE<8.61x10-5 and pC<4.60x10-25. To investigate potential pleiotropic effects of the 18 SCN5A-10A SNPs we conducted phenome-wide association (PheWAS) analysis examining clinical associations between these 18 SNPs across 744 diagnostic codes in the full eMERGE European-descent dataset (n=13,859). We identified diagnostic codes for atrial fibrillation and for cardiac arrhythmias (by definition absent at the time of index ECG recording) as the most common associated diagnoses. This result indicates that analyzing normal ECGs not only identified genomic predictors of normal conduction, but also allowed us to analyze clinical events in the EMR after the index ECG was recorded. We conclude that DNA banks coupled to EMRs not only provide a platform for GWAS, but also identify genotype-associated diagnoses in an unbiased fashion. A PheWAS approach can identify clinical conditions associated with SNPs of interest and in this case, demonstrated that sodium channel variants that influence QRS duration are also associated with arrhythmia outcomes.

Antagonism of GxxPG-Fragments Ameliorates Manifestations of Aortic Disease in Marfan Syndrome Mice. *P.N. Robinson[1,2], G. Guo[1], B. Muñoz-García[1], C.E. Ott[1], J. Grünhagen[1], S. Mousa[3], A. Pletschacher[1], Y. von Kodolitsch[4], P. Knaus[5].* 1) Institute for Medical Genetics, Charité-Universitatsmedizin Berlin, Berlin, Germany; 2) Max Planck Institute for Molecular Genetics, Berlin, Germany; 3) Department of Anesthesiology and Operative Intensive Care Medicine,Charité-Universitätsmedizin Berlin, Berlin, Germany; 4) Centre of Cardiology and Cardiovascular Surgery, Department of Cardiology/Angiology, University Hospital Hamburg-Eppendorf, Hamburg, Germany; 5) Institut für Chemie und Biochemie, Freie Universität Berlin, Berlin, Germany.

Marfan syndrome (MFS) is an inherited disorder of connective tissue caused by mutations in the gene for fibrillin-1 (FBN1), with prominent clinical manifestations in the cardiovascular, skeletal and ocular systems. The complex pathogenesis of MFS involves changes in TGF) signaling, increased matrix metalloproteinase (MMP) expression, tissue fragmentation, and abnormal matrix-cell interactions. Fibrillin-1 and elastin have repeated Gly-x-x-Pro-Gly (GxxPG) motifs that can induce a number of effects including macrophage chemotaxis and increased MMP activity by induction of signaling by the elastin-binding protein (EBP). We have previously shown that aortic extracts from the mgR/mgR mice as well as a GxxPG-containing fibrillin-1 fragment significantly increased macrophage chemotaxis compared with extracts from wild-type mice or buffer controls. Fibrillin-1 underexpressing mgR/mgR mice were treated with weekly i.p. injections of the monoclonal antibody BA4 directed against elastin and fibrillin-1 GxxPG-containing fragments beginning at the third week of life and continuing over 8 weeks at a dose of 1 mg/kg, 5 mg/kg or 10 mg/kg. Following treatment, mice were sacrificed and compared to control antibody IgG treated mgR/mgR and wild type littermates. Treatment with BA4 at dosages as low as 1 mg/kg could already rescue elastin degeneration in mgR/mgR mice. However, no effects could be observed in IgG treated group. BA4 treatment additionally significantly reduced MMP-2, MMP-9, and pSmad2 activity, as well as fragmentation and macrophage infiltration in the aorta of the mgR/mgR mice. Primary cultured aortic vascular smooth muscle cells (vSMCs) were investigated for constitutive pSmad2 levels; there was a significant reduction of the constitutive pSmad2 activation in aortic vSMCs from the BA4 treated mgR/mgR mice. Pulmonary emphysema has been previously shown to develop in mgR/mgR mice. Treatment with BA4 prevented airspace enlargement and significantly reduced pSmad2 signaling. An additional treatment arm with the NSAID indomethacin similarly attenuated MMP and pSMad2 activity, macrophage infiltration, and fragmentation in the mgR/mgR aorta. Our findings emphasize the important role of secondary cellular events caused by GxxPG containing fragments and matrix-induced inflammatory activity in the pathogenesis of aortic aneurysm in mgR/mgR mice and suggest that antagonism of the effects of GxxPG fragments may be a fruitful therapeutic strategy in MFS.

346T

Pharmacogenetic of warfarin in Iranian patients (Polymorphisms Spectrum of VKORC1 and CYP2C9). *S. Saber[1,4], O. Aryani[1], F. Ghasemi[1], A.F. Fazelifar[3], M. Haghjoo[3], R. Kia[4], M. Houshmand[2].* 1) Dept Medical Genetics, Special Medical Center, Tehran, Iran; 2) National istitude for genetic engineering and biotechnology,Tehran,Iran; 3) Rajaie Cardiovascular Medical and Research Center, Tehran, Iran; 4) Sina Special Medical Center,cardiology ward,Tehran,Iran.

Background: Personalized medicine is a medical model emphasizing the systematic use of information about an individual patient to select or optimize that patient's preventative and therapeutic care. Pharmacogenetic is the field of study that examines the impact of genetic variation on the response to medications. Warfarin has been widely used for the prevention and treatment of thromboembolism. Warfarin therapy depends on interaction between physiological, environmental, and genetic factors. The Warfarin has narrow therapeutic index and widely variable therapeutic dose. Cytochrome P450 2C9 (CYP2C9) enzyme and Vitamin K epoxide reductase (VKORC1) conjointly determine the warfarin maintenance dose. Single Nucleotide Polymorphisms (SNPs) of these genes can cause to different amount of warfarin for each patients. Allele *1 is wild type and allele *2 (430A>C) 3*(1075A>C) are two well none SNPs that correlated to reduce warfarin dose at least 22% and 34% respectively. In the VKORC1 1639 (or 3673) SNP, the common G allele is replaced by the A allele. Because people with an A allele need to reduce warfarin dose at least 30%. Material and Methods: We checked index patients who need warfarin due to clinical disorders. Polymerase Change Reaction (PCR) was done on DNA samples and those mention SNPs were evaluated by Reverse Dot Blot method. Results: In our study prevalence of allele *1, 2*and 3* were 76.47%, 11.76 %and 11.76%, respectively. Initial doses were estimated by warfarindosing site and INR has been rechecked (international normalized ratio) for controlling the initial dose. Estimation of warfarin dosing in 45% of patients receive to INR: 2.5 after take the initial dose. 15% of patients need to higher dose and 40% need to lower dose than initial dose but we haven't received any reports of side effects in these patients. Conclusion: Prevalence of allele *2 and *3 is equal and it was 11.76%, in our study and 26.74 % of our group were carried A allele. Comparing with Caucasians was reported 10% and 6% for allele *2 and *3 and 37% of Caucasians carrying the A allele. We must expand our group and other relative genes for achieving to the best result in Iranian population, these studies are on the rest. Importance of pharmacogenetic has been shown for finding the best initial dose of warfarin. Further collaboration between physicians and geneticists need to improve well-time diagnostics, optimal treatment.

347T

Do ST-elevation and non-ST-elevation myocardial infarction have different genetic backgrounds? *P. Salo[1], J. Sinisalo[2], T. Hiekkalinna[1,3], J. Kettunen[1,3], A. Havulinna[4], M. Lokki[5], S. Ripatti[1,3], V. Salomaa[4], M. Nieminen[2], M. Perola[1,3,6].* 1) Public Health Genomics Unit, National Institute For Health And Welfare, Helsinki, Finland; 2) Division of Cardiology, Department of Medicine, Helsinki University Central Hospital, Finland; 3) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Finland; 4) Chronic Disease Epidemiology and Prevention Unit, Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland; 5) Transplantation laboratory, Haartman Institute, University of Helsinki,Finland; 6) The Estonian Genome Center, University of Tartu, Estonia.

The most robustly replicated common risk allele for acute coronary syndrome (ACS) at 9p21.3 affects gene expression rather than the structure of a protein. This is consistent with the idea that differences in gene expression might explain a significant part of the genetic risk for common diseases. It is also believed that the genetic background differs for different subcategories of complex phenotypes. Taken together, this led us to test two hypotheses: First, many common expression quantitative trait loci (eQTL) are associated with ACS. Second, the effects of these loci are not equal for two subtypes of ACS, namely ST-elevation myocardial infarction (STEMI) and non-ST-elevation myocardial infarction (NSTEMI).

We performed a GWAS in a sample consisting of acute coronary syndrome (ACS) patients and healthy controls (n=3373). We selected SNP's annotated as eQTL's in a public database and used non-parametric statistical methods to compare them with unlinked non-eQTL SNP's matched for allele frequency and proximity to the closest gene.

eQTL SNP's are more strongly associated with ACS than non-eQTl SNP's. This effect is significantly stronger for NSTEMI than for STEMI. The disparity is driven by eQTL SNP's at the MHC locus on 6p21.3. Exclusion of this locus diminishes the difference between eQTL and non-eQTL SNP's for NSTEMI and ACS.

Our results add to the notion that common differences in gene expression influence the risk for developing ACS. We show that the risk conferred by some eQTL's is conditional on a clinically relevant classification of ACS and identify a locus contributing to this difference. Furthermore, the results specifically suggest genetic variation affecting immune system function provides more risk for NSTEMI than for STEMI.

348T

Increased urinary globotriaosylceramide and previously undiagnosed Fabry patients are found in a non-selected heart disease patient population. *R. Schiffmann[1], S. Forni[1], C. Swift[1], X. Wu[2], D. Lockhart[2], S. Pond[3], M. Chee[3], K. Goss[4], K. Sims[4], E. Benjamin[2], L. Sweetman[1].* 1) Inst Metabolic Disease, Baylor Res Inst, Dallas, TX; 2) Amicus Therapeutics, Cranbury, NJ; 3) Prognosys Biosciences, Inc., La Jolla, CA; 4) Neurogenetics DNA Diagnostic Laboratory, Massachusetts General Hospital, Boston, MA.

We have initiated a large screening research protocol for the Fabry disease biochemical and genetic trait in a non-selected at-risk population of patients with cardiac disease. We hypothesized that (-galactosidase A deficiency is a genetic risk factor for non-specific cardiovascular complications that commonly occur in the general population. The verification of our hypothesis will lead to confirmation of (-galactosidase A deficiency due to *GLA* mutations as a general modifiable cardiovascular risk factor, allowing for better management and prevention of cardiac disease. Screening is performed by measuring urinary globotriaosylceramide (Gb3) in random samples of whole urine using tandem MS, measuring (-galactosidase A activity in dried blood spots, and looking for *GLA* gene mutations by parallel sequencing of the whole gene supplemented by conventional Sanger sequencing. Cardiac patients and non-cardiac controls are being tested. Thus far we have consented and sampled 1066 patients with a wide variety of cardiac abnormalities, the vast majority with coronary artery disease, and 185 controls. Urinary Gb3 in cardiac patients was 136±150 ng/mL (N=981) and 94±39 ng/mL (N= 166) in the controls (p<0.0001) - Gb3 upper limit of normal (99th percentile) is 200 ng/mL. In the first 60 patients sequenced we identified two women aged 35 and 72 years with *GLA* mutation (R118C and D83N). Both had normal urinary Gb3 levels and (-galactosidase A activity. Supraventricular tachycardia and atrial fibrillation were their primary cardiac abnormalities but also valvular disease and renal insufficiency in the older patient. We conclude first that urinary Gb3 is elevated in the general population of cardiac patients, the significance of which is currently being evaluated. However, urinary Gb3 is not an adequate screening biomarker for Fabry disease in this population because it is elevated in 15% of cardiac patients and overlaps with levels seen in patients with Fabry disease. Secondly, the general cardiac disease population may be significantly enriched in previously undiagnosed individuals with Fabry disease.

349T

Metabochip meta-analysis of > 190,000 individuals reveals 77 novel loci associated with blood lipid levels. *S. Sengupta[1], E.M. Schmidt[2], Global Lipids Genetics Consortium.* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Bioinformatics Graduate Program, University of Michigan, Ann Arbor, MI.

The identification of genetic variants associated with lipid traits, which are heritable risk factors for cardiovascular disease, will give valuable insight into the biological basis of disease and may highlight new drug targets for cholesterol management or disease prevention. To date, genome-wide screening for common variants in >100,000 individuals of European ancestry has identified more than 95 loci significantly associated with various blood lipid phenotypes. Using a sample size of 99,137 individuals which nearly doubles the size of the original discovery setting, we conducted a two stage meta-analysis aimed at discovering additional lipid associated variants.

Plasma concentrations of the 4 blood lipid traits were measured in individuals from 39 cohorts, mainly of European ancestry. Individuals were genotyped for approximately 200,000 single nucleotide polymorphisms (SNPs) selected from genome wide meta-analyses of metabolic or cardiovascular traits on the Metabochip, a custom Illumina iSelect genotyping array. We carefully selected 4,763 SNPs for follow-up of high-density lipoprotein cholesterol (HDL-C), 4,780 for low-density lipoprotein cholesterol (LDL-C), 714 for total cholesterol (TC), and 4,759 for triglycerides (TG), as well as 28,927 specifically for fine mapping. By jointly meta-analyzing Metabochip results with our previous genome-wide association analysis of 23 cohorts, we identified 77 novel loci significantly associated with at least one of four lipid traits ($P<5 \times 10^{-8}$) in an interim analysis of 190,434 individuals. Of these 77 loci, 10 demonstrated a genome-wide significant association with TC, 18 with TG, 14 with LDL-C, and 35 with HDL-C. Highlights among our results include association between lipid traits and SNPs in a lipoprotein receptor gene, VLDLR ($P=9.4 \times 10^{-12}$ and $P=2.5 \times 10^{-11}$ for TC and LDL-C respectively) as well as VEGFA ($P=1.2 \times 10^{-14}$ for TG), implicated in atherogeneis, Vimentin ($P=2.0 \times 10^{-08}$ for TC), a filament responsible for transport of LDL-C from the lyosome for esterification, COPB1 ($P=4.6 \times 10^{-08}$ for HDL-C), involved in movement of lipid components to the endoplasmic reticulum, and PRKAG1 ($P=8.1 \times 10^{-09}$ for TC), responsible for inactivating HMGCR. Downstream analyses will include characterizing the proportion of variance explained by these loci and analyzing low frequency variation in previously identified loci and across the genome.

Genomic and epigenetic alterations in heart development tissue of congenital heart defects. *C. Serra-Juhé[1, 2], I. Cuscó[1, 2], B. Rodríguez-Santiago[1, 3], T. Vendrell[4], F. Borràs[4], N. Torán[4], L.A. Pérez-Jurado[1, 2].* 1) Unitat de Genetica, Universitat Pompeu Fabra, Barcelona, Spain; 2) Centro de Investigación Biomédica en Red de Enfermedades Raras, CIBERER, ISCIII, Spain; 3) Quantitative Genomic Medicine Laboratories, Ltd (qGenomics), Barcelona, Spain; 4) Hospital Universitari Vall d'Hebron, Barcelona, Spain.

The mechanisms underlying the majority of sporadic and isolated congenital heart defects (CHD) are poorly understood. Accumulation of multiple genetic, genomic and/or epigenetic variants, along with possible somatic events, is thought to converge into deregulation of developmental networks leading to a morphologically abnormal heart. About 40% of patients with Down syndrome (DS) present CHD, implying the presence of additional risk factors other than the T21 in the etiology of this malformation. With the aim of identifying genomic and epigenetic alterations involved in CHD, we studied heart tissue samples of 33 fetuses with isolated CHD (ICHD) and 6 with DS and CHD by chromosome microarray analysis. In addition, samples of each group were screened for epimutations, using two groups (DS without CHD and normal fetuses) as controls. Methylation status was studied in 27,000 CpG using the Illumina Infinium Human Methylation Platform.

Potentially pathogenic CNVs were identified in 6 samples with ICHD but none in the other groups (other than T21 in DS). Those included a single *de novo* event (deletion of 0.36 Mb containing FOX gene cluster) and five rearrangements inherited from a normal parent: the recurrent 15q13.3 deletion, deletions in 13q21, 16q23 and 14q23 and one duplication in 5q35. Interestingly, all genomic abnormalities were identified in isolated left heart hypoplasia. Regarding the epigenomic studies, a total of 18 regions were identified as being differentially methylated (p<0.01) in CHD samples compared to the control group. A single region surrounding the GATA4 gene was found relatively hypermethylated in all patient samples. The remaining differentially methylated regions were present in either single or few samples, such as a region in 14q31 hypermethylated in two DS with CHD. Other tissues are being studied to determine whether the methylation marks are or not tissue-specific. Several genes potentially deregulated are good candidates for CHD based on predicted function or previously described animal models.

Our data provide additional dosage sensitive genes responsible for CHD, mainly left heart hypoplasia, and strongly suggest a relevant role of epigenetic alterations in CHD, either as the main cause of the malformation or as a modifier such as in DS.

Novel identification of genetic risk factors in Koreans reveals association of PITX2 gene with lone atrial fibrillation. *D. Shin[1,3], A. Park[1], H. Hwang[2], N. Son[1,4], B. Park[1,4], J. Kwon[1], J. Lim[1], E. Shin[5], J. Lee[5], B. Joung[2], M. Lee[2], S. Kim[2], Y. Jang[1,2].* 1) Cardiovascular Genome Center, Yonsei Univrsity College of Medicine, Seoul, South Korea; 2) Division of Cardiology, Yonsei University Health System; 3) Yonsei University Research Institute of Science for Aging; 4) Department of Biostatistics, Yonsei University College of Medicine; 5) DNA Link Inc, Seoul, South Korea.

Atrial fibrillation (AF) is the most frequently and seriously encountered cardiac rhythm disorder in humans and is characterized by chaotic electrical activity of the atrial. Recent evidence indicates the phenotypes of lone AF are more likely to occur in patient with a genetic susceptibility. The PITX2 gene has a pivotal function in cardiac development and may be one underlying mechanism for AF development. The PITX2 gene expression identifies the left atrium during embryonic development, and also plays a crucial role in the differentiation, proliferation, and expansion of pulmonary myocardial cells. We examined a case-control study for a total of 754 Korean subjects, comprising of 354 cases with AF and 400 controls. Genotyping for variants was carried out by direct DNA sequencing and TaqMan® assay. We examined 5 tagging single nucleotide polymorphisms (tSNPs) in the PITX2 gene. We observed the significant differences in the allele and genotype distributions of rs2739200 and rs62338989 between patients with AF and control subjects (P<0.01). Logistic regression analysis represented that tSNPs, rs2739200 (-4257C/G) and rs62338989 (-4840C/T), in the promoter region confer the risk of lone AF. The significant associations were observed under a recessive model for GG genotype with a decreasing risk of AF (OR, 0.530; 0.378-0.744; p=0.0002). Whereas, PITX2 rs62338989 showed significant association in Korean AF condition under a dominant model with an increasing risk (OR, 1.885; 1.200-2.961; p=0.006). In haplotype analysis, haplotype CTCC was significantly associated with AF susceptibility (OR, 1.71; 1.246-2.347; p=0.0009). We provide evidence that PITX2 novel variants may contribute to protect or predispose Korean individuals to the risk of AF.

A comprehensive approach assessing the contribution of polygenic variation to risk of cardiovascular disease. *M.A. Simonson[1,2], A.G. Wills[1], M.B. McQueen[2], M.C. Keller[1].* 1) Psychology and Neuroscience, Institute for Behavioral Genetics, Boulder, CO; 2) Integrative Physiology, Institute for Behavioral Genetics, Boulder, CO.

Background: Traditional genome-wide association studies are generally limited in their ability explain a large portion of genetic risk for most common diseases. We sought to use both traditional GWAS methods, as well as more recently developed polygenic genome-wide analysis techniques to identify subsets of single-nucleotide polymorphisms (SNPs) that may be involved in risk of cardiovascular disease, as well as estimate the heritability explained by common SNPs.

Methods: Using data from the Framingham SNP Health Association Resource (SHARe)., three complimentary methods were applied to examine the genetic factors associated with the Framingham Risk Score, a widely-accepted indicator of underlying cardiovascular disease risk. The first method adopted a traditional GWAS approach - independently testing each SNP for association with the Framingham Risk Score. The second two approaches involved polygenic methods with the intention of providing estimates of aggregate genetic risk and heritability.

Results: While no SNPs were independently associated with the Framingham Risk Score based on the results of the traditional GWAS analysis, we were able to identify cardiovascular disease-related SNPs as reported by previous studies. A predictive polygenic analysis was only able to explain approximately 1% of the genetic variance when predicting the 10-year risk of general cardiovascular disease. However, 20% to 30% of the variation in the Framingham Risk Score was explained using a recently developed method that considers the joint effect of all SNPs simultaneously.

Conclusion: The results of this study imply that common SNPs explain a large amount of the variation in the Framingham Risk Score and suggest that future, better-powered genome-wide association studies will uncover more risk variants that will help to elucidate the genetic architecture of cardiovascular disease.

Interaction between GRK4 and BMI affects blood pressure. *R.S. Sobota[1], C.D. Schoeffel[2], R.M. Carey[2], H.E. McGrath[2], L.N. Gordon[1], M.J. Park[1], P.A. Jose[3], R.A. Felder[2], S.M. Williams[1].* 1) Human Genetics, Vanderbilt University, Nashville, TN; 2) Endocrinology and Metabolism, University of Virginia, Charlottesville, VA; 3) Pediatrics and Medicine, George Washington University, Washington, DC.

Essential hypertension is defined as high blood pressure with an unexplained etiology. Hypertension has numerous sequelae including predispositions to stroke, myocardial infarction, and aortic dissection The heritability estimates for this phenotype range from 30 to 40% and are believed to be a result of multiple genetic influences in the context of numerous environmental insults. Because of the high heritability and known physiological pathways that can affect blood pressure regulation we performed an association study between hypertension and 41 single nucleotide polymorphisms (SNPs) in 19 candidate genes from a Caucasian population that included 550 individuals. After genotyping we excluded SNPs with minor allele frequencies less than 10%. This left 23 polymorphisms in 15 candidate genes for subsequent analysis. Data on standard environmental phenotypes of gender, age and BMI were also collected for gene X environment modeling as well as epistasis analysis. Analyses were done using hypertension as a dichotomous trait, defined by systolic blood pressure more than 120 and/or diastolic blood pressure more than 80 or a previous diagnosis of hypertension. Blood pressure was also analyzed as a continuous trait for those individual who were not on anti-hypertensive medication (n= XXX). All logistic and linear models were adjusted for the gender, age and BMI. Logistic regression of hypertension status resulted in 4 SNPs being significant at the p <0.1 level, segregating in 2 genes (SNX19 and SLC4A5). Six of the 23 SNPs were significant at the 0.10 level in linear regression of both systolic and diastolic values (CAV1, DRD2 and SNX19). Explicit interactions between the genotypes and BMI were modeled with both logistic regression, which identified 3 significant SNPs (p < 0.1), and linear regression for SBP and DBP, 7 SNPs <0.1 (6 <0.05). Of note all 3 GRK4 SNPs assayed (R65L, A142V and A486V) showed a highly significant interaction term with BMI (P <0.01 in all cases). We identified an excess of associations over that expected by chance alone across all of our genes analyzed and our results identified an explicit interaction between GRK4 SNPs and BMI with blood pressure as a continuous trait. This result indicates that the action of GRK4 is BMI dependent, supporting the hypothesis that although genetics plays an important role in blood pressure regulation, its effects are strongly context dependent.

Scanning whole exomes for variants associated with arrhythmogenic right ventricular cardiomyopathy. *L.F. Tang[1], K.J. White[1], J. Pons[1], J. Wojciak[2], J. Carroll[1], J. Olgin[2,5], R.L. Nussbaum[1,2,3], M.M. Scheinman[2,5], P.Y. Kwok[1,3,4].* 1) Cardiovascular Research Institute, University of California, San Francisco; 2) Department of Medicine, University of California, San Francisco; 3) Institute of Human Genetics, University of California, San Francisco; 4) Department of Dermatology, University of California, San Francisco; 5) Cardiac Electrophysiology, University of California, San Francisco.

Arrythmogenic Right Ventricular Cardiomyopathy (ARVC), a condition that often results in sudden cardiac death, is characterized by the loss of right ventricular cardiomyocytes and their replacement by fibrofatty tissue. Recent advances in genetics and identification of genetics mutations have improved our understanding of sudden cardiac death but ARVC remains a significant cause of death in the United States. At the Comprehensive Arrhythmia Genetics Center at UCSF, a diagnosis of ARVC was made on clinical and pathological grounds based on established ARVC task force criteria. As an initial genetics screen, we sequenced 32 genes (with 382 amplicons spanning 443 exons and the promoters, totalling 185 kB of sequence) that are known to cause or might be associated with ARVC. At present, we have identified 191 variants (21 novel) in this set of 32 genes. In addition, we sequenced the whole exomes of ARVC patients without deleterious mutations in common ARVC susceptibility genes. In all, we captured and sequenced 201,121 exons from 20,794 genes as well as UTRs and miRNAs using the Illumina HiSeq 2000 platform. Confident variant calls were obtained for each individual with approximately 35,000 SNPs found in the targeted regions at 40X average coverage. Around 2,000 novel variants were found by this high throughput sequencing approach. Further analysis is now under way to identify variants that are likely to be causative for ARVC. This study allows a comprehensive catalog of genetic variants for future diagnostic purpose.

Apolipoprotein B Synthesis Inhibition by Mipomersen Reduces LDL-C When Added to Maximally Tolerated Lipid-Lowering Medication in Patients with Severe Heterozygous Hypercholesterolemia. *J. Tardif[1], R. Ceska[2], L.J. Burgess[3], H. Soran[4], I. Gouni-Berthold[5], G. Wegener[6], S. Chasan-Taber[6], M. McGowan[7].* 1) MHI Research Center, Montreal Heart Institute, Montreal, Quebec, Canada; 2) Center for Preventive Cardiology, General Teaching Hospital and First Medical Faculty of Charles University, Prague, Czech Republic; 3) Stellenbosch University and Tygerberg Hospital, Parow, South Africa; 4) Central Manchester Foundation Trust, University of Manchester, Manchester UK; 5) Department of Internal Medicine II, University of Cologne, Cologne, Germany; 6) Genzyme Corporation, Cambridge, MA; 7) Cholesterol Treatment Center, Concord Hospital, Concord, NH.

Synopsis: In 2 prior studies, mipomersen (MIPO) 200 mg sc weekly reduced LDL-C in patients with homozygous and heterozygous familial hypercholesterolemia (HeFH) by 25% and 28% respectively when added to lipid lowering therapies (LLTs), including high-dose statins. Patients with severe hypercholesterolemia (SH) often fail to normalize LDL-C despite potent LLTs. **Objective:** This randomized, double-blind, placebo-controlled, multi-center, phase 3 trial examined the safety and efficacy of MIPO in patients with SH, >90% of whom were HeFH. **Methods:** Adults (≥ 18 years) with LDL-C ≥ 300 mg/dL or LDL-C ≥ 200 mg/dL with coronary heart disease or other forms of clinical atherosclerotic disease on a maximally tolerated statin and at least one other class of LLT were enrolled. Patients continued prescribed LLT regimen and were randomized (2:1) to MIPO 200 mg sc weekly or placebo (PBO) for a 26-week period. The primary end point was percent reduction in LDL-C from baseline to week 28 or 2 weeks after the last dose for those not completing dosing. **Results:** Fifty-eight patients were randomized (39 MIPO, 19 PBO) at 26 clinical centers in 6 countries. Forty-five (78%) patients completed the treatment period. Twelve (31%) MIPO and 1 (5%) PBO patient(s) withdrew (8 of the MIPO and the 1 PBO withdrawals were due to an adverse event [AE]). LDL-C was reduced by 36% from a mean baseline level of 276 mg/dL in the MIPO group vs. an increase of 13% from a BL of 249 mg/dL in the PBO group (p<0.001). This represents a 101 mg/dL mean reduction of LDL-C in the MIPO group. Similarly, MIPO produced highly significant (p<0.001) reductions in other atherogenic lipoproteins [e.g., apo B and Lp(a)]; there was no change in HDL-C. The most common on-treatment AEs were injection site reactions (90% MIPO, 32% PBO) and flu-like symptoms (46% MIPO, 21% PBO). Six (15%) MIPO patients and no PBO patients had ALT ≥ 3×ULN on consecutive measures at least 7 days apart. One MIPO patient had a transient ALT ≥ 10× ULN. ALT elevations were not associated with clinically significant increases in bilirubin. **Conclusions:** MIPO treatment significantly reduced LDL-C and apoB in patients with severe hypercholesterolemia. The data support the potential utility of MIPO as a pharmacologic option for additional LDL C lowering in patients with heterozygous hypercholesterolemia not adequately controlled under existing LLTs.

Thoracic aortic disease in two patients with juvenile polyposis and hereditary hemorrhagic telangiectasia (JPS-HHT) due to *SMAD4* mutations. *P. Teekakirikul[1,3,4], D.M. Milewicz[2], D.T. Miller[5,7,10], R.V. Lacro[6,10], E.S. Regalado[2], A.M. Rosales[8,10], D.P. Ryan[9,10], T.L. Toler[1,10], A.E. Lin[1,10].* 1) Genetics Unit, MassGeneral Hospital for Children, Boston, MA; 2) Department of Internal Medicine, The University of Texas Health Science Center at Houston, Houston, TX; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Cardiovascular Division, Brigham and Women's Hospital, Boston, MA; 5) Division of Genetics, Children's Hospital Boston, Boston, MA; 6) Department of Cardiology, Children's Hospital Boston, Boston, MA; 7) Department of Laboratory Medicine, Children's Hospital Boston, Boston, MA; 8) Pediatric Cardiology Unit, MassGeneral Hospital for Children, Boston, MA; 9) Department of Pediatric Surgery, MassGeneral Hospital for Children, Boston, MA; 10) Harvard Medical School, Boston, MA.

Background: Dilation or aneurysms of the ascending thoracic aorta can progress to acute aortic dissection (TAAD). Mutations in genes encoding proteins in the TGF-) signaling pathway cause both syndromes and inherited predispositions to TAAD, including *TGFBR1, TGFBR2* and *SMAD3*. *SMAD4* mutations are associated with both juvenile polyposis (JPS) and hereditary hemorrhagic telangiectasia (HHT), now viewed as a single JPS-HHT syndrome. A JPS-HHT family was recently reported to have TAAD and mitral valvulopathy. We report two additional patients with JPS-HHT and *SMAD4* mutations who also have thoracic aortic disease. **Case 1:** An 11 yo white male (BSA 1.29 m^2) without Marfan features had JPS and a *de novo SMAD4* mutation (c.1340_1367dup28). Echo showed mild-mod dilation of the aortic annulus (2.40 cm, Z-score +4.19) and aortic root (3.29 cm, Z +4.04, normal range 1.87-2.80), and mild dilation of the sinotubular junction (2.44 cm, Z +2.13) and ascending aorta (2.72 cm, Z +2.63). Cardiac CT confirmed aortic dilation without aortic tortuosity and tiny pulmonary AVMs. Medication was not prescribed; follow-up echo 7 mos later showed no progression in aortic dilation. Exercise test showed no arterial oxygen desaturation. He had one blanching lesion on his forearm and is being watched for possible HHT. **Case 2:** A 34 yo white female (BSA 2.0) with JPS-HHT and Marfan-like skeletal features was found to have a *SMAD4* mutation (c.1245_1248delCAGA); mutational analysis of *TGFBR1* and *TGFBR2* was negative (*FBN1* testing declined). She had a reduced upper/lower segment ratio, narrow palate, visible veins and multiple striae, pes planus, scoliosis, joint hypermobility, and arachnodactyly. Echo showed mild aortic root dilation. The annulus, root, sinotubular junction, and ascending aorta measured 2.0 cm, 3.8 cm, 3.2 cm, 3.5 cm, respectively. She subsequently developed a pulmonary AVM and hepatic focal nodular hyperplasia. Her father also had JPS-HHT with Marfan-like features and died of an acute aortic dissection at age 60. **Conclusion:** These two new cases confirm the association of thoracic aortic disease with JPS-HHT resulting from *SMAD4* mutations. Case 2's affected father died of an acute aortic dissection. Thus, we propose that the thoracic aorta should be screened and monitored in patients with *SMAD4* mutations to prevent untimely deaths due to dissection. This report also confirms *SMAD4* as another protein in the TGF-) signaling pathway that, when mutated, predisposes to TAAD.

Functional Relationship of the COL4A1/COL4A2 Locus on Chromosome 13q34 to Coronary Artery Disease (CAD). *A. Turner, P. Lau, O. Jarinova, R. McPherson.* University of Ottawa Heart Institute, Ottawa, Canada.

Type IV collagen triple helices constitute the major structural component of basement membranes, consisting primarily of 2 COL4A1 chains arranged with 1 COL4A2 chain. *COL4A1* and *COL4A2* also have important functional roles in angiogenesis, and mutations are associated with diverse vascular abnormalities. The *COL4A1* and *COL4A2* genes on chromosome 13 are arranged in a head-to-head conformation, and uniquely share a common, bidirectional promoter. In the Ottawa Heart Study (OHS) and as part of CARDIoGRAM, a large meta analysis of genome-wide association studies for CAD (>22,000 CAD cases & >64,000 controls), we identified the COL4A1/COL4A2 locus as one of 13 novel regions associated with CAD (Nature Genetics 2011). The index SNP at this locus (rs4773144) has a minor allele frequency of 0.4 and is associated with an increased risk of CAD (allele specific odds ratio=1.21 in OHS). In a search for functional genetic variants, we resequenced the bidirectional *COL4A1/COL4A2* promoter in 500 CAD cases and 500 controls and identified four novel SNPs, in promoter/enhancer regions essential for *COL4A1* and/or *COL4A2* gene expression and in strong linkage disequilibrium with several OHS risk SNPs. In a luciferase assay, the risk allele for the rs35466678 SNP, in the 5'UTR of *COL4A2*, reduced promoter activity by 13% ($p<0.005$). Furthermore, the linked risk alleles for the rs7327528 and rs117410570 SNPs, both within an enhancer essential for *COL4A2* transcription, reduced *COL4A2* promoter activity by 17% ($p<0.0005$). Reduced *COL4A2* promoter activity *in vitro* due to these SNPs will be investigated further to determine effects on protein levels and basement membrane structure/function. These findings are important because misregulation of *COL4A1* and *COL4A2* could have important consequences relevant to CAD, including effects on basement membrane integrity and angiogenesis.

GLUT10 connects TGF) signaling to cellular metabolism in cardiovascular development. *Z. Urban[1,2], A. Willaert[2,3], S.M. Khatri[1], B.L. Callewaert[2,3], P.J. Coucke[3], S.D. Crosby[4], B.L. Loeys[3], M. Tsang[5], A. De Paepe[3].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 3) Department of Medical Genetics, Ghent University Hospital, Ghent, Belgium; 4) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 5) Department of Developmental Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Growth factor signaling results in dramatic phenotypic changes in cells, which require commensurate alterations in cellular metabolism. Such growth-metabolic coupling is well understood in the case of the IGF/PI3K/AKT/mTOR pathway, however, for other growth factors it has been a matter of conjecture. Recent studies showed that mutations in *SLC2A10*/GLUT10, a member of the facilitative glucose transporter family, were associated with altered transforming growth factor-) (TGF)) signaling in patients with arterial tortuosity syndrome (ATS). The objective of this work was to test if *SLC2A10*/GLUT10 can serve as a link between TGF) -related transcriptional regulation and metabolism during development. In zebrafish embryos, knockdown of *slc2a10* by antisense morpholino oligonucleotide injection caused a wavy notochord and cardiovascular abnormalities with a reduced heart rate and blood flow, and incomplete and irregular vascular patterning. These effects were phenocopied by treatment with a small-molecule inhibitor of TGF) receptor (tgfbr1/alk5). Array hybridization showed that the changes at the transcriptome level caused by the two treatments were highly correlated, revealing that reduced tgfbr1 signaling is a key feature of ATS in early zebrafish development. Interestingly, a large proportion of the genes, which were specifically dysregulated by knocking down the *slc2a10* gene and not by tgfbr1 inhibition play a major role in mitochondrial function. These experiments show that *slc2a10*/glut10 is essential for the development of the cardiovascular system and connective tissues by facilitating cellular respiration and TGF) signaling.

359T

Maternal origin of PEAR1 gene locus affects platelet response to collagen. *D. Vaidya[1], R.A. Mathias[1], L.R. Yanek[1], R. Qayyum[1], N. Fadaday[2], B.G. Kral[1], D.M. Becker[1], L.C. Becker[1].* 1) Medicine, Johns Hopkins University, Baltimore, MD; 2) Anesthesiology, Johns Hopkins University, Baltimore, MD.

Background: We have previously shown that the A allele of intronic SNP rs12041331 of the PEAR1 gene on Chr 1 is associated with reduced ex vivo platelet aggregation in response to collagen. A previous case series report suggested that a parentally imprinted genetic region in Chr 20 affects platelet phenotypes. We thus examined whether platelet aggregation is also affected by parental origin of rs12041331 alleles.

Methods: We used data from European ancestry samples from GeneSTAR, a family study of the genetics of platelet reactivity. Maximal platelet aggregation in platelet rich plasma was measured after stimulation with collagen 2μg/mL. We included offspring whose parents had informative genotypes such that the parent of origin of alleles could be inferred (n=613 from 406 families, 53% female, 36 ± 9 yrs of age). We used linear mixed models to examine the association of platelet aggregation with maternally or paternally transmitted rs12041331 alleles, after adjusting for age and sex.

Results: The mean and standard deviation of percent platelet aggregation by the parental origin of the A and/or G allele is tabulated below.

Mean (SD) collagen-induced % platelet aggregation by rs12041331 allele origin

Paternal G, maternal G, N= 576	Paternal A, maternal G, N= 20	Paternal G, maternal A, N= 12	Paternal A, maternal A, N= 6
65.1 (29.1)	72.2 (25.1)	31.1 (37.4)	31.2 (32.0)

Possessing an A vs. G allele of maternal origin had stronger association with lower levels of platelet aggregation (beta = -36.3, $p=4.2*10^{-7}$) as compared to an A vs. G allele of paternal origin (beta = 7.5, p=0.22; p-value of the difference between beta coefficients=$3.2*10^{-5}$).

Conclusion: We found evidence of genetic imprinting of the parent of origin of the PEAR1 locus for ex vivo collagen-induced platelet aggregation. Genetic loci for platelet function should be examined as candidates for parental imprinting.

360T

Genome-Wide Association Study of Pulse Pressure and Mean Arterial Pressure Identifies Novel Loci Associated with Cardiovascular Disease and Stroke. *C.M. van Duijn[1], L.V. Wain[2], G.C. Previous genome-wide association studies of blood pressure have identified 29 loci associated with systolic and diastolic blood pressure. We undertook a genome-wide association study of two further blood pressure phenotypes: pulse pressure (PP, the difference between systolic and diastolic blood pressure), a measure of stiffness of the main arteries, and mean arterial pressure (MAP), a weighted average of the systolic and diastolic blood pressure. Both PP and MAP are predictive of hypertension and cardiovascular disease. A total of 74,064 individuals of European ancestry were included in the discovery stage and 48,607 individuals were included in the follow-up stage. We studied 2.5 million directly genotyped or imputed single nucleotide polymorphisms. Seven novel loci showed genome-wide significant association with PP or MAP (P= 2.7x10-8 to P=2.3x10-13). Of these, four novel loci were found to be associated with PP but not to systolic or diastolic blood pressure (at 4q12 near CHIC2/PDGFRAI, 7q22.3 near PIK3CG, 8q24.12 in NOV, 11q24.3 near ADAMTS-8), highlighting the relevance of studying PP as an alternative measure of blood pressure phenotypes. In our study of persons of European descent, we found a locus associated with both PP and MAP (at 2q24.3 near FIGN), which was recently associated with systolic blood pressure in east Asians. We examined the clinical impact of the novel loci on morbidity in independent large disease consortia including Cardiogram, PROCARDIS, ECHOGEN, AortaGEN, CKDgen, KidneyGEN and Decode. These analyses included 6788 cases with hypertension, 30,657 with coronary heart disease, 2708 with stroke, 2526 with heart failure and 5807 with kidney disease. Adjusting for multiple testing, the PP risk score was associated with hypertension (P=7.9x10-6), incident stroke (P=4.9x10-4) and coronary heart disease (P=4.3x10-4) and the MAP risk score was associated with hypertension (P=5.1x10-16), coronary heart disease (P=4.0 x10-20), stroke (P=0.0019) and left ventricular wall thickness (P=2.1x10-4). Our findings demonstrate that analysis of alternative blood pressure phenotypes provide further insights into the genetic architecture of blood pressure and highlight pathways that may differentially influence systolic and diastolic blood pressure.

361T

Gene expression signatures of left ventricular mass and stroke volume change in response to endurance training. *D.D. Vance[1, 3], L. Nathanson[1, 3], M. Stoutenberg[2], G. Chen[3], R. Myerberg[3], K. Jacobs[2], J. Clark[2], A. Perry[2], D. Seo[1, 3], E. Rampersaud[1, 3], P.J. Goldschmidt-Clermont[1, 3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Department of Kinesiology and Sports Science, University of Miami, Miami, FL, USA; 3) Miller School of Medicine, University of Miami, Miami, FL, USA.

Changes in cardiac morphology including increased left ventricular (LV) mass and stroke volume (SV) have been well documented among athletes. Although the pathophysiology of these processes is well described, the biological mechanisms for these changes are unknown. To further explore this, we examined the genomic profiles of a cohort of 20 men (29.3 ±1.0yr) a subset of which experienced significant changes in LV mass and SV after participating in a 17 week half marathon training program. Overall, LV mass increased from 186.6±37.4 g to 209.2±30.0 g (p=0.009) and SV increased from 72.6±14.0ml to 91.6±20.9ml (p=0.001). Fasting blood samples and data from echocardiograms were collected at baseline and at the completion of the training program. We compared the global gene expression in the leukocytes of men who experienced ⁄ 14% increase in LV mass and ⁄ 35% increase in SV to those with less significant changes (upper quartile). Leukocyte samples were collected, stored and total RNA was isolated using the Leukolock system (Ambion). Gene expression profiling was performed using the Affymetrix GeneChip Human Gene ST array and analyses were performed with ANOVA implemented in Partek. Twelve genes were overexpressed (p<.01;fold change (FC)⁄ 1.5) among men with ⁄ 14% increase in LV mass. These genes are involved in inflammatory response and two genes mapped to the NOD-like receptor signaling pathway. In contrast, two genes (CCL3L1; RFC1) had lower expression among the men with greater increase in LV mass (p<.01; FC; ≤-1.5); CCL3L1 is a cytokine involved in immunoregulatory and inflammation. Seven genes were overexpressed (p<.01;FC⁄ 1.5) in the men with greater SV increase and map to pathways involved in inflammatory immune response, angiogenesis, and endothelial cell signaling. Validation of these data is in progress. In summary, we have identified subsets of genes that are differentially expressed in men who experienced significant changes in LV mass and SV following 17 weeks of endurance training. A common theme for the genes identified appears to be their involvement in inflammatory and tissue repair processes. Our study suggests that utilization of genomic approaches is a potentially powerful approach for understanding exercise-induced changes to cardiac morphology.

362T

microRNA-152 mediates DNMT1-regulated DNA methylation in the estrogen receptor (gene. *Y. Wang[1], W. Chou[1], K. Chen[1], H. Cheng[1], R. Lin[2], S. Juo[1].* 1) Department of Medical Genetics, Kaohsiung Medical University, Kaohsiung, Taiwan; 2) Department of Neurology, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan.

Introduction: Estrogen receptor ((ER( ) has been shown to protect against atherosclerosis. Methylation of the ER(gene can reduce ER(expression leading to a higher risk for cardiovascular disease. Recently, microRNAs have been found to regulate DNA methyltransferases (DNMTs) and thus control methylation status in several genes. Results: (1) The ER(expression was decreased and ER(methylation was increased in LPS-treated human aortic smooth muscle cells (HASMCs) and the aorta from rats under a high-fat diet. (2) Among 1,087 surveyed miRNAs, the expression level of miR-152 was decreased by 2.3-fold when HASMCs were treated with LPS. Subsequent real-time PCR experiment confirmed that LPS can decrease miR-152 expression at 48 h and 72 h (P = 0.0015 and 0.006). (3) The significant increases of DNMT1, the miR-152 targeting gene, mRNA expression and protein levels in HASMCs were found at 48 h and 72 h after the treatment of LPS. These results indicate that the reduced miR-152 can lose an inhibitory effect on DNA methyltransferase, which leads to hypermethylation of the ER(gene and a decrease of ER(level. (4) When DNMT1 was inhibited by RNA inference, the mRNA and protein levels of ER(were simultaneously increased by 4.33- and 2.32-fold, respectively. These results clearly show that ER(gene can be silenced by DNMT1. Conclusion: The present study identified a novel mechanism to regulate ER(expression in the context of epigenetic therapy in the context of atherosclerosis and cardiovascular disease. The discovery of miR-152 and ER(methylation in this study may let us gain more insight to the development of atherosclerosis. Furthermore, miR-152 can also be a therapeutic agent for atherosclerosis.

Pediatric cardiomyopathy: genetic causes and utility of testing. *S.M. Ware, M. Tariq, S.J. Kindel, T. Le, J.A. Towbin.* Molec Cardio Biol/Human Gen, Cincinnati Children's Hosp, Cincinnati, OH.

Cardiomyopathy is a disease of heart muscle causing systolic and diastolic dysfunction, or both, and, although rare, is a common cause of cardiac failure in children. Major phenotypic subgroups include dilated (DCM), hypertrophic (HCM), restrictive (RCM), left ventricular noncompaction (LVNC) and arrhythmogenic (ARVC) forms. In the pediatric population, causes include sarcomeric mutations, genetic syndromes, and inborn errors of metabolism. Despite progress in identifying various genetic causes for pediatric cardiomyopathy, in the majority of children no cause can be determined. Our inability to identify and assign causal genes to individual patients represents a clear obstacle to our ability to understand the implications of specific genotypes and precludes the integration of genotype and phenotype data for individual patient risk stratification. The aim of this study was to determine the utility and diagnostic yield of PCR-based high throughput sequencing for the diagnosis of pediatric cardiomyopathies. A cohort of 84 pediatric patients under 10 years of age was enrolled in this study including 19 RCM, 18 HCM, 19 DCM, and 23 LVNC and 5 mixed cardiomyopathy patients. Screening was performed using PCR-based next-generation sequencing (Illumina GAII) covering more than 31 sarcomeric and metabolic genes. Disease-causing mutations were identified in 40 patients (48%; 10 with RCM, 9 with HCM, 7 with DCM, 13 with LVNC and 1 mixed), including ~15% with a family history of disease. Twenty-eight percent of patients had mutations in more than one gene (compound-heterozygotes), most frequently in sarcomeric genes MYBPC3, MYH7, TPM1, and TNNT2. An additional 21 patients (25%) had variants of uncertain significance or potential disease associated alleles. This study provides large-scale, genetic mutation prevalence data for a pediatric population with systolic or diastolic dysfunction and demonstrates the importance of high-throughput technologies to identify multiple mutations in a single patient. These data also suggest that pediatric cardiomyopathy genetic testing panels should encompass a wider array of genes than currently available via clinical testing in order to account for the contribution of metabolic and syndromic causes in this population.

9p21 region is associated with brain white matter lesions. *L.R. Yanek[1], P.A. Nyquist[1], B.G. Kral[1], D. Vaidya[1], R.A. Mathias[1], B. Suktitipat[2], T.F. Moy[1], L.C. Becker[1], D.M. Becker[1].* 1) Medicine, Johns Hopkins University, Baltimore, MD; 2) Genometrics Section, Inherited Disease Research Branch, National Human Genome Research Institute, Baltimore, MD.

Background: The 9p21 locus has been associated with vascular disease phenotypes including coronary artery disease (CAD), abdominal aortic aneurysm, peripheral arterial disease, and intracranial aneurysm. We therefore evaluated the association of the 9p21 region with ischemic white matter disease represented as the ratio of white matter lesion to total brain volume (LBV). Methods: We examined adult relatives of probands with early onset CAD. Brain MRI (3T) was performed, and the total white matter lesion and total brain volume were measured; the ratio of white matter lesion to brain volume was calculated and used for analysis. Participants with a history of CAD, stroke, or transient ischemic attacks were excluded. We examined the association with all SNPs with >1% MAF genotyped in the 9p21 region on the Illumina 1Mv1_c chip in European (EA) and African Americans (AA) separately. Associations with LBV were performed under an additive model or dominant model based on genotype frequencies, adjusted for age, sex, family clustering, and population stratification. Results: Participants included 308 EA from 172 families and 184 AA from 115 families (41% male, 51.8 ± 10 years of age). In EA 64 SNPs were examined and 84 in AA. Five SNPs were associated with LBV at the p<0.05 level: in EA, rs3731238 (beta= 0.6529, p=0.0097), rs10965243 (beta=0.4027, p=0.0328), and rs2383208 (beta=0.446, p=0.0034); in AA, rs3217986 (beta=-0.7040, p=0.0402) and rs10811658 (beta=0.4214, p=0.0100). Significant SNPs were either in the 9p21 region previously found with intracranial aneurysms, but not in LD with previously reported SNPs; or, in the opposite end of the 9p21 region near/ in the ANRIL locus, where we previously reported an association with incident CAD in this same high risk family population. Conclusions: The 9p21 region appears to be associated with LBV, a measure of ischemic white matter disease, in a high risk population. Further studies of the 9p21 region may parse out locus-specific variations that are related to cerebrovascular disease.

An integrative pathway analysis using gene expression, single-nucleotide polymorphism and environmental factor successfully predicts disease status of hypertension. *H.-C. Yang[1], C.-W. Lin[1], K.-M. Chiang[2], Y.-J. Liang[1], C.-W. Chen[1], S.-M. Hwang[3], K.-S. Lynn[4], J.-W. Chen[5], W.-H. Pan[2].* 1) Institue of Statistical Science, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Bioresource Collection and Research Center, Food Industry Research and Development Institute, Hsinchu, Taiwan; 4) Institute of Information Science, Academia Sinica, Taipei, Taiwan; 5) National Yang-Ming University School of Medicine and Taipei Veterans General Hospital, Taipei, Taiwan.

[**Background**] Renin-angiotensin-aldosterone system (RAAS) pathway, calcium-signaling (CS) pathway and calcium-channel (CC) functional group are known as the relevant biosystems targeted by antihypertensive drugs such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and calcium channel blockers. In each of these biosystems, several dozens of genes are involved. If we can not consider them simultaneously, we may lose sight of the whole picture. Genetic marker and gene expression data each has its unique biological meaning. [**Methods**] Our analysis pipeline began with a biosystem enrichment analysis to verify the significance of the three biosystems based on gene expressions, single-nucleotide polymorphisms (SNPs) and a major environmental factor [body mass index (BMI)] of 200 matched case-control pairs. Gene expressions of 334 transcript probes on 248 genes and genotypes of 7,368 SNPs on the 228 genes involved in the three biosystems were collected from the experiments with Phalanx Human OneArray and Illumina 550K SNP BeadChip, respectively. Then we carried out a 10-fold cross-validation procedure for a statistical classification analysis to establish a hypertension prediction model with the highest testing accuracy. Furthermore, we evaluated the prediction model by using independent samples of 53 patients and 50 controls from the same Han Chinese population. [**Results**] A biosystem enrichment analysis verifies the significance of the three biosystems, RAAS pathway ($p < 0.0001$), CS pathway ($p < 0.0001$) and CC functional group ($p < 0.0001$). Statistical classification analysis derives the best classification model with a training accuracy of 80.1% and a testing accuracy of 85%. In the model, BMI provides a net accuracy of 52.5% in predicting hypertension. Prediction accuracy is accumulated to 60% after including two optimally selected SNPs, rs1543208 and rs7921117, and then accumulated to 85% after further including gene expressions of four best selected genes, *CACNB1*, *NOS3*, *CACNA1C* and *CACNA1G*. Finally, the derived prediction model with seven key biomarkers receives a prediction accuracy of 85.1% in an independent validation dataset of 103 samples. [**Conclusions**] RAAS, CS and CC are validated as the important biosystems relevant to hypertension in the Taiwan Han Chinese population. Gene expressions and SNPs involved in the three biosystems and environmental variable BMI provide an informative biosignature for predicting hypertension.

BRCA2 Variants and Cardiovascular Disease in a Multi-Ethnic Cohort. *K. Zbuk[1,2], M. Heydarpour[1], G. Pare[1,3], D. Davis[4], R. Miller[4], M. Lanktree[5], S. Yusuf[1,6], D. Saleheen[7], J. Danesh[7], R. Hegele[5], S.S. Anand[1,6].* 1) Population Health Research Institute, Hamilton Health Sciences, Hamilton, Ontario, Canada; 2) Dept. of Oncology, McMaster University, Hamilton, Ontario, Canada; 3) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada; 4) Six Nations Health Services, Ohsweken, Ontario, Canada; 5) Schulich School of Medicine and Dentistry, University of Western Ontario, London, Ontario, Canada; 6) Departments of Medicine and Epidemiology, McMaster University, Hamilton, Ontario, Canada; 7) Department of Public Health and Primary Care, Cambridge University, Cambridge, UK.

Background: Germline mutations of BRCA1/2 are associated with hereditary breast and ovarian cancer. Recent data suggests excess mortality in mutation carriers beyond that conferred by neoplasia, and recent in vivo and in vitro studies suggest a modulatory role for BRCA proteins in endothelial and cardiomyocyte function. We therefore tested the association of these markers with clinical cardiovascular disease (CVD). Methods: Using data from 1,170 individuals included in two multi-ethnic population-based studies (SHARE and SHARE-AP), the association between BRCA2 variants and CVD was evaluated. 21 SNPs in BRCA2 with minor allele frequencies (MAF)>0.01 were genotyped using the Illumina CVD array. 115 individuals (9.8%) reported a CVD event, defined as myocardial infarction (MI), angina, silent MI, stroke, and angioplasty or coronary artery bypass surgery. Analyses were adjusted for age, sex, ethnicity, and other traditional CVD risk factors as covariates. A single SNP (rs11571836) was subsequently genotyped using Sequenom technology in 1045 cases of incident MI and 1135 controls from the South Asian subset of an international case-control study of acute MI (INTERHEART), and imputed in 4686 cases of MI and 4500 controls from the Pakistan Risk of Myocardial Infarction Study (PROMIS) study. Results: Two BRCA2 SNPs, rs11571836 and rs1799943, both located in untranslated regions, were associated with a lower risk of prevalent CVD (OR 0.52 p=0.001 and OR 0.50 p=.002 respectively) in the SHARE studies. Analysis by specific ethnicities demonstrated an association with CVD for both SNPs in Aboriginal People, and for rs11571836 only in South Asians. No association was demonstrated in the European and Chinese subgroups. A non-significant trend towards an association between rs11571836 and lower risk of MI (OR=0.87 p=0.06) was observed in South Asians from the INTERHEART study, but was not evident in PROMIS (OR= 0.96 p=0.22). The combined p value of the replication cohorts was p= 0.10 (Stouffer's z trend) and meta-analysis resulted in a combined OR=0.94 (p=0.06 fixed effect model). These results suggest a possible role for BRCA2 in the etiology of CVD, however much larger studies are needed to confirm or refute this hypothesis. More comprehensive interrogation of BRCA gene variation, including functional analyses, is required to fully understand whether BRCA family members are involved in CVD pathogenesis.

367T

Risk Variants of Coronary Artery Disease in the Chromosome 9p21 Region are associated with *ANRIL* Expression in GENOA. *W. Zhao[1], J.A. Smith[1], M. Fornage[2], P.A. Peyser[1], S.T. Turner[3], S.L.R. Kardia[1].* 1) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 2) Brown Foundation Institute of Molecular Medicine, University of Texas Health Science Center, Houston, TX; 3) Department of Nephrology and Hypertension, Department of Medicine, Mayo Clinic, Rochester, MN.

Recent genome-wide association (GWA) studies have shown that single nucleotide polymorphisms (SNPs) in the chromosome 9p21 region are associated with coronary artery disease (CAD). Most of the SNPs identified in this region by GWA studies are non-coding SNPs, suggesting that they may influence gene expression by cis or trans mechanisms to affect disease susceptibility. Since all cells from an individual have the same DNA sequence variations, levels of gene expression in immortalized cell lines can reflect the functional effects of heritable DNA sequence variations that influence or regulate gene expression. To evaluate the functional consequences of the risk variants in the chromosome 9p21 region on gene expression, we examined the association between 137 SNPs in this region and both gene-level and exon-level RNA expression of the adjacent genes *CDKN2A*, *CDKN2B*, *ANRIL* and *C9orf53* from transformed beta-lymphocytes in 812 Caucasian participants from The Genetic Epidemiology Network of Arteriopathy (GENOA) study. Linear mixed effects modeling was used to test the association between each SNP and RNA expression using age-adjusted RNA expression as the outcome, SNP as the predictor, and pedigree as the random effect. We found that the exon-level RNA expression of *ANRIL* was significantly associated with multiple SNPs (111 SNPs) after Bonferroni correction. More importantly, 72 out of the 74 CAD-associated SNPs identified in a recent GWAS conducted by the Cohorts for Heart and Aging Research in Genetic Epidemiology (CHARGE) consortium were all associated with *ANRIL* expression. The remaining two SNPs were also significantly associated with *ANRIL* expression before Bonferroni correction. The magnitude of change in the RNA expression for significant SNPs ranges from 11% to 40%. No significant association was found between these SNPs and the other three genes. These results suggest that the effect of risk variants in chromosome 9p21 region on susceptibility to CAD is likely to be mediated through *ANRIL* expression.

368T

Identification of 132 new mutations of the *FBN1* gene in patients with suspected Marfan syndrome. *W. Zou, H. Wang, B.A. Westerfield, L.S. Pena, A. Do, G.A. Rodriguez, D.J. Penny, Y. Fan.* John Welsh Cardiovascular Diagnostic Laboratory, Section of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Marfan Syndrome (MFS) is a heritable disorder of connective tissue with multisystemic manifestations, which typically involves the skeletal, cardiovascular and ocular systems. It is usually caused by defects of fibrillin-1 (*FBN1*) gene and its diagnosis requires the presence of Ghent criteria. *FBN1* encodes a large secreted 350-kDa glycoprotein that is multidomain, highly repetitive, and known to be a major component of 10-12 nm microfibrils. *FBN1* gene mutations are associated not only with the MFS but also with a spectrum of conditions phenotypically related to MFS, including dominantly inherited ectopia lentis, severe neonatal Marfan syndrome and aortic aneurysm. There appear to be no mutation hot spots in the *FBN1* gene since the identified mutations were distributed throughout the entire gene. However, a clustering of mutations associated with the most severe form of Marfan and neonatal Marfan syndrome has been noted in a region encompassing exons 23 to 32. To date, more than 700 mutations have been identified in the *FBN1* gene in MFS patients and related diseases. We conducted FBN1 mutation analysis in a large cohort of 1025 cases with suspected MFS referred to our center for genetic analysis. Peripheral blood-derived genomic DNA was used to amplify the 65 coding exons of the *FBN1* gene by polymerase chain reaction (PCR) using intron-based and exon-specific primers. The PCR products were purified and analyzed by bidirectional sequencing using Big Dye terminator chemistry (v3.1) and ABI3730XL genetic analyzer. A total of 199 mutations were identified in 1025 unrelated cases with suspected MFS. Of these, 132 mutations were not reported previously, to our knowledge, which included 82 missense mutations, 13 predicted splicing site alterations that were expected to result in exon skipping or activation of a cryptic splice site, 6 nonsense mutations and 31 deletion/insertion mutations that were predicted to cause a frameshift and lead to the MFS phenotype via *FBN1* haploinsufficiency. These mutations were distributed throughout the entire *FBN1* gene and approximately 13% of the mutations occurred in two or more MFS patients. In summary, our study further expanded the mutational spectrum of the *FBN1* gene in patients with MFS. This data is expected to considerably improve genetic counseling for and medical care of MFS patients.

369T

The genetics of Brugada Syndrome : a new approach. *S. Le Scouarnec[1], P. Lindenbaum[2], V. Portero[2], A. Derevier[2], J-B. Gourraud[2], C. Scott[1], J. Barc[3], H. Le Marec[2], A. Wilde[3], V. Probst[2], C. Bezzina[3], E. Schulze-Bahr[4], N. Carter[1], J-J. Schott[2], R. Redon[2].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 2) L'institut du thorax, Nantes, FR; 3) Academic Medical Center, Amsterdam, NL; 4) University Hospital Muenster, DE.

Brugada Syndrome (BrS) is an inherited form of cardiac arrhythmia characterized by ST-segment elevation on the electrocardiogram, associated with a higher risk of sudden cardiac death (SCD) in young individuals. So far, genetic investigations have often been restricted to ion channel genes and the great majority of cases are still unexplained. We are combining high-throughput, genome-wide methods (exome sequencing, array-CGH, and SNP genotyping) to reveal genetic defects in familial cases of BrS and to improve molecular diagnosis of cardiac arrhythmias and prevention of SCD. Twenty families with at least 3 affected patients and a history of SCD have been included in the study, after exclusion of the most frequently involved gene, *SCN5A*. Exome sequencing and high-resolution array-CGH have been performed for one patient per family. By array-CGH, we have identified deletions and duplications absent from public databases and containing entire genes in some cases. Among these is a large de novo 670 kb deletion encompassing seven genes and adjacent to, but excluding, a gene already linked to arrhythmias, suggesting the possible deletion of a regulatory region of this gene. Exome enrichment reaches 58% on average and the mean sequencing depth per patient ranges from 84X to 136X, around 90% of the targeted sequence being covered by at least 10 reads. More than 30,000 simple nucleotide variants per patient have been identified by this approach. After excluding non-coding and synonymous variants as well as variants found by other studies and in databases such as dbSNP and the 1000 genomes project, candidate genes have been prioritized and are now followed-up. SNP genotyping of all affected family members is in progress to determine regions likely to be identical-by-descent. This will allow us to prioritize candidate variants according to their co-segregation with the BrS phenotype.

370T

Identifying at-risk genetic variants for sudden cardiac death from whole exome sequence data in the *ClinSeq™* study. *D. Ng[1], J.J. Johnston[1], F.M. Facio[1], S.G. Gonsalves[1], C. Krause[1], J.K. Teer[1,2], J.C. Mullikin[1,2,3], L.G. Biesecker[1,2], National Institutes of Health Intramural Sequencing Center, NIH, Bethesda, MD.* 1) Genetic Disease research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

U.S. estimates of sudden cardiac death (SCD) range from 180,000 to >450,000/yr. Ten to fifteen percent of SCD is due to cardiomyopathies and 1-2% to channelopathies. Identifying at-risk gene variants for SCD in asymptomatic individuals can potentially save lives. *ClinSeq™* aims to identify medically actionable genetic variants and return results to participants for monitoring, prophylaxis, and treatment. We looked for deleterious changes in channelopathy and cardiomyopathy genes in an adult cohort not ascertained for arrhythmia, cardiomyopathy or SCD. METHODS: 401 whole exome sequences were annotated for variants in 39 cardiomyopathy and 24 channelopathy genes with an algorithm that filtered results based on genotype quality, allele frequency, mutation type, and information in locus-specific databases. Variants were assigned pathologic scores ranging from 0-5 (0= poor genotype quality, 1=not pathogenic (probability <0.001), 2=likely not pathogenic (0.001-0.049), 3=uncertain (0.05-0.949), 4=likely pathogenic (0.95-0.99), 5=definitely pathogenic (>99); Plon et al. 2008). RESULTS 234 variants were found in 24 channelopathy genes. Forty-one variants were excluded (3 scored 0, 38 score 1 due to high frequency), leaving 193 variants. Human Gene Mutation Database and locus-specific databases were reviewed. Eighteen variants were designated not pathogenic (score 1); 173 were defined as variants of uncertain significance (score 2 [n=8], score 3 [n=148], score 4 [n=17]); and two variants were designated pathogenic (score 5). *SCN3B* p.Leu10Pro is associated with atrial fibrillation and Brugada syndrome. Participant's baseline ECG showed left bundle branch block and prolonged QTc 493ms. *KCNH2* p.Arg312Cys is associated with long QT syndrome type 2. Baseline ECG showed sinus bradycardia 56 bpm, 1° AV-block, and normal QTc 402ms. Neither participant reported a family history of SCD. *ClinSeq™* participants with variants scored 4-5 will be invited to the NIH for cardiology evaluation to delineate their risk for SCD. Results of cardiomyopathy gene analysis will be reported. Conclusion Whole exome sequencing has the potential to identify clinically relevant variants. Much work is needed to define genotype-phenotype risk for SCD. Sequencing costs have dropped, but clinical annotation remains costly and time consuming. Combining existing knowledge into a centralized database is crucial in achieving the goals of personalized medicine.

371T

Genetic screening of long QT syndrome (LQTS) in Sweden. *A. Norberg[1], K. Cederquist[1], J. Jonasson[1], B.A. Jonsson[1], A. Rydberg[2,3], S.M. Jensen[3,4], E.L. Stattin[1,3].* 1) Clinical Genetics, Umeå University Hospital, Umeå, Sweden; 2) Department of Clinical Sciences, Pediatrics, Umeå University Hospital; 3) Centre for Cardiovascular Genetics, Umeå University Hospital; 4) Heart Centre, Umeå University Hospital.

Background: Long QT syndrome (LQTS) is an inherited disorder characterized by prolongation of the QT interval on ECG and risk of syncope and sudden death. The most common genes implicated in LQTS are the cardiac ion channels *KCNQ1, KCNH2, SCN5A, KCNE1* and *KCNE2*, accounting for about 70% of the identified mutations in patients with a clinical diagnosis. The symptoms are very variable in LQTS patients, and genotype influences the clinical course. **Objectives:** This study aims to report the spectrum and prevalence of LQTS mutations in Sweden. Knowledge of founder mutations or certain subdiagnostic criteria for different mutations will facilitate the molecular genetic analysis. **Methods:** A cohort of 200 consecutive, unrelated patients (137 females, average age 33 years, range 0 to 79 years) referred to Umeå for LQTS clinical genetic testing between March 2006 and October 2009 have been evaluated. Coding sequences and splice sites of the five genes have been screened by DHPLC and/or DNA sequencing. MLPA has also been performed to detect any large deletions or duplications. Furthermore, 36 selected patients have been screened for mutations in *RYR2*, a gene known to be involved in the clinically overlapping disease catecholaminergic polymorphic ventricular tachycardia (CPVT). **Results:** Overall, in 102 of 200 (51%) probands, we could detect a disease-causing mutation. These genotype-positive cases stemmed from 61 distinct mutations, of which 17 (28%) were novel to this Swedish cohort. The majority (79%) of the distinct mutations were found in a single case, whereas 13 mutations (21%) were observed more than once. Two Swedish founder mutations, *KCNQ1*-R518X and *KCNQ1*-Y111C, accounted for 25% of the genotype-positive probands. Among the genotype-positive patients, 100 had a single mutation, whereas only 2 patients had more than one definitely pathogenic mutation. However, several probands carried rare variants that are difficult to interpret since they are referred to in the literature as both mutations and functional polymorphisms. Although they might contribute to the phenotype, they were not considered as disease-causing mutations, since careful interpretation of genetic test results is critical in clinical use. **Conclusion:** Two Swedish founder mutations account for about one-fourth of the identified mutations. This cohort increases the publicly known LQTS-associated mutations, of which approximately one-third of the detected mutations continue to be novel.

372T

Mysteries of the past - Genetic evaluation of families with unexplained sudden cardiac death has revealed inheritable heart diseases. *A. Wisten[1, 2], I. Boström[3], S. Mörner[2], E. Stattin[3].* 1) Department of Internal Medicine, Sunderby Hospital, Luleå, Sweden; 2) Department of Public Health and Clinical Medicine, Umeå University, Umeå, Sweden; 3) Department of Medical Biosciences, Medical and Clinical Genetics, Umeå University, Umeå, Sweden.

Background: Sudden cardiac death (SCD) in the young is a rare and tragic event. Standard forensic autopsy is often unsuccessful in determining the cause of SCD. Post mortem genetic testing or molecular autopsy has shown that these deaths can be caused by inherited arrhythmic disorders. Objectives: The purpose of this study was to determine the cause of sudden death, in subjects with normal autopsy findings. Subjects were identified in a national Swedish study of SCD in 15 to 35 year olds from 1992-1999. Methods and results: We performed molecular genetic analysis of first degree relatives to 25 subjects who suffered sudden unexplained death. Coding exons of the KCNQ1, KCNH2, SCN5A, KCNE1, KCNE2, KCNJ2, RyR2, MYBPC3 and MYH7-genes were screened. We identified the causative underlying disease in five subjects [LQTS (3), SQTS (1), HCM (1)], and molecular genetic analysis provided confirmation in three families with LQTS. Target mutation analysis of autopsy tissue confirmed the diagnosis in two of the deceased subjects. Polymorphisms were identified in relatives. In the SQTS- and HCM-families, there were two siblings, who both died from SCD. Conclusions: It is possible to identify a mutation in a next-of-kin and to verify the mutation in autopsy tissue many years after death. However, this investigation should start directly. To prevent more deaths in the families, prompt genetic and clinical evaluation should be performed. Blood or appropriate tissue for DNA extraction ought to be obtained at the post-mortem examination. We found a plausible or verified diagnosis in 20% of the families. Familial cascade screening revealed five asymptomatic carriers at risk. Effective evaluation of relatives, guided by genetic testing, can identify asymptomatic carriers and hopefully prevent further deaths in the family. Common polymorphisms may possibly act as modifier gene alleles increasing arrhythmia susceptibility.

The Spectrum of *SCN5A* Gene Mutation in Singapore Brugada Syndrome Patients. *R.Y.Y. Yong[1], M. Uttamchandani[1], B.Y. Tan[2], J.L. Neo[1], S.H. Yap[1], L.S.H. Gan[1], W.Q. Wong[2], R. Liew[2], C.K. Ching[2], D.T.T. Chong[2], C.W.F. Chong[3], T.W. Lim[3], W. Chow[4], S. Moochhala[1], E.P.H. Yap[1], S.C. Seow[3], W.S. Teo[2].* 1) Defence Medical & Environmental Research Institute, DSO National Laboratories, 27 Medical Drive #12-00, Singapore 117510; 2) National Heart Centre, Singapore General Hospital, Mistri Wing, 17 Third Hospital Avenue, Singapore 168752; 3) The Heart Institute, National University Hospital, Cardiac Department, 5 Lower Kent Ridge Road, Singapore 119074; 4) Headquarters Medical Corps, Singapore Armed Forces, HQ SAF Medical Corps, 701 Transit Road, #04-01, Singapore 778910.

Brugada syndrome (BrS) is an inherited arrhythmia syndrome with an increased risk of sudden death, resulting from polymorphic ventricular tachycardia and/or ventricular fribrillation in the absence of gross structural abnormalities. BrS is characterized by right bundle bock and ST-segment elevation in the right precordial ECG leads. The incidence of clinical event, syncope and sudden cardiac death, depends on ethnicity, with a higher rate of sudden death in patients of Asian origin. Mutations in the *SCN5A* gene, which encodes the pore-forming subunit of the cardiac voltage-gated sodium channel, are found in 20% to 30% of BrS patients in Caucasian population. We analysed the sequence of *SCN5A* gene in 40 unrelated BrS patients (36 males, 90%) from Singapore. Bi-directional Sanger sequencing was carried out on approximately 20Kb of all the exonic cum flanking sequence of *SCN5A*, including 2.8Kb of its promoter region. All DNA variants of interest identified by sequencing were verified with genotyping on Sequenom platform. The minor allele frequency of all potential mutations in normal controls were determined by genotyping 105 healthy Singapore Chinese controls. Mutation was found in 7 of the 40 patients (17.5%), with 2 patients harbouring 2 mutations. A total of 8 mutations were identified, comprising of 5 missense, 1 non-sense, 1 in-frame deletion/insertion and 1 intron mutation that is expected to affect the splice site. Of the 8 mutations, 6 had not previously been described (75%). Several polymorphisms in the coding regions, both synonymous and non-synonymous, were also identified. Of the 40 patients, family samples were available for 5 probands. Two of the probands with mutation identified demonstrated Mendelian segregation of the mutation with BrS phenotype within the family, providing further support to the DNA mutation been causal. The study is on-going. To our knowledge, this is the most comprehensive study on mutation spectrum in BrS patients in Singapore to date.

Effects of Variation in the Haptoglobin Gene on Subclinical Cardiovascular Disease in the Diabetes Heart Study. *J.N. Adams[1,2,3], A.J. Cox[2,3,4], B.I. Freedman[5], J.J. Carr[6], D.W. Bowden[2,3,4].* 1) Program in Molecular Genetics and Genomic, Wake Forest School of Medicine, Winston Salem, NC, USA; 2) Center for Human Genomics, Wake Forest School of Medicine, NC, USA; 3) Center for Diabetes Research, Wake Forest School of Medicine, NC, USA; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston Salem, NC, USA; 5) Department of Internal Medicine - Nephrology, Wake Forest School of Medicine, NC, USA; 6) Department of Radiologic Sciences, Wake Forest School of Medicine, NC, USA.

Identification of heritable risk factors for cardiovascular disease (CVD) and other complications of type 2 diabetes mellitus (T2DM) are important to help understand individual risk for disease. Haptoglobin (HP) is an acute phase protein that binds to freely circulating hemoglobin. Genetic variants in HP have previously been reported as associated with an increase in CVD events and mortality in individuals with diabetes. Haptoglobin has two distinct alleles, Hp 1 and Hp 2, with Hp2 arising from a duplication of approximately a 1700 base pair region encompassing exons 3 and 4. The aim of this study was to examine the association of the HP genotypes with measures of subclinical CVD in a sample enriched for T2DM. Haptoglobin genotypes were determined in 1208 European Americans from 474 families in the Diabetes Heart Study (DHS). Measures of subclinical CVD included coronary artery, carotid artery, and abdominal aortic calcified plaque determined by CT scanning and carotid artery intima media thickness (IMT) determined by B-mode ultrasound. Haptoglobin genotyping was performed by PCR amplification followed by resolving products by agarose gel electrophoresis specific to each HP allele. Association between HP genotypes and clinical traits was assessed using variance components analysis in SOLAR. Additive genetic models were assessed with age, sex, and T2DM affection status included as covariates. Statistical significance was accepted at $p<0.05$. This analysis revealed an association between HP genotypes and IMT ($p=0.01$); with the HP 2-2 genotype being the risk genotype. We did not observe an association between HP genotypes and either coronary ($p= 0.82$), carotid ($p= 0.12$) or abdominal aortic calcified plaque $p= 0.81$). Adjustment for other known CVD risk factors including BMI, smoking, lipid and anti-hypertensive medications did not affect the outcomes. In conclusion, this study revealed evidence for association between HP genotypes and carotid IMT in European Americans with T2DM. Lack of association with atherosclerotic calcified plaque may reflect differences in the pathogenesis of these CVD phenotypes. HP variation may contribute to the heritable risk for cardiovascular complications in T2DM.

Novel Mutations in MYBPC3 in Cardiomyopathy - An Indian Study. *A. Ali[1], T.R. Reena[1], R. Advithi[1], C. Narsimhan[2], N. Pratibha[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Care Hospitals, Hyderabad, Andhra Pradesh, India.

Cardiomyopathy is a group of disorders characterized by malfunctioning of the myocardium and is clinically identified by heart failure, arrhythmias and sudden death .The Indian population is considered to be at high risk for cardiovascular diseases. Based on the pathophysiology, cardiomyopathies are classified as HCM, RCM, ARVD/C and DCM, with the etiologies related to sarcomeric proteins, desmosomal proteins and Ryanodine receptor components of the cardiomyocytes. Hypertrophic cardiomyopathy (HCM) is a complex muscular disorder of the heart, inherited as an autosomal dominant disease with variable penetrance in at least 50% of cases. The prevalence of HCM has been reported to be one in 500 in a population of young adults. The clinical course is variable and unpredictable, ranging from a benign asymptomatic course to severe heart failure and sudden cardiac death. The present study includes clinically confirmed 97 HCM patients referred to various hospitals in India. Mutational Screening of MyBPC3 was carried out using SSCP method followed by sequencing. The following novel mutations were identified in our cohort:- a) frameshift mutation Ins A 11577 ^11578 in Exon 19 in a patient. b) A novel SNP C >T at 1093 codon in exon 31 in a proband. In silico analysis revealed structural and functional alterations of the MyBPC3 protein. The present study is an attempt to highlight the unique genetic variations in Indian population indicating hotspot variations and different gene implications from those of western populations, which will be further discussed.

376T

Network-driven integrative genomics analysis of the CARDIoGRAM GWAS reveals key drivers and subnetworks of coronary artery disease. *T.L. Assimes[1], T. Huan[2,3], S. Maouche[4], J. Zhu[2], B. Zhang[2], J. Erdmann[4], C. Nelson[5], K.I.E. Snell[5], T. Quertermous[1], N. Samani[5], H. Schunkert[4], X. Yang[1], Coronary ARtery DIsease Genome wide Replication and Meta-analysis (CARDIoGRAM).* 1) Department of Medicine, Stanford University School of Medicine, Stanford, CA; 2) Sage Bionetworks, Seattle, WA; 3) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 4) Department of Medicine, University of Lübeck, Lübeck, Germany; 5) Department of Cardiovascular Sciences, University of Leicester, Leicester, UK.

Objective: Through meta-analysis of 14 GWAS, CARDIoGRAM identified 25 loci for coronary artery disease (CAD). However, the molecular mechanisms underlying these associations remain unclear and susceptibility loci with more subtle effects were undoubtedly missed. We hypothesize that genetic variation with both strong and subtle effects drives gene subnetworks that in turn affect risk of CAD. **Methods:** We surveyed CAD-associated molecular interactions by integrating CARDIoGRAM association results, expression SNPs (eSNPs), and gene networks constructed from six tissues of orthogonal mouse and human studies. A total of 18 pre-selected coexpression network modules along with 12 CAD-related gene sets or expression signatures (positive controls) from public databases and the literature were first mapped to eSNPs to derive the corresponding eSNP sets. For each eSNP set, the significance of enrichment for low p value associations to CAD in CARDIoGRAM was evaluated using both Fisher's exact and Kolmogorov-Smirnov (KS) tests. The gene sets that were significantly enriched for CAD-association eSNPs were in turn integrated with tissue-specific Bayesian networks and a protein-protein interaction (PPI) network to identify central network nodes (key drivers or KDs) that drive these CAD-related gene sets. The top KDs were then used as seeds to derive subnetworks that link the KDs to reveal the CAD network structure. **Results:** Eleven of 12 positive control gene sets and 12 of 18 coexpression network modules were significantly enriched for eSNPs with low p value association to CAD in CARDIoGRAM at a Bonferroni-corrected $p<0.05$ for both tests. We identified both tissue-specific KDs and KDs common to multiple tissues and found them to be enriched for CAD-related biological processes such as circulation, inflammatory response and coagulation. The top KDs across tissues are IL1RN, EGR2, NCF2, and LDLR, and the tissue-specific KDs include LPL and APOE from liver, ALOX5AP and ACE from kidney, F7 and ANAX2 from adipose, BACH1 and FER1L3 from blood, and CD36 and PPARG from the PPI network. The KDs were found to be highly connected in the networks and representative subnetworks of the top KDs (21 known and 27 novel) were derived. **Conclusions:** Our network-driven integrative analysis not only identified known and novel CAD risk genes but also defined a network structure that sheds light on the molecular interactions of CAD risk genes within, between and across tissues.

Impact of genetic polymorphisms of lipoprotein lipase and the susceptibility to hypertension. *Y. Chen[1], Y. Wang[1], R. Wang[1], C. Chen[1], F. Wu[1], T. Wu[1,2].* 1) Department of Public Health, China Medical University, Taichung, Taiwan; 2) Graduate Institute of Biostatistics, China Medical University, PhD.

Hypertension is an important risk factor leading to cardiovascular diseases, such as stroke, myocardial infarction, atherosclerosis and heart failure, etc. Hyperlipidemia is not only the major risk of ischemic stroke but also associated with the severity of hypertension. Hyperlipidemia is affected by vitamin B6 and lipoprotein lipase activity. In addition, genetic factors also have been associated with hypertension development. This study investigated whether LPL genotype a factor associated with hypertension. Study subjects consisted of 136 hypertensive patients and 195 non-hypertensive subjects in Nan-tou County. Each participants completed the demographic and lifestyle questionnaire. Blood samples were collected and we used Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP) to determine LPL gene S447X genotype. All statistical analyses were conducted using statistical package SAS for Chi-square test, ANOVA test, and logistic regression. Results showed that LPL gene of S/X genotype in hypertension patients had significant differences between blood pressure level ($p < 0.0001$). Triglyceride levels and LPL gene of the S/X polymorphisms were significantly different ($p = 0.0090$) between case and control. Logistic regression analysis showed that individuals with the SX or XX genotype had a much lower risk of hypertension than those with SS genotype. (Odds ratio 0.1, 95% Confidence interval, 0.05-0.19) LPL gene S/X polymorphisms are significantly associated with hypertension. Individuate with SS genotype at higher risk of stroke.

Adiponectin SNPs do not associate with coronary artery disease in Filipino diabetics. *M.L.G. Daroy[1], M.A. Luz[1], K.A. Pasion[1], V.C. Lacuesta[1], M. Mararang[1], M.V. Mendoza[1], J.T. Asi[1], A.A. Maliglig[1], J.A. Alfon[1], S.J. Soriano[1], C.A. Mapua[1], R.R. Matias[1], F.E.B. Posas[2].* 1) Research and Biotechnology Div, St. Luke's Medical Center, Quezon City, NCR, Philippines; 2) Heart Institute, St. Luke's Medical Center, Quezon City, NCR, Philippines.

Two SNPs in the adiponectin gene, SNP 45T>G and SNP 276G>T, previously reported to be associated with the development of coronary artery disease in Type 2 diabetics, were studied in Filipinos who were examined for CAD at the Heart Institute of St. Luke's Medical Center, Philippines. Lack of association (p-value= 0.910) between SNP 45T>G and CAD (>10% stenosis) was obatained from 894 cases and 119 normal controls studied. A similar result (p-value= 0.607) was reached from SNP 276G>T in 653 cases and 102 controls. Further analyses of association across varying degrees of CAD severity (10%, 40%, >70%) likewise showed no association. While SNP 45T>G was not associated with cases of prior heart attack, a slight but not significant association of SNP 276G>T was obatained for 141 cases that had a prior heart attack (p-value= 0.075). The results of this study suggest that genetic determinants associated with CAD in Filipino diabetics are significantly different from other Asian population groups (Japanese, Korean) in which these two SNPs in the adiponectin gene are shown to be significantly associated. Hence, more powerful GWAS should be conducted in this this group of Asian Filipinos for coronary artery disease and Type 2 diabetes.

INTRODUCTION: C-reactive protein (CRP) is a heritable biomarker of systemic inflammation and a predictor of cardiovascular disease (CVD). We sought to uncover novel genetic variants and further characterize previously identified loci associated with circulating levels of CRP in a multi-ethnic sample. METHODS: Using the ITMAT Broad-CARe (IBC) SNP array, a custom 50,000 SNP gene-centric array having dense coverage of over 2,000 candidate genes for CVD pathways, we performed a meta-analysis of up to 26,065 participants of European descent and 7,584 African Americans for association with log-CRP level. Samples were from the Candidate gene Association Resource (CARe) cohorts (Atherosclerosis Risk in Communities Study, Framingham Heart Study, Cardiovascular Health Study, Coronary Artery Risk Development in Young Adults Study, Multi-Ethnic Study of Atherosclerosis Study, Jackson Heart Study and Cleveland Family Study), the Women's Health Initiative, and the KORA study. RESULTS: We observed IBC-wide significant evidence for association ($p\text{-value} < 2.2 \times 10^{-6}$) for 12 loci. Seven of these loci (CRP, APOE, TCF1, LEPR, GCKR, IL6R, IL1RN) have previously been established as being associated with CRP in multiple studies. Two of these loci (NLRP3; HNF4A) were recently identified in a large scale genome-wide association (GWA) meta-analysis that included a subsample of the present study. An independent replication analysis in the subsample of 15,637 participants that were not included in this previously published GWA study was supportive for association (NLRP3, $p=8.8 \times 10^{-5}$; HNF4A, $p=1.4 \times 10^{-3}$). Three loci meeting IBC-wide significance in the total sample have not previously been reported to be associated with CRP (ARNTL, $p=2.3 \times 10^{-7}$; FTO, $p=1.6 \times 10^{-6}$; RPS6KB1, $p=2.0 \times 10^{-6}$). An analysis restricted to subjects of European descent resulted in less significant p-values for 9 of the 12 loci meeting IBC-wide significance in the multi-ethnic meta-analysis. Finally, we observed evidence for 4 independently associated loci meeting IBC-wide significance within CRP and 2 independently associated loci within IL6R based on a conditional meta-analysis. CONCLUSION: This large multi-ethnic association meta-analysis identified 3 novel loci associated with serum CRP levels in the ARNTL, FTO, and RPS6KB1 genes and confirmed two others in the HNF4A and NLRP3 genes. These results may identify additional pathways that influence chronic inflammation.

380T

ROCK2 gene confers a risk to arterial stiffness and is translationally modulated by miR-1183. *Y.C Liao[1,2,3], K.C Chen[3], W.W Chou[3], I.W Wang[3], E. Hsi[2,4], S.H.H Juo[3,4].* 1) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 2) Graduate Institute of Medicine,College of Medicine , Kaohsiung Medical University, Kaohsiung 807, Taiwan;; 3) Department of Medical Genetics, College of Medicine , Kaohsiung Medical University, Kaohsiung 807, Taiwan;; 4) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung 807, Taiwan;.

Background: Rho-associated kinase (ROCK) has been showed to be involved in the pathogenesis of atherosclerosis. We hypothesized that single nucleotide polymorphisms (SNPs) at ROCK2 gene, the major isoform in muscle cells, are associated with susceptibility of arterial stiffness.

Methods and Results: Stiffness parameters including beta ()), elasticity modulus (Ep) and pulse wave velocity (PWV) were obtained by carotid ultrasonography. Seven tagging SNPs of ROCK2 were genotyped in 856 subjects from the general population. Two functional SNPs, miRSNP rs978906 and non-synonymous SNP rs9808232, showed significant associations with the stiffness parameters. We then conducted a serial of cellular experiments with constructs carrying different alleles at rs978906 and rs9808232. We found that miR-1183 targeting at the sequences around rs978906 was able to prohibit ROCK2 expression. Suppression of miR-1183 levels accompanied with over-expression of ROCK2 protein was noted in smooth muscle cells treated with ox-LDL. Although rs9808232 caused an amino acid substitution, there was no significant difference in the ROCK2 activity between two alleles of rs9808232. The association between rs978906 and stiffness parameters was replicated in another group of 527 high risk subjects.

Conclusions:ROCK2 polymorphism rs978906 was associated with stiffness parameters in Taiwanese population. ROCK2 expression could be modulated by miR-1183, indicating a potential role of miR-1183 during atherosclerosis process.

381T

Genome-wide linkage and regional association study of obesity-related phenotypes. *A. Liu[1], T. Kelly[1], D. Rao[2], J. Hixson[3], L. Shimmin[3], C. Jaquish[5], D. Gu[4], D. Liu[4], J. He[1].* 1) Epidemiology Dept, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 2) Division of Biostatistics, Washington University School of Medicine, St Louis, MO; 3) Human Genetics Center, School of Public Health, University of Texas, Houston, TX; 4) Chinese Academy of Medical Sciences, Beijing, China; 5) National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD.

Background The genetic mechanisms underlying obesity remain largely unknown. The objective of the current study was to conduct a genome-wide linkage scan and regional association study of obesity-related phenotypes.

Methods Height, weight, waist circumference and other important covariables were collected from 3,142 participants from 633 Han, Chinese families of the Genetic Epidemiology Network of Salt-Sensitivity (GenSalt) Study. Lymphocyte DNA samples were also collected and used for genotyping microsatellite markers and single nucleotide polymorphisms (SNPs). Multipoint quantitative trait linkage-analysis was performed using body mass index (BMI) and waist circumference (WC) phenotypes. Additive associations between each SNP in the linkage region and BMI and WC were assessed using a mixed linear regression model to account for family dependencies. Phenotypes were adjusted for the fixed effects of age, gender and field center in all analyses.

Results Maximum multipoint LOD scores of 3.13 and 1.89 were observed for WC and BMI, respectively, at 22q13.33. Within this region, novel marker rs16996195 [minor allele frequency (MAF) = 0.019)] was significantly associated with the WC phenotype. Based on its physical position, marker rs16996195 is located in the TBC1 domain family, member 22A gene (TBC1D22A), a novel gene never implicated in obesity. Compared to those who were homozygous for the major C allele of this variant, carriers of the minor T allele had significantly decreased WC [80.67 (80.09, 81.2) versus 77.55 (76.00, 79.10) cm; p-value = 3.86E-5; FDR p-value= 0.048]. Although not significant after adjustment for multiple comparisons, a similar trend was observed for the BMI phenotype. Additional adjustment of obesity-related phenotypes for rs16996195 revealed that some of the observed linkage could be explained by this marker.

Conclusions Our findings suggest that genomic region 22q13.31-22q13.33 harbors important QTLs for WC and BMI. Furthermore, a novel variant in the TBC1 domain family, member 22A gene was important predictors of obesity-related phenotype. Futther research into the TBC1 domain family, member 22A gene is warranted.

Primary osteoarthritis of the hip and knee shows linkage to chromosome 2q21 in Finnish families. *M. Taipale[1], E. Jakkula[1], O. Kämäräinen[1], S. Barral[2], I. Kiviranta[3], H. Kröger[4], J. Ott[5], L. Ala-Kokko[1,6], M. Männikkö[1].* 1) Oulu Center for Cell-Matrix Research, Biocenter Oulu and Department of Medical Biochemistry and Molecular Biology, University of Oulu, Oulu, Finland; 2) Gertrude H. Sergievsky Center, College for Physicians and Surgeons, Columbia University, New York, USA; 3) Department of Orthopaedics and Traumatology, Helsinki University Hospital, Helsinki, Finland; 4) Department of Orthopaedics and Traumatology, Kuopio University Hospital, Kuopio, Finland; 5) Institute of Psychology, Chinese Academy of Sciences, Beijing, China; 6) Connective Tissue Gene Tests, Allentown, Pennsylvania, USA.

Studies with twins and families have shown that hereditary factors have a major role in the development of osteoarthritis (OA). Several genome-wide linkage scans have indicated suggestive linkage to most of the chromosomes, but no major disease causing variants have been identified so far, even though many variants in several genes have been implicated through previous linkage scans and following association analyses. We identified a novel susceptibility locus for primary hip and knee OA in Finnish families. Genome wide linkage analysis was performed using ten independent families (225 individuals) originating from Central Finland. Additional five families with 54 individuals were included in the following fine mapping. Genome wide analysis identified two potential loci on chromosomes 2 and 11 with suggestive logarithm of odds (LOD) ⁄ 1.5. Fine mapping confirmed the susceptibility locus on chromosome 2q21 with a multipoint LOD score of 3.96 peaking at the marker D2S1260 using a recessive model of inheritance. Two-point analysis confirmed linkage to the same locus with a LOD score of 3.63. Based on the observation that only one family (family 10) contributed significantly to the LOD score, one healthy and two affected family members from the family 10 were chosen for targeted resequencing. The entire 15.5 Mb segment of chromosome 2 consisting the linkage peak and neighboring regions was targeted by NimbleGen Sequence Capture 2.1M array (Roche) and the sequencing was performed by The Genome Analyzer IIx (Illumina) in the Institute for Molecular Medicine Finland (FIMM, Helsinki, Finland). Targeted resequencing resulted in 27 964 high quality variant calls (reference sequence GRCh37). Two affected family members shared 4006 variant calls, of which 241 (6%) were not previously annotated in dbSNP. Out of these 4006 variant calls 760 variant calls were found under the linkage peak of chromosome 2 (3.2 Mb), of which 46 (6%) were absent from dbSNP. In order to reveal OA associating sequence variant in family 10, these 46 variants will be genotyped in all family members for whom DNA is available by Sequenom SNP genotyping method.

383T

A high density screening of the MHC region identified two independent signals for susceptibility to ulcerative colitis. *P. Goyette[1], G. Boucher[1], P-A. Gourraud[2], A. Latiano[3], C. Lagacé[1], V. Annese[3,4], S.L. Hauser[2], J.R. Oksenberg[2], J.D. Rioux[1,5].* 1) Montreal Heart Institute, Montréal, Canada; 2) Department of Neurology, School of Medicine, University of California San Francisco; 3) Lab. Research Gastroenterology Unit, IRCCS "Casa Sollievo della Sofferenza" Hospital, San Giovanni Rotondo, Italy; 4) Azienda Ospedaliero Universitaria (AOU) Careggi, Unit of Gastroenterology SOD2, Florence, Italy; 5) Université de Montréal, Montréal, Canada.

The major histocompatibility complex (MHC) region has been associated to several autoimmune and inflammatory diseases. It encompasses 7.6Mb on chromosome 6p21.3 and contains over 400 genes, 40% of which encode proteins with immunological functions. Among these, the classical HLA class I (*HLA-A, -B, -C*) and class II (*HLA-DP, -DQ, -DR*) gene clusters, involved in antigen processing and presentation, are well characterized in terms of structure, variability and function. Ulcerative colitis (UC) is a chronic inflammatory disease of the colon and rectum showing inflammation primarily limited to the mucosal layer. Both genetic and non-genetic risk factors are believed to play a role in disease susceptibility. Several linkage and genome-wide association studies have demonstrated an important role for the MHC in UC susceptibility, but none have clearly identified the origin of the signal(s) due to the low density of markers tested, extensive allelic variation and linkage disequilibrium (LD) in the region. While the main association signal detected in UC is located in the class II gene cluster, it is unclear whether this represents association to specific HLA alleles or to neighboring loci. We have typed a total of 993 UC cases and 630 controls for SNPs tagging the variability of the MHC region, and performed HLA typing on a subset of these samples (516 UC cases and 490 controls). First, we selected 6411 SNPs capturing the variability of the MHC, and screened a cohort of 386 UC cases and 630 controls. Our preliminary association results and conditional analyses indicate the presence of 3 independent signals distributed across the MHC, including signals near the *IER3* gene (nominal P= 7.04E-6), the *HLA-A* gene (nominal P=5.37E-5) and the *HLA-DQA2* gene (nominal P=1.92E-5). The addition of 607 cases typed at lower density (800 SNPs) increased the significance for 2 of these signals (nominal P=1.93E-7 for the *HLA-A* locus and 1.02E-6 for the *HLA-DQA2* locus), while the *IER3* signal was not captured by the lower density SNP panel. We used results from direct typing of HLA alleles on a subset of the samples to determine whether the association signal originated primarily from HLA alleles or from neighboring markers. Our results indicate that HLA alleles do not represent the main association signal in either class I or class II regions. Our data confirms the involvement of MHC in the pathogenesis of UC and identifies at least two independent signals in the region.

Association study of celiac disease genes in Finnish inflammatory bowel disease patients. *A. Parmar[1,2], M. Lappalainen[1,3], P. Paavo-Sakki[3,4], L. Halme[5], M. Färkkilä[4], U. Turunen[4], K. Kontula[1,3], A. Aromaa[6], V. Salomaa[6], L. Peltonen[7,8], J. Halfvarson[10], L. Törkvist[11], M. D'Amato[9], P. Saavalainen[1,2], E. Einarsdottir[1,2].* 1) Research Program for Molecular Medicine, University of Helsinki, Helsinki, Finland; 2) Department of Medical Genetics, Haartman Institute, University of Helsinki, Finland; 3) Department of Medicine, Helsinki University Hospital, Helsinki, Finland; 4) Department of Gastroenterology, Helsinki University Hospital, Helsinki, Finland; 5) Department of Surgery, Helsinki University Hospital, Helsinki, Finland; 6) National Institute for Health and Welfare, Helsinki, Finland; 7) Institute for Molecular Medicine Finland, Helsinki, Finland; 8) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 9) Karolinska Institutet, Department of Biosciences and Nutrition, Stockholm, Sweden; 10) Örebro University Hospital, Department of Medicine, Örebro, Sweden; 11) Karolinska Institutet, Department of Clinical Science Intervention and Technology, Stockholm, Sweden.

Crohn's disease (CD) and ulcerative colitis (UC) constitute the two major forms of inflammatory bowel disease (IBD), characterised by remitting and relapsing chronic inflammation of the gastrointestinal tract. Finland, Sweden and Denmark are among high incidence areas in Europe and epidemiological studies show that IBD incidence in these countries is still increasing. A number of genes predisposing individuals to IBD have been identified. These genes may be involved in the regulation of innate-or adaptive immune responses, autophagy and the regulation of cell death. As in the case of IBD, celiac disease (CelD) is an immunological disease which primarily affects the gastrointestinal tract. A recent genome-wide association study (GWAS), consisting in part of Finnish samples, identified a number of celiac disease susceptibility loci harbouring genes involved in the regulation of the immune system. A subset of these CelD risk loci may also be associated with increased risk for other autoimmune diseases, including CD and UC. In the current study, we investigated whether the novel CelD risk loci may also affect susceptibility to IBD in the Finnish population. In total, we tested the association of 45 SNPs with CD, UC, and IBD as well as subphenotypes of CD and UC. A meta-analysis on a combined Finnish-and Swedish UC dataset was also performed. None of the tested markers showed significant association (uncorrected p<0.01) to CD, whereas rs2298428, downstream of the gene UBE2L3, was associated with early onset of CD (0-18 years), p_{corr} 0.008, OR 2.51 (1.55-4.06). Furthermore, rs917997, downstream of the IL18RAP gene, was associated with structuring phenotype in CD (p_{corr} 0.035, OR 1.78 (1.27-2.49). Rs864537, within the CD247 gene, showed some association to UC, p_{uncorr} 0.007, OR 0.80 (0.68-0.94). Rs6974491, within the gene ELMO1, was associated with early onset of UC (0-18 years), p_{corr} 0.016, OR 2.19 (1.43-3.36). All of the loci in the current study are strong candidates for celiac disease susceptibility, and some of the markers associated with CD and/or UC or their subphenotypes in the current study have been shown previously to be associated with IBD (CD or UC). Studying these polymorphisms in the Finnish materials is thus likely to help us understand the aetiology of IBD, as well as give us a better understanding of the risk genes that are relevant to IBD patients in Finland.

Association analysis of 71 susceptibility loci for European Crohn's disease in the Japanese population. *K. Yamazaki[1], A. Hirano[1,2], J. Umeno[1,2], M. Takazoe[3], S. Motoya[4], T. Matsui[5], T. Matsumoto[5], Y. Nakamura[6], N. Kamatani[7].* 1) Laboratory for Genotyping Development, Center for Genomic Medicine, RIKEN, Kanagawa, Japan; 2) Department of Medicine and Clinical Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 3) Department of Medicine, Division of Gastroenterology, Social Insurance Chuo General Hospital, Tokyo, Japan; 4) Department of Gastroenterology, Sapporo Kosei Hospital, Sapporo, Japan; 5) First Department of Internal Medicine, Sapporo Medical University School of Medicine, Sapporo, Japan; 6) Laboratory of Molecular Medicine, Institute of Medical Science, The University of Tokyo, Japan; 7) Director, Center for Genomic Medicine, RIKEN, Kanagawa, Japan.

Inflammatory bowel disease (IBD) represents the two common types of chronic intestinal disorders, Crohn's disease (CD) and ulcerative colitis. The success of genome-wide association studies (GWAS) revolutionized the field of complex disease genetics through the identification of many susceptibility loci. On 2010, a meta-analysis of six GWAS for CD reported 71 susceptibility loci in European descents. Since we found apparent ethnic differences in the CD susceptibility loci between European and Japanese populations, it is unclear whether these susceptibility loci are also associated with CD in Japanese population. To investigate the association of CD susceptibility loci in Japanese CD patients, we genotyped 71 reported SNPs using a total of 701 CD patients and 3,389 controls. After excluding two SNPs with HWE *P* value of less than 0.01, we found 19 SNPs that showed nominal association with Japanese CD patients (uncorrected $P<0.05$). Among them, five SNPs showed significant association after adjustment of multiple testing by Bonferroni correction; rs3810936 in *TNFSF15* on 9q32 ($P=1.46\times10^{-18}$), rs415890 near *CCR6* on 6q27 ($P=4.38\times10^{-5}$), rs6738825 in *PLCL1* on 2q33 ($P=8.35\times10^{-5}$), rs6556412 near *IL12B* on 5q33 ($P=1.03\times10^{-4}$) and rs4409764 near *NKX2-3* on 10q24 ($P=6.61\times10^{-4}$). One of these candidates, rs2476601 in *PTPN2* showed the opposite direction of effect as compared to European population and further studies were required to examine association. *IL23R* and *NOD2*, the two strongest susceptibility loci for CD in European population, were not associated with Japanese CD patients because risk alleles in these genes were very rare or monomorphic in the Japanese population (risk allele frequency of rs2076756 in *NOD2* was 0.0007 and that of rs11209026 in *IL23R* was 0, respectively). In addition, SNPs in *SP140* and *TYK2* were also monomorphic in Japanese. These results indicate that there exists different genetic architecture for CD susceptibility between European and Japanese populations. In conclusion, we examined 71 CD susceptibility loci identified by European GWAS meta-analysis in a Japanese population. We found 19 common susceptibility loci for both European and Japanese populations, however, *IL23R* and *NOD2* were not associated in Japanese. We are applying these results for pathway-based analysis to clarify the differences in the pathogenesis of CD between European and Japanese.

Gene-environment interaction effects of 17q21 variants and rhinovirus wheezing illness on risk for childhood-onset asthma. *M. Caliskan[1], D.A. Loisel[1], G. Du[1], D.J. Jackson[2], J.E. Gern[2], R.F. Lemanske[2,3], D.L. Nicolae[1,4,5], C. Ober[1,6].* 1) Department of Human Genetics, The University of Chicago, Chicago, IL, USA; 2) Department of Pediatrics, University of Wisconsin-Madison, Madison, WI, USA; 3) Department of Medicine, University of Wisconsin-Madison, Madison, WI, USA; 4) Department of Medicine, The University of Chicago, Chicago, IL, USA; 5) Department of Statistics, The University of Chicago, Chicago, IL, USA; 6) Department of Obstetrics and Gynecology, The University of Chicago, Chicago, IL, USA.

The 17q21 asthma locus, including the *ORMDL3* and *GSDML* genes, represents the most highly replicated asthma susceptibility locus and is one of the most significant genetic risk factors for childhood asthma. However, the biology of this locus and its role in asthma are still largely unknown. To characterize the role of this locus in childhood asthma, we conducted a candidate gene association study of 6 previously associated 17q21 SNPs and asthma in 247 children participants in the Childhood Origins of ASThma (COAST) birth cohort and the RhinoGen Study, both in Madison, Wisconsin. We also tested for gene-environment interactions between 17q21 genotypes and common environmental risk factors for asthma: rhinovirus wheezing illness (RV-WI) or respiratory syncytial virus wheezing illness (RSV-WI) in early childhood in 185 COAST children (67 with asthma), in whom information on WI with RV and RSV infections in the first 3 years of life was collected prospectively. Genotypes at all 6 SNPs were associated with childhood onset asthma (p=0.00045-0.0036); however, the association with asthma was significant only in the 61 COAST children who had RV-WI (p=0.0011) and not in the 124 children who did not have RV-WI in childhood (p=0.78), resulting in a significant gene-environment interaction (GEI) effect on asthma risk (17q21 genotype x RV-WI, interaction p = 0.014). No such interaction was observed for RSV-WI ($p > 0.40$). Moreover, genotypes at this locus were not associated with the occurrence of RV-WI in the first 3 years of life, number of RV-WI, duration of RV-WI or cold symptom burden during viral illness (p=0.05-0.91). We interpret these findings to indicate that variants at the 17q21 locus do not influence the risk for RV infection per se, or persistence and severity of RV infection. Instead, we propose that children with 17q21 risk variants may respond differently to RV-induced damage, which increases their subsequent risk for asthma. Our study is the first to specifically attribute 17q21 locus-associated risk for asthma to early-life WI with RV infection, which provides clues as to role of the 17q21 variants in the etiology of asthma.

Analysis of gene-environment interaction for plasma CRP level in a Korean cohort. *E.P. Hong[1], J.G. Seo[1], D.H. Kim[2], J.W. Park[1,*].* 1) Dept. of Medical genetics; 2) Dept. of Social Medicine, Hallym University, College of Medicine, Chuncheon, Gangwon-do, Korea.

High sensitivity C-reactive protein (hs-CRP) level is a well-known inflammatory biochemical marker to predict a variety of age-related disease such as cardiovascular disease. The plasma CRP level differs by age, gender, and ethnic groups. Multiple genetic and non-genetic factors influence the plasma hs-CRP level. We evaluated gene-environment interaction affecting the plasma CRP level using a six-year follow up data obtained from a community-based cohort study in Korea. We firstly performed linear regression analyses to identify risk factors for the elevated plasma hs-CRP level among 32 clinical and environmental variables. We genotyped 969 Koreans aged above 46 for 50 single nucleotide polymorphism (SNP) markers located near or in 6 candidate genes (i.e. APOC1, CRP, HNF1A, KIAA0182, NAV2, and ULK4). We performed single SNP analyses under three genetic models (i.e. additive, dominant, and recessive models) and compared the hs-CRP level by genotype of each SNP using a cox proportional hazard model. Finally, we evaluated gene-environment interaction using the method of survival dimensionality reduction. We identified risk factors such as a history of smoking (HR = 1.7, p = 0.0004) and a high waist-hip ratio (HR = 18.4, p = 0.0218) for the elevated hs-CRP level. We found evidence for gene-environment interaction; for example, a NAV2 gene variant (11p15.1) significantly interacted with cigarette smoking to result in the elevated hs-CRP level. The evidence for gene-environment interaction in the determination of plasma CRP level shown in this study may warrant further study.

Liability threshold modeling of covariates increases power in case-control association studies. *A. Price[1], N. Zaitlen[1], S. Lindstrom[1], B. Pasaniuc[1], M. Cornelis[2], G. Genovese[3], A. Barton[4], D. Bowden[5], S. Eyre[4], B. Freedman[5], D. Friedman[3], L. Groop[6], B. Henderson[7], P. Hicks[5], L. Kolonel[8], C. Langefeld[5], L. Le Marchand[8], K. Waters[7], C. Haiman[7], D. Hunter[1], R. Plenge[9], J. Worthington[4], D. Schaumberg[1], D. Chasman[2], D. Altshuler[9], B. Voight[9], P. Kraft[1], N. Patterson[9].* 1) Harvard School of Public Health, Boston, MA; 2) Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 3) Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA; 4) Manchester Academic Health Science Centre, The University of Manchester, Manchester, U.K; 5) Wake Forest University School of Medicine, Winston-Salem, NC; 6) Scania University Hospital, Lund University, Malmö, Sweden; 7) University of Southern California Keck School of Medicine, Los Angeles, CA; 8) Cancer Research Center, University of Hawaii, Honolulu, HI; 9) Broad Institute, Cambridge, MA.

Genetic case-control association studies often include data on covariates, such as body mass index (BMI) or age, that may modify the underlying genetic risk of case or control samples. For example, in type 2 diabetes, odds ratios estimated from low-BMI cases are larger than those estimated from high-BMI cases. An unanswered question is how to optimally use this information to maximize statistical power. In this study we show via simulation that our approach to fitting liability threshold models and computing association statistics, which accounts for disease prevalence and non-random ascertainment, can use this information to increase power. Our method outperforms standard case-control association tests, case-control tests with covariates, tests of gene x covariate interaction, and tests that restrict to a subset of samples. We investigate empirical case-control studies of type 2 diabetes, prostate cancer, breast cancer, rheumatoid arthritis, age-related macular degeneration, and end-stage kidney disease over a total of 78,256 samples. In these data sets, liability threshold modeling outperforms logistic regression for 104 of the 140 known associated variants investigated (p-value < 10-9). The improvement varied across diseases with a 17% median increase in test statistics, corresponding to a greater than 25% increase in power. Application of liability threshold modeling to future case-control association studies of these diseases, or other diseases with analogous effects of covariates on genetic risk, will yield a substantial increase in power for disease gene discovery.

389T

Detection of Intergenerational Genetic Effects: A Plea for Pedigrees. *J.S. Sinsheimer[1], E.J. Childs[2], E.M. Sobel[1], C.G.S. Palmer[1].* 1) Department of Human Genetics, Univ California, Los Angeles, Los Angeles, CA, 90095; 2) Department of Epidemiology, Johns Hopkins University, Baltimore, MD, 21218.

Background: In most cases, genome-wide association studies (GWAS) have failed to account for more than a modest amount of the disease risk attributed to genetic variants. Intergenerational genetic effects provide one potential source of the remaining risk. In general, GWAS using unrelated individuals cannot detect intergenerational genetic effects contributing to disease. Thus, alternative study designs and statistical methods are needed.

Methods: To detect intergenerational genetic effects, we improve the extended maternal fetal genotype (MFG) incompatibility test to estimate any combination of maternal effects, offspring effects, and their interactions at polymorphic loci or multiple SNPs, using any size pedigrees. We apply our improved EMFG test to simulated and actual pedigree data.

Results: We show that intergenerational effects can explain a substantial portion of the heritability of a trait but that GWAS of unrelated individuals are poorly powered to detect these effects. Through simulated data, we explore the advantages of using extended pedigrees rather than nuclear families. In particular, we find that using the EMFG test with extended pedigrees increases power and precision, whereas partitioning extended pedigrees into nuclear families can underestimate intergenerational effects. Application of the EMFG to data from families affected by schizophrenia demonstrates that intergenerational effects may play an important role in complex disease susceptibility. Alternative explanations such as ascertainment and mate selection biases cannot explain our results.

Conclusions: Our results demonstrate the power of the EMFG test to examine intergenerational genetic effects, highlight the importance of pedigree rather than case/control or case-mother/control-mother designs, and demonstrate that pedigrees provide an opportunity to examine alternative, non-causal mechanisms.

Localization of rare variants influencing complex traits using lineage-specific linkage analysis in extended pedigrees. *H.H.H. Goring, J.W. Kent Jr., E. Drigalenko, T.D. Dyer, J. Blangero.* Dept Gen, Texas Biomedical Research Institute, San Antonio, TX.

Large-scale genome-wide association studies (GWAS) have successfully identified common SNPs associated with many complex traits, but the identified loci collectively explain only a small fraction of estimated heritability. This has led to the speculation that rare variants may explain much of the “missing heritability”. A key problem when seeking to identify rare variants is their rarity, necessitating either enormous sample sizes or various collapsing strategies. Both of these two limitations can be overcome by studying extended families. The reason is that a rare allele, if present in a founder individual of one of the available pedigrees, will often be present in multiple copies in a study, for the simple reason that the allele will have been passed on randomly in meiosis from the founder to offspring and further downstream generations. The expected number of copies of an allele from a founder, no matter its population rarity, is given by the sum of the kinship coefficients of all descendants with that founder. If the observed copy number is sufficiently high, then rigorous statistical evaluation of co-segregation of rare allele and complex trait is possible. Based on this idea, we have developed a mixed model variance components approach to localize rare variants of strong individual effect in extended pedigree samples. We first identify founders with a sufficiently many descendants (⁄ 10) such that linkage analysis of a single lineage may yield a genome-wide statistically significant signal. We then perform a genome-wide linkage analysis on each of the two haplotype lineages of a given founder, with the lineages changing along the genome at the positions of recombination events. Ultimately, each significant linkage peak comprises a candidate region where the DNA sequence of that lineage's founder is examined for putatively causal sequence variants. We have evaluated the performance of this approach via simulation of rare variants, demonstrating that the method is able to obtain significant linkage peaks in specific lineages even if linkage analysis of the entire dataset, with or without a locus-heterogeneity component, fails to do so. We applied this approach to quantitative traits (including expression profile data) in the San Antonio Family Heart Study. Our results indicate that classical quantitative trait linkage analysis misses many potential rare QTLs that can be detected using our efficient lineage-specific localization method.

A mutation in *BMP3* Contributes to Canine Brachycephaly. *E.A. Ostrander[1], S. Hutchinson[2], A. Byers[1], B. Carrington[3], D. Faden[1], R. Sood[3], A. Boyko[4], J.W. Fondon 3rd[5], R.K. Wayne[6], C.D. Bustamante[4], B. Ciruna[2], J.J. Schoenebeck[1].* 1) Cancer Gen Br, Bldg 50, NHGRI/NIH, Bethesda, MD; 2) Program in Developmental Biology and Stem Cells, The Hospital for Sick Children and the University of Toronto, Toronto, ON, Canada; 3) National Human Genome Research Institute Zebrafish Core, Bethesda, MD; 4) Department of Genetics, Stanford School of Medicine, Stanford, CA; 5) Department of Biology, University of Texas at Arlington, Arlington, TX; 6) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA.

Cephalic disorders occur with a frequency greater than 1 in 2,500 live births, yet the genetic underpinnings of most cephalic disorders remain unknown. For many purebred dogs, skull shapes reminiscent of cephalic disorders such as brachycephaly, dolichocephaly, and hydrocephalus are breed-defining features. Geometric morphometric analysis of 348 purebred dog skulls from 93 breeds was used to quantify skull shape. After correcting for size, we used principal components analysis to characterize remaining shape variance. Fifty-four percent of variance was explained by the first principal component (PC1), whose factor loadings included changes in rostrum length, cranial vault depth, and width of the zygomatic arches. Thus, PC1 is a quantitative measure of morphological changes pertinent to brachycephaly (rostrocaudal skull shortening). A genome-wide association scan of PC1 revealed numerous, highly significant QTLs. Detailed analysis of the association on chr32: 8-8.5 Mb (best SNP, $P<3x10^{-44}$) revealed a depression in heterozygosity (H_o) among brachycephalic dogs. Loss of H_o is a hallmark of selective sweeps and can be indicative of a locus experiencing strong, selective pressure over generations of planned breedings. Fine mapping on chr32 revealed a missense F->L mutation in the predicted signaling portion of canine *BMP3*. Among the TGF) superfamily, the amino acid mutated in *Bmp3* is invariably aromatic (Phe or Tyr), leading us to hypothesize that such a mutation could lead to loss of function. To test our hypothesis, we turned to zebrafish as an experimental surrogate for testing *Bmp3* function. Our data show that during development, zebrafish *bmp3* is expressed in neurocranial tissues. Furthermore, morpholino knockdown of *bmp3* led to loss of cartilaginous head structures. Overexpression of wild type and mutant canine Bmp3 RNA demonstrates that only the first is biologically active in fish. Together, these experiments reveal a conserved role for *Bmp3* during vertebrate cranioskeletal development and suggest that the canine F->L mutation renders this molecule inactive. Identification of *Bmp3* as a contributor to canine brachycephaly demonstrate the power of studying dog genetics to uncover factors and pathways likely to be relevant to human cephalic disorders, thus enabling genetic diagnostics and new treatment paradigms.

392T

Architecture of glaucoma endophenotypes in heterozygotes carrying the myocilin K423E mutation. *P. Belleau[1], S. Dubois[1], K. Lebel[1], R. Arseneault[1], E. Shink[1], G. Côte[2], M. Amyot[3], V. Raymond[1,2].* 1) Laboratory of Molecular Genetics of Sensory Systems, CHUL (Université Laval Hospital) Research Centre, Québec City, QC, Canada; 2) Dept of Ophthalmology, Université Laval, Québec City, QC, Canada; 3) Dept of Ophthalmology, Université de Montréal, Montréal, QC, Canada.

Chronic open-angle glaucoma (COAG, as defined in Shields Textbook of Glaucoma, 6th Ed., 2011) is characterized by optic nerve degeneration and visual field impairments. Potential disease mechanisms implicate elevated intraocular pressures (IOP, a known risk factor), optic nerve hypersensitivity to stressful events and/or inflammation. COAG is a complex genetic disease that can also segregate in a Mendelian fashion in some families. We studied the CA family, a huge French-Canadian pedigree, in which autosomal dominant COAG was caused by the myocilin (MYOC) K423E mutation. The disorder showed a very wide range of ages at onset (AAO) and, elevated IOPs were detected before optic nerve degeneration. The goal of this study was to establish if any of its endophenotypes could be controlled by modifier genes. To do so, we assessed seven (7) traits potentially implicated in its disease mechanisms. We also analyzed if WDR36, a putative modifier gene, had any effect on the endophenotypes. Quantitative traits values (QT) were extracted from the records of 150 $MYOC^{K423E}$ heterozygotes. Traits relative to intraocular pressures were: age of the 1st IOP $\geq$ 22 mm Hg (age at onset: AAO), maximal IOP and number of years with at least 1 IOP value $\geq$ 22 mm Hg. Traits relative to optic nerve hypersensitivity were: cup to disk ratio (C/D), first C/D $\geq$ 0.7, variation of the C/D per time period (ΔC/D) and a novel index defined as ΔC/D pondered by IOP measurements. We further analyzed the heritability (h^2) of these QT. To evaluate the effects of WDR36 variations on QT, we compared QTs displayed by double mutants who simultaneously carried 1 $MYOC^{K423E}$ mutation and 1 WDR36 variation versus the medians of QT displayed by $MYOC^{K423E}$ carriers who were WDR36 wild-type and shared a kinship coefficient of $\geq$ 0.0625 with the double mutants (at most 1st degree cousins). In our heterozygotes, AAO and IOP max were characterized as 2 heritable traits relative to IOP since of their h^2 values were both $\geq$ 0.4. On the other hand, the other 4 QTs relative to optic nerve hypersensitivity showed no significant h^2. The majority of WDR36/ $MYOC^{K423E}$ double mutants displayed a younger AAO and higher IOP max when compared to their respective controls. In conclusion, our study strongly suggests that MYOC-related modifier genes primarly act on mechanisms leading to elevated intraocular pressures. Our data also suggest that WDR36 may act as a modifier by altering similar mechanisms leading to elevated IOPs.

393T

Hepatic steatosis, hepatic inflammation and the *CPN1-ERLIN1-CHUK-CWF19L1-BLOC1S2* gene cluster in the NHLBI Family Heart Study (FamHS). *M.F. Feitosa[1], M.K. Wojczynski[1], K.E. North[2], J. Wu[1], M.A. Province[1], J.J. Carr[3], I.B. Borecki[1].* 1) Div Statistical Genomics, Washington Univ Sch Medicine, St Louis, MO; 2) Dept Epidemiology, Univ of North Carolina, Chapel Hill, NC; 3) Dept Radiology, Wake Forest University School of Medicine, Winston Salem, NC.

Nonalcoholic fatty liver disease (NAFLD) is a common disease and ranges from simple steatosis, to nonalcoholic steatohepatitis, to cirrhosis. CT measured liver attenuation (Hounsfield Units) is inversely related to the amount of fat in the liver (FL), and represents a non-invasive measure of steatosis. Serum ALT levels are indicators of the inflammatory severity of hepatic steatosis and have been used as a biochemical inflammatory marker of NAFLD. The phenotypic correlation between CT measured FL and ALT levels was 27% ($p<0.0001$) in FamHS. A correlated meta-analysis (CMA) approach can improve power to detect variants that have pleiotropic effects on correlated traits. We investigated whether genetic variants accounted for concomitant variation in FL and ALT in 2,679 subjects of European descent using a CMA approach. We excluded heavy drinkers and subjects with hepatitis C. FL and ALT levels were adjusted for age, sex, clinical center, alcohol consumption, genotype batch effects, family relatedness, and population stratification. FL was also adjusted to an external calibration standard. We performed univariate genome-wide association (GWA) scans on ~2.5 million imputed SNPs, and used the univariate GWA results in a CMA, correcting for correlations between FL and ALT GWA scans. We found evidence for association between variants of the *CPN1-ERLIN1-CHUK-CWF19L1-BLOC1S2* gene cluster on 10q24-q25 with concomitant variation in FL and ALT levels. Among the 42 SNPs in this gene cluster (CMA-p $<7.7\times10^{-6}$), seven SNPs in complete LD were strongly associated with the CMA phenotype of FL and ALT ($9.50\times10^{-11} \leq$ CMA-p $\leq 1.68\times10^{-9}$) as compared with suggestive univariate GWA of FL and ALT (e.g. CMA-p=9.50×10^{-11} vs. FL p=4.18×10^{-7} and ALT p=9.20×10^{-6}). To investigate whether the 42 variants were associated with "inflammatory severity of hepatic steatosis", we created a categorical trait using ALT ($\geq$ 40 U/L) and/or FL ($\geq$ 40 HU) to define steatosis-inflammatory affection status. The results endorsed evidence of association between the 42 variants with steatosis-inflammatory affection ($1.9\times10^{-2} < p < 1.1\times10^{-4}$). This gene cluster is involved in transcription factors, cell proliferation, lipid-raft-like domains, liver-expressed proteins, and inflammatory mediator-protein of hepatic and systemic insulin resistance. Our findings suggest that variants of *CPN1-ERLIN1-CHUK-CWF19L1-BLOC1S2* gene cluster influence both hepatic steatosis and hepatic steatosis with inflammation.

Background: Obesity is of global health concern. Recent genome-wide association studies (GWAS) of age at menarche identified several variants that had been previously associated with body mass index (BMI). Well-described associations between childhood obesity, earlier pubertal timing in girls, and adult obesity, may be in part due to genetic factors. **Methods:** To systematically test if known genetic variants for BMI are also associated with pubertal timing in girls, we conducted a meta-analysis of the association of 68 single nucleotide polymorphisms (SNP) with age at menarche (ranging from 9-17 years) in 55,203 women of European descent from 23 studies in the ReproGen Consortium. Each study performed a separate analysis using additive models and adjusting for birth year, site (as appropriate), and population stratification. Between-study heterogeneity was investigated using meta-regression techniques. **Results:** Eight BMI loci were previously reported to associate with age at menarche in this dataset. We identified novel associations with age at menarche at four out of 18 recently published BMI loci (*TNNI3K, RBJ, STK33, TMEM160*). In each case, the BMI-increasing allele decreased age at menarche (between 0.41 to 0.58 weeks per allele). **Conclusions:** We identified several novel associations of age of menarche with recently reported BMI GWAS variants. Our findings suggest complex genetic relationships influencing both menarche and obesity, which are consistent with a role of these genes in growth and development.

Modeling genome-wide association SNP impact on metabolic diseases through structural equations. *R. Karns[1], P. Succop[1], G. Zhang[2], G. Sun[1], S. Indugula[1], S. Missoni[3], Z. Durakovic[3], R. Chakraborty[4], P. Rudan[3], R. Deka[1].* 1) Environmental Hlth, Univ Cincinnati, Cincinnati, OH; 2) Human Genetics Division, Cincinnati Children's Hospital, Cincinnati, OH; 3) Institute for Anthropological Research, Zagreb, Croatia; 4) Center for Computational Genomics, University of North Texas Health Science Center, Fort Worth, TX.

This study provides structure and context to the complex relationships between genome-wide association (GWA) variants, biochemical and anthropometric traits, metabolic syndrome, and cardiovascular diseases through latent variable analysis and structural equation modeling. We have performed GWA of fifteen age- and gender-adjusted quantitative traits indicative of cardiovascular health in an isolated population of the eastern Adriatic (n=1325). From each GWA, the most significant SNPs were extracted for inclusion as manifest predictors in a structural equation model of traits involved in the development of metabolic syndrome (MetS) and cardiovascular diseases. In our final model, eleven metabolic and anthropometric traits were distilled into a single manifest variable (HbA1c) and three latent factors (described as obesity, blood pressure, and lipid factors), each with loadings of at least 0.4, that predicted MetS (all *P*-values<0.05). MetS was most strongly associated with the obesity factor (*P*<0.0001), and in turn predicted increased risks of gout and coronary heart disease (*P*-values<0.0001 and 0.002, respectively). Coronary heart disease was also predicted by HbA1c (*P*<0.0001). Odds for kidney disease were predicted by type-2 diabetes and coronary heart disease (*P*-values<0.0001). Type-2 diabetes was also associated with increased risk for stroke (*P*<0.0001), and gout predicted increased odds for type-2 diabetes (*P*=0.003). Additionally, thirty-one GWA-extracted variants were significantly associated with the latent factors and HbA1c. One HDL-related variant, rs16855289, was directly and significantly associated with MetS (*P*=0.002). Two glucose-related variants (rs7100623 and rs12243326) were associated with type-2 diabetes (*P*-values 0.002 and <0.0001, respectively), which was also predicted by HbA1c (*P*<0.0001). The derived structural equations model provides a context for the whole-system impact of GWA variants and clarifies the relationships between anthropometric and biochemical traits indicative of cardiovascular health. In addition, we provide further support of the functionality of MetS as a predictor of the development of cardiovascular diseases. Supported by NIH grants R01-DK069845 and T32-ES010957.

Gene set enrichment analysis with distal *cis*-regulatory elements in genetics of vascular dementia. *Y. Kim, J. Ryu, M. Kong, C. Lee.* Soongsil University, Seoul, Korea.

Vascular dementia (VD) has been greatly concerned to the elderly and their families as the second most common dementia after Alzheimer's disease. Knowledge on its genetic basis has been quite limited from association studies conducted with candidate genes. Recently, a genome-wide association study (GWAS) was conducted for susceptibility to VD. Nevertheless, genetic associations have not been observed with any nucleotide sequence variants. This might be attributed not only to a quite conservative significance threshold of Bonferroni multiple test but also to a considerable complexity for genetic architecture of VD. In the current study, a gene set analysis by functional annotation including distal *cis*-regulatory sequences was employed using a variant set with potential false negative associations from the previous GWAS. As a result, the variants were significantly enriched near genes involved in critical biological processes to VD such as associative learning ($P = 2.29\times10^{-11}$) and memory ($P = 1.73\times10^{-7}$). Since we could not obtain such results by gene-based annotation analysis with the sequences from 5kb upstream to 1kb downstream, this study suggested that distal regulatory elements might play considerable roles in susceptibility to VD. Further examination on functions of the distal regulatory elements using chromatin immunoprecipitation (ChIP) data revealed potential enhancers regulating their target genes.

Geographic differences in genetic susceptibility to IgA nephropathy: GWAS replication study and geospatial risk analysis. *K. Kiryluk[1], Y. Li[1], M. Rohanizadegan[1], S. Sanna-Cherchi[1], M. Choi[2], F. Scolari[3], L. Gesualdo[4], S. Savoldi[5], A. Amoroso[6], B. Julian[7], R. Wyatt[8], J. Novak[7], B. Stengel[9], L. Thibaudin[10], F. Berthoux[10], F. Eitner[11], J. Floege[11], U. Panzer[12], J. Nagy[13], R. Lifton[2], A.G. Gharavi[1].* 1) Dept Medicine, Columbia University, New York, NY; 2) Department of Genetics, Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, USA; 3) University of Brescia and Second Division of Nephrology, Montichiari Hospital, Montichiari (Brescia), Italy; 4) Department of Biomedical Sciences, University of Foggia, Foggia, Italy; 5) Nephrology and Dialysis Unit, Ciriè Hospital, Torino, Italy; 6) Department of Genetics, Biology and Biochemistry, University of Torino, Torino, Italy; 7) Departments of Microbiology and Medicine, University of Alabama at Birmingham, Birmingham, AL, USA; 8) Children's Foundation Research Center at the Le Bonheur Children's Hospital, and the Division of Pediatric Nephrology, University of Tennessee Health Sciences Center, Memphis, TN, USA; 9) Inserm, Centre for Research in Epidemiology and Population Health, Villejuif, France; 10) Nephrology, Dialysis and Renal Transplantation Department, University North Hospital, Saint Etienne, France; 11) Department of Nephrology, University of Aachen, Aachen, Germany; 12) III Medizinische Klinik, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany; 13) Nephrology Center and 2nd Department of Internal Medicine, Medical Faculty, University of Pécs, Hungary.

IgA nephropathy (IgAN) is a major cause of kidney failure worldwide. It is common among Asians, moderately prevalent among Europeans and rare in Africans. In a recent GWAS, we localized 5 IgAN susceptibility loci, including 3 independent loci in the MHC, a common deletion CFHR1,3Δ, and a 5th locus on chr.22q12. The goals of this study were: (1) to replicate the GWAS loci in independent cohorts, (2) to assess differences in the effects of these loci in diverse populations, and (3) to model the distribution of risk alleles in the worldwide populations. We studied the five IgAN risk loci in an independent cohort composed of 5 nationalities (French, Italian, German, Hungarian, and African-American, totaling 1,120 cases and 1,665 matched controls). After stringent QC measures, the association analysis was performed individually in each cohort followed by a joint analysis with 4 cohorts from the original GWAS (Beijing, Shanghai, Italian and North American; combined N=8,687). Heterogeneity was assessed using Cochrane's Q-test and het. index (I2). A genetic risk score was calculated and after validation, the risk prediction model was applied to 1,042 HGDP individuals (57 world populations). Spatial interpolation of the risk trend surface was used to construct topographical disease risk maps across 6 continents (Spatial and Maps packages, R v.2.9).

Four out of 5 loci demonstrated significant direction-consistent replication (ORs 0.70-0.86, p-values 9x10-8-1x10-2) with minimal heterogeneity (I2<25%, Q-test p>0.05). Heterogeneity was observed only for the TAP1/2-PSMB8/9 locus within the MHC region (I2=75%, Q-test p<0.01). This locus replicated in Italians and Germans (OR=0.60 and 0.67, P=5x10-3 and 2x10-2), but not in French, Hungarians, or African-Americans. However, in the combined analyses, all 5 loci remained highly significant with minor alleles conferring protective effects (ORs 0.66-0.81, p-values 4x10-27-7x10-10). The risk score model explained ~5% of the total variance in disease risk. In the geospatial analysis, the genetic risk of IgAN increases sharply with distance from Africa (P<2x10-16), and thus closely parallels the geographic distribution of IgAN.

The five IgAN risk loci explain a significant proportion of the risk of IgAN. These data suggest that variation in risk allele frequencies in part contributes to the known variation in disease prevalence among different ethnicities.

Phenotype mapping: An approach for integrating multidimensional genetic and phenotypic data. *E.R. Martin, D. Ma, M.L. Cuccaro.* Dr. John T. Macdonald Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Complex human diseases are marked by both genetic and phenotypic multidimensionality; that is, we expect that several genetic variants lead to the disease, which itself is often composed of several phenotypic dimensions. For example, autism spectrum disorder is a common neurodevelopmental disorder characterized by impairments in social, communicative, and behavioral dimensions. Dealing with such genetic and the phenotypic multidimensionality simultaneously in analysis is challenging. Traditionally, the mapping of complex diseases begins by reducing the phenotype to a simple composite trait (often a binary disease diagnosis) to allow for thorough analysis of multiple genetic variants, thereby mapping genetic variants to the composite trait. We suggest an alternate strategy that begins with reducing genetic variants to a composite genotypic value, which allows for more thorough analysis of phenotypic dimensions. This strategy provides a framework for mapping phenotypic dimensions to a composite genotype value. The Phenotype Mapping (PM) approach examines genetic variants in a gene/set of genes already known (or hypothesized) to be associated with the disease. It is designed to test the hypothesis that genotypic associations (from one or a combination of variants) with the disease are explained by their association with a specific phenotypic dimension (or combination of dimensions). The PM procedure involves two steps: (1) Given a set of genetic variants, stepwise logistic regression is conducted in cases and controls to determine best model for predicting affection status from genotypes. This model then is used to determine fitted (genotypic) values for each individual. (2) General linear regression is conducted in cases only to test for association between the genotypic values from step 1 (as the response variable) and the phenotypic dimensions (as main effects and interactions). A benefit of this approach is that there is no penalty for selecting the best model in step 1 since the analysis in step 2 is independent. Using computer simulations, we explore several genotype-phenotype models to demonstrate the best uses of the PM approach and compare it to traditional approaches where possible. The PM approach provides an approach to simultaneously incorporate genetic and phenotypic data into an integrated analysis. This approach has the power to reveal more homogeneous phenotypic subsets that will improve the success of replication and follow-up studies.

Gene-expression Guided Selection of Candidate Loci and Molecular Phenotype Analyses Enhance Genetic Discovery in Systemic Lupus Erythematosus. *T. Niewold[1], Y. Koldobskaya[1], A. Kumar[1], S. Agik[1], J. Arrington[1], B. Franek[1], M. Kumabe[1], T. Utset[1], R. Mikolaitis[2], M. Jolly[2], A. Skol[3].* 1) Section of Rheumatology, Univ Chicago, Chicago, IL; 2) Section of Rheumatology, Rush University, Chicago, IL; 3) Section of Genetic Medicine, Univ Chicago, Chicago, IL.

Objective: Systemic lupus erythematosus (SLE) is a highly heterogeneous autoimmune disorder characterized by differences in autoantibody profiles, serum cytokines, and clinical manifestations. This study aims to use gene expression data to rationally select novel candidate genes associated with molecular phenotypes in SLE. Methods: We devised an algorithm to select additional candidate SNPs from an existing case-case genome-wide association study of SLE patients stratified by autoantibody profile and serum interferon alpha. The top 200 SNPs from the GWAS were searched in the SCAN database, which compares genome-wide expression data to genome-wide SNP genotype data in HapMap cell lines. SNPs were chosen if they were associated with differential expression of 15 or more genes at a significance of p<9x10-5. This resulted in 11 SNPs which were genotyped in 453 SLE patients and 526 matched controls. Logistic regression models were used to detect associations between the candidate SNPs and serum IFN-(and autoantibodies in SLE patients. Results: A Q-Q plot demonstrated clear deviation from the null distribution in favor of positive findings in our autoantibody-SNP association results (p=3.2x10-37). 6 of 11 SNPs showed associations with specific autoantibody classes within either the European- or African-American ancestral backgrounds (p<0.05), and three of these six would withstand a Bonferroni correction for multiple comparisons (p<4.5x10-3). Two SNPs were associated with serum IFN-(, and one of these was independent of any autoantibody association (p=1.5 x 10-3). Case-control analysis showed no large differences in allele frequencies. Conclusions: This study illustrates the utility of gene expression data to rationally select candidate genetic loci implicated in complex genetic diseases such as SLE. Stratification by molecular phenotypes should be useful in the discovery of additional genetic loci and in elucidating pathogenic pathways in SLE.

Increasing association mapping power and resolution in mouse genetic studies through the use of meta-analysis for structured populations. *E. Kang[1], N. Furlotte[1], A. Van Nas[2], A. Lusis[2], E. Eskin[1,2].* 1) Department of Computer Science, University of California, Los Angeles, CA, USA; 2) Department of Human Genetics, University of California, Los Angeles, CA, USA.

Mouse models have played an integral role in the discovery and understanding of the mechanisms underlying many human diseases. The primary mode of discovery has traditionally been linkage analysis applied to crosses between two inbred strains. Although this method results in high power to identify regions that effect traits, resolution is often low, making it difficult to identify the causal variant. More recently, a panel of mice termed the hybrid mouse diversity panel (HMDP) has been developed to combat this issue. By utilizing population structure correction and genome-wide association study methodologies, mapping results within this panel tend to have both high resolution and high statistical power. However, power in the HMDP is limited by the number of available inbred strains. In this paper, we introduce a study design based on the concept of meta-analysis, in which HMDP data is combined with F2 cross data, in order to achieve high power and increase resolution. Due to the drastically different genetic structure of F2 crosses and the HMDP, the best way to combine results from the two studies for a given SNP is dependent on the strain distribution pattern of the SNP in each study. We present a method based on meta-analysis that takes into account the genetic structure when combining results and show that it significantly outperforms standard meta-analysis techniques. We apply our method to simulated data and show that by combining results we obtain increased power and resolution over traditional F2 mapping and mapping with HMDP.To further increase resolution, we also introduce a fine mapping method, which utilizes the linkage disequilibrium structure between SNPs in order to find the most likely causal SNP within a candidate region. We show through simulation that this method can increase resolution even further than combining F2 and HMDP results. We use our method to map HDL cholesterol and show that we are able to identify loci that are known to be associated with HDL cholesterol.

Discovering Pleiotropy in Complex Phenotypes by Multivariate Latent Modeling. *A.T. Kraja[1], D.C. Rao[2], D.K. Arnett[3], I.B. Borecki[1], S.C. Hunt[4], M.A. Province[1].* 1) Div of Statistical Genomics, Center for Genome Sciences & Systems Biology, Washington Univ Sch of Med, St Louis, MO; 2) Div of Biostatistics, Washington Univ Sch of Med, St Louis, MO; 3) Dep of Epidemiology, Univ of Alabama Sch of Pub Health at Birmingham, AL; 4) Div of Cardiovascular Genetics, Univ Utah Sch of Med, UT.

Nowadays abundant SNPs and next generation sequencing (NGS) products represent great resources in juxtaposition with the existing state of phenotypes in statistical prediction models. A search on PubMed using keywords “PRINCIPAL COMPONENT ANALYSIS” / “STATISTICAL FACTOR ANALYSIS” / “CLUSTER ANALYSIS” / “DISCRIMINANT ANALYSIS” / “STATISTICAL NEURAL NETWORKS” and “SNP” / “SEQUENCING” produced respectively 14,228/ **92**/ **98**; 16,608/ **5**/ **18**; 32,643/ **162**/ **1,289**; 12,281/ **10**/ **17**; and 3,043/ **9**/ **7** citations. These citation numbers reflect the fact that multivariate statistical methods pervade medical literature, but their use lags in relation to NGS. We provide theoretical statistical reasoning why multivariate latent modeling of phenotypes represents an attractive methodology for discovering polymorphisms' pleiotropic effects. We also worked on a number of complex traits considered as risk factors for metabolic syndrome and focused on a special region of chromosome 3p25-26 in humans. We had already reported for this region a linkage peak of a LOD score above 3 for obesity-insulin factor in the HyperGEN study; we provide also linkage findings for each contributing trait. Association results based on mixed models, with latent modeling of phenotypes, for the above referred chromosomal region with data from the African Americans and whites of the HyperGEN study, the whites of Family Heart Study and of the Framingham Heart Study support two significant association peaks. One, with SNPs related to *CNTN6-CNTN4* and the other to, SNPs that are part of a region of genes *IL5RA*, *TRNT1*, *CRBN*, and *LRRN1*. In this study, we discern the relation among the linkage peak and association test results, by additionally simulating such a region and SNPs pleiotropic effects on simulated correlated traits. We conclude that multivariate latent modeling of phenotypes represent a useful statistical methodology that empowers pleiotropy detection.

A wavelet-based nonparametric approach to association analysis of functional data. *H. Shim[1], M. Stephens[1, 2]*. 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

High-throughput sequencing technologies are now routinely applied at a genome-wide scale to collect a variety of phenotypic data. For example, ChIP-Seq, RNA-Seq, and DNase-Seq are used to assay transcription factor binding, gene expression and chromatin accessibility, respectively. Here we consider the development of statistical methods for testing for differences in these types of "functional" data between two or more groups. This problem arises both in genetic association studies (e.g. in testing for genetic variants that affect chromatin accessibility) or more generally in testing for differences among multiple treatment groups. In this work we introduce a Bayesian nonparametric approach to this problem, based on a wavelet regression known to be well suited for modeling spatially heterogenous functional data. Specifically, the functional data is projected into the wavelet space by a wavelet transformation and then the transformed wavelet coefficients are tested for association in a Bayesian regression model. We impose a shrinkage prior on the wavelet coefficients, which results in denoising of the signal in the wavelet space where the signal tends to be contained in a small subset of the coefficients. In addition to testing for association, our approach aims to provide a better interpretation of the analysis such as which parts and features of the functional data are associated with a given variant. We illustrate the proposed method on DNase-Seq data from 70 HapMap Yoruba lymphoblastoid cell lines and compare its performance with an analysis previously performed on the same data using a heuristic procedure.

403T

Pain-free conditional and joint association analysis from meta-analysis summary statistics uncovers additional variants for complex traits. *J. Yang[1], M.E. Goddard[2,3], P.M. Visscher[1], DIAGRAM consortium, GIANT consortium*. 1) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 2) Department of Food and Agricultural Systems, University of Melbourne, Victoria, Australia; 3) Biosciences Research Division, Department of Primary Industries, Bundoora, Victoria, Australia.

Genome-wide association studies (GWAS) have been successful in identifying variants, genes and pathways involved in genetic variation for human complex traits and diseases. For many traits such as height and body mass index (BMI) and diseases such as type 2 diabetes and breast cancer, more and more associated genetic variants have been identified by meta-analyses of a large number samples. Here we present a "pain-free" conditional and joint association analysis that uses summary-level GWAS statistics from a meta-analysis and estimated linkage disequilibrium (LD) from a reference sample with individual-level genotype data. We analysed the summary data of the GIANT meta-analysis for height and BMI with the LD structure estimated from genotype data of two independent cohorts. We identified 32 loci with multiple association signals (33 primary and 44 additional SNPs) for height, which cumulatively explain ~3.5% of variance at these loci compared to ~2.1% if we consider only the leading SNPs at each locus. We did not find any loci showing multiple signals for BMI. The method is also applicable to case-control data and we demonstrate this by examples from the DIAGRAM meta-analysis of type 2 diabetes. Our new method is computationally fast and facilitates fine-scale genetic mapping even when only summary statistics are available in the discovery sample.

404T

Understanding the Genetics of Vesico-Ureteric Reflux: from Mouse Models to a Human Cohort. *C.L. Watt[1], J. El Andalousi[2], I.R. Gupta[1,2]*. 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Pediatrics, Research Institute of the McGill University Health Center, Montreal, Quebec, Canada.

Introduction: Vesico-ureteric reflux (VUR) is the retrograde flow of urine from the bladder to the kidneys due to a defect of the uretero-vesical junction (UVJ). It occurs in 1% of the population and is associated with recurrent urinary tract infections, hypertension and end stage renal disease. Most affected children have kidneys that are normal in size and form. VUR is genetically heterogenous and is associated with multiple genes and loci in humans. To identify mouse models with VUR and normal kidneys, we screened inbred mouse strains for these phenotypes and found that the C3H and DBA mice have a 100% and 38% incidence of VUR respectively, while the C57BL/6 (B6) mouse does not reflux. All of these strains have kidneys of normal size. Genetic characterization of the C3H mouse has revealed that VUR is recessive and maps to a locus on chromosome 12: *Vurm1*. This region is orthologous to a VUR susceptibility locus previously identified in humans. Complementation analysis between C3H and DBA mice suggests *Vurm1* also confers VUR susceptibility in DBA mice. Statement of purpose: To refine the *Vurm1* locus using existing C3H and newly generated DBA backcross (N2) mice and to apply the findings from mouse models to a human cohort with VUR. Methods: F1 hybrids derived from crossing refluxing DBA mice and non-refluxing B6 mice were backcrossed to DBA mice to generate N2 mice. All progeny were tested for VUR and kidney surface areas were obtained. To establish a human cohort, children with VUR are being recruited from the Montreal Children's Hospital. Saliva samples are taken for DNA extraction and medical histories are obtained from affected children and their immediate family. Grade of VUR, kidney length by ultrasound and glomerular filtration rate (GFR) of affected children are recorded. Results: DBA X B6 F1 hybrids do not reflux, confirming VUR is recessive. DBA N2 mice exhibit a 51% incidence of VUR (n=116). C3H and DBA N2 mice have kidneys of normal size by planar surface measurements. To refine *Vurm1*, DBA and C3H N2 mice will be genotyped for SNPs spanning chromosome 12 and will be subject to a linkage analysis. To date, 137 children have been recruited: 22 of them have a sibling or another family member with confirmed VUR. 95% of the patients have phenotypically normal kidneys (confirmed by kidney length and GFR). As *Vurm1* is refined in the mouse, candidate genes will be prioritized and examined in both mouse models and the human cohort.

405T

Next-generation sequencing of *IL23R* reveals a novel low-frequency non-synonymous SNP that is associated with ankylosing spondylitis in a Han Chinese population. *S.I. Davidson[1], L. Jiang[2], E.A. Glazov[1], A. Cortes[1], M. Donskoi[1], P.A. Danoy[1], G.P. Thomas[1], H. Xu[2], M.A. Brown[1]*. 1) Human Genetics Group, The University of Queensland Diamantina Institute, Woolloongabba, Queensland, Australia; 2) Shanghai Changzheng Hospital, The Second Military Medical University Hospital, Shanghai, China.

Aims: Ankylosing spondylitis (AS) is a highly heritable common inflammatory arthritis affecting 0.5% of white Europeans that predominantly targets the spine and sacroiliac joints of the pelvis, causing pain and stiffness leading eventually to joint fusion. *IL23R*, a cytokine receptor gene known to play a role in regulating inflammation and autoimmune disease, is strongly associated with AS in white Europeans. We performed an association study in Han Chinese AS cases and healthy controls to assess whether *IL23R* is associated in this ethnically distinct population in which the disease has similar prevalence and presentation. No association was found, suggesting that *IL23R* either plays no role in Han Chinese or novel genetic variants contribute. We therefore screened *IL23R* to identify novel rare variants associated with AS.

Methods: A 170kb region containing *IL23R* and its flanking regions was sequenced in 50 cases and 50 controls, as well as the 30kb region of peak association in white Europeans in 650 cases and 1300 controls. Sequencing of pooled overlapping 5kb and 10kb amplicons was performed using an Illumina GAII sequencer. Validation genotyping using the ABI OpenArray platform was undertaken in 872 cases and 1397 controls.

Results: We identified 1007 variants, of which 713 are novel variants not found in dbSNP b130. Several novel potentially functional variants in *IL23R* were identified, including one nsSNP Gly149Arg (chr1:67421184 GA) which is predicted to be functionally deleterious by SIFT, one splice site variant, and one 5' UTR and seven 3' UTR variants. Validation genotyping showed that the Gly149Arg variant is associated with AS in Han Chinese (P=1.07x10^{-3}, OR=0.57), with five further low-frequency variants showing association at P<0.05.

Conclusions: This is the first study to implicate rare variants in *IL23R* in AS pathogenesis, and has identified a rare, novel nsSNP with deleterious effects that is associated with AS in Han Chinese. This suggests that decreased IL-23R function protects against AS. These findings confirm disease associations with different SNPs in the same gene in ethnically remote populations, indicating the importance of performing genetic studies in multiple populations when searching for associated loci.

Initial results from the UK10K project to study the effects of rare variants by whole genome and exome sequencing in 10,000 phenotyped samples. *R. Durbin[1,2] on behalf of the UK10K Project Consortium.* 1) Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) www.uk10k.org.

The UK10K project was launched in 2010 to investigate the role of low frequency and rare genetic variants in health and disease. We are in the process of sequencing whole genome at low coverage (average 6x) 4,000 samples from two longitudinal cohorts with rich clinical and molecular phenotype data, TwinsUK and ALSPAC, and by exome pull-down 6,000 samples selected for extreme phenotypes in neurodevelopmental disorders (autism and schizophrenia), severe obesity, and a range of other more rare disorders. The project is a collaboration of the Wellcome Trust Sanger Institute, and multiple UK clinical collaborators from across the country.

Samples are being analysed using pipelines developed from those used for the 1000 Genomes Project. At the time of abstract submission, we are analyzing data from approximately 800 whole genome samples from TwinsUK, and a similar number of exome samples. More have been sequenced and await analysis, and we are on track to complete whole genome sequencing around the end of 2011, and exome sequencing in mid 2012. In the neurodevelopmental arm cases have been weighted in favor of a number of “high value” criteria, including multiply affected families, and depth of additional phenotype data. By the time of the meeting 280 autism and 870 schizophrenia cases are estimated to be sequenced. We are implementing automated pipelines for the efficient and effective annotation of variants to facilitate detection association with the medically-relevant phenotypes of interest. We already have some promising indications of functional association in rare disease samples.

All primary data and variant call sets will be released to the EGA at the EBI for access for research purposes under a Data Access Agreement. An extensive consultation and discussion process led to an Ethical Governance Framework document http://www.uk10k.org/ethics.html which in particular lays out a management pathway for the return of `pertinent' individual findings to research participants. This policy document constitutes a work in progress but is a first step at finding a practical solution to some of the ethically challenging issues that are raised by whole genome and exome sequencing, and has proved useful in multiple contexts by people associated with the project.

Estimating Genetic Effects and Quantifying Missing Heritability for Rare Variant Complex Trait Association Studies via Sequence Data. *S.M. Leal[1,2], D.J. Liu[1,2].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of statistics, Rice University, Houston, TX.

Complex trait rare variant association studies using next generation sequence data are being performed for a wide variety of phenotypes. It has been demonstrated that analyzing rare variants individually is extremely underpowered. Therefore many powerful methods have been developed specifically to analyze rare variant data, which are all based upon jointly analyzing multiple rare variants within region, which is usually a gene. After a significant association is identified, it is also of great importance to estimate genetic parameters of interest and quantify the proportion of heritability explained by the gene. Although rare variant association methods are powerful a drawback is that within the statistical testing framework it is not possible to tease apart causal from non-causal variants. Consequently, the causative-variant-effect is not estimable. Alternatively, we describe how it is possible to efficiently estimate the locus-average-effect which is defined by the mean quantitative trait difference between rare variant carriers and non-carriers. Due to the presence of non-causative variants, genetic variance explained by the locus-average-effect will underestimate but provide a lower bound for the true underlying locus genetic variance. In addition, incorporating assumptions on the effect size distributions of rare variants for complex traits, an estimated upper bound for the true locus genetic variance can also be obtained. An additional problem is when the locus-average-effect is estimated using the same dataset where a significant association is detected, the naïve estimator can be seriously inflated due to the winner's curse. The bias is quantified under a rigorous population genetic model and complex trait phenotypic models. A bootstrap-sample-split algorithm is applied to correct for the winner's curse and can be used for any rare variant test. It is shown through extensive simulations that the boot-sample-split procedure can greatly reduce the bias of the estimates, even for poorly powered studies (e.g. ~30%). Not only are these methods vital for estimating the amount of missing heritability due to rare variants, but they are also important for designing replication studies and risk prediction.

Whole exome sequencing in affected members of a large, multigenerational spina bifida family. *C.A. Markunas, B. Rusnak, A.E. Ashley-Koch, S.G. Gregory.* Center for Human Genetics, Duke University, Durham, NC.

Neural tube defects (NTDs) encompass a range of birth defects that result from a failure of the neural tube to close during the 3rd and 4th weeks of development. The incidence of NTDs is estimated to range between 1 and 10 per 1000 births worldwide, with the two most common forms being anencephaly and myelomeningocele, which is more commonly referred to as spina bifida. Anencephaly occurs when the neural tube fails to close in the cranial region, while myelomeningocele occurs when the neural tube fails to form in the spinal region. NTDs are thought to have a complex etiology, resulting from both genetic as well as environmental factors. In order to identify genetic factors, we performed whole exome sequencing on four, distantly related family members diagnosed with myelomeningocele from a large multigenerational, Mendelian-like family. Agilent's SureSelect Human All Exon 50Mb kit was used for whole exome capture and Illumina's HiSeq 2000 was used to generate 100 bp paired end reads. On average, we achieved 89x coverage within the target interval across our samples. Sequencing reads were aligned to the human reference (1000 genome's b37) using BWA. Following alignment, duplicate removal (Picard), and assessment of data quality (Picard), GATK was used for further processing and multi-sample variant calling (target +/- 200 bp window). A series of variant quality filters were applied to the raw call set, leaving a total of 88,780 variants. Out of the quality filtered variants, 55.9% were intronic, 16.2% were coding-synonymous, 14.9% were missense, 6.9% were intergenic, and the remaining 6% included variant classes such as nonsense. By further restricting these variants to autosomal and setting a relatively low minimum genotype quality threshold for each individual ($N_{remaining}$=78,362), we found that 4.3% and 10.7% of the variants were shared across all 4 individuals in a heterozygous and homozygous state, respectively. The application of additional filters, such as allele frequency and variant class, produced several potentially interesting genes, including one which may be involved in cell polarity.

Identification, replication, and fine-mapping of loci associated with adult height in individuals of African ancestry. *A. N'Diaye[1], G.K. Chen[2], C.D. Palmer[3,4], B. Ge[5], B. Tayo[6], R.S. Cooper[6], T. Pastinen[5], B.E. Henderson[2], J.N. Hirschhorn[3,4,7], G. Lettre[1,8], C.A. Haiman[2].* 1) Montreal Heart Institute, Montreal, Canada; 2) Department of Preventive Medicine, Keck School of Medicine and Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA, USA; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 4) Divisions of Genetics and Endocrinology and Program in Genomics, Children's Hospital Boston, Boston, MA,, USA; 5) Department of Human Genetics, McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 6) Department of Preventive Medicine and Epidemiology, Loyola University Chicago Stritch School of Medicine, Maywood, IL, USA; 7) Department of Medicine, Harvard Medical School, Boston, MA, USA; 8) Département de Médecine, Université de Montréal, Montréal, Québec, Canada.

Adult height is an ideal phenotype to improve our understanding of the genetic architecture of complex diseases and traits: it is easily measured and mostly influenced by genetics (h2~0.8). More than 180 single nucleotide polymorphisms (SNPs) are associated with height. They were mostly identified in populations of European descent, convey modest effects and explain ~10% of the variance in height. To search for novel loci for height in populations of African ancestry, and to explore the replication of known height loci in other ethnic groups, we combined height genome-wide association results at 3,310,998 genotyped or imputed SNPs from nine studies (20,809 African Americans). Association analysis was performed using linear regression. Results were combined using the inverse variance meta-analysis method. From our meta-analysis we prioritized 153 SNPs with P<1x10-5 for in silico replication in up to 16,436 African Americans. After combining data, 40 SNPs from 11 different genomic regions reached genome-wide significance (P≤5x10-8), including two novel loci (rs12393627, P=3.4x10-12 and rs4315565, P=1.2x10-8). rs12393627 on chromosome Xp22 is located 3.2 kb upstream of the arylsulfatase E (ARSE) gene. Mutations in this gene cause X-linked brachytelephalangic chondrodysplasia punctata, a congenital disorder of bone and cartilage development also characterized by short stature. rs4315565 on 2p14 is located at 189 kb upstream of the bone morphogenetic protein 10 (BMP10) gene, a member of the TGF-) signaling pathway implicated in human growth. We tested for replication in the African height meta-analysis of the 180 European height SNPs using a procedure based on linkage disequilibrium (LD) differences between populations of European and African descent. We found strong overall evidence of replication (P≤3.1x10-4), indicating a shared genetic basis for height in populations separated since the out-of-Africa event. We also used LD differences to attempt to fine-map the European height association signals in African-ancestry individuals, and developed an experiment using allelic gene expression phenotypes in the HapMap YRI cell lines as functional readouts. The fine-mapping results showed an enrichment of SNPs that are associated with expression of nearby genes when compared to the index European height SNPs (P<0.01). Our results highlight the utility of genetic studies in non-European populations to understand the etiology of complex human diseases and traits.

Whole-genome sequencing to identify the genetic basis for resistance to HIV infection. *K. Pelak, K.V. Shianna, D. Ge, D.B. Goldstein, National Institute of Allergy and Infectious Diseases Center for HIV/AIDS Vaccine Immunology (CHAVI).* Center for Human Genome Variation, Duke University School of Medicine, Durham, NC, 27708, USA.

Variants in the human (host) genome have been shown to play a role in determining the course of infection after a person is exposed to a number of different infectious diseases, including HIV-1. Of particular interest for this study are the genetic variants that can protect individuals from HIV-1 infection. Individuals who are homozygous for a 32bp deletion in the CCR5 gene, which encodes a coreceptor that HIV uses to enter the cell, are resistant to infection from most strains of HIV-1. About 1% of people of northern and western European descent are homozygous for this deletion, and the proportion of CCR5d32 homozygotes increases in European populations that are at high risk but have remained seronegative (HRSN). However, much of the “HIV-resistance” observed in the rest of the HRSN population cannot be explained by host or viral genetic variants. In this study, we seek to identify additional host genetic variants that may provide resistance to HIV infection. We have done whole-genome sequencing on 44 HRSN individuals with hemophilia who were highly exposed to contaminated blood products between 1979 and 1984, but who did not become infected by HIV-1. I have compared the whole-genome sequences from these individuals to the whole-genome sequences of 43 white population controls. Based on this comparison, we have selected 1,390 variants for follow-up genotyping on an Illumina iSelect chip. All of these variants show some amount of enrichment in the HRSN individuals as compared to the population controls. Among the variants chosen for follow-up are 692 variants that were homozygous in one or more of the HRSN cases and had a MAF<0.08 in the controls. Another 307 variants were chosen because they were enriched in the cases according to an allelic or recessive Fisher's Exact Test. An additional 84 stop gain variants were chosen because they were at a higher frequency in the cases than in the controls. These variants are being genotyped in 361 other high-risk seronegative individuals, in 3200 population controls, and in 1000 HIV+ individuals. We would expect a potentially protective variant to be heavily depleted or entirely absent in the HIV+ individuals. We would also expect a potentially protective variant to continue to show enrichment in the other HRSN samples, and to occur at low frequency in the population controls.

Sequencing Workflow at a Medium-Scale Genomics Center. *J. Romm, B. Marosy, B. Craig, K. Hetrick, H. Ling, M. Barnhart, S. Griffith, E. Pugh, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR has developed a high-throughput NGS lab, workflows and an automated data processing/analysis QC pipeline designed to provide high quality NGS data including variant calls, supporting data, and QC metrics. We aim to achieve 90% of on-target bases at a minimum sequencing depth of 8X. Our dedicated Project Management team initiates contact with PI's and serves to answer questions throughout the process. DNA samples are received in 2D barcoded tubes and enter our Sample Handling LIMS. Samples are evaluated for degradation on 2% e-gels and quantitated on the Nanodrop® ND-1000 Spectrophotometer. All samples intended for whole-exome sequencing (WES) are genotyped on a GWAS array to perform checks such as gender, unexpected duplicates, IBD sharing and concordance with previous genotyping prior to processing. The GWAS array also enables a data quality check with the sequencing data results (concordance and sensitivity). Lab processing is tracked in the Exemplar™ LIMS modified in-house. The lab work is a modification of the Broad Institute's 100ng with-bead protocol (Genome Biology 2011, 12:R1). The protocol was optimized by CIDR to work with the Agilent© SureSelect™ XT kits for WES. Shearing of the DNA is performed with the Covaris™ E210, library prep with the Beckman Coulter Biomek® 2000 or Perkin Elmer® Multiprobe® II HT PLUS, and QC'ed with the Agilent Bioanalyzer™. After the 24 hour capture, post-hyb processing is performed on the Agilent Bravo™, quantitated on the Agilent Bioanalyzer and normalized to run on the Illumina® HiSeq 2000™. We currently index 4 samples per lane using TruSeq v3 chemistry and 600GB runs. Data QC includes evaluating batch and individual sample level metrics such as array concordance, sensitivity, Ts/Tv, % in dbSNP, % on target, % duplicates and library size. CIDRSeqSuite was developed in-house to process our sequencing data in order to obtain QC metrics and release-ready files. Samples are demultiplexed and aligned with BWA; local realignment and base call quality recalibration using the Genome Analysis Toolkit (GATK) from the Broad; duplicates flagged with Picard; SNVs and indels called and QC filtered using SAMtools then annotated using ANNOVAR.

Pathway-based genetic association analysis for exome sequencing data. *G. Wu[1], K. Wang[2], D. Zhi[1].* 1) Biostatistics, University of alabama at Birmingham, Birmingham, AL; 2) Zilkha Neurogenetic Institute, Department of Psychiatry and Department of Preventive Medicine, University of Southern California, Los Angeles, CA.

Exome sequencing emerges as a powerful approach for the detection of coding variants, enabling genetic association studies for both common and rare variants. While a plethora of rare variant association methods are developed, most methods are gene-based and have insufficient power for genome-wide scale analysis. Pathway association analysis can detect biological pathways significantly enriched for high-ranking variants and genes, even when few of them reach genome-wide significance individually, and thus is more appropriate for exome sequencing data. However, existing variant-level pathway association analysis methods are targeted to genome-wide association studies (GWAS) data, and cannot tackle rare variants. In this study, we develop a new practical approach for pathway-based association for exome sequencing data. We adopt a penalized hierarchical generalized linear model that takes into account biological information at variant-, gene-, and pathway-levels. Estimation is achieved by using an efficient algorithm for sparse group lasso. In simulations with 200,000 rare and common variants in 20,000 genes and 200 pathways, with some realistic assumptions on the genotype allele frequency distributions and on the underlying genetic model, our approach can generate an estimate in less than a second. More importantly, we show that our approach is powerful in terms of identifying truly causal pathways. When pathway-wide heritability is high (50%), our method can achieve a power of 60% for a sample size of merely n=200. Furthermore, we find that identifying causal genes and variants are much more challenging, suggesting that pathway-based association might be a more powerful and practical approach for exome sequencing data analysis at the current stage.

Imura[2], A.L Petrin[1], E. Leslie[1], J. L'Heureux[1], A.C Lidral[10], M.E Cooper[4], N. Natsume[2], T.H Beaty[3], M.L Marazita[4,5], J.C Murray[1,7,8].* 1) Pediatrics, University of Iowa, Iowa city, IA; 2) , Division of Research and Treatment for Oral and Maxillofacial Congenital Anomalies, School of Dentistry, Aichi-Gakuin University, Japan; 3) Johns Hopkins University, School of Public Health, Baltimore, Maryland, USA; 4) , Center for Craniofacial and Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA 15260; 5) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA 15219; 6) Faculty of Psychological and Physical Science, Aichi-Gakuin University, Japan; 7) University of Iowa, Departments of Pediatric Dentistry, Epidemiology and Biology, Iowa City, IA 52242; 8) College of Nursing, University of Iowa, Iowa City, IA 52242; 9) and Children's Health Research Center Hospital, Ulaanbaatar, Mongolia; 10) Department of Orthodontics, College of Dentistry, University of Iowa.

Background:Genome wide association studies (GWAS) of cleft lip with or without cleft palate (CL(P)) have identified several significant and near-significant genetic associations for non-syndromic CL(P)(Beaty et al.,2010).To replicate two of the near-significant GWAS signals, the present study investigated the role of both common and rare variants in the PAX7 and VAX1 genes. Methods:Direct sequencing was used to search for sequence variations in coding regions and conserved non-coding regions in and around the PAX7 and VAX1 genes in 1454 individuals of European and Asian (Filipino,Mongolian,Japanese)ancestry.TaqMan genotyping was carried out using GWAS markers in VAX1 and PAX7 on 5,421 individuals,and TDT was used to investigate family based association in each population.Case-control comparisons were carried out using Fisher's exact test. Results:Nineteen new variants were found in PAX7 (eight missense, three synonymous and eight non coding variants) Eleven new variants were found in VAX1(two missense mutations,two synonymous mutations and seven non- coding mutations).A statistically significant difference(p= 0.007)was observed between cleft cases and controls from the Philippines for a VAX1 new variant in the 3'UTR (chr10_118880130).TDT analysis showed strong associations with markers in VAX1 (rs7078160, p=1.46E-06 and rs475202 p=0.0008) in both Mongolian case and Japanese case-parent triads. Analysis using PLINK analyses suggested a possible maternal genotype effect for a VAX1 marker in Mongolian and Japanese combined CL(P)cases versus controls (rs7078160,p=9.7E-05,OR=2.33).A significant association with CL(P) was also observed in the Philippines case-parent triads for rs70781860(p= 0.03).Furthermore,CL(P) males were mostly responsible for the effects in both Japanese and Mongolian populations (rs7078160, p=5.2E-05, OR= 3.40).Note, no significant association was observed for these markers in VAX1 for the Iowa CL(P)case-parent triads,the T-allele at rs6659735 trinucleotide marker in PAX7 was significantly under -transmitted(p=0.02). Conclusions:Our study replicated previous GWAS findings for markers in VAX1 across three independent Asian populations, and identified rare variants in PAX7 that may contribute to the etiology of CL(P).The role of these rare variants warrants further investigation through deep sequencing around these and other candidate genes. Comparison of "synthetic associations" and "natural associations" in human population genetic data. *D. Chang, A. Keinan.* Cornell University, Ithaca, NY.

Genome-wide association studies (GWAS), based on the Common Disease-Common Variant hypothesis, have been highly successful in associating thousands of loci to many complex traits and diseases. While they have greatly expanded our knowledge, for most phenotypes associated markers explain only a small fraction of heritability and the leap from association to causality has been limited. Rare variants have been suggested as one possible cause underlying these shortcomings due to their exclusion in most GWAS, potentially higher effect sizes, and differing patterns of linkage disequilibrium. Recent studies have attempted to quantify the nature of associations due to underlying rare variants ("synthetic associations"). While these simulation-based studies offered key insights into synthetic associations, a study accounting for the empirical genetic variation patterns in humans, and their impact on signals of associations, is warranted to provide a more complete picture of the phenomenon in light of human evolutionary history. Hence, we studied the characteristics of synthetic associations as compared to associations due to common causal variants ("natural associations") in real data. Considering rare and common risk alleles in HapMap3 sequencing data, we assigned individuals as cases or controls, and performed an association test using HapMap3 genotyping data. We found that the median distance from an association to the furthest causal variant is at least 1.5-fold greater for synthetic associations than natural associations. However, our results predict that this increased distance of synthetic associations is much less pronounced than previously suggested, thus significantly reducing the length of the region required for fine mapping to discover most underlying rare causal variants. In further analysis, we discovered that this increased distance can partially be explained by the age of the mutation, with more recent rare mutations introducing further synthetic associations. Additionally, we found that independent synthetic associations are twice as likely as independent natural associations. Despite these clear trends, the characteristics vary greatly between different populations and regions of the genome. This heterogeneity testifies to the effect of evolutionary history and locus-specific attributes on GWAS signals. Overall, our results recount a more complex relationship between rare and common variation than depicted by simulations alone.

The MHC association in celiac disease maps to a few amino acid polymorphisms in HLA-DQ. *J. Gutierrez-Achury[1], G. Trynka[1], K.A Hunt[2], J. Romanos[1], C. Wijmenga[1], D. van Heel[2], P.I.W de Bakker[3, 4, 5].* 1) Department of Genetics, University Medical Hospital Groningen - University of Groningen, Groningen, Netherlands; 2) Blizard Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, London E1 2AT, United Kingdom; 3) Brigham and Women's Hospital, Boston, MA; 4) Broad Institute of Harvard and MIT, Cambridge, MA; 5) University Medical Center, Utrecht, The Netherlands.

Background: Variants in the major histocompatibility complex have been widely associated to many inflammatory and infectious diseases. However, the analysis of this region presents particular challenges because of its characteristic genetic structure. In order to identify independent effects in celiac disease, we have used a custom genotyping array (Illumina immunochip) to genotype >10,000 SNPs within the MHC in 11,850 cases and 12,109 controls. Methods: Using a reference panel of European ancestry, we imputed classical alleles of the *HLA-A*, *B*, *C*, *DQA1*, *DQB1*, *DRB1*, *DPA1* and *DPB1* genes at 2 and 4-digit resolution as well as polymorphic amino acid positions in those gene products. We used conditional analysis to identify independent associations. Results: Of all variants tested, the strongest association was at amino acid position 55 in the DQ) 1 protomer (χ^2= 6280, df=2, -log(p)=1364), which is located in the binding groove and likely interacts with the gluten antigen. Adjusting for position 55, we also found significant associations for positions 57 in DQ) 1 (-log(p)=56) as well as 25 and 215 in DQ(1 (-log(p)=20 and -log(p)=294, respectively). The haplotypes formed by these four positions recapitulate the known risk-conferring effects of the DQ2.5 (OR=12.21, -log(p)=1662), DQ2.2 (OR=3.4 , -log(p)=1710), and DQ8 (OR=4.7, -log(p)=1701) alleles. After controlling for these HLA-DQ effects, we found >10 markers associated across the MHC. The association within class I was located around *HLA-A*, whereas the associations in class II mainly clustered near *TAP1* and *TAP2*. Conclusions: Although the DQ2 and DQ8 molecules are well-established genetic risk factors for celiac disease, we have pinpointed specific amino acids of HLA-DQ that can explain the bulk of the observed MHC association. Our analysis also provides evidence for multiple additional independent effects outside HLA-DQ that require further study.

Genome-wide association study to identify variants associated with amphetamine sensitivity in humans. *A.B. Hart[1], B.E. Engelhardt[2], M. Wardle[3], A. Skol[4], M. Stephens[1,5], H. de Wit[3], A.A. Palmer[1,3].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Computer Science, University of Chicago, Chicago, IL; 3) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 4) Department of Medicine, University of Chicago, Chicago, IL; 5) Department of Statistics, University of Chicago, Chicago, IL.

Humans vary in their response to the drug *d*-amphetamine, and this variation has been shown to have a genetic basis through twin studies. Previous studies to identify genetic polymorphisms associated with this variability have focused on genes that have known, related functions or that have been previously implicated in similar phenotypes, such as response to methylphenidate. Instead, we ran a genome-wide association study with a cohort of 381 non-drug-abusing individuals. The subjects were given a capsule over three double-blind sessions of randomized order (placebo, 10 mg, and 20 mg of *d*-amphetamine) during which subjects were phenotyped at six time points, utilizing established drug response questionnaires (POMS, DEQ, ARCI) and physiological measures (blood pressure, heart rate). We used sparse factor analysis (SFA) to summarize the resulting complex phenotype data, projecting this large set of phenotypes down to a reasonable number of interpretable, smoothed phenotypes. SFA generated eleven biologically meaningful factors that were able to explain the bulk of the phenotypic variance; these factors represented different types of drug response measures and pre-drug personality and physiological characteristics. Subjects were genotyped on the Affymetrix 6.0 array at 906,598 SNPs, and imputation was used to expand coverage to approximately 8 million SNPs. Association mapping was performed in Bayesian and frequentist frameworks with software packages BIMBAM and SNPTest, respectively. From these analyses, we identified numerous potential associations with interesting biological implications. Potential associations include the association of a SNP (rs248797) in the *SRD5A1* gene, which is involved in the synthesis of the known GABA(A) receptor agonist allopregnanolone, with feelings of pre-drug friendliness, and the association of a SNP (rs73036321) in the *ZNF30* gene with mood response to 10 mg and 20 mg doses of the drug. By taking advantage of rigorous phenotyping to capture drug response and sparse factor analysis to project the survey responses to a small number of interpretable phenotypes, we have identified novel genetic associations with both pre-drug personality traits and amphetamine sensitivity in humans.

417T

Genetics of Allergy and Related Phenotypes in Participant Driven and Cross Sectional Cohorts. *D.A. Hinds[1], G. McMahon[2], A.K. Kiefer[1], C.B. Do[1], N. Eriksson[1], M. Curran[3], M. Loza[3], D. Talantov[3], N.J. Timpson[2], D.M. Evans[2], B. StPourcain[4], S.M. Ring[4], K.C. Nadeau[5], D. Miralles[3], G. Davey-Smith[2], J.Y. Tung[1].* 1) 23andMe, Inc., Mountain View, CA, USA; 2) MRC CAiTE Centre/School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 3) Pharmaceutical R&D, Johnson & Johnson, San Diego, CA, USA; 4) School of Social and Community Medicine, Oakfield House, Oakfield Grove, Bristol, United Kingdom; 5) Division of Allergy and Clinical Immunology, Department of Pediatrics, Stanford University, Stanford, CA, USA.

We have collected survey information from the 23andMe participant cohort covering a range of immune hypersensitivity phenotypes including allergy, asthma, and eczema. We describe results of genome-wide association analyses of these traits, representing a combined total of nearly 16,000 cases. We find genome-wide-significant associations (P<5E-08) for variants upstream of *HLA-C* with grass allergies (rs9266270: P=3.7E-09, OR=0.81) and for a non-synonymous variant in *TLR1* with seasonal allergies (rs4833095: P=1.5E-09, OR=1.15), as well as suggestive associations for several additional loci with established biological roles in immune response, including *CLEC16A* (rs725613) and *IL1R1*/*IL1R2* (rs11674302). In specific lookup analyses, the *TLR1* and *HLA* associations specific to grass are corroborated in a GWAS of allergy skin prick response tests from the Avon Longitudinal Study of Parents and Children (ALSPAC), with the *TLR1* finding reaching genome-wide significance for allergy to mixed grasses (P=9E-09, OR=1.7). The *TLR1* variant has been reported to affect responsiveness to bacterial antigens, and the *CLEC16A* variant has been previously associated with type 1 diabetes and multiple sclerosis. We also replicate many known associations with asthma, including *IL18R1*, *HLA-DQB1*, *IL33*, *SMAD3*, *GSDMB*, *GSDMA*, and *IL2RB*, with effect sizes consistent with the original reports. Our results further support the existence of a shared genetic etiology for these conditions, as well as distinct patterns of association across phenotypes. Our findings also demonstrate that self report is an effective method for collecting phenotypic information for genetic analysis of allergy related phenotypes.

418T

High Through-Put Genotyping at CIDR. *M. Hurley, M. Zilka, C. Oncago, J. Romn, K. Doheny.* CIDR, Johns Hopkins Univeristy, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next gen-sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR began production level genotyping in 1996 with Human STRP linkage panels (~400 markers per sample). Today CIDR is running arrays with greater than 2.5 million polymorphisms per sample. Even with the recent advent of NGS, the demand for genotyping has remained high. CIDR releases data for an average of 1 study per week. Over the 1st 5 months of 2011, we have completed 19 studies involving 38,000 samples. 85% of studies were genome-wide association studies (GWAS), 12% custom SNP, 2% linkage and 1% methylation. All samples received at CIDR are pretested using an AIMS focused 96-SNP GoldenGate® SNP "barcode" panel to check unexpected duplicates, gender, sample quality and relationships. To verify that samples are not degraded, a 2% e-gel is run. After pretesting is complete, the PI is given the opportunity to replace samples or fix sample information based on the results. Throughout the entire process, samples are tracked using a customized sample handling LIMS that integrates with both the Illumina® LIMS (used for GoldenGate® processing) and an in-house developed Infinium® LIMS. Using three Illumina® iScans™ with autoloaders and the first dual HiScan™ autoloader, CIDR is able to process over 100,000 samples a year. CIDR can process 2,000 samples per week based on the Omni 2.5-Quad and 4,000 GoldenGate® samples. All GWAS experiments are analyzed using an automated pipeline for the generation of quality control statistics. These QC metrics are stored and available for daily QA/QC of data produced in the lab. All assay failures are repeated one time. Genotype cluster positions for GWAS studies are generated by re-clustering the data using a project's samples before release and a technical filter is performed on the data to identify gross assay failures. CIDR performs a manual review of the clustering for each SNP for GoldenGate® and custom iSelect® up to 1,000's of SNPs. While processing high numbers of samples, CIDR has been able to maintain high quality standards through the use of automation, rigorous QC measures and strict LIMS control. Overall, the cumulative GWAS error and missing rate are 0.015% and 0.2% respectively and the custom genotyping error and missing rate are 0.009% and 0.18%.

419T

A Genome-Wide Association Analysis for chroidal neovascularization in highly myopic eyes in Japanese. *M. Miyake[1,3], K. Yamashiro[1], H. Nakanishi[1,3], H. Hayashi[1,3], I. Nakata[1,3], Y. Kurashige[1,3], A. Tsujikawa[1], M. Moriyama[2], K. Ohno-Matsui[2], M. Mochizuki[2], T. Kawaguchi[3], R. Yamada[3], F. Matsuda[3], N. Yoshimura[1].* 1) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Kyoto, Japan; 2) Department of Ophthalmology and Visual Science, Tokyo Medical and Dental University Graduate School of Medicine, Tokyo, Japan; 3) Center for Genomic Medicine/Inserm U.852, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Myopia is the most common type of ocular disorder in the world. Pathological myopia, also called high myopia, is one of the leading causes of legal blindness in developed countries. The main cause of visual acuity loss in highly myopic eyes is a development of choroidal neovascularization (CNV). The CNV formation leads to serous retinal detachments and subretinal hemorrhage with fibrotic membrane formation, which results in irreversible visual impairment. To identify genetic determinants associated with the development of CNV in highly myopic eyes, we conducted a 2-stage-genome-wide association study (GWAS). In the first stage, we genotyped 481 patients with high myopia (axial lengths >28.0 mm in both eyes) using Illumina HumanHap 550k or 660K arrays. We divided them into 2 groups whether they have CNV (n=171) or not (n=310), and performed case-control study for each SNPs. We selected 11 SNPs that showed P-values smaller than 5.0×10-5 in the first stage and evaluated the association to CNV formation in the second stage analysis with 351 patients with high myopia (axial lengths > 26.0 mm in both eyes) using Taqman SNP assay. Patients with CNV (n=139) are older (62.6 ± 13.3 vs 54.8 ± 16.2; p=0.02) and more female-dominant (Male:female=31:108 vs 72:140; Odds ratio 0.56; 95% confidence interval 0.34-0.91) than patients without CNV (n=212). To adjust the age and gender difference, we used multivariate logistic regression analysis. Out of the 11 selected SNPs, no SNP showed a significant association with CNV occurence in the second stage. Most correlated SNPs are rs4284034 (Adjusted Odds ratio 1.41; p=0.12) and rs4556082 (Adjusted Odds ratio 1.34; p=0.15). In the present study, we could not find a locus that associates with the development of CNV in highly myopic eyes. Further studies with larger cohort may reveal the genetic background of CNV development.

Allele-specific enhancer variants in open chromatin at the *GALNT2* human high-density lipoprotein cholesterol locus. *T.S. Roman[1], M.P. Fogarty[1], S. Vadlamudi[1], A.F. Marvelle[1], K.J. Gaulton[1], A.J. Gonzalez[1], Y. Li[2], K.L. Mohlke[1].* 1) Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Epigenomic maps of predicted regulatory regions offer a promising approach to identify functional variants at genome-wide association (GWA) signals. We used regulatory maps from HepG2 cells to predict functional variants associated with HDL-C level within intron 1 of *GALNT2*, encoding an N-acetylgalactosaminyltransferase. We tested for SNP association with *GALNT2* expression using eQTL and allelic expression imbalance (AEI) experiments in primary human hepatocytes, and we examined allele-specific regulatory activity of all 23 variants in strongest linkage disequilibrium (r^2>.8) with the HDL-C-associated index SNP. In eQTL experiments using hepatocytes from 50 individuals, we found that the HDL-C-increasing alleles showed suggestive evidence of association with increased *GALNT2* mRNA expression. In our AEI experiments, hepatocyte RNA from 36 individuals heterozygous for an HDL-C-associated SNP showed a 7% increase (P= $5.4x10^{-7}$) in *GALNT2* intron RNA expression correlated with the HDL-C-increasing alleles. Based on the observation that the HDL-C-associated variants are correlated with *GALNT2* expression, we hypothesized that one or more of these associated variants would affect *GALNT2* expression. Of the 23 variants considered, 16 overlap HepG2 open chromatin, histone modification, and/or transcription factor ChIP-seq peaks. Transcriptional reporter assays in HepG2 cells detected enhancer activity at 5 variants, which are located in epigenomic-predicted regulatory regions. Of these 5, allele-specific enhancer activity was observed with a 3-variant haplotype and one additional SNP, rs2281721. Site-directed mutagenesis experiments showed that at least two of the SNPs in the haplotype (rs4846913 and rs2144300) act additively to increase transcriptional activity. Our data thus suggest that rs4846913, rs2144300, and rs2281721 are the most likely HDL-C-associated candidate SNPs to influence *GALNT2* expression. These eQTL, AEI, and transcriptional enhancer data all show a consistent direction of association; HDL-C-increasing alleles are correlated with increased *GALNT2* expression. This direction of effect differs from a study of *Galnt2* overexpression in mouse liver that led to decreased plasma HDL-C levels. Epigenomic data helped discern regulatory regions and may have aided identification of the functional variants underlying this GWA signal; however, the link between *GALNT2* expression and HDL-C level through DNA variants remains unclear.

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease affecting mainly women. There are currently about 30 confirmed SLE susceptibility loci, most of which have been identified through genome-wide association studies (GWAS). Typically the associated variants reside in non-coding DNA, and few causal alleles have been identified to date. However, these are often assumed to affect gene regulation. By mapping differences in allelic expression (AE) it is possible to identify *cis*-acting regulatory variants affecting gene expression. We have utilized AE-mapping to identify regulatory variants of relevance in SLE by intersecting AE-mapping data from cell lines with data from an US SLE GWAS. The AE data was generated by quantifying the allelic ratios between transcripts in 53 CEU lymphoblastoid cell lines on Illumina Human1M BeadChips (Ge *et al.* Nat Genet. 2009) and the SLE GWAS was performed in 1,310 US Caucasian SLE patients and 7,859 controls genotyped on the Illumina 550k SNP platform (Hom *et al.* N Engl J Med 2008). Sixty regions were identified to have overlapping AE-mapping ($P_{mapping}$ <5x10^{-5}) and SLE GWAS signals ($P_{association}$ <5x10^{-3}). In these regions candidate functional variants were selected using information from the ENCODE project (www.genome.gov/10005107). A panel of 214 SNPs, including the potentially regulatory variants and the SLE GWAS SNPs, for these loci were then genotyped using a custom Illumina GoldenGate assay in two SLE case-control cohorts: one from Sweden and one from Finland, to investigate their relevance for SLE susceptibility. We analyzed a total of 1,300 SLE patients and 2,300 controls, and found that the association statistics for the GWAS and candidate regulatory variants were highly correlated (r^2=0.8), indicating that the candidate regulatory variants could be responsible for the observed SLE association signals. Additional functional follow-up will be required to validate the exact functional role these *cis*-regulatory variants play in SLE susceptibility.

Identification of novel genes that contribute to both asthma and COPD, with replication in a large population-based cohort. *J. Smolonska[1,2], G.H. Koppelman[2], C. Wijmenga[1], J.M. Vonk[3], P. Zanen[4], M. Bruinenberg[5], L. Franke[1], H.M. Groen[2], H.M. Boezen[3], D.S. Postma[2].* 1) Genetics, University Medical Center, Groningen, Netherlands; 2) Pulmonology, University Medical Center Groningen, the Netherlands; 3) Epidemiology, University Medical Center, Groningen, Netherlands; 4) Pulmonology, University Medical Center, Utrecht, the Netherlands; 5) LifeLines, University Medical Center Groningen, the Netherlands.

In 1961, Orie postulated the Dutch hypothesis stating that asthma and chronic obstructive pulmonary disease (COPD) share genetic and environmental risk factors, ultimately leading to either asthma or COPD depending on the timing and type of environmental exposure. Genome wide association studies (GWAS) have been performed in asthma and in COPD, but no overlapping genes have been identified. We aimed to establish whether there are common genes in asthma and COPD in two populations from the same Northern region in the Netherlands. We performed GWA studies on 921 asthma patients characterized by hyperresponsiveness and lung function (reversibility) with 3246 controls from LifeLines, a general population cohort, and on 1030 COPD cases (FEV1/FVC<70% and at least 20 packyears smoking) with 1799 controls. After meta-analysis, all SNPs with p<0.001 were replicated in an independent set of LifeLines samples (asthma: 534 cases and 2569 controls, COPD: 711 cases and 1854 controls). Results were combined using Fischer's exact method. We found one SNP with p= 9.96*10e-09, and 19 SNPs with suggestive p <1*10e-05. All of them point to three loci located on chromosomes 2, 5 and 13, however only one contains a gene. Together with a gene upstream locus associated on chromosome 2 it is seen in a protein network with NFKB2 This study identifies novel loci associated with both asthma and COPD development, contributing to the hypothesis that these respiratory diseases share some genetic origins. We replicated these genes in a large cohort of asthma and COPD patients and controls from the general population.

Statistical approaches for assessing missing heritability. *M. Stephens, X. Zhou, P. Carbonetto.* Statistics & Human Gen, Univ Chicago, Chicago, IL.

Although recent genome-wide association studies have identified numerous loci associated with complex traits, in most cases the identified loci account for only a small proportion of total phenotypic variation, usually substantially smaller than previous estimates of the ``heritability'' of these traits. This gap has been referred to as the "missing heritability", and it has attracted considerable research interest. One source of missing heritability is genetic variants with small effect sizes that lie below the genome-wide significance threshold used in typical GWAS. Evaluating the likely combined contribution of these small-effect variants to the missing heritability could help in planning future studies (e.g. deciding whether larger studies of the same genetic variants might yield further helpful insights, or whether it might be important to look at different genetic variants, by sequencing for example). Although these individual small-effect variants cannot be identified with confidence, their combined effects (specifically the total proportion of phenotypic variance explained, or PVE) can nonetheless be estimated by statistical modeling approaches. There exist at least two published statistical modeling approaches along these lines: one based on linear mixed models (LMM), and the other based on Bayesian variable-selection regression (BVSR). These two approaches make very different assumptions: in particular the BVSR is motivated by a sparsity assumption, whereas LMM is motivated by a model with a very large number of causal SNPs with small effects. They also have very different computational properties: LMM is computationally fast genome-wide, whereas existing implementations of BVSR are generally tractable only if the total number of genetic variants contributing to the trait is limited (eg <200). Here we compare and contrast these methodologies on simulated phenotype data with real genotypes. We show that when the number of causal SNPs is small BVSR provides more accurate estimates for the PVE. However, when the number of causal SNPs is large the LMM is more accurate. To take advantage of the merits of both methods, we introduce a hybrid approach. We demonstrate its effectiveness in estimating the PVE in both scenarios regardless of the number of causal SNPs and their effect sizes. This hybrid approach thus provides a useful tool for estimating the PVE and contributes to understanding the genetic architecture underlying complex traits.

Genome-wide association study of rheumatoid arthritis in an isolated population. *K.E. Taylor[1], Y.S. Aulchenko[2], J. Nititham[1], B. Oostra[2], P.K. Gregersen[3], C.M. van Duijn[2], L.A. Criswell[1].* 1) Rosalind Russell Medical Research Center for Arthritis, University of California San Francisco, San Francisco, CA; 2) Dept. of Epidemiology and Biostatistics and Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 3) Feinstein Institute for Medical Research, Manhasset, NY.

Background. Rheumatoid arthritis (RA) is a genetically complex autoimmune disease causing severe disability through joint destruction and deformity. Alleles of the *HLA-DRB1* locus in the major histocompatibility complex (MHC) have long been known to increase risk of RA; recent genome-wide association studies have resulted in over 30 established loci associated with RA risk. However, effects of these loci are small and much of the heritability of RA is not explained. Isolated populations offer a unique opportunity for the study of genetic diseases, as disease-causing alleles may be enriched in such populations; furthermore there is a much more genetically homogeneous background than in a broader population. Together these may allow associations to be observed which would be more difficult to detect in a traditional genetic association study. **Methods and Results.** We performed Illumina 660W genotyping on 201 RA cases and 100 healthy controls from a genetically-isolated Dutch population, and utilized Illumina 317K genotyping on another 500 healthy controls from the isolate. After strict quality control, SNPs were imputed up to the HapMap2 using MACH, and SNPs retained with quality score > 0.8 and RSQ > 0.3. We are currently testing for association using the software ProABEL in order to account for imputed genotype probabilities and to adjust for relatedness in the population. In spite of the relatively small size of this study, 58 SNPs in the MHC reached genome-wide significance ($p < 5x10^{-8}$), with the top hit as expected in the *HLA-DRB1-HLA-DQA1* region; we are investigating an additional 169 signals genome-wide with $p<5x10^{-8}$. New SNP associations will be investigated in replication cohorts. Also, any regions with multiple associations obtained in the initial association screen will be tested for independence using conditional analysis methods such as multivariate logistic regression and log-ratio testing of haplotypes. **Conclusions.** Previously-unknown loci associated with RA may be discovered using this isolated population, as well as confirmation of previously unreplicated loci.

425T

Caucasian and Asian specific rheumatoid arthritis risk loci identified by GWAS and meta-analysis show limited replication and apparent allelic heterogeneity in north Indians. *B.K. Thelma[1], P. Prasad[1], R. Gupta[2, 3], A. Kumar[2, 4], R.C. Juyal[5].* 1) Dept Genetics, Univ Delhi, South Campus, New Delhi, India; 2) ex-All India Institute Of Medical Sciences, New Delhi, India; 3) Division Of Rheumatology & Clinical Immunology, Medanta Bone & Joint Institute, Medanta The Medicity, Gurgaon, India; 4) Department Of Rheumatology, Fortis Flt. Lt. Rajan Dhall Hospital, New Delhi, India; 5) National Institute Of Immunology, New Delhi, India.

Several genes/loci have shown to be consistently associated with rheumatoid arthritis (RA) in European and Asian populations based on Genome-wide association studies and meta-analysis. To evaluate the transferability status of these findings to an ethnically diverse north Indian population, we performed a replication analysis. We investigated the association of 47 single-nucleotide polymorphisms (SNPs) at 43 of these genes/loci with RA in a north Indian cohort comprising 983 RA cases and 1007 age and gender matched controls. Genotyping was done using Infinium human 660w-quad. Association analysis by chi-square test implemented in plink was carried out in two steps. Firstly, association of the index or surrogate SNP (r2 >0.8, calculated from reference GIH Hap-Map population) was tested. In the second step, evidence for allelic/locus heterogeneity at aforementioned genes/loci was assessed for by testing additional flanking SNPs in linkage equilibrium with index/surrogate marker. Of the 44 European specific index SNPs, neither index nor surrogate SNPs were present for nine SNPs in the genotyping array used in the study. Of the remaining 35, associations were replicated at seven genes namely rs1217407 (p=3×10-3) in PTPN22; rs13119723 (p=0.008) in IL2-21; rs660895 (2.56×10-5); rs6457617 (p= 1.6×10-09); rs13192471 (p=6.7×10-16) in HLA-DRB1; rs9321637 (p=0.046) in TNFA1P3; rs13293020 (p=0.01) in CCL21; rs2104286 (p=1.9×10-4) in IL2RA and rs2793108 (p=0.006) in ZEB1 with SNPs in HLA-DRB1 and IL2RA withstanding Bonferroni correction. Of the three Asian specific loci tested, rs2977227 in PADI4 showed modest association (p<0.02). Further, of the 140 flanking SNPs (in LE with index/surrogate variant) tested, we observed association at five additional genes namely PTPRC, AFF3, CD28, CTLA4, and IL2RB. This study indicates limited replication of European and Asian specific index SNPs and apparent allelic/locus heterogeneity in RA etiology among the genetically distinct north Indians warranting independent GWAS in this population. However, replicated associations of HLA-DRB1, PTPN22 (which together are known to explain around 50% of the heritable risk to RA) and IL2RA suggest that cross-ethnicity fine mapping of such genes/loci is apposite for identification of the causal variants.

426T

Genome-wide association study for biliary atresia in a Caucasian population. *E.A. Tsai[1,3], B.A. Haber[3], H.C. Lin[2,3], N.B. Spinner[3], M. Devoto[4,5].* 1) Genomics and Computational Biology, University of Pennsylvania SOM, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Division of Gastroenterology, Hepatology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, University of Pennsylvania SOM, Philadelphia, PA.

Biliary atresia (BA) is a rare liver disease of neonates that accounts for 50% of all pediatric liver transplantations in the United States and has a worldwide incidence of 1:12,000. The etiology of BA is unknown. It is hypothesized that BA may be caused by a genetic predisposition, an environmental exposure (virus or toxin) or a combination of factors. A previous genome-wide association study (GWAS) of Chinese individuals (324 cases, 481 controls) identified a potential susceptibility locus within 10q24.2. To test the hypothesis that there is a genetic susceptibility to BA, we carried out a pilot GWAS on a Caucasian population of 171 cases and 1,630 controls to look for loci that confer susceptibility to BA. Samples were genotyped on the Illumina HumanHap 550v3 and 610 Quad BeadArrays. Our BA population was identified by the NIH funded Childhood Liver Disease Research and Education Network (ChiLDREN). While our sample size is small, we were unable to replicate the GWAS signal on 10q24.2. In our study, there was only one signal that passed genome-wide significance (p=1.0E-23). This signal maps within 4q35.1 in a gene desert. We hypothesize that there are genomic susceptibility loci that do not achieve genome-level significance due to limited sample size. To investigate SNPs with a suggestive p-value that did not reach genome-wide significance, we annotated the intragenic SNPs with p<0.001 with their corresponding gene and examined this 241 gene list. From the GNF Gene Expression Atlas 2 dataset, we found that 54/241 of these genes are upregulated in fetal liver. We then asked which transcription factors regulate these genes and found that genes regulated by each of NKX6.1, FOXD3, HNF3B, FOXF2, LHX3, TBP and CEBPA were enriched over twofold. Four of the seven TFs are important in the regulation of genes in the liver. FOXD3 has been shown to be an important TF that drives embryonic stem cell development into endoderm and serves as a regulator of endodermal-specific promoter expression. Moreover, a microarray analysis study has shown that HNF3B, LHX3 and FOXF2 target genes were downregulated in zebrafish with a BA phenotype. Although there were no genome-wide significant GWAS signals in our cohort, the enrichment of genes associated with liver-specific TFs among our top hits shows that a replication in a larger cohort may uncover a genetic susceptibility to BA. This work is currently underway.

Genome wide association studies of adult height identified 180 associated loci that together explain ~12% of heritability, are enriched for functional variants and highlight genes relevant to growth. The results also suggested the presence of multiple signals at single loci (allelic heterogeneity). Testing of allelic heterogeneity has not been extensively evaluated in large consortia. We use new association data to identify additional height loci and to test for allelic heterogeneity using summary association statistics.

Within the GIANT consortium, we analyzed the metabochip genotyping array in an independent set of 71,838 individuals. This array includes 1050 SNPs representing ~300 of the loci most strongly associated with height from a previous GWAS of 133,000 individuals. We combined association statistics with those from the previous GWAS and tested for the presence of multiple signals at individual loci using an approximate conditional and joint multiple SNP regression analysis. This method is an alternative to individual-study conditional analyses and uses summary-level statistics from the meta-analysis and individual-level genotype data from a reference sample. We validated the approximate conditional analysis using 400 individuals from each of the short and tall 1% tails of height from the HUNT population of ~50,000 individuals. We added SNPs from the same loci as independent variables in a multivariable test, and tall or short status as the dependent variable.

Analyzing the 71,838 individuals in GIANT, we identified 80 variants associated with height at p<5x10-8 that were independent (based on an r2 <0.025) of previously identified signals. Of 123 independent signals with joint p-values < 5e-8 by a stepwise model selection procedure, 21 loci showed evidence of at least two independent signals. Of these 21 loci, LD between primary and secondary association signals ranged from r2 <0.01 to 0.54, eight secondary signals were validated at p<0.05 in a multivariable model comparing the 1% shortest to 1% tallest individuals in the HUNT study.

In conclusion, detailed analysis of height loci in existing and extended sample sizes increased the number of loci identified and revealed multiple signals in known loci.

428T

Using genome-wide SNP data to estimate the additive genetic variation caused by common and rare causal variants. *M.C. Keller[1], T. de Candia[1], J. Yang[2], M.E. Goddard[3,4], P.M. Visscher[2].* 1) Department of Psychology, Univ Colorado, Boulder, Boulder, CO; 2) Genetic Epidemiology, Molecular Epidemiology and Queensland Statistical Genetics Laboratories, Queensland Institute of Medical Research, Brisbane, Australia; 3) Faculty of Land and Food Resources, University of Melbourne, Victoria, Australia; 4) Department of Primary Industries, Victoria, Australia.

The relative importance of rare versus common causal variants has long been an issue of debate in the field of human genetics, but to date there has been little empirical evidence that could shed light on this issue. Recently, a method was developed to estimate the amount of additive genetic variation in a trait that is explained by considering all genome-wide SNPs simultaneously (Yang et al, 2010). Because rare variants (MAF < .01) are not highly correlated with (common) marker SNPs, we show that most of the additive genetic variation detected using this method must be due to common (MAF > .01) causal variants (see also Wray, Purcell, & Visscher, 2011). We then introduce a new method of estimating a trait's additive genetic variation that uses haplotypic information derived from genome-wide SNP data. This method can reliably detect additive genetic variation caused by moderately rare (.01 < MAF < .001) as well as common causal variants, although variation caused by extremely rare causal variants (MAF < .001) remains mostly undetectable. By combining information from both the Yang et al (2010) approach and the current approach, these genome-wide methods of estimating additive genetic variation are among the first to provide direct empirical evidence on traits' allelic spectra.

429T

Is microsatellite polymorphism an important regulator of human phenotype? *A.T. Bagshaw[1], S. Sawaya[2], N. Gemmell[2], D.M. Fergusson[3], L.J. Horwood[3], P.R. Joyce[3], M.A. Kennedy[1].* 1) Dept Pathology, Univ Otago, Christchurch, New Zealand; 2) Dept Anatomy and Structural Biology, Univ Otago, Dunedin, New Zealand; 3) Dept Psychological Medicine, Univ Otago, Christchurch, New Zealand.

Short tandem repeat arrays, also known as microsatellites, are common in promoters and may be underestimated as regulators of gene expression. Array length polymorphisms of these elements have been linked to variation in several human phenotypes, and evidence from model organisms shows that many microsatellites serve as mechanisms for rapid evolutionary adaptation, for which they are suited due to their high mutation rate several orders of magnitude greater than single nucleotide substitution. Microsatellite length changes are not detected by standard genome-wide SNP or CNV arrays, so this source of genetic variation remains under-studied [1]. We have selected 35 microsatellites from human gene promoters based on novel measures of conservation of the microsatellites among mammalian species [2] and previous evidence suggesting or directly measuring association of the genes with particular phenotypes. We will report association data of microsatellite genotypes with novelty seeking and other specific heritable components of personality measured by the Temperament and Character Inventory (TCI) questionnaire [3], and also human height and body size, in several cohorts (more than 1000 individuals). 1. Phenome-wide studies of SNPs from GWAS in a broadly phenotyped population. *N. Eriksson, J.Y. Tung, D.A. Hinds, C.B. Do, A.K. Kiefer, B.T. Naughton, J.L. Mountain.* 23andMe, Inc., Mountain View, CA.

In many cases, SNPs associated with one trait have been found to be associated with others. This apparent pleiotropy may be due to shared etiology, correlation between the traits, or different causal variants tagged by one SNP. Here we present the results of a systematic search for pleiotropic effects using a broadly phenotyped population of over 65,000 individuals. Participants were drawn from the customer base of 23andMe, Inc. and provided self-reported information on subsets of the approximately 1000 phenotypes, including disease diagnoses, morphological traits, personality tests, and much more. We tested several thousand SNPs (limited to associations found via GWAS as well as rare variants associated with Mendelian disease) against the database of phenotypes. Our approach leads to a number of interesting hypotheses. For example, we find that an HLA SNP originally reported with ulcerative colitis (rs2395185) is associated with type 2 diabetes in our data. SNPs originally associated with tooth development near EDA (rs5936487 and rs4844096) are also associated with other morphological traits, including unibrow, attached earlobes, and lower back hair. The well-known association between FTO and obesity also correlates in our data with choice of sweet versus salty foods. We see evidence for interaction between FTO genotype and food choice with obesity. An association with Crohn's disease near a cluster of interleukin genes (rs2188962) is also linked to severity of mosquito bite reaction in our data. As a final example, we show that a SNP near TERT originally reported with glioma is also associated with skin tags (benign skin growths). Our findings also include many well known facts and novel negative findings. For example, SNPs associated with lung cancer and esophageal cancer influence smoking and drinking frequency in our data. On the other hand, we show that ACTN3 null alleles are not associated with sports choice (or other of our phenotypes) in the general population. Widely studied polymorphisms near DRD2 (rs1800497) and COMT (rs4680) are not significantly associated with any phenotypes. These results are based on a cutoff of 1e-6 for significance and are computed in a group of unrelated individuals of European ancestry controlling for sex, age, and projections onto five principal components. A false-discovery rate analysis yields an estimated false-discovery rate of about 0.025 for these results.

Association study between telomere length and Age-Related Hearing Impairment in 3527 Caucasian individuals and 663 Japanese individuals. *E. Fransen[1,2], S. Bonneux[1], N. Suzuki[3], S.-I. Usami[3], G. Van Camp[1].* 1) Center for Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) StatUa Center for Statistics, University of Antwerp, Antwerp, Belgium; 3) 3Department of Otorhinolaryngology, Shinshu University School of Medicine, Matsumoto, Japan.

Several reports suggest that individuals with shorter telomere length are more susceptible to age-related disorders. In somatic cells, telomere length declines with age contributing to loss of cells with age when telomeres reach a critical minimal length. Average telomere length was shown to be a heritable trait (Slagboom et al., 1994). Age-Related Hearing Impairment (ARHI) is the most common sensory disorder and the most important cause of hearing loss in the elderly, with a negative impact on the quality of life. It is a complex disease influenced by genetic as well as environmental factors. Here we test whether a shorter average telomere length leads to increase of ARHI susceptibility. In 3527 European and 663 Japanese individuals, we determined the telomere length in white blood cells using a monochrome multiplex quantitative PCR protocol (described by Cawthon, 2009). We performed association testing between the telomere length and the 3 Principal Components of the ARHI phenotype (Huyghe et al., 2008). In addition, we tested this association adjusting for environmental factors that were previously implicated in telomere shortening. The most important of these factors include smoking and BMI. Slagboom et al. (1994), Am J Hum Genet. 55:876-882. Cawthon (2009), Nucleic Acids Rev. 37:e21. Huyghe et al. (2008), Am J Hum Genet. 83:401-407.

SimRare: A program to generate and analyze sequence-based data for association studies of quantitative and qualitative traits. *B. Li[1,2], G. Wang[1,2], S. M. Leal[1,2].* 1) Baylor College of Medicine, Houston, TX; 2) Rice University, Houston, TX.

Currently there is great interest in detecting complex trait rare variant associations using next generation sequence data. A number of methods have been developed to detect rare variant associations. On a monthly basis new methods are being developed for which the power and type I error need to be evaluated. In order to fairly compare rare variant methods it is necessary to generate data using realistic population demographic and phenotype models. Currently it is difficult to compare rare variant association methods because there is no standard to generate data and often the comparisons are biased. SimRare generates variant data for “gene” regions using forward-time simulation which incorporates population demographic models for Europeans or Africans. It is possible to generate both case-control and quantitative traits (random selection or selection on quantitative trait values). The phenotypic effects of variants can be detrimental, protective or non-causal. For causal variants the effect size can be determined by frequency or purifying selection coefficients. It is possible to model confounders which can either be environmental or genetic, e.g. population substructure. Additionally gene x environment and gene x gene interactions can be modeled. SimRare has a user friendly interface which allows for easy entry of genetic and phenotypic parameters. Additionally to evaluate novel association methods R libraries can be imported into SimRare or conversely the simulated data can be written to external files. SimRare has built-in functions to evaluate the performance for 15 currently available rare variant association methods. In addition to be able to evaluate type I error and power it is also possible to use SimRare to evaluate computational efficiency, control of confounders, and ability to detect interactions. Using SimRare we evaluated 15 rare variant association methods. It is demonstrated that there is not a single most powerful method and most rare variant association methods are not robust to confounders. Additionally due to the computational speed some methods are more advantageous to use especially for the analysis of exome or whole genome sequence data.

Associated alleles at the CAV1/CAV2 locus in primary open angle glaucoma. *C. Pang[1], M. Zhang[2], C. Tham[1], L. Chen[1], P. Tam[1], D. Lam[1].* 1) Ophthalmology & Visual Sciences, The Chinese University of Hong Kong, Hong Kong, HKSAR, China; 2) Joint Shantou International Eye Center of Shantou University and the Chinese University of Hong Kong, Shantou, China.

Purpose: To study multiple CAV1/CAV2 SNPs in primary open angle glaucoma (POAG). Methods: We genotyped six candidate SNPs, rs926201, rs6975771, rs4730742, rs4236601, rs959173 and rs6466587, by TaqMan technology in 833 Chinese study subjects of two cohorts. The Hong Kong cohort contained 185 patients with POAG and 248 controls, and a Shantou cohort of 102 patients and 298 controls. Results: When the two cohorts were combined, rs4236601 was present at low frequencies (3.1% in POAG and 0.73% in controls). The higher-risk genotype AG was significantly associated with increased risk of glaucoma (P=0.02, OR=4.26) and the association was consistent in individual cohorts. In contrast, rs6975771 and rs959173 conferred milder protection for glaucoma (OR=0.65 and 0.61 respectively). We identified a risk haplotype G-G-A-T and a protective haplotype A-T-G-C defined by rs6975771, rs4730742, rs4236601 and rs959173, with their risk and protective alleles occurring in respective haplotypes. Conclusions: We have confirmed the association of rs4236601 with POAG. Risk and protective alleles in different haplotypes of CAV1 and CAV2 were also identified.

Exome Sequencing versus Whole-Genome Genotyping: Lessons from Population Genomics of High-Altitude Adaptations in Tibetans. *S. Xu[1], L. Jin[2].* 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shangh; 2) State Key Laboratory of Genetic Engineering and Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China.

Although the cost and the time barrier of next-generation sequencing (NGS) are expected to be constantly reduced, whole-genome sequencing (WGS) of a large number of samples is currently not practical for many researchers. Alternatively, genomic capture sequencing technologies such as exome sequencing will be cost-effective approaches for years to come. On the other hand, whole-genome genotyping (WGG), a type of high-throughput technologies to rapidly determine individual genotypes at numerous loci, could still serve as a long-term routine approach for genome-wide complex trait mapping or population genetic studies. In this context, we conducted comparative analyses of the data from five recent genome-wide studies on high-altitude adaptation (HAA) in Tibetans which based on either exome sequencing or whole-genome genotyping, to explore the the pros and cons of the two strategies. The results indicated that exome sequencing did not necessarily take advantage over whole-genome genotyping approach. On the contrary, the study based on exome sequencing almost missed the top HAA signals which were identified by most of the other studies based on WGG. Our analysis also showed that evolutionary and population genetic parameters could be biased estimated based on exome sequencing data. In addition, allele frequencies of some critical loci were also significantly biased estimated from exome sequencing data, which were probably resulted from uncertainty in genotype calls or data quality per se. By considering all aspects, we suggest a two-stage study design with mixed approaches of WGG and targeted sequencing in future genome-wide studies of local adaptation and disease mapping.

Dual genetic structure of the Japanese population based on autosomal SNPs and haplotypes. *Y. Yamaguchi-Kabata[1], T. Tsunoda[1], N. Kumasaka[2], A. Takahashi[2], N. Hosono[1], M. Kubo[1], Y. Nakamura[1,3], N. Kamatani[1].* 1) Ctr Genomic Med, RIKEN, Yokohama, Japan; 2) Ctr Genomic Med, RIKEN, Tokyo, Japan; 3) Inst Med Sci, Univ Tokyo, Tokyo, Japan.

Although the Japanese population has a rather low genetic diversity, it appears to have a “dual structure” arising from at least two major migrations. We recently confirmed the presence of this dual structure through principal component analysis of genome-wide SNP genotypes. Understanding the genetic differences between the two main clusters (the Hondo and Ryukyu clusters) requires a further genome-wide analysis based on a dense SNP set and comparison of haplotype frequencies. In the present study, we determined haplotypes for the Hondo cluster of the Japanese population by detecting SNP homozygotes with 388,591 autosomal SNPs from 18,379 individuals and estimated the haplotype frequencies. Haplotypes for the Ryukyu cluster were inferred by a statistical approach using the genotype data from 504 individuals. We then compared the haplotype frequencies between the Hondo and Ryukyu clusters. In most genomic regions, the haplotype frequencies in the Hondo and Ryukyu clusters were very similar. However, in addition to the HLA region on chromosome 6, other genomic regions (chromosomes 3, 4, 5, 7, 10 and 12) showed dissimilarities in haplotype frequency. These regions were enriched for genes involved in immune system, cell-cell adhesion and intracellular signaling cascade. These differentiated genomic regions between the Hondo and Ryukyu clusters likely contain genes responsible for morphological or physiological differences between the two groups.

Impact of human population expansion on the load of rare and deleterious variants, and consequences for association studies. *A. Clark[1], E. Gazave[1], A. Coventry[1], E. Boerwinkle[2], C.F. Sing[3], A. Keinan[1].* 1) Dept Molec Biol & Gen, Cornell Univ, Ithaca, NY; 2) UT Houston Health Science Center, Houston, TX; 3) Univeristy of Michigan, Ann Arbor, MI.

It has long been appreciated that the human global population has been growing rapidly, from fewer than one million people with the advent of agriculture ~10,000 years ago to ~7 billion today. This 7000-fold growth in fewer than 400 generations can be divided into two epochs, with moderate exponential growth throughout most of this period followed by explosive, super-exponential growth starting fewer than 100 generations ago. This extraordinary situation challenges nearly every aspect of theoretical population genetics as it implies a massive departure from equilibrium. In particular, this recent rapid growth has generated a load of rare variation that is due to recent mutations, which are likely to play an important role in the genetic burden of complex disease. We modeled the site frequency spectrum of mutations arising in a population with accelerating growth, and show that only sample sizes in the thousands can accurately represent very recent mutations. The use of such large sample sizes is therefore necessary but has some consequences that need to be taken into consideration. First, we observe that the larger the sample size, the higher the proportion of singletons, and the stronger the deviation from the classical constant population size model, which is particularly important given the increasing sample size of genome-wide association studies. As a consequence, we observed that in each newly sequenced genome, a relatively large fraction of observed mutations are newly discovered mutations that are private to individuals. As the sample size grows to exceed the historical effective population size other aberrations occur. In this case, genealogies are expected to have multiple coalescent events at the tips, which leads to haplotype and LD patterns that differ from standard theory, and may require special consideration in the search of rare disease-causing variants. Finally, simulations designed to match observed human expansion over the last few hundred generations allowed us to test the expected accumulation of rare variants with rapid population expansion and the inflated individual load of deleterious mutations in this non-equilibrium scenario. Our simulations show how recent explosive growth of the human population can have a critical impact on the genetic architecture of complex disease and on the means by which genotype-phenotype association can best be detected.

A coalescent model for genotype imputation using large reference panels. *E.M. Jewett[1], M. Zawistowski[2, 3], N.A. Rosenberg[4, 1, 5], S. Zöllner[2, 3, 6, 7].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI 48109, USA; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109, USA; 3) Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan 48109, USA; 4) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan 48109, USA; 5) Life Sciences Institute, University of Michigan, Ann Arbor, Michigan 48109, USA; 6) Bioinformatics Program, University of Michigan, Ann Arbor, Michigan 48109, USA; 7) Department of Psychiatry, University of Michigan, Ann Arbor, Michigan 48109, USA.

Genotype imputation is the estimation of genotypes at untyped markers on a chromosome. Several empirical studies based on simulations and on real data have investigated features of reference panels that affect their suitability for imputation. Here, we present a theory-based approach to genotype imputation using a coalescent model to investigate how imputation accuracy changes as a function of parameters such as reference panel size and the level of divergence between target and reference populations. We find that a small internal reference panel (e.g., 100 haplotypes) sampled from the same population as the target sequences will, on average, yield higher imputation accuarcy than a large external reference panel (e.g., >1,000 haplotypes) sampled from a different population, even if the level of divergence between the two populations is small. However, the overall improvement in accuracy obtained by using such an internal reference panel is typically also small. In addition, we find that sampling many (e.g., >1,000) haplotypes from either an internal or external reference panel produces only small gains in imputation accuracy over smaller panels (e.g., <100 haplotypes). The model we develop and the distributions we derive can be used to perform detailed analyses of factors that affect imputation accuracy, and to improve the selection of optimal choices of reference panels.

438T

Allele surfing and selection evidenced from a spatial analysis of human genealogies in Quebec. *C. Moreau[1], C. Bherer[1], H. Vézina[2], M. Jomphe[2], D. Labuda[1,3], L. Excoffier[1,4,5].* 1) Research Center, Ste-Justine Hospital, University of Montreal, Montreal, PQ, Canada; 2) BALSAC Project, University of Quebec at Chicoutimi, Chicoutimi, PQ, Canada; 3) Pediatrics department, University of Montreal, Montreal, PQ, Canada; 4) CMPG, Intitute of Ecology and Evolution, University of Berne, Baltzerstrasse 6, 3012 Berne, Switzerland; 5) Institute of Bioinformatics, 1015 Lausanne, Switzerland.

Records of human genealogies offer a unique possibility to study the genetic consequences of recent demographic processes and to check predictions of theoretical models. Extensive genealogies are available for the whole population of Charlevoix-Saguenay-Lac-St-Jean (CSLSJ), a region of North-Eastern Quebec recently colonized in a stepping-stone manner in the last three centuries. This large pedigree including the genealogical relationships among more than one million individuals born over three centuries appears ideal to study the genetic impact of a documented range expansions in humans. The recorded time and location of the marriages of all the individuals and their children allowed us to precisely reconstruct the spatial and temporal dynamics of the range expansion and to distinguish demographic processes happening on the wave front, defined as newly opened parishes. Overall, we find that individuals reproducing at the wave front had a higher fertility than the other individuals, corresponding to a 9-16% selective advantage of reproducing at the front, depending on the regions. This resulted in ancestors reproducing at the wave front leaving up to 2.4 fold larger genetic contribution to the present CSLSJ population than ancestors who did not reproduce on the front. We also find that the ancestors of the SLSJ population reproduced significantly more at the front than expected, whereas the reverse situation is found in Charlevoix, the oldest settlement of CSLSJ. These results are compatible with the allelic surfing phenomenon predicting an overrepresentation of genes originating on the wave front in newly colonized territories. It is also the first documented evidence in humans of a selective advantage to be on an expanding wave front, and the implications of this result will be discussed in the context of recent human evolution. (Supported by Réseau de Médecine Génétique Appliquée of Fonds de Recherche en Santé du Québec).

Saudi NGHA biobank; designed study as a longitudinal investigation of constitutional and environmental factors influencing genetics disease in Saudi Arabia. *I. Alabdulkareem[1], M. Albalwi[1,2], M. Aljumah[1].* 1) KAIMRC, National Guard Health Affairs, Riyadh, Riyadh, Saudi Arabia; 2) Department of Pathology and Laboratory Medicine. King Abdulaziz Medical City, Riyadh, Saudi Arabia.

Biospecimens storage is one of the modern practices to secure high standard research materials available for investigators worldwide. Saudi Biobanking (SB) is designed study as a longitudinal investigation of constitutional and environmental factors influencing illness in Saudi Arabia. The SB objective is to implementation the highest standards of biological banking as it is vital towards perform genomic/proteomics databases. These databases will increase the quality of health care by creating a linking them life style, environmental factors and clinical practice. The SB is 4 phases plan that as follow; DNA/RNA banking, blood components/urine/tissues and bone/infectious banking respectively. SB team is targeting 200,000 individuals for families and diseased subjects for fluid and solid samples while DNA/RNA reservoir capacity is 1.8Million matrix tubes for genetics diseases that seen in day to day clinical practice. Phase one is already lunched by banking DNA using a complete automated DNA banking that carried out a complete robotic extraction of DNA from blood followed by banking the samples at -20C°. Retrieving the sample(s) is also auto programmed by the LIMS system. Additional to that, each subject's DNA is extracted manually and sent for semi automated dry storage as a back up.

Secretor Genotype (FUT2 gene, rs601338) Is Strongly Associated with the Composition of Bifidobacteria in the Human Intestine. *N. Alakulppi, P. Wacklin, H. Mäkivuokko, J. Nikkilä, H. Tenkanen, P. Sistonen, J. Räbinä, J. Partanen, K. Aranko, J. Mättö.* Finnish Red Cross Blood Service, Helsinki, Finland.

Intestinal microbiota plays an important role in human health, and its composition is determined by several factors, such as diet and host genotype. However, thus far it has remained unknown which host genes determine the microbiota composition. We studied the diversity and abundance of dominant bacteria and bifidobacteria from the faecal samples of 71 healthy individuals. In this cohort, 14 were non-secretor (NS) individuals and the remainders were secretors (S). The secretor status is defined by the expression of the ABH and Lewis histo-blood group antigens in the intestinal mucus and other secretions. It is determined by fucosyltransferase 2 enzyme, encoded by the FUT2 gene. Non-functional enzyme resulting from a nonsense mutation (rs601338) in the FUT2 gene leads to the NS phenotype. To verify that rs601338 defines the NS-S phenotypes, 255 healthy Finnish individuals were sequenced for the FUT2 coding exon. All individuals had the same serological phenotype deducted from the rs601338 genotype. Compared with HapMap, the same strongest LDs were found between SNPs rs601338 and rs492602 or rs681343. A total of 1040 genotypes from samples representing the whole Finland showed significant differencies between the counties (NS rs601338 frequency min - max = 3 - 30%, mean 15%). PCR-DGGE and qPCR methods were applied for the intestinal microbiota analysis. Principal component analysis of bifidobacterial DGGE profiles showed that the 14 samples of NS individuals formed a separate cluster within the 57 S samples. Moreover, bifidobacterial diversity ($p<0.0001$), richness ($p<0.0003$), and abundance ($p<0.05$) were significantly reduced in the samples from the NS individuals as compared with those from the S individuals. In contrast to bifidobacteria, several bacterial genotypes were more common and the richness ($p<0.04$) of dominant bacteria as detected by PCR-DGGE was higher in the NS individuals than in the S individuals. We showed that the diversity and composition of the human bifidobacterial population is strongly associated with the histo-blood group ABH S/NS status, which consequently appears to be one of the host genetic determinants for the composition of the intestinal microbiota. This association can be explained by the difference between the S and NS individuals in their expression of ABH and Lewis glycan epitopes in the mucosa.

Facts related to the collection of biological samples in the National Health Examination Survey - Portuguese Component of the European Health Examination Survey. *M. Barreto[1], V. Francisco[1], P. Rasteiro[2], E. Sousa[2], A. Vicente[1], M. Bourbon[1], A. Fernandes[2], A. Beleza[2], F. Mendonça[3], A. Gil[1], C. Matias Dias[1].* 1) Instituto Nacional de Saúde Doutor Ricardo Jorge, Lisboa, Portugal; 2) Laboratório de Saúde Pública Dra. Laura Ayres, Faro, Portugal; 3) Administração Regional de Saúde do Algarve, Faro, Portugal.

The objective of the National Health Examination Survey (NHES), which corresponds to the Portuguese component of the European Health Examination Survey (EHES), is to collect health data, related risk factors and biological samples of the Portuguese population, using the EHES recommended methodology. These surveys involve an interview, clinical and physical measurements and blood collection. In this context, we herein describe the pilot study performed in S. Brás de Alportel in the Algarve region. For this pilot study, we have recruited 221 individuals (95 males and 126 females), between 25 and 91 years old, who were enrolled in the Health Centre of S. Brás de Alportel (Algarve). For each participant, we have collected 16.5 ml of total blood, in five different Vacutainer® tubes, which was later processed into serum, plasma and DNA. We have performed several biochemical analyses(total cholesterol, LDL, HDL, glucose, tryglicerides, creatinine, ALT, AST, . -GT, CRP and iron) and a complete blood count. From the 221 participants in this pilot study, we were able to collect blood to 219 (99.5%). To 185 of these (84.5%) we were able to collect the total amount of blood. The biochemical analyses were performed in all the samples. The total blood count was performed in 103 samples (47%) due to transport constraints. We have also collected DNA from 210 participants (95.9%). We have created a biobank comprising 1847 serum aliquots and 959 plasma aliquots, which have been stored at -80°C and 210 DNA aliquots which have been stored at 4°C. In conclusion, during this study, we have optimized the logistics and procedures to perform the large scale study for the NHES and EHES. In addition, we have created a biobank comprising detailed questionnaire data, physical and clinical data and biological samples from a representative sample of S. Brás de Alportel in Algarve, Portugal. This biobank will allow us to perform future studies, including the determination of the prevalence of gene variants of public health interest, the characterization of gene-environment interactions in the development of chronic diseases and the genetic structure of the Portuguese population. The success rate, the quality of the data and of the biological samples was high and comparable to similar studies.

442T

Complexities in geneticists' views on "race" crossing: No evidence for change on "political" grounds. *E.B. Hook.* School of Public Health, Univ California, Berkeley, CA. 94720-7360 USA.

Virtually all human geneticists today would not view "race" crossing as "dysgenic", in fact the opposite because of diminished autosomal recessive disorders in offspring. But in the 1920s a major concern was that segregation and recombination might break up any "adaptive gene complexes" (AGC) in the genome. Presumably any AGC within "races"; had evolved in response to selective pressures, so outcrossing would be deleterious. Because of this theoretical objection, in the absence of empirical data many US and UK geneticists in the 1920s, ostensibly on "social policy" grounds condemned strongly "race crossing". In the late 1930s, 1940s and 1950s however, US and UK geneticists expressed opposition to this blanket condemnation. W.B. Provine has claimed that this change was based not on any new evidence but, rather, because of revulsion to Nazi doctrines on race biology and their implications. Geneticists changed their minds on this matter he claimed, in essence, to fit their political viewpoints (Science 1973 182:790-6). I queried five eminent geneticists established professionally before World War 2 (Dobzhansky, Dunn, Huxley, Stern, and Wright), as well as four who were graduate students (Crow, Neel, Reed and Steinberg) about the claims. None knew of any who changed their minds on effects of race crossing in response to Nazi views or any other reason. Huxley reiterated an earlier view that "wide" crosses could have adverse effect. Curt Stern, who had fled Nazi Germany, in all editions of his textbook, (1949, 1960, 1973) took an agnostic position on race crossing, and referred to adverse outcomes resulting from Rh incompatibility if races differed in blood group proportions. Moreover, the theoretical issue of possible dysgenic effect was still regarded as an open one in the 1960s as exemplified by investigations in Hawaii (Morton et al. 1967). In summary, there is no evidence anyone changed his/her mind about race crossing for political reasons. Those who strongly opposed race crossing died or tended to grew silent out of recognition of affinity with Nazi views; others appeared who spoke out against extremist views on race crossing. Provine wrote when political and social implications of human genetics and race were emerging as part of major public debates about many policies. The notion that the zeitgeist changed geneticists views appeared popular to sociologists of scientific knowledge, but distorts a complex history of genetics.

443T

Tracing the population origin of non-European chromosomal segments identified by the method of rare heterozygotes and homozygotes (RHH) in admixed subjects of European Caucasian descent. *R. McGinnis[1], W. McLaren[2].* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) European Bioinformatics Institute, Cambridge, United Kingdom.

By rapid software analysis of GWAS SNP genotypes, the method of rare heterozygotes and homozygotes (RHH) can visualize genome mosaicism in admixed European Caucasians with African or Asian ancestry (McGinnis et al, Human Molecular Genetics 19:2539-2553, 2010). This raises the methodological issue of determining the exact non-European population from which a visualized chromosomal segment of admixture arises. This determination is complicated since typically only one of the subject's two extended haplotypes spanning the segment derives from the non-European population. To identify segment origin in admixed Caucasians of the 1958 British Birth Cohort (58BBC) genotyped on the Illumina 550K (Illm550K) chip, we pursued several strategies. To date, the most promising has been to derive the "European" haplotype spanning a subject's admixed segment by "zeroing" the subject's heterozygous Illm550K SNPs in the segment and imputing the zeroed genotypes using (a) the subject's homozygous Illm550K SNPs plus (b) genotypes at all Illm550K SNPs in the segment from ~1500 unadmixed 58BBC subjects. The resulting combination of imputed and called homozygous genotypes define the European haplotype which in turn yields the non-European haplotype by subtracting the imputed allele from each zeroed heterozygote. In this way, we derived a non-European haplotype from ten 58BBC subjects with RHH-identified African or Asian admixture across a 15 megabase (Mb) region on chromosome 1 which contained ~3300 Illm550K SNPs; and we similarly derived the 15 Mb non-European haplotype from multiple simulated admixed Caucasian subjects (who were simulated by pairing a phased HapMap 3 European [CEU] chromosome with a phased chromosome 1 from a HapMap3 non-European [CHB, YRI, LWK, or GIH]). We applied principle components-multidimensional scaling (PC-MDS) analysis to compare each derived non-European haplotype with haplotypes or genotypes of 51 populations in the Human Genome Diversity Panel (HGDP) typed by Illm550K. We will illustrate our results - which achieved partial success: each non-European haplotype derived from a simulated subject clustered with the correct subset of HGDP populations and we were able to trace each 15 Mb segment from the ten admixed 58BBC subjects to a subset of Subsahara African or Asian HGDP populations. However the approach currently lacks sufficient resolution to precisely trace a 15 Mb segment to a single HGDP population.

Killer cell Immunoglobulin like Receptors distribution in healthy Brazilian Caucasian Kidney donors. *M.M. Moraes[1], R. Benvenutti[2], C. Gomes[2], C. Pozzi[2], F.L.C. Contieri[2], M.G. Bicalho[1].* 1) Departamento de Genética, Universidade Federal do Paraná, Curitiba, Paraná, Brazil; 2) Unidade de Transplante Renal do Hospital Universitário Evangélico, Faculdade Evangélica do Paraná, Curitiba, Paraná, Brazil.

Killer-cell Immunoglobulin like Receptors (KIRs) are Natural Killer (NK) cell surface proteins that play an important role modulating the cytotoxicity of these innate immune system cells. The balance of activating and inhibitory signals from HLA class I on target cells and KIR interactions results in induction or inhibition of NK-mediated target cell lysis. These receptor interactions were recently studied in kidney transplant patients where patient's NK cells may recognize donor cells that do not express specific ligands and thus avoid cell lysis. These KIR genes can be present or absent into individual repertory and thus exhibit different combinations of 14 genes (8 functional genes encoding inhibitory receptors and 6 genes encoding activator receptors) and 2 pseudogenes setting genotypes. KIR frequencies and genotypes data may contribute to a better-understanding of these genes evolution and the mechanisms involved in NK-mediated cytotoxicity. In this study, KIR genotyping was carried out using the KIR SSO Genotyping Test (One Lambda Inc.) according to manufacturer's instructions and PCR-SSOP from peripheral blood leucocytes of 93 Caucasian unrelated kidney donors from HUEC Hospital (Paraná - Brazil). Results and analysis were produced with HLA Visual® (One Lambda Inc.) software package. We compare KIR gene carrier frequency (rxc Contingency Tables) from our sample with frequency data from other Caucasian populations (Brazilian and European) described in the literature. Gene frequencies found in the present study were: KIR3DL3(1.00), KIR2DS2(0.53), KIR2DL2(0.45), KIR2DL3(0.90), KIR2DP1(1.00), KIR2DL1(0.99), KIR3DP1(1.00), KIR2DL4(1.00), KIR3DL1(0.94), KIR3DS1(0.41), KIR2DL5(0.55), KIR2DS3(0.37), KIR2DS5(0.22), KIR2DS1(0.41), KIR2DS4(0.82) and KIR3DL2(1.00). These frequencies are very similar to frequencies found in another Brazilian population from a different region, as well as for the French and British Caucasian populations. 39 different genotypes were identified and the most frequently observed were KG-01-1001111110000011 (0.33), KG-02-1111111110000011 (0.06) and KG-03-1111111110110011 (0.05). The differences found in gene frequencies and genotypes may reflect the contribution of two other important components (Africans and Amerindians) of the Brazilian population. Knowledge of the immune systems genetic background of a population may help in understanding the mechanisms mediated by KIR involved in innate immune response of NK cell.

Genetic ancestry and population structure of geographically separated African American populations. *M.C.Y. Ng[1], S. Sajuthi[2], A. Cupples[3], J. Divers[4], J. Dupuis[3], M. Fornage[5], L. Kao[6], E. Larkin[7], M. Li[8], C.T. Liu[3], S. Musani[9], J. Mychaleckyj[10], G. Papanicolaou[11], A. Reiner[12], D. Siscovick[12], X. Zhu[7], B. Freedman[13], J. Wilson[9], D.W. Bowden[1].* 1) Center for Genomics and Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Program in Molecular Genetics and Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 4) Department of Biostatistical Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 5) Research Center for Human Genetics, The University of Texas Health Science Center at Houston, Houston, TX; 6) Department of Epidemiology, Johns Hopkins School of Medicine, Baltimore, MD; 7) Center for Clinical Investigation, Case Western Reserve University, Cleveland, OH; 8) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA; 9) University of Mississippi Medical Center, Jackson, MS; 10) Public Health Sciences, University of Virginia School of Medicine, Charlottesville, VA; 11) NHLBI, Bethesda, MD; 12) Department of Medicine and Epidemiology, University of Washington, Seattle, WA; 13) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

African Americans (AA) are a recently admixed population formed from their African and European ancestral populations. It is unclear whether AA are genetically homogeneous between US geographic regions. This has implications in study design such as the selection of appropriate reference haplotypes for imputation and controlling population structure in association studies. This study examined the African ancestry and population structure of 8130 unrelated AA from six studies in the Candidate Gene Association Resource (ARIC, CARDIA, CFS, JHS, MESA) and a Wake Forest Health Sciences sample. We analyzed 86472 autosomal uncorrelated SNPs genotyped using Affy 6.0 platform in AA from the six studies as well as 578 HapMap samples of Africans (YRI, LWK, MKK), Europeans (CEU) and AA (African American Southwest, ASW). Estimation of ancestry proportions in AA including ASW using FRAPPE revealed a wide range (0-100%) of African ancestry within each study, with mean African ancestry of 74-84% across studies. The allele frequencies were highly correlated among AA ($0.85 < r < 0.99$). F_{ST} and principal component analyses also revealed little population structure among AA in different studies ($0 < F_{ST} < 0.001$), and AA were genetically more close to YRI than LWK and MKK (F_{ST} to YRI=0.004-0.006, LWK=0.007-0.008, MKK=0.013-0.014). Our results are consistent with the history of West Africa origin of AA. While there is substantial variation of African ancestry within studies, the population structures of each sample, including ASW, are similar to other AA recruited at different geographic areas. Geographically different AA samples are statistically indistinguishable. These results suggest the generalizability of ASW to represent the general AA population in US.

446T

Human Adaptation and Evolution in Response to Helminth Parasites. *B. Sadler.* Arizona State University Tempe, AZ.

The gut of humans, and indeed all vertebrates, is colonized by other species. There are three main categories of organisms that can live, grow, and reproduce within the human gut for extended periods of time. These are 1)helminths, multicellular eukaryotic worms, 2)protozoan parasites, and 3)gut bacteria that typically make up what is referred to as our microbiome. A variety of observations suggest that humans have been coevolving with helminths for an extended period of time. For example, evidence for the presence of human-specific helminths in ancient feces indicates that humans have been parsitized by helminthes for tens of thousands of years. The presence of helminths in our closest living relatives, non-human primates adds additional support for an evolutionarily old relationship between humans and helminths. Finally, isolated indigenous groups, who are the closest living examples of our ancestral hunter-gatherer state, have a high prevalence and incidence of helminth infections. Together, these observations suggest that helminth infection was common in past human environments. Parasitism by helminths decreases host fitness in a number of ways. For example, helminth infection can impact host fertility and reproduction, stunt host growth, increase visibility to predators, impair gastrointestinal function, and suppress the immune system. Therefore, adaptive responses to these selective pressures leading to evolutionary changes should exist. This poster will discuss 1)the role of helminths in directing vertebrate host adaptation and evolution, 2)current evidence of various types of host adaptations including behavioral, anatomical and metabolic, as well as evidence of immunological evolution in response to helminths, and 3)specific immunological pathways and genetic variants that have been implicated in human susceptibility to helminth infection. These lines of evidence support the hypotheses that 1)helminths have had a profound effect on our own evolutionary trajectory, especially with regard to immune response, 2)the fact that phylogenetically diverse species response similarly to helminths says something about the antiquity of this host/parasite relationship, and 3)heritability of certain immunological genetic susceptibility variants explains some of the variance in susceptibility within and between populations, but that helminth species-specific resistance variants may be difficult to identify, so other types of candidate genes may be helpful.

Integrating population diversity, conservation, and epigenomic information at regulatory elements, noncoding transcripts, and disease-associated regions. *L.D. Ward[1,2], R.C. Altshuler[1,2], P. Kheradpour[1,2], J. Ernst[1,2], O. Zuk[2], M. Garber[2], K. Lindblad-Toh[2,3], E. Birney[4], M. Kellis[1,2], The ENCODE Consortium.* 1) CSAIL, Massachusetts Institute of Technology, Cambridge, MA; 2) The Broad Institute of MIT and Harvard, Cambridge, MA; 3) Departmentof Medical Chemistry and Microbiology, Uppsala University, Uppsala, Sweden; 4) European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK.

In previous work, we used the ChromHMM method to identify enhancers in nine human cell lines from ENCODE histone modification data, and discovered motifs associated with the cell-type specificity of enhancers (Ernst *et al.*, 2011). These enhancer maps and putative regulatory motif instances allow us to generate hypotheses of causal SNPs in strong LD with variants associated with phenotypes by GWAS. We have now extended this analysis to bring in conservation data from low-coverage sequencing of 29 mammals, using the SiPhy method (Garber *et al.*, 2009) to identify constrained elements at unprecedented resolution. In particular, we were interested in cases where the lead SNP reported by an association study did not lie in a conserved element, but a strongly-linked variant did. We find several compelling examples: (1) a tooth development-associated variant rs6504340 located in an unconserved region between the developmental genes *HOXB1* and *HOXB2* (Pillas *et al.*, 2010) is strongly linked to another intergenic variant, rs8073963, which disrupts a deeply-conserved instance of a motif recognized by Forkhead family proteins and is predicted to be a strong enhancer in K562 cells; (2) lead SNP rs10948197 associated with height in Koreans (Kim *et al.*, 2009) is in an unconserved region but is linked to rs3799976 in a conserved element and disrupts a Forkhead family motif; (3) a height-associated variant discovered in two studies, rs10906982 (Weedon *et al.*, 2008; Liu *et al.*, 2010), does not lie in a conserved element but is strongly linked to a variant in a conserved element, rs7183263, which lies in a motif recognized by homeodomain proteins and is a strong enhancer in skeletal muscle myoblast (HSMM) cells. We also studied the pattern of conservation and population variation associated with regulatory elements, by combining heterozygosity values from the 1000 Genomes Project with transcription factor binding data and ChromHMM chromatin states from ENCODE. We find a signal of decreased heterozygosity, evidence of selection in the human population, at intergenic, TSS-distal motif instances bound by their regulators, as well as strong enhancers identified by histone modifications; this constraint is also seen across mammals. In addition, at novel intronic and intergenic transcripts identified by ENCODE (and currently absent from the GENCODE annotation), we consistently find decreased heterozygosity among humans.

***EPAS1* and *EGLN1* associations with High Altitude Sickness in Han and Tibetan Chinese at the Qinghai-Tibetan Plateau.** *N. Buroker[1], X-H. Ning[1], Z-N. Zhou[2], K. Li[3], W-J. Cen[3], X-F. Wu[2], W-Z. Zhu[2], C.R. Scott[1], S-H. Chen[1].* 1) Pediatrics, 356320, University of Washington, Seattle, WA; 2) Laboratory of Hypoxia Physiology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China; 3) Lhasa People Hospital, Tibet, China.

Acute (AMS) and chronic (CMS) mountain sicknesses are illnesses that occur among lowlander Han Chinese visiting or highlander Tibetan Chinese inhabiting high altitude environments, respectively. Both diseases are influenced by genetics. Consequently, some individuals are genetically less fit than others when stressed by an extreme high-altitude environment. The *EPAS1* [ch2: 46441523 (hg18], *EGLN1* (rs480902) and (rs516651) SNPs were studied in association with high altitude illness among Tibetan residents and Han Chinese visitors at the Qinghai-Tibetan plateau. Direct sequencing was used to identify individual genotypes for the three SNPs. Age was found to be significantly associated with the *EPAS1* SNP in the CMS Tibetan patients while HR and SaO2 were found to be significantly associated with the *EGLN1* (rs480902) SNP in the AMS Han patients went compared to Tibetan and Han control study groups. The CMS patients were found to diverge significantly for the *EPAS1* SNP from their Tibetan control group as measured by genetic distance (0.123) indicating directional selection of the *EPAS*-G allele with age and illness. The *EGLN1* (rs480902) and (rs516651) SNPs are found in NFE2L1 and PPAR transcriptional factor response elements, respectively. The *EGLN1* (rs480902) SNP has a significant correlation with HR and SaO2 in AMS patients. In conclusion, AMS and CMS were found to be significantly associated with the *EPAS1* and *EGLN1* SNPs indicating these mutations have an affect on both illnesses.

Recombination, along with mutation, is the ultimate source of variation in populations. A key tool for understanding recombination is a “genetic map” measuring the probability of crossover events at each position in the genome. We leverage the recent mixture of people of African and European ancestry in the Americas to build a map based on about 2.1 million crossovers in 30,000 unrelated African Americans. At intervals of more than three megabases it is nearly identical to one built in Europeans . At finer scales it differs significantly, with 2,454 recombination hotspots that are active in people of West African ancestry but nearly inactive in Europeans. The probability of a crossover at these hotspots is almost fully controlled by the alleles an individual carries at PRDM9 (P<10-245). We identify a 17 base pair DNA sequence motif that is enriched in these hotspots, and is an excellent match to the predicted binding target of African-enriched alleles of PRDM9.

450T

Ancestry informative marker set for Han Chinese population. *H.Q. Qu[1], Q. Li[2], J.B. McCormick[1], S. Xu[3], M. Xiong[4], J. Qian[5], L. Han Chinese accounts for 91.51% of Chinese population, or ~1.226 billion people. Chronic diseases including cancer, vascular disease, and infectious diseases, are the three leading causes of death in this population (He et al, 2005). Genetic association study (GAS) is a critical approach to understand molecular mechanisms and population-specific risk of these diseases, that can lead to the development of effective interventions at an individual or population level. Currently, a major issue of genetic association study is the confounding effect of population stratification. Our recent study (Li Jin group) identified obvious genetic heterogeneity between northern Han Chinese (N-Han) and southern Han Chinese (S-Han), historically divided by the natural barrier Yangtze river (Xu et al, 2009). This study highlighted the importance of the correction for population stratification in GASs on the Han Chinese population. The structured association method represented by Eigenstrat (Price et al, 2006) has been extensively demonstrated to be an effective approach. To minimize the genotyping cost of structured association studies, we developed a set of ancestry informative markers for genetic studies of Han Chinese populations. A sample of 308 Han Chinese individuals with 158,015 autosome SNPs genotyped from different regions in China (Xu et al, 2009) was analyzed. As shown by principle component analysis (PCA), N-Han and S-Han individuals formed two obviously distinct clusters by the first principle component (PC). 261 individuals were unambiguously distinguishable without obvious admixture. In these 261 individuals, ancestry information content I_n of each autosome SNP was calculated using the infocalc program (Rosenberg et al, 2003). Across 22 autosomes, an initial set of AIMs including 5,001 SNPs were selected by choosing one SNP marker with the largest I_n in each 500kb window. By a stepwise procedure, we decreased the number of AIMs by removing AIMs with the smallest I_n, and assessed the classification effects of PCAs by the maximum Matthews correlation coefficient (MCC). The classification effect was compromised significantly when less than 30 AIMs were used. We recommend at least the top 30 AIMs should be used in any structured association study on the Han-Chinese population. Robust correction for population stratification can be achieved if the top 150 AIMs are used, which can differentiate N-Han and S-Han unambiguously.

451T

Spinal Muscular Atrophy: Improved Detection of Silent (2+0) Carriers by Identification of SMN1 Founder Alleles. *M. Luo, L. Liu, I. Peter, S. Scott, C. Eversley, R. Kornreich, R.J. Desnick, L. Edelmann.* Dept Gen & Genomic Sci, Mount Sinai Sch Med, New York, NY.

Spinal muscular atrophy (SMA) is one of the most common and severe autosomal recessive diseases with a carrier frequency of 1 in 35 to 1 in 117, depending on ethnicity. SMA results primarily from *SMN1* gene copy number loss on chromosome 5q13 by either *SMN1* deletion or gene conversion with the highly homologous *SMN2*. Carrier screening is therefore performed by dosage sensitive methods; however, the detectability varies from 71-94% due to the inability to identify silent (2+0) SMA carriers with two copies of *SMN1* on one chromosome 5 and zero copies on the other. Since identification of deletion/duplication founder alleles might provide a general approach to identify silent carriers and improve carrier detection in various ethnic/racial groups, the occurrence of founder alleles in the Ashkenazi Jewish (AJ) population was investigated. Carrier screening of 692 healthy AJ adults by multiplex ligation-dependent probe amplification (MLPA) identified 1 in 46 (2.2%) deletion (1+0) carriers and 1 in 7 duplication (2+1) individuals, indicating that the detectability in this population using only *SMN1* gene dosage is ~90%. Microsatellite analyses using markers flanking the SMA locus identified two deletion and one major duplication founder haplotypes. Importantly, two tightly-linked polymorphisms in *SMN1*, g.27134T>G in intron 7 and g.27706_27707delAT in exon 8, were detected on the major AJ duplication allele, but not in 351 AJ individuals with two *SMN1* copies, making the haplotype highly specific for duplication alleles and effectively increasing the accuracy of carrier detection from 90 to 94% in this population. Surprisingly, these two linked polymorphisms were also identified on duplication alleles from other tested populations including African Americans, Hispanics and Asians. The finding that this duplication allele is shared by several ethnic groups suggests that it represents an ancient allele. Moreover, its identification among individuals who screen negative by dosage sensitive methods will improve SMA carrier detection and decrease the current residual risk that is due to the inability to detect silent (2+0) SMA carriers in different ethnic groups.

Low depth, whole genome sequencing of Dai population isolate demonstrates superiority over use of whole genome genotyping arrays in uncovering population structure, demographic history and selective pressures in non-European populations. *L.J.M. Coin[1,2], R.Y. Chen[1,3], F. Zhang[1,4], Y.R. Li[1], C. Yu[1], R.N. Gutenkunst[5], Y. Wang[6], R. Nielsen[1,6], W.W. Wu[1].* 1) BGI-Shenzhen, Shenzhen, China; 2) Department of Epidemiology and Biostatistics, School of Public Health, Imperial College London, St Mary's Hospital, London, UK; 3) Wuhan University, Wuhan, China; 4) South China University of Technology, Guangzhou, China; 5) Theoretical Biology and Biophysics and Center for Nonlinear Studies, Los Alamos National Laboratory, Los Alamos, New Mexico, USA; 6) Departments of Integrative Biology and Statistics, UC Berkeley, Berkeley CA, USA.

The development of whole genome sequencing (WGS) technology provides an opportunity to overcome the limitations of previous approaches for calculating population genetic parameters. In particular, genome-wide inference using SNP genotyping arrays is largely based on a limited set of variants tagging common variation in a reference cohort, rather than all variation actually present in the study samples, which may limit resolution in the study of non-European populations. In this project, we sought to compare inferences made from genotyping arrays with those from low coverage WGS data in order to assess biases present in either approach and to demonstrate the increased power and resolution available from low coverage sequence data. We generated genotyping as well as low-coverage (4x) WGS data on 80 samples from the Dai population, one of the minority groups in Yunnan province, South China, whose demographic history has yet to be resolved. WGS genotype calls were generated using the Broad Institute pipeline incorporating allele-specific read counts and subsequent refinement via imputation with Beagle. Indel genotypes were obtained from Dindel. Genotype concordance between WGS and array derived genotypes was high (98%) after imputation. We identified 2,889,232 novel SNPs. 31.2%, 35.8% of all Dai SNPs were tagged with r^2 > 50% by the Illumina 610k, and Illumina Omni `China' 1M chip respectively, compared to 31.2%, 37.3% in Han Chinese, and 39.4%, 43.0% in CEPH European samples, indicating bias towards European genomes in array design. WGS identified 3964 SNPs with allele frequency differences between Dai and Han greater than 80%, of which 90 were fixed differences. Only 5 of these fixed differences were visible to the array, indicating a vastly improved ability to identify putative sites of positive selection with WGS data. Using WGS data we provided finer resolution of the internal structure of the Dai population than with array data, obtaining more IBD segments, and resolving relatedness within the sample more accurately. We also obtained more precise estimates of population genetic parameters relating to the history of Dai, and performed an analysis of the Y chromosome not possible with a 610k Illumina array. Our results suggest Dai originated in central China prior to migrating southwest, leading to greater migration and higher gene flow between Dai and Cambodia.

453T

Host genetic variants and Epstein-Barr viral load in the HapMap lymphoblastoid cell lines. *C.J. Houldcroft, A. Gall, A.L. Palser, S.J. Watson, P. Kellam.* Virus Genomics, Wellcome Trust Sanger Institute, Cambridge, Cambs, United Kingdom.

Statement of purpose The HapMap collection of lymphoblastoid cell lines (LCL) is a widely used resource for studying human genetic variation and phenotypic traits. The LCLs were derived by immortalising human B cells with the B95.8 strain of Epstein-Barr virus (EBV), a human gammaherpes virus. Several studies have demonstrated that EBV viral load within LCLs, including the HapMap cell lines, is a variable trait and this potentially contributes to the variance in some cellular phenotypes. Gammaherpesviruses can change between two major viral gene expression programmes (latency and lytic replication) and this effects host gene expression. This study absolutely quantifies the EBV load within a subset of the HapMap CEU panel, assesses whether any of the LCLs show evidence of a change to the lytic replication cycle of EBV, and considers to what extent the variation in EBV viral load between cell lines may be under control by host genetic variants. It also examines if there is any EBV sequence diversity within a subset of the HapMap CEU and YRI samples in 1000 Genomes. Methods Quantitative polymerase chain reaction was used to absolutely quantify viral load in a panel of HapMap CEU individuals, normalised to GAPDH. Relative quantification of EBV lytic gene transcript BZLF1 was also performed by qPCR. Western blotting assayed lytic viral protein expression in a subset of cell lines. Low-coverage Illumina sequencing of HapMap samples from the pilot and phase 1 of the 1000 Genomes data was used to assay sequence diversity within the EBV DNA content of the HapMap samples. EBV genome sequences were assembled with Bowtie. Results Viral load in the HapMap LCLs varied from 2 to 350 copies/cell (normalised to GAPDH content). The average EBV load was 77 copies/cell. LCLs with high viral loads demonstrated 2 log fold greater expression of the lytic EBV BZLF1 mRNA than in a defined latent cell line. LCLs with the highest EBV loads also exhibited viral lytic protein expression by western blot. Assembly of the EBV genome sequences of 66 CEU and YRI HapMap samples revealed no variation in the EBV genomes present in the cell lines. Future work will explore host and viral factors controlling EBV viral load within the HapMap samples. The effects of Epstein-Barr virus immortalisation of lymphoblastoid cell lines should also be considered as a source of phenotypic variation in assays.

Exome Sequencing in an Isolate Population. *A. Ramachandran[1], E. Sehayek[2], J. Breslow[3], J. Friedman[4], R. Lifton[5], I. Pe'er[1].* 1) Computer Science, Columbia University, New York City, NY; 2) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 3) Laboratory of Biochemical Genetics and Metabolism, Rockefeller University, New York City, NY; 4) Laboratory of Molecular Genetics, Rockefeller University, New York City, NY; 5) Department of Genetics, Yale University, New Havan, CT.

Background: Small, isolate populations have been previously used in rare variant studies. This study examines the population of Kosrae in Micronesia. Since the introduction of a western diet in the late 1980s, there has been an increased incidence of metabolic diseases on the island. Several forays to the island have provided us with samples from 3000 individuals and measurements of about 30 phenotypes. Due to the high relatedness among the individuals of the island, a few dozen individuals are highly representative of the entire population of 7000. Previous studies have examined the genotypic and haplotypic data present on the island. Previous studies have identified or replicated dozens of associated SNPs and haplotypes across multiple phenotypes in this data. **Methods**: In this study, we use exome sequencing to identify potential causal variants. A pilot sample of 10 individuals chosen from extremes in BMI have been sequenced. Analysis of this pilot sample has shown several potential variants associated with extreme BMI. Some of those individuals are carriers for associated variants found using in the GWAS analysis. This allows us to examine the local regions of previously associated loci for potential causal variants. Due to the high relatedness of the population, we will impute the variants for the remaining population from the 10 sequenced exomes. Using the imputed variants, we can examine potential causal variants in greater detail. **Results**: The analysis was carried out for previously associated phenotypes with carriers in the 10 samples. Among these, several carriers of a variant associated with Campesterol, a plasma plant sterol, indicate the presence of a causal variant at the associate locus. Campesterol levels have been previously associated in Kosrae to two independent causal variants (p-value = 5E-39 and 3E-31) at the ABCG5/G8 locus. We report further refining the residual association signal, detecting an additional association signal at that locus (p-value = 4.87E-08). Exome sequencing identified a novel proximal missense variant in only carriers of the associated allele. **Conclusion**: We find that a combination of exome sequencing and GWAS data can find interpretable, likely causal, associated variants.

Derived SNP allele are more frequently used as a risk-associated variants in common human diseases. *O. Gorlova, J. Ying, C. Amos, M. Spitz, I. Gorlov.* Univ Texas MD Anderson CA Ctr, Houston, TX.

The results of more than 200 genome-wide association studies (GWAS) have been published to date. We used the GWAS data to address a question whether ancestral and derived (mutant) alleles are used as risk alleles randomly, which is important for understanding evolution of the genetic control of common human diseases. We found that rarer alleles are more likely to be risk variant and common alleles to be protective. When we have analyzed ancestral and derived alleles separately, 0.96±0.01 of rare (0-0.1) derived alleles were risk variants compared to only 0.67±0.04 of rare ancestral alleles being risk alleles. Among minor alleles, mean proportion of the risk variants was 0.84±0.05 for derived and 0.63±0.02 for ancestral alleles. The mean proportion of the risk variants among derived minor alleles was 0.79±0.06 and for ancestral variants only 0.41±0.05 for early onset diseases (onset< age 30), while the corresponding proportions for the late onset diseases were 0.78±0.07 and 0.62±0.05. Thus early onset diseases are likely to have a rare derived variant as a risk allele. For the late onset diseases risk alleles tend to be more uniform both in terms of population frequency and of the ancestral versus derived status. We also examined whether the population frequency and derived status are independent predictors of the risk variant status. Low frequency but not the derived status was a predictor of being the risk variant overall, but both were predictors in early onset diseases. Mutations causing early onset diseases are likely subjected to negative selection. However such mutations can reach substantial population frequency because of the effects of the random factors like genetic drift, founder and bottle neck effects. For the late onset diseases, the negative selection does not affect allelic frequency. One can expect that mutations causing late onset diseases are evolutionary neutral, have stochastic dynamics and may completely replace ancestral allele leading to the situation when the risk allele is the ancestral (common) and protective allele is the derived (rare). This can explain why in the late onset diseases risk alleles are more random both in terms of population frequency and ancestral/derived status.

456T

Studies on different samples of western Amazon populations converge to a genetic association between a specific region of Human chromosome 4 and malaria infection. *J. Pescarini[1,2,4], A. La Luna[1,4], R.M.G. Ferreira[3,4], L.C. Pereira[1,4], C.E.M. Kawamata[1,4], F.A.B. Santos[1,4], L.M.A. Camargo[1,4], H. Krieger[1,4], L.M. Garrido[1,4].* 1) Instituto de Ciências Biomédicas, Universidade de São Paulo, São Paulo, Brazil; 2) Instituto de Biologia Molecular do Paraná, Paraná, Brazil; 3) Fundaçao Oswaldo Cruz, Rondônia, Brazil; 4) Instituto Nacional de Genética Médica Populacional (INAGEMP), São Paulo, Brazil.

According to the WHO there are over 250 million new cases of Malaria each year. In 2008, Brazil was responsible for over 300 thousand cases of this disease. Most of these take place in the Amazon region. Several studies on the existence of genetic factors associated to resistance/susceptibility to several infectious diseases were reported in the past years. These findings can help to the understanding, treatment, prevention and eventually cure of these infections. Recent studies (Ferreira et al, 2008) in a western riverine Amazon population using a STR panel, postulated the evidence of linkage between the number of past malaria episodes reported by individuals and a specific region located in the short arm of chromosome 4. In order to test this hypothesis, a new study was done on a independent sample from the Municipality of Monte Negro (10º15'S, 63º18'W). From an original sample of 925 individuals, 96 individuals corresponding to both tails of the normal distribution of reported malaria episodes of malaria were selected. The number of episodes was corrected by sex and age. Cases were considered those who have shown one standard deviation above the mean and controls were those who have shown one s.d. below the mean. None of the selected individuals have relatives within the sample. Also cases and controls did not differ on their ethnic composition. Available data from a GWAS of the selected individuals using the Affymetrix GeneChip Human Mapping 250K Nsp Array were used in this analysis in order to test those previous findings. The association was studied with PLink Package using the following criteria for SNP inclusion: Belonging to chromosome 4; MAF of 1%; 100% of SNP call rate and Hardy-Weinberg equilibrium > 0.001. Twenty five SNPs satisfied these criteria and were included in an association analysis. The SNP rs17527389 (X^2=12.22; P=4.724x10^{-4}) showed a significant association with reported episodes of malaria infection after Bonferroni correction (P<0.012). This SNP is located in the intron region of APBB2/FE65L1 gene. There are evidences that the protein encoded by this gene bind amyloid beta precursor protein (APP) and also suggests a role in gene expression, cell cycle regulation and apoptosis. It should be stressed that this association matches with previous results using different techniques and in an independent sample, indicating that this region includes genes with significant effects on malaria infection.

457T

Bayesian inference of genealogy from population genomic data by the spatial Markov coalescent with recombination. *C. Zheng, E.A. Thompson.* Department of Statistics, University of Washington, Seattle, WA., USA.

The population based association studies have recently become popular to uncover the genetic architecture of complex traits. Under the widely used assumption of selectively neutral mutations on complex traits, inferring genealogies from population genomic data can be separated from the further gene mapping. Unfortunately, inference of genealogies for the Wright-Fisher population under the coalescent with recombination model has been shown computationally prohibitive mainly because the number of historical recombination events exponentially increases with the length of chromosomes. We present a Bayesian framework to infer genealogical trees from single-nucleotide polymorphism (SNP) data by using the spatial Markov coalescent with recombination, where the genealogical tree at a nucleotide site is assumed to be dependent only on the tree at the previous site. The Markov assumption results in high computational efficiency, linearly scaling-up with the length of chromosomes. A novelty of our framework is that it accounts for the typing errors of SNP data that are unavoidable for large data size. We use Markov chain Monte Carlo to sample from the posterior distribution of genealogical trees, together with the recombination rate and the type error. We evaluate the model performance by simulating an ancestral recombination graph (ARG) based on the coalescent with recombination, simulating SNP data from the ARG, and analyzing them in the Bayesian framework. The results show that the true marginal genealogical trees defined by the ARG are successfully estimated with uncertainties. The Bayesian formwork can analyze SNP data with length of chromosomes ~1 megabases, one order of magnitude larger than the previous full likelihood approach based on the coalescent with recombination. Thus, it opens the possibility of making use of the posterior distribution of genealogical trees along chromosomes in the fine-scale mapping of complex traits.

Bustamante[1].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Institute for Human Genetics, University of California San Francisco, CA; 3) Dipartimento di Biologia Evoluzionistica Sperimentale, Università di Bologna, Bologna, Italy; 4) Department of Structural Biology, Stanford Unviersity School of Medicine, Stanford, CA; 5) Centre for Genomics and Oncological Research (GENYO), University of Granada, Granada, Spain; 6) Oklahoma Medical Research Foundation, Oklahoma City, OK; 7) Department of Anthropology, Stanford University, Stanford, CA; 8) Center of Experimental Medicine “Miguel Layrisse”, Venezuelan Research Institute (IVIC), Caracas, Venezuela; 9) Laboratorio de Genética Molecular, Universidad de Antioquia, Medellín, Colombia; 10) Department of Genetics, Evolution and Environment, University College London, UK.

South Amerindians comprise a diverse population with distinct cultures and linguistic families. A better understanding of the genetic diversity and substructure within Amerindian populations in South America is necessary when analyzing complex health disorders and in understanding the genomic and demographic factors shaping the genome of admixed individuals living in the Americas. In order to shed light on the fine-scale patterns of genetic structure among South Amerindian populations we have genotyped nearly 1 Million SNPs (Affy 6.0 array) on 126 individuals from six different indigenous groups both from the Andean region and the Amazon Basin, combined with publicly available Native American SNP data from Brazil, Colombia, Bolivia and Peru. Using both PCA and clustering algorithms, we have found significant substructure within the Amerindian populations. In particular, each population isolate from Brazil and Venezuela cluster separately from the rest, while populations from Colombia, Peru and Bolivia show varying proportions of a shared genetic component, suggesting some degree of genetic continuity across the Andean region. We have also performed IBD and haplotype sharing analyses as well as *FST* calculations to further evaluate population differentiation. In addition, we calculated runs of homozygosity among individuals and applied a rejection-based algorithm to estimate effective population size and bottleneck timing for each population. We demonstrate that Amerindian populations are clearly dominated by bottlenecks but their severity varies substantially among regions, suggesting differential contributions to present day admixed populations across the Americas. In order to evaluate this, we have intersected our genotypes with SNP array data from 964 admixed individuals from Colombia, Peru, Chile, and Argentina genotyped as part of a larger collaborative effort as well as part of the 1000 Genomes project. We applied a novel PCA-based method for local ancestry estimation (PCADMIX) based on phased haplotypes and allowing for multiple K admixture models. Our results show that the Native American component of the different Hispanic/Latino populations varies across geographic regions, making the characterization of their genetic structure an essential step to inform present and future GWAS in the Americas.

Association between high myopia-associated genetic polymorphisms and ocular biometric parameters in middle-aged and elderly people. *J.H. Chen[1,2], S. Huang[1], Y. Zheng[1], H. Chen[1,2], P.O.S Tam[2], D.S.C Lam[2], M. Zhang[1], C.P. Pang[2].* 1) Joint Shantou International Eye Center, Shantou University/The Chinese University of Hong Kong, Shantou, Guangdong, China; 2) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong, China.

Purpose: Myopia is a common visual impairment. One of the notable features of myopia is the elongation of the axial length in eye balls. Recent studies showed that the genetic variants of gap junction protein delta 2 (*GJD2*), insulin-like growth factor-1 (*IGF-1*) and hepatocyte growth factor (*HGF*) were associated with high myopia. In this study, we investigated single nucleotide polymorphisms (SNPs) of these genes in the ocular axial length and other ocular biometric parameters in Chinese middle-aged and elderly people in Nan'ao Island in southeast China. **Methods:** A cohort of 459 subjects age／ 45 years old was recruited. The axial length and anterior chamber depth, lens thickness, and vitreous chamber depth were measured by A-scan ultrasound biometry. SNP rs634990 near *GJD2*, rs6214 in *IGF-1* and rs3735520 in *HGF* were genotyped using Taqman assay. The results were analysed by multivariate linear regression implemented by the R statistical language, controlling age and sex. **Results:** All 3 SNPs showed high minor allele frequencies, 42.7% to 49.0%. None of them deviated from HWE (*P*-values > 0.05). Associations between the 3 SNPs and the axial length or vitreous depth were not significant (all *P*-values > 0.05). However, SNP rs6214 in *IGF-1* was associated with lens thickness in an additive model (*P*-value = 0.021), estimated regression coefficient 0.06±0.026. Analysis of the dominant and recessive models gave similar results (*P*-values = 0.061 and 0.053 respectively). Association with lens thickness was not found in the other two SNPs. *HGF* SNP rs3735520 showed marginally significant association with anterior chamber depth (*P*-value = 0.078) in a dominant model, while no association was found in the other two SNPs. **Conclusions:** No association of *GJD2* and *IGF-1*, *HGF* with the axial length was found. However, the associations between *IGF-1* and lens thickness, and between *HGF* and anterior chamber depth, suggest a biological role of these growth factors in the elongation of the eye ball.

The polymorphisms of the APOBEC3H gene in the Pumwani sex worker cohort and the associations with the susceptibility/resistance to HIV-1. *M. Luo[1,2], S. Wang[1], D. Tang[1], J. Sainsbury[1,2], P. Lacap[1], J. Kimani[2,3], C. Wachihi[3], M. Kimani[3], F. Plummer[1,2].* 1) HIV and Human Genetics, National Microbiology Laboratory, Winnipeg, MB, Canada; 2) Department of Medical Microbiology, University of Manitoba, Winnipeg, Manitoba, Canada; 3) University of Nairobi, Nairobi, Kenya.

Background: Human APOBEC3H has the capability to interfere with the replication of HIV-1 by mutating the negative strand of the viral DNA after reverse transcription. Studies have shown that single nucleotide polymorphisms (SNPs) and alternative splicing influence the APOBEC3H's anti-HIV activity and its interaction with HIV-1 viral protein Vif. Objective: To examine whether SNPs in the APOBEC3H gene play a role in the resistance to HIV-1 infection observed in a subgroup of women in the Pumwani sex worker cohort (PSWC). Methods: The region between exon 2 and intron 4 were amplified, sequenced, and genotyped from genomic DNA samples of women (n=1029) enrolled in the PSWC. Genotyping results were statistically analyzed using SPSS-13.0, and linkage disequilibrium and haplotype frequencies were analyzed using Helixtree®. The influence of SNPs on alternative splicing and exonic splicing enhancers (ESE) were analyzed in-silico using Alamut v1.54. Results: We identified several novel SNPs in the analyzed region and a novel SNP(+321) C>T (F107F) was enriched in the HIV-1 infected group (P=0.022,odd ratio:0.288, 95% CI:0.094-0.888) and associated with faster seroconversion (P=0.000638, Log Rank:11.66). SNP rs77993299 (+315) C>T(G105G) was enriched in the HIV resistant women (P=0.005, odds ratio:2.662, 95%CI:1.315-5.388) and showed a trend towards slower seroconversion (P=0.336). In-silico analysis predicted SNP(+321)C>T to abolish an ESE site while SNP rs77993299 had no effect. The SNPs were predicted to not have any effects on splicing. Conclusion: SNP rs77993299 and novel SNP(+321)C>T are associated with HIV-1 resistance and susceptibility, respectively. ESEs are binding sites for proteins that recruit splicing machinery an/or antagonize nearby silencer elements. The abolishment of an ESE by SNP+321C>T may decrease splicing accuracy or efficiency of APBOBEC3H, may explain its association with HIV-1 infection.

461T

Haplotypes from the SLC45A2 gene are associated with the presence of freckles and eye, hair and skin pigmentation in Brazil. *C.T. Mendes-Junior[1], N.C.A. Fracasso[2], E.S. Andrade[2], C.C.F. Andrade[2], L.R. Zanão[1], M.S. Silva[1], L.A. Marano[2], C.E.V. Wiezel[2], E.A. Donadi[3], A.L. Simões[2].* 1) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, 14040-901, Ribeirão Preto-SP, Brazil; 2) Departamento de Genética, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14049-900, Ribeirão Preto-SP, Brazil; 3) Divisão de Imunologia Clínica, Departamento de Clínica Médica, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, 14048-900, Ribeirão Preto-SP, Brazil.

The SLC45A2 (solute carrier family 45, member 2) gene (5p13.2) encodes the Membrane-Associated Transporter Protein (MATP), which mediates melanin synthesis by tyrosinase trafficking and/or proton transportation to melanosomes. Two coding SNPs (E272K and L374F) have been associated with variation in eye, hair and skin pigmentation. Yuasa *et al*. (*Ann Hum Genet* 2006:802-811) studied a set of 12 SNPs spanning more than 38kb within SLC45A2 and observed different haplotype distributions in Germans, Japaneses and Sub-Saharan Africans. In spite of the small sample sizes, 84.4% of the 32 haplotypes were found in single populations. However, many of these haplotypes may be found at the Brazilian population, which is the result of intensive inter-ethnic crossings. Since the determination of eye, hair and skin pigmentation of unknown samples found in crime scenes would be of great value for forensic caseworks, the present study aimed at evaluating the influence of SLC45A2 haplotypes in the determination of such pigmentation traits in a highly admixed population sample. To achieve this goal, 12 SLC45A2 SNPs (Yuasa *et al*., 2006) were evaluated in 150 unrelated individuals from the Ribeirão Preto area, located at the Northwestern region of the São Paulo State, Southeastern Brazil. SNPs were genotyped by PCR-RFLP or Allele-Specific PCR, followed by Polyacrylamide Gel Electrophoresis. Haplotypes of each individual were inferred by two independent computational methods: PHASE and PL-EM. These methods presented same results for 139 (92.7%) individuals, with average probabilities of 0.9589 and 0.9836, respectively. Considering these 139 individuals, 23 different (10 new) haplotypes were identified. Seven haplotypes presented at least one association with a pigmentation feature, and skin color was influenced by five of them. Haplotype *hp9*, for instance, was associated with the presence of blond/red hair, pale skin and freckles, and also with absence of dark eyes, hair and skin. All haplotypes significantly associated with dark or light pigmentation features harbor the 374L and 374F alleles, respectively. However, it is noteworthy that the remaining set of haplotypes harboring the 374F allele is more frequent among individuals with intermediate than light pigmentation. These results reinforce the relevance of SNP L374F in human pigmentation, but also suggest an important role played by its surrounding variation. FINANCIAL SUPPORT: CNPq/Brazil (Grant 478843/2009-7) and CAPES.

Optimal Algorithm for Haplotype Phasing with Genome-sequencing and Imputation. *D. He, B. Han, E. Eskin.* UCLA, Los Angeles, CA, 90095.

Haplotype phasing is an important step for analyzing genetic variations in the human genome in that haplotypes contain all the alleles in the human genome. There are typically two types of haplotype phasing methods: (1) Haplotype imputation using Hapmap on genotypes obtained from microarray; (2) Haplotype assembly based on reads obtained via sequencing techniques such as Sanger sequencing and next-generation sequencing. Haplotype imputation requires very low coverage but it often can only impute common alleles in the haplotypes. Haplotype assembly can assemble both common and rare alleles but it requires very high sequencing coverage and it is usually not able to fully reconstruct the haplotypes. In this work, we combine the two methods and develop an optimal algorithm to impute haplotypes based on sequencing reads. We show our method only requires low sequencing coverage and in the mean time it is able to reconstruct both common and rare alleles accurately.

LD patterns in dense variation data reveal information about the history of human populations worldwide. *S. Myers[1,2], G. Hellenthal[2], D. Lawson[3], G. Busby[4], S. Leslie[5], B. Winney[5], P. Donnelly[2], W. Bodmer[5], The. POBI Consortium[1,2,5], C. Capelli[4], D. Falush[6].* 1) Dept of Statistics, Oxford University, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, Oxford University, United Kingdom; 3) Department of Mathematics, University of Bristol, United Kingdom; 4) Dept of Zoology, Oxford University, United Kingdom; 5) Cancer and Immunogenetics Group, Department of Clinical Pharmocology, Oxford University, United Kingdom; 6) Max Planck Institute for Evolutionary Anthropology, Department of Evolutionary Genetics, Leipzig.

A detailed understanding of population structure in genetic data is vital in many applications, including population genetic analyses and disease gene mapping, and relates directly to human history. However, there are still few methods that directly utilize information contained in the haplotypic structure of modern dense, genome-wide variation datasets. We have developed a set of new approaches, founded on a model first introduced by Li and Stephens, which fully use this powerful information, and are able to identify the underlying structure in large datasets sampling 50 or more populations. Our methods utilize both Bayesian model-based clustering and principal component analyses, and by using LD information effectively, consistently outperform existing approaches in both simulated and real data. This allows us to infer ancestry with unprecedented geographical precision, in turn enabling us to characterize the populations involved in ancient admixture events and, critically, to precisely date such events. We applied our new techniques to combined data for 30 European populations sampled by us, or publicly available, and the worldwide HGDP data. We find almost all human populations have been influenced by mixture with other groups, with the Bantu expansion, the Mongol empire and the Arab slave trade leaving particularly widespread genetic signatures, and many more local events, for example North African (Moroccan) admixture into the Spanish that we date to 834-1394AD. Dates of admixture events between European groups and groups from North Africa and the Middle East, seen in multiple Mediterranean countries, vary between 800 and 1700 years ago, while Greece, Croatia and other Balkan states show signals of admixture consistent with Slavic migration from the north, which we date to 600-1000AD. At the finest scale, we are able to study admixture patterns in data gathered by a project (POBI) examining people within the British Isles. Our approaches reveal genetic differences between individuals from different UK counties, and show that the current UK genetic landscape was formed by a series of events in the millennium following the fall of the Roman Empire.

SLE is a chronic, heterogeneous autoimmune disorder characterized by inflammation, loss of tolerance to self-antigens, and dysregulated interferon responses. In this study, we sought to replicate loci with suggestive association with SLE from a previously published genome-wide association scan. Genotyping was performed using Illumina iSelect technology. Stringent quality control measures were applied and genetic outliers determined using principal component (PC) analysis. Only SNPs with minor allele frequencies >1% were considered. After quality control filtering, 3562 SLE cases and 3491 controls of European ancestry (EA), 1527 cases and 1811 controls of African-American (AA) descent, and 1265 cases and 1260 controls of Asian (AS) origin were included in the replication analysis. SNP-SLE association was tested using logistic regression under an additive genetic model in PLINK while adjusting for the first three PCs and gender. Meta-analysis was performed using METAL. Three regions exceeded genome-wide significance (GWS) after the trans-racial replication study. One region that replicated in EA, AA, and AS subjects was located at 11q24.1 outside the 3'UTR region of interferon regulatory factor 8 (IRF8; Pmeta=4.97x10E-10). Approximately 300 additional SNPs were genotyped in the region of IRF8. Two risk haplotypes were observed within the EA subjects (P=3.85x10E-7 and P=7.99x10E-10). Logistic regression conditioning on the most significant SNP in each haplotype indicated that these effects were independent. The other two loci included a coding SNP in TMEM39A (transmembrane protein 39A; Pmeta=4.16x10E-9), and an intra-genic SNP at 17q21 between the genes IKZF3/ZBP2 in a shared promoter region (Pmeta=7.41x10E-9). All three regions have been implicated in other autoimmune diseases. In addition, 13 other loci were replicated in EA but did not exceed GWS with 5x10E-8 < P < 9.99x10E-5 (CFHR1, CADM2, LOC730109/IL12a, LPP, LOC63920, SLU7, ADATMTSL1, C10orf64, SEN3, OR8D4, FAM19A2, STXBP6, and TMCO5). IRF8 is a transcription factor involved in the regulation of the interferon pathway, which has been widely reported to be dysregulated in SLE and other autoimmune diseases. No biologically functional relevance has been published for TMEM39A. IKZF3 is an important transcription factor regulating B lymphocyte proliferation and differentiation. Thus, this study identified 3 novel SLE risk loci exceeding GWS and replicated 13 additional loci suggestive of association.

Differential Expression of CD8 Variants Amongst Infected and Uninfected Men Enrolled in the Pittsburgh Center of the Multicenter AIDS Cohort Study. *R.S. Bosko Marino, L. Kingsley, J. Martinson, Multicenter AIDS Cohort Study.* Infectious Diseases & Micro, Grad School of Public Health, Univ Pittsburgh, Pittsburgh, PA.

HIV infection is known to devastate an individual's immune system but its effects on host gene expression are still only partially understood. To address this, we have begun a study of whole transcriptome variation in a cohort of men who have sex with men (MSM), including both HIV+ and HIV- participants. For this study we have recruited 478 men from the Pitt Men's Study, a participating center of the Multicenter AIDS Cohort Study (MACS). RNA was extracted from whole blood collected into PAXgene tubes at the most recent clinic visit. Following globin reduction, these RNA samples were used to synthesize cDNA for whole transcriptome expression analysis, using Illumina HT-12 arrays, at the University of Pittsburgh Genomics and Proteomics Core Laboratories. Bioconductor R modules (lumi, limma, GOstats, gplots) were used to analyze the array data. Preliminary results have identified 6 transcripts with significant differences in expression between a group of HIV- men (n=50) and HIV+ men (n=38), with adjusted p-values <0.05. The majority of these are transcript variants of the (and) chains of the T-cell surface antigen CD8, with the minority being a transcript for the predicted gene PATL2. Additional cluster analysis showed subgroups of shared expression patterns in the HIV+ and HIV- groups. In general, CD8 expression was lower in HIV infected individuals than in those uninfected with the virus. CD8 is expressed on the surface of cytotoxic T cells, which attack and destroy virus-infected cells, but it is not yet clear if these differences seen in CD8 expression represent a consequence of HIV infection or an innate characteristic of the host that may in fact influence HIV infection itself. All of the HIV+ men in this study are receiving antiviral therapy, and have low viral loads as a consequence, suggesting that their current state of infection is not the main determinant of their levels of CD8 expression. The current results of this study suggest a relationship between HIV infection and CD8 expression levels, and demonstrate that RNA samples extracted from whole blood are a viable source material for the study of the host response to infection.

466T

Polymorphisms in IL22RA2 are associated with aggravation of severe hepatic fibrosis caused by Schistosoma japonicum and S.mansoni. *A. Dessein[1,2,3], M. Sertorio[1,3], X. Hou[6], J. Li[6], X. Luo[6], M. Abdelwahed[4], A. Ahmed Hamdoun[4], H. He[6], S.A Abdelmaboud[4], J. Zhou[6], A. Monis[4], A. Varoquaux[1,2,3], N. Eldin Elwali[4], L. Argiro[1,3], Y. Lee[5,6].* 1) INSERM, U906, Marseille, F-13385, France; 2) Assistance Publique, Hôpitaux de Marseille, Marseille F-13005; 3) Université de la Méditerrannée, Marseille F-13385; 4) Institute of Nuclear medicine, Wad Medani. Gezira Sudan; 5) Queensland Institute of Medical Research, PO Royal Brisbane Hospital, Queensland 4029, Australia; 6) Hunan Institute of Parasitic Diseases; Hua-Ban Qiao Road Yueyang Hunan 414000 China.

M.Sertorio and A.Dessein are first authors. **Rationale** : Schistosomes cause severe hepatosplenic disease in humans accounting for 300.000 deaths every year. Schistosome eggs induce hepatic inflammation and extended hepatic fibrosis (HF) in 5 percent of infected subjects. HF leads to Portal Hypertension (PH) that contributes to splenomegaly which in turn aggravates PH, varices, bleedings and ascites. We have shown HF is controlled by a major locus on 6q23 and SNPs in CCN2 (CTGF)at this locus aggravate HF (J.Exp.Med. 206,2321-2328). We have observed IL-22 is increased in schistosome-infected subjects. Others reported IL-22 protects against hepatic damage and IL22RA2, also located on 6q23, encodes a soluble form of the IL-22 receptor that competes for the binding of IL-22 to its receptor. These findings prompted us to evaluate whether SNPs in IL22RA2 could aggravate HF. **Methods**: Case control studies were performed on 3 independent samples of 404 Chinese farmers (S.japonicum, sample 1) 279 Chinese fishermen (sample 2), 167 Sudanese farmers (S.mansoni, sample 3) all living in endemic regions. HF was evaluated using echography by at least two observers for each sample. All Tag SNPs in IL22RA2 (MAF > 10 percent;) were tested on both Chinese samples. To rule out that SNPs in linkage disequilibrium (LD) with the tested SNPs could account for the observed associations, we evaluated SNPs in the 500 Kb regions in 3' and 5' of IL22RA2. **Results**: We found that two SNPs in IL22RA2 in two different correlation bins were associated with HF in sample 1: SNP1: p=0.03, OR= 1.6 (1.1-2.5) and SNP2: p=0.008, OR=6.8 (1.4-33). The independent associations of these SNPs with HF were confirmed by multivariate analysis. No SNPs in LD with these SNPs could account for this result. We then tested these SNPs in sample 2 and obtained SNP1: p=0.02, OR=2.3(CI=1.1-4.7); SNP2: p=0.4. Finally, we evaluated these SNPs in sample 3 and obtained SNP1: p=0.02, OR=3 (1.2-7.6). SNP2: p=0.04, OR=6.2 (1.1-35.1). Finally, both SNPs were associated with HF in a Brazilian sample (not shown). **Conclusion**: Two SNPs in IL22RA2 are independently associated with severe HF in subjects infected with the two schistosome strains of medical importance. This is, at our knowledge, the first report of the association of SNPs in IL22RA2 with human tissue fibrosis. This indicates that IL-22 plays a crucial role in the control of HF in schistosomiasis and possibly in other chronic liver inflammations(HCV,HBV).

Fine-mapping of 13q14 locus associated with susceptibility to leprosy and Crohn's disease. *F. Takeuchi.* Pathogen Genomics Center, National Institute of Infectious Diseases, Tokyo, Japan.

Although leprosy and Crohn's disease are diseases with distinct symptoms, the two diseases share many susceptibility loci found in genome-wide association studies (Zhang et al. *N Engl J Med*, 2009, 361:2609; Barrett et al. *Nature Genetics*, 2008, 8:955). One locus at 13q14 includes two genes, *CCDC122* and *C13orf31*, whose functions are both unknown. Aiming to identify the causal variant and the causal gene in the locus, we studied the association of single nucleotide polymorphism markers and haplotype classes. For testing the genotype-phenotype association, we combined previous studies on Crohn's disease, leprosy and related diseases, such as tuberculosis. Haplotype classes and frequency in various ethnicities were assessed using the HapMap and Human Genome Diversity Panel data. Utilizing the 1000 genomes data, we narrowed down the list of possible causal variants. We found that the locus could include more than one causal variant. This study shows the possibility of fine-mapping by combining multiple diseases that partially share common etiology.

The impact of linkage disequilibrium on inferring coancestry in populations. *E.A. Thompson, M.D. Brown, C.G. Glazner, C. Zheng.* Department of Statistics, University of Washington, Seattle, WA.

In both pedigree-based linkage studies and in population-based association studies there has been much interest in the use of modern dense genetic marker data to infer segments of gene identity by descent (ibd) among individuals not known to be related, in order to increase power and resolution in localizing genes affecting complex traits. The ability to make such inferences derives from the fact that ibd segments in remote relatives are generally rare but not short, being typically an order of magnitude longer that the extent of linkage disequilibrium (LD). However, LD remains a major confounding factor, since LD is itself a reflection of coancestry at the population level. We have developed a hidden Markov model (HMM) approach to detection of ibd in populations. To evaluate performance, we simulated descent of genome in a population of 7000 individuals over 200 generations, and determined the realized ibd in pairs of individuals in this population. For the current study, our data consist of 500 pairs of individuals, sampled from the final generation of the simulated population. We evaluate our approach through the ability of the HMM to detect the realized segments of ibd among either the four haplotypes or the two genotypes in these 500 pairs of individuals. To study the impact of LD, we developed a simulation approach which first uses BEAGLE to fit an LD model to 1917 haplotypes from a real data study with high LD. These haplotypes are observed for 6913 markers over 140cM. From the simulated population descent and the fitted BEAGLE model, we generated realistic dense marker data for the same simulated individuals for the same set of markers but at five levels of LD. Although our HMM ignores LD, it was quite successful in detecting segments as small as 1 Mbp, among the four chromosomes of pairs of individuals, using either phased haplotypic or unphased genotypic data. Using the same calling threshold, as LD was decreased, the percentage of markers for which the correct ibd state was called increased from 50% to 97%, and the percentage failing to reach the threshold decreased from 33% to 2%. Generally, haplotypic data provided somewhat better performance than genotypic data. At all LD levels, the rates of failing to detect true ibd were higher for genotypic data. However, at the highest LD levels, the false-positive rate was higher for haplotypic data, showing the clear impact of LD on the haplotypic similarity of non-ibd segments of genome.

Linkage disequilibrium decay and past population history in the human genome. *L. Park.* Natural Science Research Inst., Yonsei University, Seoul, Korea.

The fluctuation of population size has not been well studied in the previous studies of theoretical linkage disequilibrium (LD) expectation. In this study, a theoretical prediction of LD decay was derived, based primarily on the population sampling procedure, which accounted for the effects of changes of effective population sizes. The theoretical predictions and the simulated values were in excellent agreement. The equation that was derived was used to estimate effective population size (N_e) assuming a constant N_e and LD at equilibrium. These N_e estimates implied the past changes of N_e for a certain number of generations till equilibrium, which differed depending on recombination rate. When applying to human genome data, an excellent correspondence with the recent growth of human population was obtained. Specifically, four populations with three African and one Mexican ancestries showed the population growth significantly less than that of other populations. The inferred past population history of each population showed a good correspondence with historical studies, proving that the genome data could be an objective source for the population history. During the examination of overall LD decay in the human genome, in all populations, a selection pressure was observed on chromosome 14, the gephyrin gene.

Population substructure effect in a case-control study of Multiple Sclerosis (MS) in Bogota - Colombia. *W.A. Cardenas[1], R. Pereira[2], M.C. Lattig[1], H. Groot[1], J. Toro[3], A. Amorim[2,4], L. Gusmão[2].* 1) Laboratorio de Genética Humana, Facultad de Ciencias Universidad de los Andes, Bogotá, Colombia; 2) IPATIMUP - Institute of Molecular Pathology and Immunology of the University of Porto, Porto, Portugal; 3) Unidad de Neurología, Hospital Universitario, Fundación Santa Fe de Bogotá, Facultad de Medicina-Universidad de Los Andes, Bogotá, Colombia; 4) Faculty of Sciences of the University of Porto, Porto, Portugal.

Latin American populations are known to have a complex genetic structure indicative of recent admixture events between European (EUR), Sub-Saharan African (AFR), and Amerindian/Native American (AMR) ancestral populations. These population substructures are known to lead to spurious associations in case-control research studies since allele frequency differences among subpopulations can result in frequent false-positive results. To take into account the effects of population stratification in a previous association study in Multiple Sclerosis (MS), we used 46 multiplex Ancestry Informative INDELs to determine the ethnic ancestry of 173 individuals (52 MS patients and 121 healthy controls) from the heterogeneous population of Colombia's capital - Bogota. Genotypes were evaluated using the STRUCTURE software to discriminate among the three major subpopulations characteristic of our population sample. The ancestry percentage for this population was established as: 55.6% EUR, 11.2% AFR and 33.2% AMR. Exact test of sample differentiation based on the ancestry percentage distribution in patients and controls [(EUR) 52.9% - 56.7%; (AFR) 12% - 10.8%, and (AMR) 35.1% - 32.4%, respectively] did not reveal significant differences (non-differentiation exact P value: 0.89525±0.0058) arguing that previous associations among mtDNA haplogroups, the Fok1 polymorphism in the vitamin D receptor (VDR) gene and HLA-DRB1 allele seem to be real effects in MS susceptibility, since population substructure is not affecting the results. Additionally, the use of this multiplex of 46 Ancestry Informative INDELs was able to discriminate the three ancestral subpopulations indicating that they are good markers to determine individual and population ancestry percentages in our population and are, therefore, good markers to be used in future studies examining population genetic substructure in complex disease association studies.

Meta-analysis of genome-wide ancestry on over 7,000 African-American and Hispanic/Latino individuals identifies novel asthma-associated genetic loci. *C.R. Gignoux[1], D.G. Torgerson[1], J.L. Galanter[1], L.A. Roth[1], R.D. Hernandez[1], S. Sen[1], R. Mathias[2], K.C. Barnes[2], E. González Burchard[1], the EVE consortium.* 1) UCSF, San Francisco, CA; 2) Johns Hopkins University, Baltimore, MD.

Genome-Wide Association Studies have contributed new insights to the study of complex diseases. However, they do not capture all heritability of a trait and have had limited findings in ethnic minority populations. We leveraged the power of a diverse set of 9 studies in the EVE asthma genetics consortium: four African-American and five Hispanic/Latino studies, to look for additional loci associated with asthma. Following the initial GWAS meta-analysis we performed a different test to harness the intrinsic admixture in these populations: genome-wide ancestry association testing (or admixture mapping) for differences in ancestry, rather than genotype, at each locus on the genome. Ancestry association in theory can have more power than GWAS due to better coverage in admixed populations and fewer effective comparisons. It may also identify candidate regions more likely to contain population-specific rare variants.

We first estimated ancestry at each locus in the genome for each study followed by interpolation across SNPs based on the block-like nature of local ancestry. Our final dataset included over 2 million sites across the autosomes in 3,106 African Americans and 3,902 Latinos. We performed meta-analyses (both ethnic-specific and combined) using weighted p-values, and for our top hits we implemented a mixed effects model to account for ethnic differences.

We found strong evidence for associations between African ancestry and asthma, with two significant hits in 4p12 and 6q14 ($p < 10^{-8}$). In addition, we found suggestive associations with the other two ancestries: 7q31 for Native American ancestry ($p \sim 7 \times 10^{-6}$), and 1q42 ($p \sim 10^{-7}$) for European ancestry. Combining African-American and Latino studies narrows our peaks to small regions of the genome. Our most significant association for ancestry on 4p12 had a combined OR of 1.49 (1.25-1.78) for African ancestry in African Americans with no evidence of heterogeneity across all studies ($I^2 \sim 0$) including an Afro-Caribbean population from Barbados. This region also has biological plausibility as it contains *GABRA2*, known to be induced in the airway epithelium of individuals with asthma.

To our knowledge this study is the first meta-analysis of genome-wide ancestry association. We highlight the importance of studying diverse ethnicities for complex disease and demonstrate the hidden potential of available genome-wide data for additional disease mapping strategies.

Association of Mitochondrial DNA Sequence with Longevity in Turkish Population. *H.H. Aydin, O. Guney, H. Ak Celik.* Dept. of Medical Biochemistry, School of Medicine, Ege University, Bornova, Izmir, Turkey.

Aging is a multiple factor related process, associated with progressive decrease in physiological functions, lower survival and decreased ability for reproduction as the age increases, and ultimately resulting in death. One of the widely recognized mechanisms for aging is mitochondrial mutations. Maternally inherited mitochondrial genome, lacking genome recombination and having inadequate repair mechanisms, is more vulnerable to mutations as the mitochondria itself is a source for free radicals. Mitochondrial DNA variations, resulted from either inherited mutations or somatic mutations, may affect life expectancy by altering respiratory chain and free radical formation. Individuals older than 90 (n=25) and middle-aged individuals having no chronic disease (n=25), were included to our study as +90 group and control group respectively. Mitochondrial DNA sequence analysis for both groups was carried out with Affymetrix microarray system. From this sequence data polymorphic variants were detected by using rCRF sequence as a reference and haplogroup clusters to which individuals belong were indentified accordingly. Polymorphic variant and haplogroup cluster differences between +90 group and control group were revealed and statistically evaluated. Frequency of C150T polymorphism, which was previously identified as a longevity region by 3 similar studies, was found to be higher in +90 group compared to control group. T16304C polymorphism was found to be at a higher frequency in control group compared to +90 group. It is considered that this variant may have a negative effect on longevity. Data obtained from haplogroups suggest that H, HV, R and N are more common haplogroups in Turkish population. No significant difference was detected between +90 group and control group regarding to the haplogroup status. This study is the first of its kind conducted in Turkish population. Mitochondrial sequence data and haplogroup data of Turkish population will be a source for future studies.

Mitochondrial DNA in Myanmar: insights into the peopling of South-East Asia. *J. Horst[1], M. Summerer[2], D. Horst[3], G. Erhart[2], B. Horst[4], A. Manhart[2], T. Sanguansermsri[2], F. Kronenberg[2], A. Kloss-Brandstätter[2].* 1) Institut für Humangenetik, Universität Münster, Germany; 2) Division of Genetic Epidemiology, Innsbruck Medical University, Innsbruck, Austria; 3) Pathologisches Institut, Ludwig-Maximilians-Universität, Münster, Germany; 4) Department of Dermatology, Section of Dermatopathology, Columbia University, New York, NY.

BACKGROUND: The Union Myanmar (Burma) is the largest country in Southeast Asia, with an estimated population of around 56 million people. As a consequence of its history, Myanmar is inhabited by various ethnic groups, amongst them the Tibeto-Burman Bamar represent 68% of the population. Originating from present-day Yunnan (China) they migrated to Ayeyarwady valley in the 7th century AD replacing and absorbing the Pyu and the Mon. Until the British controlled Burma between 1886 and 1948, Burma was ruled by changing kingdoms and dynasties. We analyzed the entire mtDNA control region of 327 unrelated donors from Myanmar according to highest forensic quality standards. To refine haplogroup information, especially in the complex haplogroup M, 43 selected lineages were subjected to complete mitochondrial genome sequencing. In order to describe the mtDNA setup of Myanmar more thoroughly, the data were subjected to population genetic comparisons with other Southeast and East Asian groups.

RESULTS: In general, the Myanmar mtDNA profiles were characteristic for Southeast Asian populations in terms of haplotype composition and genetic structure, however, genetic comparisons with surrounding populations revealed genetic differentiation. The Myanmar sample exhibited pronounced mtDNA diversity, reflecting the huge number of ethnic groups. We detected 8 new so far un-described mtDNA lineages represented by 13 haplotypes. No traces of European contribution to the gene pool were detected.

CONCLUSIONS: In this study, we portray the great mtDNA variety of Myanmar for the first time. Our findings will contribute to clarify the migration history of the region. They encourage setting up regional and subpopulation databases, especially for forensic applications.

Diversity of the 3' untranslated region of the *HLA-G* gene in Amerindians from the Brazilian Amazon and the influence of Natural Selection. *N.F. Cagnin[1], C.T. Mendes-Junior[2], E.C. Castelli[3], E.A. Donadi[4], A.L. Simões[1].* 1) Department of Genetics, FMRP, University of São Paulo, USP, Ribeirão Preto, São Paulo, Brazil; 2) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Brazil; 3) Department of General Biology, Biological Sciences Institute, Federal University of Goiás, Goiânia, Brazil; 4) Division of Clinical Immunology, Department of Medicine, School of Medicine of Ribeirão Preto, University of São Paulo, Brazil.

The *HLA-G* gene, primarily expressed on trophoblast cells at the maternal-fetal interface, plays a key role in the modulation of the maternal immune system during pregnancy, enabling foetuses to survive unharmed in a genetically foreign host during successful pregnancies. This fact has triggered interest on aspects of population dynamics of this gene, especially the regulatory regions, such as the 3' untranslated region (3'UTR) that would be related to different levels of gene expression due to post-transcriptional mechanisms. The involvement of the 3'UTR in the gene expression patterns suggests that this region is under influence of natural selection, which can be best evaluated in isolated populations such as Amerindians from the central Brazilian Amazon. Evidence of balancing selection at *locus* 14bp insertion/deletion located in the *HLA-G* 3'UTR, has already been found, but analysis of the effect of natural selection on the haplotypes formed by this and other polymorphic *loci* of the 3'UTR has not been reported. So, this study aimed to determine the frequencies of haplotypes at the *HLA-G* 3'UTR in Amerindians from the Brazilian Amazon, and verify the existence of selective pressure on this gene region. For this, we sequenced the 3'UTR of the *HLA-G* in 144 Amerindians from villages belonging to five Brazilian Amazon's tribes: Bom Jardim, Campo Alegre, Nova Itália and Marajá, villages of *Tikúna* tribe, Sete Estrelas and Morada Nova of *Katukina*, Cana Brava and Paredão of *Kaxináwa*, Vida Nova of *Marúbo* and a *Yaminawa* village. We found a total of seven polymorphic *loci*, the 14bp insertion/deletion and SNPs at the positions +3010G/C, +3027A/C, +3035C/T, +3142G/C, +3187G/A, +3196G/C. Departures from Hardy-Weinberg equilibrium weren't found. These polymorphic *loci* defined seven haplotypes, but only two were found in all villages. The haplotype frequencies varied a lot between villages and tribes. Departure from selective neutrality was tested by two different tests, Tajima's D and Ewens-Watterson's neutrality tests, and both revealed evidence of balancing selection. Statistically significant values were found in *Katukina*, Morada Nova, *Marúbo*, and the whole Amerindian sample by Tajima's D test and in *Yaminawa* and Campo Alegre by Ewens-Watterson's test. Seven other marginally significant values ($p \leq 0.1$) were observed. In conclusion, the neutrality tests suggest great possibilities of balancing selection acting in the 3'UTR of the *HLA-G* gene.Financial support: CNPq.

Search for selection in coding regions surrounding large insertions and deletions between humans and four primate species. *W. Guiblet[1], K. Zhao[3], A.L. Roca[3], J.C. Martinez-Cruzado[1], S. Massey[2], T.K. Oleksyk[1].* 1) Department of Biology, University of Puerto Rico at Mayagüez, Mayagüez, PR 00680; 2) Department of Biology, University of Puerto Rico at RÍo Piedras, San Juan, PR 00931; 3) Department of Animal Sciences, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA.

Genes are highly conserved sequences and usually show very few differences between closely related species, such as humans and primates. In this study, we are focusing on >10 bp insertions and deletions (indels) found when comparing humans, chimpanzees, gorillas, orangutans and rhesus macaque genome sequences with the purpose of testing indel flanking regions for selection. From 33,479 indels identified by comparing reference genomes pairwise, we chose 186 within coding sequences with a potential high-impact on protein sequence. These fragments have been validated in laboratory by PCR and electrophoresis to distinguish real features from computational artifacts, and further tested for the presence of polymorphism in multiple human populations. First, we used five different algorithms (PAML package) to produce over 7,000 pairwise Ka/Ks values. Among the 186 indel regions, eight fragments showed significant Ka/Ks ratios between human and at least one primate sequence. Next, we searched if these features are found within selective sweep regions demonstrating diminished multilocus heterozygosity and high divergence (FST) by comparing genotype data between populations of the Human Genome Data Panel (HGDP). Finally, indels were further interrogated for recent signatures of selection in human populations by evaluating extended haplotype homozygosity around ancestral and derived alleles in the polymorphic loci. The significance of our approach was evaluated by the resampling method, where exactly the same procedures and tests have been performed with a 10x dataset of randomly created indels matched by size distributed across the reference genome.

476T

Intra-European allele frequency differences at height-associated SNPs suggest widespread selection on standing variation. *J.N. Hirschhorn[1,2,3], M.C. Turchin[1,2], C.W.K. Chiang[1,2], C.D. Palmer[1,2], S. Sankararaman[2], D.E. Reich[2,3], GIANT consortium.* 1) Endocrinology and Genetics, Children's Hospital, Boston, MA; 2) Dept of Genetics, Harvard Medical School, Boston, MA; 3) Broad Institute, Cambridge, MA.

Individuals of Northern European ancestry are on average taller than those of Southern European ancestry. It is unknown whether this phenotypic difference is driven by genetic differences, and if so, whether due to natural selection or drift. As human height is polygenic, partly influenced by common, ancient genetic variation, a recent change in height could occur through effects on pre-existing variation at a large number of loci in the genome. Signals of such polygenic adaptation have been difficult to detect, but, given genome-wide data on the effects of common variants on height, we hypothesized that we might be able to observe a signal as a systematic increase in allele frequency (AF) of the height-increasing allele in a Northern European (NEur) compared with a Southern European (SEur) population. We examined height-associated SNPs for which we had access to directly measured AF data in >200 individuals from NEur and SEur, focusing first on 180 loci previously identified by the GIANT consortium . The height-increasing alleles at these loci had significantly higher AF in NEur than in SEur (average AF NEur-SEur = 0.012, $p<4.3\times10^{-4}$, $p<0.0056$ compared with random frequency-matched SNPs). The increased AF in NEur of height-increasing alleles persisted through much of the genome, suggesting that many more height-associated variants beyond these 180 loci contribute to the height difference between NEur and SEur. The alleles with higher AF in NEur were, as a group, associated with increased height in a family-based sample of 1,762 sibships, so stratification does not account for our results. We modeled the combined effects of drift and selection, and the genome-wide AF data were much more consistent with a model incorporating selection than with a model of genetic drift alone (likelihood ratio $p<10^{-100}$). Our results also suggest that individual selection coefficients might be in the order of 10^{-5}. In summary, our study indicates that the height gradient seen in Europe is at least partially attributable to AF differences at height-associated variants, including potentially many common variants with quite small effects, and is not likely due to the effects of random drift. This finding suggests that there may have been selection in Europe on many variants associated with height, representing one of the first examples of widespread selection on standing genetic variation that underlies a human polygenic trait.

Shared signatures of selection in the genomes of chimpanzees and humans. *E.M. Leffler[1], S. Pfeifer[2], L. Ségurel[1], A. Auton[3], O. Venn[3], R. Bontrop[4], R. Bowden[2], J. Broxholme[3], A. Fledel-Alon[1], R. Hernandez[5], P. Humburg[3], Z. Iqbal[3], G. Lunter[3], J. Maller[3], S.C. Melton[1], T. Street[2], A. Venkat[1], S. Myers[2], P. Donnelly[2,3], G. McVean[2,3], M. Przeworski[1,6].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Oxford, Oxford, UK; 3) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) Biomedical Primate Research Centre, Rijswijk, The Netherlands; 5) Department of Bioengineering and Therapeutic Sciences, University of California - San Francisco, San Francisco, CA; 6) Department of Ecology and Evolution, University of Chicago, Chicago, IL.

Since the chimpanzee and human lineages split 5-7 million years ago, genetic changes on each lineage have led to differences between the two species today. The proportion of changes that were adaptive, the modes of selection that were important, and how these differ for humans and chimpanzees are of great interest for understanding how modern humans and our closest relatives evolved. Until recently, data for comparative, genome-wide population analyses was limited, particularly for chimpanzee. We have sequenced 10 western chimpanzees (Pan troglodytes verus) to 8-10X coverage as part of the PanMap project and combined these with 1000 Genomes low coverage data to assess evidence and identify candidates for positive selection in both humans and chimpanzees. We used a McDonald-Kreitman based approach to test whether similar groups of genes show evidence for high rates of non-synonymous substitution on both lineages. We also used the joint polymorphism data to look for long-term balancing selection, of which there are currently very few known examples. To this end, we focused on single nucleotide polymorphisms (SNPs) present in both species. We find that approximately 0.8% of the chimpanzee SNPs are shared, in excess of what is expected by chance after accounting for variation in the mutation rate. Moreover, we identify specific regions with several shared polymorphic sites in linkage disequilibrium, suggestive of long-term balancing selection.

Population specific susceptibility to Crohn's disease and signals of natural selection on standing variation. *S. Nakagome[1], S. Mano[1,2], L. Kozlowski[3], J.M. Bujnicki[3,4], H. Shibata[5], Y. Fukumaki[5], J.R. Kidd[6], K.K. Kidd[6], S. Kawamura[7], H. Oota[8].* 1) The Institute of Statistical Mathematics, Tokyo, Japan; 2) Japan Sciece and Technology Agency, Saitama, Japan; 3) International Institute of Molecular and Cell Biology in Warsaw, Warsaw, Poland; 4) Institute of Molecular Biology and Biotechnology, Faculty of Biology, Adam Mickiewicz University, Poznan, Poland; 5) Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 6) Yale Uiversity School of Medicine, New Haven, CT; 7) Graduate School of Frontier Sciences, University of Tokyo, Chiba, Japan; 8) Kitasato University School of Medicine, Kanagawa, Japan.

It is generally thought that population specific susceptibility of complex diseases is attributed to geographic differences in the risk allele frequency. The risk alleles are widespread in diverse populations, which can be primarily explained by random genetic drift through demographic history, and rarely by natural selection. Elucidating the evolutionary history of complex disease alleles is, therefore, of fundamental importance for understanding the ethnic-differences in the disease susceptibility. We focus on Crohn's disease (CD) as a model of evolutionary study of complex disease alleles. Recent genome-wide association studies and classical linkage analyses have identified more than 70 susceptible genomic regions to CD in Europeans, while few of them have been reproduced in non-European populations. Our population genetics analysis on the eight European-specific susceptibility genes (*NOD2*, *IL23R*, *TNFSF15*, *ATG16L1*, *SLC22A4*, *SLC22A5*, *IRGM*, 10q21) using the HapMap data shows that, only in the *NOD2* locus, the CD-risk alleles are linked with a specific haplotype to CEU whose frequency is significantly higher compared with those of the entire genome regions. We subsequently examined nine global populations including 192 Africans, 268 Europeans, and 95 East Asians, and found that the *NOD2*-risk alleles inducing serious conformational and functional changes spread over Europeans. The risk alleles hitchhiked with a high-frequency haplotype (H1) exclusive to Europeans, and the time to most recent common ancestor (TMRCA) of the H1 predated the human dispersal out of Africa. Further, the H1 is likely to have experienced negative selection: the haplotype has almost become extinct in Africans and has not been affected by historical European expansion. Nevertheless, the H1 has survived only in European populations, suggesting the haplotype is advantageous to the populations. Here we propose a hypothesis that the CD-risk alleles have been maintained by natural selection from the standing variation whereby the deleterious haplotype of *NOD2* can become advantageous in diploid individuals because of heterozygote advantage and/or inter-genic interactions.

479T

Metabolic insight into mechanisms of high-altitude adaptation in Tibetans. *T.S. Simonson[1], R.L. Ge[2], R.C. Cooksey[1], C.D. Huff[2], T.N. Wuran[1], J. Xing[2], G. Qin[1], D.J. Witherspoon[2], B. ZhengZhong[1], J.T. Prchal[1], D.M. McClain[1], L.B. Jorde[1].* 1) Departments of Human Genetics, Hematology, and the Division of Endocrinology, Metabolism, and Diabetes, University of Utah, Salt Lake City, UT; 2) Qinghai University Medical School, Xining, Qinghai, People's Republic of China.

Recent studies have used various different analytical methods to identify genes targeted by natural selection in high-altitude populations located throughout the Tibetan Plateau. Despite differences in analytic strategies and population samples, several of the same hypoxia-related genes were identified in multiple studies. The mechanisms that afford adaptation to high-altitude hypoxia, however, remain unclear. By employing the same analytic strategies (iHS and XP-EHH statistics) used in our previous study of Tibetan high-altitude adaptation, we have identified common targets of natural selection in a second linguistically distinct Tibetan population from a different region of the Tibetan Plateau. Our analysis provides evidence for positive selection in each population at the $p < 0.01$ significance level for *EPAS1*, *EGLN1*, *HMOX2*, and *CYP17A1*. Three genes have previously been shown to be associated hemoglobin (Hb) levels in Tibetans (*EPAS1*, *EGLN1*, and *PPARA*), although it is unclear whether these associations reflect direct selection on Hb level or are consequences of selection on other advantageous traits. We considered these replicated selection targets for analysis with additional, potentially adaptive metabolic phenotypes that may provide insight into mechanisms of high-altitude adaptation. Considering the strong metabolic demands imposed by hypoxia, we hypothesized that a shift in fuel preference from fatty acid oxidation to glucose oxidation and glycolysis would provide adaptation to decreased oxygen availability at high altitude. Measurements of serum metabolites collected from these Tibetan groups are consistent with this hypothesis: the previously identified *EPAS1* and *PPARA* haplotypes are associated with increased serum lactate ($p = 0.0007$) and triglyceride ($p < 0.04$) levels, respectively. Although further studies are required to assess the molecular mechanisms underlying these patterns, these changes suggest that genetic adaptation to high altitude involves alteration in energy utilization pathways.

Accelerated evolution of brain specific microRNAs in Homo sapiens. *S. Chakraborty[1], MM. Ali[1], R. Chakravorty[2].* 1) Department of Biochem and Molelular Biology, University of Dhaka, Dhaka-1000, Bangladesh; 2) Department of EEE, University of Melbourne, National ICT Australia, Victoria 3010, Australia.

The hallmark of human evolution encompasses the dramatic increase in brain size and complexity. This prominent phenotypic evolution of human brain has been correlated with the accelerated positive selection of the genes linked to nervous system development. In this study we focused on the evolution the microRNAs-the widespread post transcriptional regulators of gene expression that are defined by their unique biogenesis, which involves their precise excision from the stem of a fold-back precursor. The intricate interplays of mature miRNAs and their target genes are indispensable in human brain development. This study involves systematic mining of various miRNA databases, analysis of gene expression profiles and sequence divergence of miRNAs with known conserved functions across primates and rodents. Specifically we studied the evolutionary patterns at different functional regions of a large number of precursor miRNA sequences, extracted from the miRBase. Our analysis revealed primate brain specific miRNAs bear traces of relatively higher rate of evolution compared to rodents while among the primates the rapid evolutionary pattern is salient in the case of human compared to other primates. Moreover our findings indicated that brain specific pre-miRNA in primates have evolved at a faster rate than those that are not expressed in brain. These results suggest the distinct patterns of sequence divergence that may exist within the human brain specific precursor miRNA sequences, possibly reflecting the evolution of structural determinants involved in miRNA processing and expression in human brain. These results also signifies the co-evolution of miRNAs and their brain specific target genes since the genes involved in the brain development have also undergone an accelerated evolution and serve as targets of miRNAs.

481T

Association of the European Lactase Persistence variant (LCT-13910 C>T polymorphism) with obesity in the Canary Islands by Mendelian randomization. *R. ÁLMON[1], E.E. AlVAREZ-LEON[2], LI. SERRA-MAJEM[2].* 1) Örebro University, Family Medicine Research Centre, School of Health and Medical Sciences, Örebro, Sweden; 2) Preventive Medicine Service. Canary Health Service; and Department of Clinical Sciences, Faculty of Health Sciences, University of Las Palmas de Gran Canaria. Canary Islands, Spain.

European lactose tolerance genotype (LCT -13910 C>T) has been positively associated to body mass indexes (BMI) in a meta-analysis of 31,720 individuals of northern and middle European descent. A strong association of LP (lactase persistence) with BMI and obesity has also been traced in a Spanish Mediterranean population. The T-allele of the LCT-13910 C>T has been subject to a strong positive selection in recent history enabling an unrestricted diet concerning milk and milk products, and stands proxy for the lifetime exposure pattern, milk intake, that may increase the susceptibility to develop obesity. The aim of this study was to analyze a potential association of LP compared to LNP (lactase non-persistence) with BMI (kg/m2) in inhabitants of the Canary Islands in Spain using Mendelian randomization (MR). A representative, random sample of adults belonging to the Canary Islands Nutrition Survey (ENCA) in Spain, aged 18-75 years (n = 551), was genotyped for the LCT - 13910 C>T polymorphism. Milk consumption was assessed by a validated questionnaire. Anthropometric variables were directly measured. LP individuals were significantly more obese than LNP subjects ($\chi 2=10.59$; $p<0.005$). LP showed in a multivariate linear regression analysis a positive association to BMI compared to LNP, () =0.96; 95% CI: 0.08-1.85, $p<0.033$). In a multinomial logistic regression analysis normal range weight LP subjects showed an odds ratio (OR) for obesity of 2.41; 95%CI 1.39-418, ($p=0.002$) compared to LNP. Overweight LP subjects showed an OR of 2.32; 95%CI 1.39-3.88; ($p=0.001$) to develop obesity compared to LNP. The T-13910 of the allele LCT-13910 C>T polymorphism is positively associated to BMI. LP is positively associated with obesity in this population. In nutritionally replete countries and high average life expectancy LP status might increase the susceptibility to develop obesity.

482T

Differential selection pressures drive allelic variation of the *Toll-like receptor-2* (*TLR2*) locus in two closely related genus *Macaca* species, *M. mulatta* and *M. fuscata*. *M. Yasunami[1], A. Takaki[1], A. Yamazaki[1], T. Maekawa[1], H. Shibata[1], K. Hirayama[1], A. Kimura[2], H. Hirai[3].* 1) Inst Trop Med, Nagasaki Univ, Nagasaki, Japan; 2) Med Res Inst, Tokyo Med Den Univ, Tokyo, Japan; 3) Primate Res Inst, Kyoto Univ, Inuyama, Japan.

Macaca species of old world monkeys share the last common ancestor of 25 million years ago (Mya) with human and hominoids, and have been widely used for biomedical research as good model organisms mimicking humans in many aspects. Divergent speciation of different genus *Macaca* species with distinct geographic distribution in Asia is estimated at 0.9 - 2.5 Mya, which is similar to the settlement of modern human populations out of Africa. *Toll-like receptor 2* (*TLR2*) plays an important role in the recognition of molecular pattern derived from a variety of pathogenic microbes, such as bacterial lipopeptides, and polymorphism of human *TLR2* locus may explain individual susceptibility to certain infectious diseases to some extent. In the present study, we compared polymorphisms of *TLR2* locus in two closely related old world monkey species, rhesus monkey (*Macaca mulatta, Mamu*) and Japanese monkey (*M. fuscata, Mafu*). By nucleotide sequencing of the coding exon of *TLR2* gene from 21 *Mamu* and 35 *Mafu* individuals, we could assign 17 haplotype combinations of 17 coding SNPs of ten non-synonymous and seven synonymous substitutions. A non-synonymous substitution at codon position 326 appeared to be differentially fixed in each species, asparagine for *Mamu* whereas tyrosine for *Mafu*, and may contribute to certain functional properties which were predicted by computational chemistry, because it locates in the region contributing to ligand binding and interaction with dimerization partner of TLR2-TLR1 heterodimeric complex. Although *TLR2* alleles have diverged to similar extent in both species, they have evolved in significantly different ways; *TLR2* of *Mafu* has undergone purifying selection, while the membrane-proximal part of the extracellular domain of *Mamu TLR2* exhibits higher rates of non-synonymous substitutions, indicating a trace of Darwinian positive selection.

483T

Genomic Variation in a Brazilian Population. *G. Ananina[1], J.P.C. Vasconcellos[2], R. Vicentini[1], F. Menaa[1], F.F. Costa[3], M.B. de Melo[1].* 1) Center for Molecular Biology and Genetic Engineering (CBMEG), UNICAMP, Campinas, São Paulo, Brazil; 2) Department of Ophtalmology and Otorhinolaryngology (HEMOCENTRO), UNICAMP, Campinas, São Paulo, Brazil; 3) Department of Hematology and Hemotherapy (HEMOCENTRO), UNICAMP, Campinas, São, Paulo, Brazil.

Genomic studies on the population level have both theoretic and applied importance. They may contribute to our knowledge on anthropological and genetic history of a population, and, may also be crucial for pharmacological and public health applications. Genetic studies using microsatellites, mtDNA and some nuclear markers appoint that Brazilian population is highly admixed and this admixture occurred quite recently. Altogether, studies of Brazilian population on the genomic level are at the very beginning. We present genomewide analysis of the first cohort of 22 Brazilian individuals (BR) from the São Paulo State. Recruitment methods and blood collection were approved by the Ethic Committee of FCM-UNICAMP (Campinas, SP, Brazil). Genotyping was done with Affymetrix® Genome-Wide Human SNP 6.0 Array (Affymetrix Inc., CA, USA) following manufacturer's recommendations. For SNPs markers, genotype calls were obtained using the birdseed algorithm (v2.0) implemented in the Affymetrix Genotyping Console software. Samples passing the recommended control values (contrast QC > 0.4; median absolute intensity pairwise differences MAPD < 0.3) were analyzed for CNV. Toronto CNV map was used as the default map for comparison. Simultaneously, the data of three populations of HapMap270 Project (CEU, YRI, JPT, 20 unrelated individuals of each) were processed. Population stratification was accessed by statistical methods implemented in EIGENSOFT (v 3.0) software package. F_{ST} values of pairwise population differentiation, based on SNPs markers, were: 0.021 (BR-CEU); 0.096 (BR-YRI); 0.101 (BR-JPT). Mean number of autossomic copy number variants (CNVs) longer than 1kb was about 97 per individual. The overall mean size of the losses was 26.6 kbp, ranging from 1 to 3,144 kpb, while the overall mean size of the gains was about 86 kbp (1-23,536 kbp). In our samples, we found one variant (520kbp) not present in the reference map; but has been found in one individual of Yorubian (African) origin (McKernan et al. 2009). Furthermore, we observed 25 de novo CNVs ranging from 100 to 500 kbp (6 gains, 6 losses) and 142 smaller variants (50-100 kpb; 105 gains, 37 losses). Actually, we are increasing the sample size, the number of worldwide populations, and validating the found CNVs. We expect that our results will contribute to the better knowledge of genetic variation in the Brazilian population, one of the biggest on the South American continent. **Financial support: CNPq, FAPESP**.

Mitochondrial DNA (mtDNA) heterogeneity within and among East African Bantu ethnic groups and their complex evolutionary histories. *K. Batai[1], C.M. Kusimba[2], E. Leenheer[1], S.R. Williams[1].* 1) Department of Anthropology, University of Illinois at Chicago, Chicago, IL; 2) Department of Anthropology, Field Museum, Chicago, IL.

Many linguists, historians, and archaeologists believe that Bantu-speaking farmers bearing iron technology carried their language with them as they spread relatively rapidly from central Africa throughout sub-Saharan Africa around 2,000-3,000 years ago. The genetic homogeneity found among Bantu-speaking people today is one of the arguments used to support a rapid expansion model. The nature of interactions between Bantu migrants and other people already living in these areas, however, is still debated.

The goal of this study was to examine mtDNA variation in two Bantu ethnic groups, the Taita and Mijikenda, on the northeastern periphery of the Bantu expansion in east Africa where the greatest genetic, cultural, and linguistic variation exists, in order to examine the nature of Bantu and non-Bantu interactions. We sequenced mtDNA HVRI of 474 individuals from three Taita and nine Mijikenda tribes and compared them with the mtDNA variation in other Bantu and non-Bantu populations.

Our results confirm that the east African Bantu populations are comparatively more heterogeneous than other Bantu populations. The east African Bantus spread between non-Bantu east Africans and the central African Bantus on the multidimensional scaling plot. When the Mijikenda and the Taita were compared with each other, we observed a different pattern. Although Bantu-speaking populations are generally genetically less diverse than other sub-Saharan populations, the Taita are genetically very diverse. They show little internal differentiation and have mtDNA variation similar to mtDNA variation observed in the Turkana, Kenyan Nilo-Saharan speakers. The Mijikenda are genetically less diverse than the Taita and show significant internal tribal differentiation. Their mtDNA variation is similar to the central African Bantu mtDNA variation. The estimated migration rates among the east African Bantus and between east African Bantus and the non-Bantu east Africans are high. These results emphasize that individual east African Bantu populations have unique histories of interactions with non-Bantu speaking populations. These findings have important implications for genetic epidemiological studies because the high levels of population differentiation in Africa may complicate association studies.

Estimating Genetic Ancestry Using a 5-Population Model. *M. Bauchet, J.J. Bryan, A.B. Carter, V.L. Vance, H.Y. Chen, C.L. Mouritsen.* Research and Development, Sorenson Genomics, Salt Lake City, UT.

The estimation of an individual's genetic ancestry can be an important tool with many applications. The pharmaceutical and personal care product industries can greatly benefit from qualitatively stratifying study participants when their products may have potential varied effects on a consumer, relative to genetics and ancestry. In the field of Forensics, genetic ancestry estimations may provide additional information about DNA evidence collected at a crime scene, when little or no other evidence is available. Genetic ancestry can also be informative to professional genealogists and satisfy one's curiosity about their genetic ancestry as a hint to their ethno-geographic background. We have designed a novel methodology of estimating human genetic ancestry against a model of 5 genetically distinct, putative parental populations. The populations and the reference samples representing them are as follows: Western European (HapMap CEU, Northwest European descent residing in Utah), West Sub-Saharan African (HapMap YRI, Yoruba from Ibadan, Nigeria), East Asian (HapMap CHB from Beijing, China), Indigenous American (Compilation of samples identified as being from populations indigenous to North, Central, and South America including Maya, Pima, Karitiana, Surui, and Arawak descent), and the India Subcontinent (HapMap GIR, Gujarati Indian descent residing in Houston, TX). Our method uses 190 SNP Ancestry Informative Markers (AIMs) chosen from their scored ability to specifically differentiate between the 5 reference populations using Principal Component Analysis (PCA) as the comparative analysis tool and includes some markers identified as informative in previous genetic ancestry estimation publications. Using the program FRAPPE and uniquely designed algorithms, the method compares an unknown individual sample to at least a hundred randomly selected subsets of individuals from the reference populations. Background interference is calculated simultaneously and is used to estimate confidence intervals based on a calibration that was effected using thousands of worldwide individuals. We also evaluated hundreds of individuals of known origin different from any of the reference populations, giving us an indication of ancestry profiles for people who do not match exactly our model. We show that our method and test offer a comprehensive estimate of an individual's genetic ancestry.

486T

Changes in site frequency spectrum due to recent genealogic connections in the Quebec population. *C. Bherer[1], MH. Roy-Gagnon[1,2], L. Excoffier[1,3,4], H. Vézina[5], D. Labuda[1,6].* 1) Sainte-Justine Hospital Research Center, Université de Montréal, Montréal, Québec, Canada; 2) Dept. of Social and Preventive Medicine, Université de Montreal, QC, Canada; 3) CMPG, Institute of Ecology and Evolution, University of Bern 6, Baltzerstrasse, CH-3012 Bern, Switzerland; 4) Swiss Institute of Bioinformatics, 1015 Lausanne, Switzerland; 5) BALSAC Project, Université du Québec à Chicoutimi, QC, Canada; 6) Dept. of Pediatrics, Université de Montreal, QC, Canada.

Deep individual genealogies recapitulate the recent and potentially complex demographic history of populations. Here, we use extensive and unique information on the genealogy of the Quebec population to study the effect of recent demographic history on its gene pool by performing genetic simulations conditional on genealogical structure. By using both genomic and genealogical data, we have recently shown that the regional populations of Quebec are stratified and thus exhibit allele frequency differences. In this study, we investigate how the specific demographic history of Quebec regional populations shaped their site frequency spectra. We used a sample of 2,221 individuals representative of Quebec population, which was then partitioned into eight subsamples corresponding to specific geographic regions. These individuals belong to a 153,447 ancestors genealogy spanning on average 9.3 generations back to the immigrant founders and reconstructed using the BALSAC database. Allele dropping simulations of the full spectrum revealed no distortion of the allele frequency spectra between the founders and the regional samples, nor between regions for frequency classes larger than 2%. However, we observed a general loss of rarer alleles in contemporary samples, which was more pronounced in eastern regions. The joint site frequency spectra computed for all pairs of regions were very similar, thus suggesting that the differences between regions could be explained by frequency changes occurring at specific loci. Indeed, assuming a given allele frequency among the founders, we observed a larger variance in the extent of drift for the eastern regions of Quebec. Backward coalescent-like simulations conditioned on the genealogical structure revealed highly variable distributions of the number of founder's genes surviving in their contemporary descendants. For a given locus, a majority of the founders' alleles usually goes extinct and a small minority expands in the population. All these features might explain the elevated prevalence and regional distribution of rare Mendelian diseases in the Quebec population. Our findings have implications for better design of epidemiological studies conducted in the population of Quebec.

487T

The occurence of factor V Leiden in Roma (Gypsy) and majority population in Slovakia. *A. Bozikova[1, 2], I. Bernasovsky[1, 2], D. Gabrikova[1, 2], R. Behulova[2], I. Boronova[1, 2].* 1) Excellence Centre of Animal and Human Ecology, Faculty of Humanities and Natural Sciences, University of Prešov, Prešov, Slovakia; 2) Department of Biology, Faculty of Humanities and Natural Sciences, University of Prešov, Prešov, Slovakia.

The most common hereditary form of thrombophilia in the Caucasian population is factor V Leiden (G1691A), causing APC resistency. The prevalence of this mutation varies widely in healthy Caucasian population. The aim of our study was to determine the frequency of factor V Leiden mutation in Roma and majority population from Eastern Slovakia. We analyzed 540 asymptomatic individuals (269 Slovak majority individuals and 271 Slovak Romanies) by real-time PCR method. The occurrence of factor V Leiden in Roma population was significantly higher than in majority population, detected allele frequencies were 2.97% vs. 6.64% (p=0.0049) in majority and Roma population respectively. The allele frequency of factor V Leiden in Roma population from Eastern Slovakia is one of the highest in Europe. Our results confirm an uneven geographical and ethnic distribution of factor V Leiden.

488T

An admixture simulation program for use in validating genetic ancestry estimation systems. *J.J. Bryan, V.L. Vance, M. Bauchet, C.L. Mouritsen.* Research and Development, Sorenson Genomics, Salt Lake City, UT.

A key area of interest in studying population genetics is detection and estimation of genetic admixture in offspring from parents with mixed ancestry. Current methods used to estimate admixture vary in the type and number of genetic markers analyzed as well as the statistical algorithms used in the calculations. The goal of each method is to measure the genetic affinity of an individual to representative populations, generally reported in terms of relative percentages. It is important to determine the ability of the method to accurately estimate levels of population admixture through controlled experiments, testing as many permutations as possible. Identifying and testing subjects with known levels of admixture for specific populations can be very costly and time consuming. In reality, finding and testing samples to represent all possible admixture ratios, even between just a few populations, can be extremely difficult. To address this problem, we have designed a program wherein we may generate and control for, targeted levels of admixture between the population reference samples in order to validate systems for estimating genetic ancestry. The simulation algorithm is capable of randomly generating innumerable offspring, each with unique genotypes, selected from virtual unions of up to 8 parental (P1) individuals. This program allows one to control admixture contributions from parental populations in increments of 12.5% in the 3rd filial (F3) generation. P1 samples are randomly chosen and paired from an established parental genotype database to fulfill desired admixture ratios for a final resultant F3 generation individual. At each union in a generation, 1 allele for every bi-allelic marker in each individual is randomly selected to contribute to the next generation. By using this new program, 10,000 admixed simulations were generated from 383 real samples used in the P1 generation. The P1 samples were selected from 5 putative parental populations and were compared in a variety of combinations and ratios in increments as low as 12.5% with multiple unique offspring generated from each simulated mating. Reproducibility was tested using different P1 samples for each admixture combination and ratio. This simulation program was developed to facilitate the validation of a 190 SNP, human genetic ancestry estimation algorithm. The program allowed for well-controlled experimentation and significant savings in time and expenses.

489T

Estimating heterozygosity rates of low-coverage sequence genomes by leveraging joint spectra. *K. Bryc[1], N. Patterson[2], D. Reich[1,2].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Broad Institute of Harvard and MIT, Cambridge, MA.

Heterozygosity, or the fraction of nucleotides within an individual that differ between their two parental chromosomes, can be informative about population demographic history and natural selection. In practice, estimating heterozygosity from sequence data is confounded by sequencing errors and lack of power to detect SNPs. Obtaining an unbiased estimate of heterozygosity is especially difficult for ancient genomes (such as Neandertal or Denisova) where the sequences are expected to have a high error rate, or with low-coverage sequence data where there is low power to detect heterozygous SNPs.

Here, we present a method that leverages the genome-wide joint information across sequence reads from a panel of individuals, to estimate the heterozygosity of an individual of interest. We assume independence between the observed alleles of the individual at a particular locus and the combination of observed alleles in a panel of individuals, conditional on the true underlying genotype. We then apply an Expectation-Maximization (EM) algorithm to estimate the most likely distribution of counts across the unknown underlying genotypic states, from which we obtain an estimate of the proportion of loci that are heterozygous in that individual. An advantage of this method is that it returns an unbiased and accurate estimate of heterozygosity even when the individual has low sequence coverage (as low as 2X on average). Our method learns the joint spectrum directly from the sequence read data without requiring an explicit assumption of the demographic relationships among the analyzed samples. Since it can utilize panels assembled from individuals from any population or set of populations and it does not require genotype calls, our method is robust to any inaccuracies that might stem from demographic modeling and from sequence error processes.

We apply our EM method to simulated data of 1Gb of sequence at 2X, 5X, 10X, and 20X coverage, and find that our method performs well at estimating the true heterozygosity even when the sequence error rate is extreme and coverage is low. We also report results from subsampling of real data from NA12878, a deeply sequenced European American individual, and compare the estimates of heterozygosity for the low-coverage compared with the high-coverage data.

Gnocchi, IRCCS, 20148 Milano, Italy.

Contrasting results have been reported concerning the association of a splice-site polymorphism (rs10774671) in OAS1 with multiple sclerosis (MS). We analysed two OAS1 regions encompassing alternatively spliced exons. While the region carrying the splice-site variant is neutrally evolving, a signature of long-standing balancing selection was observed across an alternative exon 7. Analysis of variants in this exon identified an insertion/deletion polymorphism (rs11352835, A/-) that originates predicted products with distinct C-termini. This variant is located along the major branch of the haplotype genealogy, suggesting that it may represent the selection target. A case/control study for MS indicated that rs11352835 is associated with disease susceptibility (for an allelic model with the deleted allele predisposing to MS, OR: 1.27, 95% CI: 1.072-1.513, p=0.010). No association was found between rs10774671 and MS. As the two SNPs are in linkage disequilibrium in Europeans, the previously reported association between rs10774671 and MS susceptibility might be driven by rs11352835, possibly explaining the contrasting results previously observed for the splice-site polymorphism. Thus, we describe a novel susceptibility variant for MS in OAS1 and show that population genetic analyses can be instrumental to the identification of selection targets and, consequently, of functional polymorphisms with an effect on phenotypic traits.

The development of interactive maps to further describe Y and mtDNA haplogroups— A new educational tool. *H.Y. Chen, C.L. Mouritson, A.B. Carter.* Research and development, Sorenson Genomics, Salt Lake City, UT.

Background: Mitochondrial DNA and Y chromosome haplogroup maps can provide visual depictions of the geographical distributions of known haplogroups. 14 peer-reviewed publications were reviewed and a database was developed of 109 different populations each being evaluated for their proportional makeup from any of 18 primary Y haplogroups. Latitude and longitude coordinates for each population were determined from the original location of the samples used in each publication. In the database, haplogroup percentages were assigned to a relevant global geographic coordinate using the Boundary Map feature of Mapview software. Through the global coordinates the haplogroups could be populated on maps with geographical associations. Ultimately, 540 data points were used to create 26 Y haplogroup maps (18 world gradient maps, 7 continental pie maps and 1 world pie map). Utilizing the same method, a database of 96 different mtDNA populations was constructed, each being evaluated for 27 primary mtDNA haplogroups according to 23 peer-reviewed articles. This resulted in 790 data points used in the creation of 34 mtDNA haplogroup maps (27 world gradient maps, 6 sub-continental pie maps and 1 world pie map) **Validation**: Data within the newly constructed database were verified against the Haplogroup specifications defined by YCC (Y Chromosome Consortium) for Y haplogroups and PhyloTree for mtDNA haplogroups. **Map descriptions**: a) Gradient maps were developed to exhibit the approximate geographical distribution of a specific haplogroup using representative color intensity; b) Continental/sub-continental pie maps were created to show the percent makeup of each haplogroup in association with other haplogroups for a specific region; c) World pie maps were created to demonstrate the percent makeup of each haplogroup in association with other haplogroups for the entire world. **Features**: Special features were designed to allow viewers to navigate the maps without the need of returning to the home map. 1) Clicking map graphics to view corresponding gradient maps; 2) Clicking the title or space between letters allows one to observe the world pie map; 3) When viewing the world pie map, users can select continental/sub-continental areas to view continental/sub-continental pie maps. **Conclusion**: This educational tool provides 60 data-dependent maps of Y and mtDNA haplogroups with convenient navigation features.

Inferring admixture proportions and recent admixture events. *D.J.M. Crouch, M.E. Weale.* King's College London, London, United Kingdom.

The identification of admixture proportions for forensic DNA samples has recently had some success in criminal investigations (Phillips et al. (2009), PLoS ONE 4: 8). If researchers were able to differentiate first generation admixture events, this might shed new light on the identity of samples. We describe a new method, based on maximum likelihood estimation, for simultaneously inferring admixture proportions in a SNP-genotyped individual, and the genetic divergence of their unobserved parents with respect to the general population, based on allele frequencies from reference groups. This is achieved by examining the reduction in homozygosity that one expects to see after first generation admixture. We use simulated individuals, under various parental admixture scenarios, to validate the method. The simulations showed that, with 80,000 independent SNPs, most parental admixtures could be accurately identified at the intercontinental level of divergence (Fst>0.1), although large effects such as pure first generation admixture can be predicted for more closely related populations (Fst>0.02). These results take into account the sampling errors in the reference allele frequencies.

493T

Genomic stability of B lymphoblastoid cell lines established from the Sonoda-Tajima Cell Collection, the collection of South American indigenous populations. *I. Danjoh, K. Saijo, M. Nagayoshi, Y. Nakamura.* Cell Engineering Division, RIKEN BioResouce Center, Tsukuba, Ibaraki, Japan.

<Objectives>

The Sonoda-Tajima Cell Collection includes peripheral blood mononuclear cell (PBMNC) samples obtained from over 3,500 individuals belonging to a range of ethnic minority groups across the world, in particular from South America. Drs. Sonoda and Tajima, a professor emeritus at Kagoshima University in Japan and the director of Aichi Cancer Center Institute in Japan, had spent nearly 30 years to collect the samples, and the collection is made all the more valuable by the fact that some of these ethnic populations have since died out, and thus it will be impossible to prepare a similar cell collection again.

The collection was donated to our institute, a public cell bank in Japan, in 2005 by Dr. Sonoda to make it available to researchers throughout the world. As the original PBMNC collection would obviously have been rapidly exhausted if used directly, we, therefore, have immortalized 533 samples with the Epstein-Barr Virus and established B lymphoblastoid cell lines (B-LCLs).

As there is continuing controversy over whether the B-LCL genome is stably maintained, we performed an array comparative genomic hybridization (array CGH) analysis to confirm the genomic stability of the cell lines.

<Methods>

We first checked karyotypes by conventional G-band staining method, and then analyzed detailed genome structures by array CGH with 2x400K microarray (Agilent). PBMNCs prepared from the same individuals were used as parental somatic cell controls for array CGH. B-LCLs at early stage (approx. passage 10) or at progressed stage (approx. passage 30) after establishment, or FACS-sorted B lymphocyte population were used as the sample for array CGH, and monitored the structural alteration of genomes during culture period of B-LCLs.

<Results and Conclusion>

There were no detectable aberrations of karyotypes analyzed by G-band staining of chromosome. Although array CGH analysis showed some alteration in B-LCLs at early stage, most of them were also detected in B lymphocyte population, which shows they were not introduced during establishment of B-LCLs. In addition, array CGH data suggested the genomic rearrangements occurred within somatic cells. In progressed passage of B-LCLs, genome structure was well-maintained but clonal expansion was observed in some cases in comparison to early stage B-LCLs.

Our data indicate the stable genome structure of B-LCLs, especially at early stage, to be used for genetic analysis.

494T

Sampling scheme as a determinant of the major axis of genetic variation in principal components analysis. *M. DeGiorgio[1], N.A. Rosenberg[1,2].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics and the Life Sciences Institute, University of Michigan, Ann Arbor, MI.

Principal component (PC) maps, which plot the values of a given PC estimated on the basis of allele frequency variation at the geographic sampling locations of the set of populations analyzed, have commonly been used to investigate the properties of past range expansions. Some studies have argued that the axis of greatest variation (i.e., the first PC) is parallel to the axis of expansion. In contrast, others have identified an opposite pattern in which the axis of greatest variation is perpendicular to the axis of expansion. In this study, we seek to resolve this disagreement by investigating the effect of sampling scheme on the direction of the axis of greatest variation under a two-dimensional range expansion model. From simulated datasets generated using each of two different schemes for the sampling of populations under the range expansion model, we create PC maps for the first PC. We find that depending on the sampling scheme, the axis of greatest variation can be either parallel or perpendicular to the axis of a range expansion. We provide explanations for this result in terms of within- and between-population coalescence times.

495T

Genomic insights into recent human adaptations driven by selection on standing variation. *L.S. Emery, J.M. Akey.* Dept. of Genome Sciences, University of Washington, Seattle, WA.

Recent studies have demonstrated that classic selective sweeps were relatively rare in recent human history. Instead, emergent selective pressures due to a changing environment could act on pre-existing variation. This model, called selection from standing variation, results in different genomic signatures than that of the classic selective sweep. While statistical tests to detect classic selective sweeps are well-established, it remains difficult to identify the signatures of selection from standing variation. Here we develop, test, and optimize several statistics to detect and fine-scale map recent selection acting on standing variation in human populations. We extensively validate the power and operating characteristics of these statistics thorough coalescent simulations over a broad range of demographic parameters and selective models. Finally, we apply our statistics to whole-genome sequences from the 1,000 Genomes Project and Complete Genomics data sets. These analyses provide new insights into the molecular substrates of positive selection acting on standing variation and have important implications for human health.

SCN1B sequence variations in Iranian Patients with Epilepsy. *B. Sedaghatikhayat[1], M. Moghaddasi[2], M. Houshmand[5], S. Zeinali[3], S.H. Tonekaboni[4], M.S. Fallah[3], M. Mamarabadi[2], A. Ebrahimi[1].* 1) Parseh Medica Genetics Center, Tehran, Tehran, Iran; 2) Rasool Akram Hospital, Tehran University of Medical Sciences, Tehran, Iran; 3) Kawsar Human Genetics Research Center, KAWSAR Genomics & Biotech Center, Tehran, Iran; 4) Shahid Beheshti University of Medical Sciences, Tehran, Iran; 5) National Institute of Genetic Engineering and Biotechnology (NIGEB), Tehran - Karaj Highway, Tehran, Iran.

Epilepsy is a common chronic neurological disorder that is characterized by recurrent unprovoked seizures. Molecular studies of candidate genes can help us to define a correct differential diagnosis. So we studied SCN1B gene in Iranian patients with Idiopathic Epilepsy includes Febrile Seizure, Generalized Epilepsy with Febrile Seizures (GEFS+) or Dravet syndrome, diagnosed clinically, to explain genotype-phenotype correlation. Materials and Method: We screened 34 selected epileptic unrelated Iranian probands for all coding regions of SCN1B by PCR amplification and direct Sequencing. All families and probands were previously screened for SCN1A and mtDNA mutations. Results: PCR amplification of whole coding regions and splicing sites of SCN1B followed by direct sequencing revealed two novel sequence variations in patients (p.248 R>S, p.210 L>P) which did not detected in the healthy normal family members. Conclusions: According to final results it seems that these two novels SCN1B variations are not causative mutations in epileptic patients' but they can act as genetic predisposition factors in epileptic phenotypes which introduce a susceptibility especially in response to antiepileptic drugs. Key Words: Epilepsy, SCN1B, SCN1A, GEFS+.

497T

Clinical and genetic heterogeneity in autosomal dominant partial epilepsy with auditory features: Implications for genetic counseling. *F.Rossi. Torres[1], E. Bilevicius[2], R. Secolin[1], N.F. Santos[1], E. Kobayashi[3], L.A.C. Sardinha[2], F. Cendes[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, Universidade Estadual de Campinas; 2) Department of Neurology, Universidade Estadual de Campinas; 3) Department of Neurology and Neurosurgery, McGill University.

Autosomal dominant partial epilepsy with auditory features (ADPEAF) also known as autosomal dominant lateral temporal lobe epilepsy (ADLTLE) is a monogenic form of epilepsy syndrome characterized by partial seizures with predominant auditory symptoms originating in the temporal lobe cortex. Mutations in the leucine-rich, glioma inactivated 1 gene (*LGI1*) are found in about 50% of patients with ADPEAF/ADLTLE. It has been described that patients with ADPEAF/ADLTLE do not have structural abnormalities in the brain. We assessed different families with ADPEAF/ADLTLE in order to further investigate genetic, clinical and neuroimaging findings in this disorder. We studied four families (S, MG, N and B), all with clinical features of ADPEAF/ADLTLE. Families were subjected to clinical evaluation, including neurological exam, electroencephalogram and high resolution magnetic resonance imaging (MRI). Mutation screening was performed by automatic sequencing of the entire coding region of *LGI1*, *LGI2*, *LGI3*, and *LGI4* genes. Auditory auras were identified in all families; however, there was an excess of *dejá-vù* episodes in the MG family (n = 12/21). Structural abnormalities in the left temporal lobe were identified in individuals belonging to the S family (n = 8/ 14). A point mutation in the acceptor splice site of exon 8 of *LGI1* gene (IVS7-2A> G) was identified in all affected individuals of family S. However, mutation screening in *LGI1*, *LGI2*, *LGI3*, *LGI4* genes did not identify pathogenic variations in families MG, N and B. We observed genetic and clinical heterogeneity in our group of ADPEAF/ADLTLE families. While individuals carrying the *LGI1* mutation in the S family have a clear identifiable structural abnormality in the left temporal lobe, individuals from families without *LGI1* mutations have normal MRI findings. These results suggest that temporal lobe structural abnormalities, when present, may indicate the presence of mutations in *LGI1*. In addition, we found evidence that a high frequency of *déjà vu*, as it is observed in the MG family could indicate that the presence of mutations in *LGI1* is less likely. These clinical findings may prove to be important for initial genetic counseling of families with ADPEAF/ADLTLE, especially when considering genetic testing for *LGI1*.

498T

A wide spectrum of clinical and brain MRI findings in patients with *SLC19A3* mutations. *K. Yamada[1], K. Miura[2], K. Hara[3], M. Suzuki[2], N. Nakanishi[4], T. Kumagai[2], N. Ishihara[1], Y. Yamada[1], R. Kuwano[5], S. Tsuji[6], N. Wakamatsu[1].* 1) Gen/Aichi Human Serv Ctr, Inst Dev Res, Aichi, Japan; 2) Pediat. Neurol/ Aichi Human Serv Ctr, Ctrl Hosp, Aichi, Japan; 3) Neurol/ Niigata Univ, Brain Res Inst, Niigata, Japan; 4) Perinatol/ Aichi Human Serv Ctr, Inst Dev Res, Aichi, Japan; 5) Mol Genet/Niigata Univ, Brain Res Inst, Niigata, Japan; 6) Neurol/ Univ, Tokyo, Tokyo, Japan.

We conducted on the detailed clinical, brain MRI and molecular genetic analysis of four patients in a Japanese pedigree who presented with epileptic spasms in early infancy, severe psychomotor retardation, and characteristic brain MRI findings of progressive brain atrophy and bilateral thalami and basal ganglia lesions. Genome-wide linkage analysis revealed a disease locus at chromosome 2q35-37, which enabled identification of the causative mutation in the gene *SLC19A3*. A pathogenic homozygous mutation (c.958G>C, [p.E320Q]) in *SLC19A3* was identified in all four patients and their parents were heterozygous for the mutation. SLC19A3 (solute carrier family 19, member 3) is a thiamin transporter with 12 transmembrane domains. Homozygous or compound heterozygous mutations in *SLC19A3* cause two distinct clinical phenotypes, biotin-responsive basal ganglia disease and Wernicke's-like encephalopathy. Biotin and/or thiamin are effective therapies for both diseases. However, administration of a high dose of biotin for one year improved neither the neurological symptoms nor the brain MRI findings in one patient. Our cases broaden the phenotypic spectrum of disorders associated with *SLC19A3* mutations and highlight the potential benefit of biotin and/or thiamin treatments and the need to assess the clinical efficacy of these treatments. We constructed mouse model of our patient and discuss brain phenotypes of this model.

Heritability and Familiality of Personality Dimensions in the Korean Schzophrenic LD Families. *B. Lee[1,2], Y. Chung[1,2], J. Park[1,2], S. Kim[1,2], C. Kang[1,2], J. Kim[1,2], Y. Lee[1,2], E. Moon[1,2].* 1) Department of Psychiatry, Pusan National University Hospital, Busan, Korea; 2) Department of Psychiatry, Pusan National University, Busan, Korea.

Purpose: Schizophrenia is the most devastating mental illness that causes severe deterioration in social and occupational functioning. But the mystery for elucidating its causes is in line with brain's mystery. One possible mechanism for causing that syndrome may be the genetic aberrations in neurodevelopment and neurodegeneration. Categorical syndrome such as schizophrenia could be the complex of many continuous mental structure phenotypes including several personality development/degeneration dimensions. This is the study to search heritability and familiality of personality dimensions in the Korean schizophrenic LD(Linkage Disequilibrium) families. Method: We have recruited 306 probands(with schizophrenia) with their parents and siblings whenever possible. For best estimation of diagnosis, we have used medical records and a Korean version of DIGS & FIGS. We have used MMPI, SCL-90R, TCI, NEO questionnaires for measuring personality and symptomatic dimensions. Heritabilities of personality dimensions in total 738 family members were estimated using Sequential Oligogenic Linkage Analysis Routines(SOLAR). Personality dimensions in total family members were compared with those in 336 healthy unrelated controls for measuring the familialities. Genetic/environmental correlations with symptomatic dimensions for significant personality dimensions aggregated in families were investigated. Result: Four of the 10 MMPI variables, two of the 5 NEO variables, five of the 7 TCI variables were not significantly heritable and were excluded from subsequent analyses. The three groups(control, unaffected 1st degree relative, case) were found to be significantly different and with the expected order of average group scores for five of the MMPI scales, three of the NEO scales, and two of the TCI scales. Genetic/environmental correlations with symptomatic dimensions for significant personality dimensions aggregated in families will be suggested. Conclusion: Our results show that the aberrations in several personality dimensions could form the complexity of schizophrenic syndrome as a result of genetic-environment coactions or interactions in spite of some limitations(recruited family, phenotyping). These will be the base as important coefficients of so mysterious equations forming schizophrenia. But still, most areas in positional genetic variations and environmental factors as loaded variables of equations for causing that syndrome remain doubtful.

Fragile X, intermediate, and premutation alleles in the Autism Genetic Resource Exchange (AGRE). *W. Brown, A. Glicksman, X. Ding, N. Ersalesi, C. Dobkin, S. Nolin.* Dept Human Genetics, NYS Inst Basic Res in DD, Staten Island, NY.

AGRE is an autism family registry and biosample resource that includes primarily multiplex families, having two or more children, that are affected by autism spectrum disorders (ASD). Family data are available online, and genetic material is available for analysis. The families were recruited by ads and via support groups by Cure Autism Now/Autism Speaks. Thus, they represent a relatively unbiased sample. ~35% of the first 480 families had genetic testing prior to entering the registry. The individuals receive confirmatory ADI-R and ADOS testing. We have screened the FMR1 locus in one proband from 1641 families. We found 7 families with fragile X (FX) present. Among these, 6 were found among the first set of 480 families and among 312 AGRE families that had had no prior genetic screening, the rate was ~1.9%. An estimate of the Raven IQ score of the autistic subjects was 80±35 with range 34-144. Thus, the AGRE sample is likely to have a higher IQ distribution than typical for FX subjects (mean ~40±25). Previous prevalence studies of FX in autistic samples range from 0-16%; with a mean of ~4%; (Feinstein 98). Our 1.9% is similar to a report of 1.6% among 123 unrelated autistic individuals (Bailey 93), but lower than the 13% we found on an earlier multicenter study of 183 individuals (Brown 86). A growing awareness of FX has likely decreased the probability of finding FX in the more recently recruited multiplex ASD families due to screening and exclusion. The 1.9% is lower than the expected 4%, perhaps due to higher IQs in AGRE subjects typical than for FX. But it confirms an association of FX and ASD. **Possible association of ASD and premutations (PRE).** Among 1447 male probands tested, there were 2 with PRE (59 & 64 CGGs) and 12 with intermediate (45-54) alleles (IA) (46, 47, 47, 47, 48, 48, 48, 49, 50, 50, 51, 54) for an IA prevalence of 0.83%. Among 194 female probands tested there were 2 with PRE (55, 59) and 7 with IA (45, 46, 48, 50, 52, 53, 54). Since females have two alleles, dividing by 2 gives an IA prevalence of 1.8% in female alleles or an overall IA prevalence of 0.9%. Our published control value for 2500 X chromosomes was 1.7% (Brown 96), and our more recent control value based on carrier screening of 9064 X chromosomes was 1.15%. Thus, there was no excess of IA or PRE among the AGRE registry ASD probands. This finding suggests ASD is **NOT** associated with IA or PRE alleles.

Translational Profiling Mouse Models of Fragile X-associated Tremor/Ataxia Syndrome. *J.N. Galloway, C. Shaw, P. Yu, D.L. Nelson.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Fragile X-associated Tremor/Ataxia Syndrome (FXTAS) is a late-onset neurodegenerative disorder primarily affecting male premutation allele carriers of Fragile X Mental Retardation 1 (*FMR1*) gene. The current molecular model for the disease suggests the clinical features of FXTAS result from elevated expression of the expanded CGG repeat in the premutation *FMR1* mRNA. Since there are rarely alterations in the level of the *FMR1* gene product, FMRP, it is likely that the expanded CGG repeat in this RNA is toxic. Indeed, models in both fly and mouse have demonstrated that expanded CGG repeats in heterologous mRNAs are sufficient to confer degeneration of neurons with similar features. This observation has led to the hypothesis that aberrant interactions between the expanded CGG sequences and RNA-binding proteins may be responsible for the pathology in FXTAS, possibly manifested in changes in regulation of RNA splicing, transport or translation. We have previously described a Purkinje neuron specific transgenic mouse model of FXTAS that exhibits many human FXTAS clinical features including the formation of ubiquitin positive intranuclear neuronal inclusions and death of Purkinje neurons along with motor coordination and motor learning deficits. Our current efforts focus on understanding changes in translational profiles of diseased Purkinje neurons in our mouse model of FXTAS. Using the Purkinje neuron specific model, developed by the Heintz group at Rockefeller University, that expresses an EGFP-tagged ribosomal protein L10a, and the translating ribosome affinity purification (TRAP) methodology to affinity purify polysomal mRNAs, we have performed comparative analysis of gene translational profiles of various age groups of our FXTAS model using microarray technology. Our results suggest that translational profiles are altered as early as 4 weeks of age by the presence of expanded CGG repeat RNA. More than 400 mRNAs are significantly elevated or decreased in abundance on polyribosomes. The profiles reflect changes in genes involved in alternative splicing, mRNA transport, miRNA metabolism, translational regulation and programmed cell death. Preliminary data indicated that one candidate, *Adcy7*, is elevated nearly 16 fold over wildtype by four weeks. Work is in progress to validate additional genes from our microarray study of 8 and 12 week models. This study will identify many new candidate genes involved in the progression of FXTAS related pathology.

502T

***NAT1* and tobacco smoke exposure in multiple sclerosis: evidence for a gene-environment interaction.** *L. Barcellos[1,2], F. Briggs[1], B. Acuna[2], L. Shen[2], P. Ramsay[1], H. Hong[1], A. Bernstein[2], C. Schaefer[2].* 1) Div Epidemiology-SPH, Univ California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) is a complex and heterogeneous autoimmune disease of the central nervous system with a multifactorial etiology, involving both genetic and environmental components. While many environmental exposures have been investigated, exposure to tobacco smoke has consistently demonstrated association with increased risk of MS and disease progression. However, not all smokers develop MS, and only some individuals with MS were ever smokers. We hypothesized that host genetics contribute to metabolism of tobacco smoke constituents, and therefore to development of MS in smokers. A gene-environment (GxE) investigation was conducted to determine whether variation within *NAT1* located on chromosome 8p22 encoding the enzyme n-acetyl transferase 1 modifies the risk of MS associated with tobacco smoke exposure *NAT1* is known for its important role in tobacco smoke constituents metabolism, and variation within this locus has been well-established in several cancers. To investigate this possibility in MS, we utilized comprehensive smoke exposure and genetic data collected from ~2,000 White, non-Hispanic MS case and control members of the Kaiser Permanente (KP)Northern California Region HealthPlan. The KP MS Research Program was established to support rigorous epidemiologic investigations of both genetic and environmental risk factors in a large, population-based study sample. Tobacco smoke exposure before the age of 20 was significantly associated with greater risk of MS using logistic models adjusted for age and other risk factors including gender, history of infectious mononucleosis and *HLA-DRB1*1501* status. Tobacco smoke exposure before the age of 20 was significantly associated with greater risk of adult-onset MS (odds ratio [OR] (95% Confidence Interval)=2.0 (1.5-2.6), p=7x10-7) analyses. Six of 16 SNPs within *NAT1* significantly increased the risk of MS conferred by tobacco smoke: rs6586711: odds ratio of interaction (OR_I)=1.6, p=0.004; rs11996662: OR_I=1.7, p=0.005; rs7012951: OR_I=1.7, p=0.008; rs2188023: OR_I=1.5, p=0.02; rs3901866: OR_I=1.5, p=0.02, rs4986990: OR_I=2.6, p=0.03. Interestingly, none of the *NAT1* variants demonstrated a marginal association with MS, despite power for detection. We have identified a potential MS susceptibility locus that is important in the context of environmental exposure. Results from this study provide insight to underlying disease mechanisms in MS; our approach has strong application to additional GxE studies in MS.

503T

Gene-environment and functional classification analyses suggest novel candidate genes and processes that may be contributing to the susceptibility of adult-onset multiple sclerosis. *F. Briggs[1], B. Acuna[2], L. Shen[2], P. Ramsay[1], H. Quach[1], A. Bernstein[2], C. Schaefer[2], L. Barcellos[1,2].* 1) Sch Pub Hlth, Univ California, Berkeley, Berkeley, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) is an inflammatory and demyelinating autoimmune disease with complex genetic and environmental components. The search for genetic risk factors has been successful, however much of the genetic component remains unknown, particularly the identity of variants and biological pathways that modulate exposure to environmental risk factors. A large body of evidence has demonstrated, convincingly, that socioeconomic position (SEP), perhaps in childhood and adulthood, is one of the most significant predictors of chronic disease and long-term health outcomes in adults. To investigate this possibility in MS, we utilized comprehensive exposure and genome-wide association (GWA) data collected from ~2,000 White, non-Hispanic MS case and control members of the Kaiser Permanente Northern California Region HealthPlan. The Kaiser Permanente MS Research Program was established to support epidemiologic investigations of both genetic and environmental risk factors in a large, population-based study sample. Logistic models were used, and analyses were adjusted for age, and established MS risk factors (gender, history of smoking and infectious mononucleosis, and *HLA-DRB1*15* status). Several related measures of SES collected demonstrated significant associations with risk of MS, including: *low household education at age 10*: odds ratio [OR=1.3, p=0.002; *less than a college education*: OR=1.4, p=0.003; *low life-course socioeconomic position*: OR= 1.9, p= $2x10^{-5}$, and *low social mobility*: OR=1.7, p=$8x10^{-4}$. We conducted GxE analyses using SEP exposures and identified several gene candidates that distinguished low from high SEP, including *NPAS3*, p=$2x10^{-6}$; *DPP6*, p=$2x10^{-6}$; *DIP2C*, p=$3x10^{-6}$, and *KANK1*, p=$5x10^{-6}$. Functional classification tools using KEGG PATHWAY and Gene Ontology, performed pathway analyses of gene candidates (p<0.001). Genes participating in axon guidance were significantly overrepresented (p=$6x10^{-5}$; KEGG). Based on Gene Ontology databases, genes involved in cell adhesion (p=$3x10^{-6}$), MAPKK activation (p=$7x10^{-4}$), plasma membrane (p=$9x10^{-4}$), and neuron differentiation (p=$1x10^{-3}$), were overrepresented. Our results demonstrate evidence for specific biological pathways acting through gene products important to MS pathogenesis in the context of life course SEP. The combined bioinformatics approach described here to characterize genes and pathways relevant to environmental exposures in MS may shed light on mechanisms contributing to disease etiology.

504T

A study of depression and anxiety among female carriers of the *FMR1* premutation and the impact of raising a child with fragile X syndrome: evidence for moderation by the corticotrophin-releasing hormone receptor 1 gene. *J.E. Hunter[1], A. Abramowitz[2], J.F. Cubells[1,3], S.L. Sherman[1].* 1) Dept Human Genetics, Emory Univ, Atlanta, GA; 2) Dept Clinical Psychology, Emory Univ, Atlanta, GA; 3) Dept Psychiatry and Behavioral Sciences, Emory Univ, Atlanta, GA.

The *FMR1* contains a polymorphic CGG repeat in the 5'UTR of exon 1. Once unstable, this triplet repeat is capable of expansion across generations with maternal transmission. Thus women who carry a premutation, defined as an allele with 55-199 repeats, are at risk of passing on a full mutation, defined as an allele with >200 methylated repeats, to their offspring, leading to the intellectual disability disorder, fragile X syndrome (FXS). Mounting evidence suggests that some premutation carriers may be vulnerable to anxiety and depression. The goal of this study was to test the hypothesis that among females who carry a premutation, the stress of raising a child with FXS would be moderated by their endogenous cortisol activation influencing their potential for anxiety and depression outcomes. To this end, we genotyped the corticotrophin releasing hormone receptor 1 gene (*CRHR1*) among 279 female carriers of the FMR1 premutation (111 with a child with FXS, 168 without a child with FXS) who had completed self-report questionnaires assessing symptoms of depression [Centers for Epidemiological Studies Depression Scale (CESD)] and anxiety [State Trait Anxiety Inventory (STAI) and Social Phobia and Anxiety Inventory (SPAI)]. Results indicate a statistically significant interaction between *CRHR1* genotypes and the status of raising a child with FXS to predict anxiety symptoms reported on the SPAI across multiple SNPs (rs7209436, p=0.0005; rs242924, p= 0.0071; rs173365, p=0.0022). Overall, our data provide evidence that differential cortisol activation as measured by variants in the corticotrophin-releasing hormone receptor mediates levels of anxiety related to the stress of raising a child with FXS among female carriers of *FMR1* premutation alleles.

505T

A molecular mechanism underlying the interaction of serotonin transporter gene polymorphism and stress on central serotonin transmission and risk of depression. *A.J. Jasinska[1], C.A. Lowry[2], M. Burmeister[3].* 1) Psychology and Neuroscience Program, University of Michigan; 2) Integrative Physiology and Center for Neuroscience, University of Colorado-Boulder; 3) Human Genetics, Psychiatry, and Molecular and Behavioral Neuroscience Institute, University of Michigan.

The serotonin transporter gene (5-HTT)-linked polymorphic region (5-HTTLPR) is the most studied genetic variant in psychiatric neuroscience. Drawing on neuroanatomical, neurochemical, and neuroimaging studies of the central serotonin system, we propose a mechanism underlying the interaction of the 5-HTTLPR and stress on central serotonin transmission and risk of depression. These results add to our understanding of gene-environment interactions in psychiatric and behavioral genetics. The proposed mechanism has four key features. (1) Serotonergic projection neurons, which project from the dorsal raphe nucleus (DRN) to most areas of the forebrain, are regulated by serotonergic interneurons, whose axon terminals are contained within the DRN. In the absence of severe stressors, the projection neurons are tonically active, while the interneurons are silent. When a severe stressor is detected, the interneurons are activated and inhibit some projection neurons, terminating serotonin release in some projection regions. (2) The serotonin transporter (encoded by the SLC6A4 gene) is responsible for reuptake of serotonin from the extracellular space. The efficiency of serotonin reuptake in the DRN determines the duration of stressor-induced inhibition of serotonin release in forebrain regions: a lower efficiency of reuptake means a relatively longer inhibition. (3) This difference in duration alters the balance in a critical circuitry connecting the DRN, the amygdala, and the ventromedial prefrontal cortex (VMPFC), responsible for stressor reactivity and emotion regulation. Specifically, if the efficiency of serotonin reuptake is compromised, the VMPFC remains inhibited for longer and fails to inhibit serotonergic interneurons, resulting in a positive feedback loop between the amygdala and the DRN. Over time, these neural signaling pathways are strengthened due to synaptic plasticity, yielding a hyper-reactivity to stress in the amygdala and a hypo-reactivity of emotion regulation in the VMPFC. (4) Importantly, the variable efficiency of serotonin reuptake in the DRN has an impact only in the presence of a severe stressor. Thus, the effects of functional variation in the serotonin transporter gene (including, but not limited to, the 5-HTTLPR) on central serotonin transmission and risk of depression depend on stressor exposure. This dependency, we propose, is the underlying mechanism of the gene-environment interaction first observed by Caspi et al. (2003).

506T

BDNF Val66Met genotype as a moderator of early life stress response but not late life stress response and its impact on negative affectivity. *C. Lattig[1], C. Perea[1], A. Paternina[1], Y. Gomez[2].* 1) Dept Genetics, Univ de los Andes, Bogota, Colombia; 2) Dep. Psychology, Univ de los Andes, Bogota, Colombia.

Background: Gene x environment (G x E) interactions are known to predict susceptibility to disorders such as depression and anxiety. Childhood adverse experiences and number of stressful life events (SLEs) have been widely studied as environmental risk factors; however response to SLEs has not been studied. Here we present a first attempt to look at the interaction between the response to personal and academic stressful events during different life stages and the gene polymorphisms 5-HTTLPR, 5-HTTVNTR (STin2), HTR1A C(-1019)G, and BDNF Val66Met in the prediction of negative affectivity (NA). Methods: Standardized questionnaires (ST-DEP and STAI) were used to measure negative affectivity derived from depression and anxiety in a sample of 303 undergraduate students. Response to stressful events during childhood, high school and college years was evaluated together with a self-report format of personal history. Multiple logistic regression analysis was used to perform association and G x E analysis using SSPS, R and Plink statistical programs. Results: Negative affectivity is strongly associated with childhood maltreatment and stress response. Gene associations were observed between 5-HTTVNTR allele 12 and the S_12 haplotype with NA derived from both depression and anxiety high scores. The BDNF gene variant was not associated with NA derived from depression or anxiety alone, but it was associated with the comorbid presentation. A significant G x E interaction was observed between the BDNF Val66Met and stress response during childhood and college years although the risk for negative affectivity conferred by stress response during childhood was only significant among the Met allele carriers, while stress response during college years was a significant risk factor regardless of the BDNF Val66Met genotype. A significant G x E interaction was also found between the HTR1A C(-1019)G variant and childhood maltreatment. Conclusion: Altogether, our results demonstrate that the BDNF Val66Met variant moderates the effect of stress during both childhood and college years; although this effect seems to be more critical during childhood given that the risk conferred by childhood stress was restricted to the Met allele carriers. We also found that the HTR1A C(-1019)G variant moderates the effect of childhood maltreatment in our study population.

507T

Alcohol Use in the Onset of Rapid-Onset Dystonia-Parkinsonism, DYT12. *B.M. Snively[1], D.F. Hill[1], N. Boggs[1], L. Ozelius[2], K.J. Sweadner[3,4], C. Suerken[1], W.V. McCall[1], A. Brashear[1].* 1) Wake Forest School of Medicine, Winston-Salem, NC; 2) Mount Sinai School of Medicine, New York, NY; 3) Harvard Medical School, Boston, MA; 4) Massachusetts General Hospital, Boston, MA.

Rapid-Onset Dystonia-Parkinsonism (RDP), DYT12, is characterized by rapid onset and stabilization of symptoms without recovery. RDP is caused by mutation of the (3 subunit of the Na+/K+-ATPase gene (*ATP1A3*) and is dominantly inherited with reduced penetrance. RDP is unique among dystonias in that onset has been associated with triggers: life stress, physical stress, exposure to excessive heat, and alcohol use. Each of these 4 categories of triggers has been reported across multiple families. Our focus here is to describe data on alcohol use at the time of RDP onset in 20 affected individuals with one copy of either the recurrent mutation T613M (12 individuals in 3 families) or I758S found in one large family (8 individuals). *ATP1A3* variants were confirmed in patients and family members by direct sequencing; 3 were unaffected carriers. Among the RDP patients, 30% were female; average age (SD) at onset of RDP was 25 (14) years. The RDP severity score (1-4) was 1 in 15% (mild limb dystonia), 2 in 5% (affected arm and bulbar muscles with normal gait), 3 in 30% (also legs affected but walking unassisted), and 4 in 50% (severe bulbar and limb involvement and unable to walk). Among the RDP patients overall, 79% reported a trigger of some type, including 40% reporting alcohol use in the 24 hours before symptom onset. Of these, 75% (6 of 8) said they had been drunk within 24 hours prior to onset. Among the RDP patients stratified by T613M and I758S respectively, 25% and 63% reported alcohol use at the time of onset, and of these, 67% and 80% said they had been drunk. Stratifying by sex, 17% of females (1 of 6) and 50% of males (7 of 14) reported alcohol use at the time of onset; of these, the one female and 83% of males said they had been drunk within 24 hours. Differences in alcohol use by affection status were not evaluated due to limited numbers. In conclusion, the *ATP1A3* gene codes for the (3 subunit of the Na,K-ATPase protein implicated in synaptic physiology in neurons throughout the brain. The association of alcohol as a possible trigger of RDP highlights the interaction of genetic variants and environmental causes of RDP. Further study of alcohol as a trigger of RDP may suggest possible preventive measures and/or treatment of this disabling dystonia. This work is supported by NINDS grant R01NS058949 (AB).

508T

Childhood adversity increases risk for nicotine dependence and interacts with alpha-5 nicotinic acetylcholine receptor genotype specifically in males. *P. Xie[1,3], H.R. Kranzler[4], H. Zhang[2,3], D. Oslin[4], R.F. Anton[5], L.A. Farrer[6], J. Gelernter[1,2,3].* 1) Department of Genetics, Yale University, New Haven, CT; 2) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 3) VA CT Health care Center, West Haven, CT; 4) Department of Psychiatry, University of Pennsylvania and the Philadelphia VA Medical Center, Philadelphia, PA; 5) Center for Alcohol and Drug Programs, Department of Psychiatry, Medical University of South Carolina, Charleston, SC; 6) Departments of Medicine, Neurology, Ophthalmology, Genetics and Genomics, Epidemiology, and Biostatistics, Boston University Schools of Medicine and Public Health, Boston, MA.

Both genetic and environmental factors influence the risk for nicotine dependence (ND). Several large genome-wide association studies have consistently observed significant association signals in the alpha-5 nicotinic acetylcholine receptor gene (CHRNA5) with smoking behaviors [1,2,3]. Dysfunctional CHRNA5 causes an increase in nicotine intake in rodent experiments [4]. In this study, we genotyped a nonsynonymous SNP, rs16969968, in CHRNA5 for 2206 EAs (1301 men and 905 women) to investigate the presence of a sex-specific gene-by-environment interaction effect of this marker on ND risk. We observed that childhood adversity significantly increased ND risk in both sexes; the effect in women was twice that in men. Significant interactive effects of childhood adversity and rs16969968 genotype were observed in men (OR=1.79, 95% CI=1.18-2.71, P =.0049). No interaction was found in women. We conclude that the effect of childhood adversity on ND risk is moderated by in CHRNA5 in EA men, but not in EA women. [1] Liu, Tozzi, Waterworth, et al. Nat Genet 42:436-440 (2010). Interaction of Personality and CHRNA5 in Cocaine Dependence and Cocaine-Induced Paranoia. *T. Zayats[1], BZ. Yang[1], H. Kranzler[2], P. Xie[1], J. Poling[1], D. Oslin[2], L. Farrerr[3], J. Gelernter[1,4].* 1) Department of Psychiatry, Yale University School of Medicine, West Haven, CT, USA; 2) Department of Psychiatry, University of Pennsylvania, and Philadelphia VAMC, Philadelphia, PA, USA; 3) Departments of Medicine, Neurology, Ophthalmology, Genetics and Genomics, Biostatistics and Epidemiology, Boston University Schools of Medicine and Public Health, Boston, MA, USA; 4) Departments of Neurobiology and Genetics, Yale University School of Medicine, New Haven, CT, USA.

Introduction and Purpose: CHRNA5 SNP rs16969968 and personality both contribute to cocaine dependence (CD) risk. However, little is known about how these risk factors act in contribution to the phenotype. We studied the interaction of personality traits and rs16969968 in relation to CD and cocaine-induced paranoia (CIP) in both European Americans (EAs) and African Americans (AAs). Materials and Methods: The sample was comprised of 1432 EA subjects (418 screened controls and 1014 cases) and 1514 AA subjects (336 screened controls and 1178 cases). All participants were assessed with Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA). The diagnosis of CD was made using DSM-IV criteria and subjects with schizophrenia or bipolar disorder were excluded. For analysis of CIP, all subjects were divided into 3 groups: (A) Controls with no CIP (418 EA and 336 AA); (B) Cases without CIP (328 EA and 364 AA) and (C) Cases with CIP (686 EA and 814 AA). Personality was assessed by the NEO-PI-R: a 240-item measure of the Five Factor Model: Extraversion, Agreeableness, Conscientiousness, Neuroticism and Openness to Experience. Analysis was based on logistic regression. All models were adjusted for sex and age. Bonferroni correction was used to account for multiple testing (independent tests only). Results: Among EAs, conscientiousness (controls mean: 50.28, SD: 11.72 and cases mean: 38.77, SD: 10.81) was the only NEO measure that revealed a significant interaction with rs16969968 on CD risk (p=0.001; OR=1.62, 95%CI: 1.23-2.12). Similarly, in EAs, conscientiousness (group A mean: 50.28, SD: 11.72; group B mean: 39.29, SD: 11.08; group C mean: 38.53, SD: 10.68) interacted with rs16969968 on risk of CIP (p=4.0e-04, OR=1.72, 95%;CI: 1.28-2.30 comparing group A versus group C; p=0.042, OR=1.45, 95%CI: 1.06-1.98 for group A versus group B). No significant interaction was observed in the AA sample. Conclusion: Conscientiousness may interact with rs16969968 in CHRNA5 in determining the risk of CD and CIP in EA subjects.

Changes in expression profiles of differentiated SK-N-SH cells resulting from over-expression of *MECP2*_e1 and *MECP2*_e2. *M. Orlic-Milacic[1], L. Kaufman[1], A. Mikhailov[1], P. Gianakopoulos[1], B. Minassian[2], J. Vincent[1].* 1) Neurogenetics, CAMH, Toronto, Canada; 2) Genetics & Genome Biology, The Hospital for Sick Children, Toronto, Canada.

Rett syndrome (RTT) is a progressive neurodevelopmental disorder that affects almost exclusively females with a frequency of 1:10000 births. Features of RTT include loss of speech and motor skills, autistic-like social behavior and intellectual disability. Mutations in the *MECP2* gene are responsible for the majority of Rett syndrome cases. *MECP2* functions in transcription regulation and has two transcript variants, *MECP2*_e1 and *MECP2*_e2. There is accumulating evidence that *MECP2*_e1 is the etiologically relevant variant for RTT. In this study we aim to detect genes that are differentially regulated by two *MECP2* isoforms. For this purpose, the human neuroblastoma cell line SK-N-SH was stably infected by lentiviral vectors over-expressing *MECP2*_e1, *MECP2*_e2, or eGFP. Infected neuroblastoma cells were subsequently differentiated into neurons. RNA from these cells was used for gene expression analysis on human Agilent microarrays. There were ~800 genes with at least 3-fold change in expression level when *MECP2*_e1 was overexpressed in comparison with the eGFP control, with uncorrected p values less than 0.05. When *MECP2*_e2 was over-expressed, levels of ~230 genes changed at least 3-fold. We used quantitative RT-PCR to verify microarray results for 30 of these genes that, in addition to significant change in expression level, are known to be involved in cognitive function and neuronal development. We found significant up-regulation of several genes resulting from over-expression of the *MECP2*_e1 isoform including *NAV3* (5-fold increase), *SRPX2* (17-fold increase), *ITGA3* (5-fold increase), *NDN* (3-fold increase), *NPY1R* (6-fold increase), *NEFM* (2-fold increase), *SYN3* (2-fold increase) and *SEMA3D* (6-fold increase). Both *MECP2*_e1 and *MECP2*_e2 up-regulated *GABRA2* (18 and 3-fold increase, respectively), *KCNA1* (7 and 3-fold increase, respectively), *FOXG1* (6 and 3-fold increase, respectively), *NROB1* (8 and 4-fold respectively) and *FOXP2* (induced by over-expression of both isoforms). Down-regulation of expression in the presence of *MECP2*_e1 was seen with *CNTN4* (2-fold decrease), *UNC5C* (40% decrease) and *RPH3A* (30% decrease). Several genes, while potentially relevant to RTT, had very low levels of expression and could not be validated by this method, including *DLGAP2*, *CRH*, *GABRB1*, *GRIN2A* and *PTCHD1*. Studying differential regulation of genes by different isoforms of *MECP2* can help us to understand RTT etiology and determine the clinical relevance of specific mutations.

Exploring established multiple sclerosis susceptibility loci in a Hispanic cohort. *A.H. Beecham[1], A. Hadjixenofontos[1], P.L. Whitehead[1], I. Konidari[1], D. Martinez[1], E. Lalanne[1], K. Belanger[1], L. Espinoza[1], S. Clarke[1], S. Delgado[2], J.L. Haines[3], M.A. Pericak-Vance[1], J.L. McCauley[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Multiple sclerosis is a neuroimmunological and neurodegenerative disease. As with most genetic studies of complex disease, the primary focus of genetic studies has been on individuals of European descent. The genetics of MS is no exception to this phenomenon. While there are few epidemiological surveys in MS on individuals originating from Latin America, those that exist suggest a higher prevalence of MS than was previously believed. As the US population continues to grow in part due to immigration from this region, the proportion of individuals with MS of Hispanic/Latino ethnicity will also grow. Understanding the etiology of MS in individuals with Hispanic/Latino ethnicity is therefore an important undertaking. Moreover, the generalization of current findings to individuals of different ancestry is an important and unstudied area. As members of the International Multiple Sclerosis Genetics Consortium (IMSGC), we have access to the Immunochip panel, a custom Illumina iSelect array containing 196,524 SNPs representing loci identified in numerous autoimmune diseases. Using this panel, we have genotyped an initial 200 Hispanic MS samples (~150 cases/ ~50 controls). Our current analyses are limited to examining established MS loci (~24 loci including the well-established HLA-DRB1501) within this dataset. Association analyses, using logistic regression and covariates PCA1-2 from Eigenstrat analysis, indicate that a number of these loci (e.g. HLA-DRB1501: p= 0.004, *PTGER4*: p=0.01, *ZMIZ1*: p=0.04) replicate within our population using a modest significance threshold ($p \leq 0.05$). Of even more interest, these loci are trending with stronger effect sizes in our population compared with the expected range of effect sizes seen in studies of European populations. We acknowledge and appreciate the limited power to detect small effect sizes within known MS risk loci and moreover the small sample size at this stage. However, it is important to point out that from our own collaborative studies within the IMSGC, we find that different European populations have vastly different effect sizes for established MS loci. In this regard, and as our preliminary data might suggest, we may find significantly different effect sizes for certain loci within our Hispanic dataset.

Genome-wide Association Analyses Identifies Novel Loci Associated with the Onset Age among Cases with Late-Onset Alzheimer's disease. *K.L. Hamilton-Nelson[1], A.C. Naj[1], Y.S. Park[1], R. Rajbhandary[1], G.W. Beecham[1], E.R. Martin[1], R. Mayeux[2], J.L. Haines[3], L.A. Farrer[4], G.D. Schellenberg[5], M.A. Pericak-Vance[1], The Alzheimer's Disease Genetics Consortium.* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Taub Institute for Research on Alzheimer's Disease, Columbia University, New York, NY; 3) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 4) School of Medicine, Boston University, Boston, MA; 5) School of Medicine, University of Pennsylvania, Philadelphia, PA.

While studies of late-onset Alzheimer Disease (LOAD) have found that some risk loci, notably *APOE*, may also contribute to earlier age of onset (AAO) of LOAD, variants in newly identified LOAD risk loci such as *CLU* and *PICALM* have not been similarly examined. We examined associations of variants at ten LOAD risk loci (*APOE*, *CLU*, *PICALM*, *CR1*, *BIN1*, *CD2AP*, *EPHA1*, *ARID5B*, the *MS4A* region, *ABCA7*, and *CD33*) from two recent genome-wide association studies (GWAS) to determine if they may also contribute to earlier AAO among 9,160 LOAD cases from 14 datasets of the Alzheimer's disease Genetics Consortium (ADGC). We examined association with AAO among the variants most significantly associated with LOAD at each locus, modeling genotypic effect on AAO linearly using generalized estimating equations (GEE) with adjustment for population substructure and cohort effects.Preliminary analyses confirmed association of APOE regional variation with AAO (*APOC1*, $P=4.7\times10^{-100}$). Variants at several of the other nine LOAD risk loci also demonstrated statistically significant associations ($P<0.005$), including rs6701713 in *CR1* (P=0.0053), rs7561528 in *BIN1* (P= 0.0029), rs561655 in *PICALM* (P=0.0014), and were similarly associated after additional covariate adjustment for sex and number of *APOE* , 4 alleles. As genomic variation may contribute to severity (i.e., earlier AAO) and not necessarily risk of disease, we also examined 2,324,442 genotyped and imputed SNPs with associations of $P>10^{-5}$ from the ADGC GWAS of LOAD risk to identify previously unknown genetic contributors to AAO of LOAD. In a model adjusting for sex and dosage of the *APOE* , 4 allele, with which associations in *APOE* faded as expected, the AD candidate gene *VDR* demonstrated association with AAO near genome-wide significance ($P= 6.18\times10^{-7}$), as did variants in several other regions, including a chromosome 8q24.11 region including *RAD21* ($P=2.38\times10^{-6}$), chromosome 6q16.1 ($P= 6.17\times10^{-6}$), *CIB4* ($P=7.70\times10^{-6}$), and *ABCC4* ($P=9.25\times10^{-6}$). In AAO analyses among LOAD cases, we confirmed associations of variation near 19q13.32 (*APOE* region) with genome-wide statistical significance and observed associations with AAO at risk loci *CR1*, *BIN1*, *PICALM*, and *ABCA7*, and detected several strong associations among genes with weak or no association with risk in the ADGC, including the previous AD candidate gene *VDR*. Potential roles for these SNPs merit further investigation, including replication in other GWAS datasets.

513T

A Novel Set of Genetic Variants Associated with Autism Spectrum Disorder (ASD) Susceptibility Is Revealed by Application of the Pathway-PDT. *Y.S. Park[1], M. Schmidt[1], E.R. Martin[1], P.W. Whitehead[1], I. Konidari[1], M.L. Cuccaro[1], J.L. Haines[2], M.A. Pericak-Vance[1], R.H. Chung[1].* 1) John P. Hussman Institute of Human Genomics, University of Miami Miller School of Medicine, Miami, FL, USA; 2) Vanderbilt Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Pathway analysis, jointly considering the effect of a set of genes, provides an alternative to single-locus association tests in genome-wide association studies (GWAS). This has become an attractive secondary analysis that can uncover associations missed by single-locus screens. However, most pathway analyses conducted thus far focused on unrelated cases and controls or used only P-values calculated from GWAS, which is not optimal for family-based study as LD and family structures can't be specifically modeled in the analysis. We recently developed a novel family-based pathway analysis tool, Pathway-PDT, that uses raw genotype data from nuclear families with one or more affected siblings. Pathway-PDT tests for the significance of an enriched set of genes in a pathway relative to the background genes. We applied Pathway-PDT to two independent family datasets for ASD - the Hussman Institute for Human Genomics (HIHG) dataset and the Autism Genetic Resource Exchange (AGRE) dataset. The joint datasets contained a total of 2,153 individuals with ASD and 2,847 unaffected family members from 1,444 independent families. Markers were imputed based on HapMap3 data with IMPUTE2, which resulted in 817,127 common autosomal SNPs. We tested a total of 4,312 gene sets defined by the Gene Ontology (GO) Database by their associated biological processes, cellular components and molecular functions in humans. Interestingly, the set of genes involved in the positive regulation of response to external stimulus (GO:32103) was significant in the Pathway-PDT analysis even when the p-value was adjusted for multiple testing (Pathway-PDT $P<0.0005$, FDR adjusted P=0.012, permutation adjusted P=0.0095). The gene set includes interesting subsets of genes involved in the regulation of the inflammatory response (GO:50729, Pathway-PDT $P<0.0005$) and chemotaxis (GO:50921, Pathway-PDT P = 0.0025), that have been associated with autism in other studies. Within these gene sets are several genes, such as cadherin 13 (CDH13) and protein kinase C alpha (PRKCA), that we previously reported as possibly associated with autism using the noise-reduction GWAS analysis. In conclusion, our analysis of ASD GWAS data using Pathway-PDT identified significant association for the gene set for the positive regulation of response to external stimulus. This suggests that genes in this pathway should be looked at more closely and, in particular, considered jointly for association with ASD.

514T

Fine-mapping of the MHC association in multiple sclerosis using imputation. *NA. Patsopoulos[1,2,3], PL. De Jager[2, 3], PIW. de Bakker[1, 3, 4, 5] on behalf of ANZgene, GeneMSA, IMSGC.* 1) Medicine Dept., Division of Genetics, Brigham & Women's Hospital, Harvard Medical SChool, Boston, MA; 2) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham & Women's Hospital, Boston, MA; 3) Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, MA; 4) Department of Medical Genetics, Division of Biomedical Genetics, University Medical Center, Utrecht, The Netherlands; 5) Julius Center for Health Sciences and Primary Care, University Medical Center, Utrecht, The Netherlands.

Background: Multiple sclerosis (MS) is a neurodegenerative inflammatory disease with a heritable component. *HLA-DRB1*15:01* has been identified as the strongest association with MS. Many studies have suggested additional independent associations in HLA class I and II genes, implicating *HLA-A*02*, *HLA-B*44*, *Cw*05/08*, and *DQB1*03/06*, but the evidence is not conclusive.

Methods: We have used a novel imputation method to impute HLA class I and II alleles and their corresponding amino acids, using 6 GWAS data sets. The method leverages a reference panel of 2,767 individuals of European descent with information for SNPs and classical alleles at *HLA-A*, *-B*, *-C*, *-DRB1*, *-DQA1*, *-DQB1*, *-DPA1* and *-DPB1*. We have imputed 4,220 cases and 7,296 controls in total. We used logistic regression to identify independent HLA associations at 4-digit resolution and to test if amino acid polymorphisms within classical HLA molecules can explain the observed associations.

Results: We successfully imputed 103 classical HLA alleles at 4-digit resolution, and 335 amino acid positions. *HLA-DRB1*15:01* was the most significant effect (OR=3.0, p=1.0e-183). Conditional on *DRB1*15:01*, we found another three DRB1 alleles that were significantly associated: **03:01* (OR=1.37, p=1.48e-12), **13:03* (OR=2.39, p=3.00e-11), **04:04* (OR=1.59, p=2.68e-07). Adjusting for the *DRB1* gene effect, we identified another independent effect in *HLA-A*02:01* (OR=0.74, p=1.26e-26). Adjusting for *DRB1* and *HLA-A*02:01*, we found *DPB1*03:01* (OR=1.43, p=5.27e-13). Collectively, these classical alleles explain up to 14% of the trait variance (Nagelkerke r2). After testing individual amino acid positions in the HLA proteins, the most association position is an amino acid (-5) in the signal peptide of *DQ*) *1* (OR=3.07, p=4.78e-180 for Leu), consistent with near-perfect LD (r^2=0.98) between Leu-5 and *DRB1*15:01*. A model based on the four best independent DR) 1 amino acid positions was not better than a model based on the four classical alleles in *DRB1*.

Conclusions: We have replicated known associations of HLA class I and II alleles in MS and identified an independent *HLA-DPB1* association.

From linkage to sequencing: Using cross-family IBD sharing to refine susceptibility loci in Tourette Syndrome multi-generational families. *V. Ramensky[1], D. Yu[2], S. Service[1], C. Mathews[3], P. Heutink[5], B. Oostra[6], P. Sandor[7], C. Barr[8], R. Kurlan[9], D. Pauls[2], N. Cox[4], N. Freimer[1], J.M. Scharf[2], TSAICG (Tourette Syndrome Association International Consortium for Genetics), Bayside, NY.* 1) Center for Neurobehavioral Genetics University of California, Los Angeles, CA; 2) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General, Hospital Harvard Medical School, Boston, MA; 3) Department of Psychiatry, University of California, San Francisco, San Francisco, CA; 4) Departments of Medicine and Human Genetics, University of Chicago, Chicago, IL; 5) VU University Medical Center, Amsterdam, Netherlands; 6) Erasmus University Medical Center, Rotterdam, Netherlands; 7) Department of Psychiatry, University Health Network and University of Toronto, Toronto, Canada; Division of Brain, Imaging, and Behaviour Systems, Toronto Western Research Institute, University Health Network, Toronto, ON, Canada; 8) Genetics and Development Division, Toronto Western Research Institute, University Health Network, Toronto, ON, Canada; Program in Neurosciences and Mental Health, The Hospital for Sick Children, Toronto, ON, Canada; 9) Atlantic Neuroscience Institute, Overlook Hospital, Summit, NJ.

The recent increased focus on rare susceptibility variants in non-Mendelian disorders has resulted in a resurgence of interest in multi-generational, phenotypically loaded families. However, new approaches are needed to optimize the selection of individual family members for sequencing and to refine previously identified linkage regions that are too large for comprehensive, targeted next-generation sequencing. Here, we present analyses of large, multi-generational families with Tourette Syndrome (TS) as an example in which high-density SNP genotyping can be used to identify shared identity-by-descent (IBD) regions across apparently unrelated individuals from different families contributing to a genome-wide significant non-parametric linkage signal. TS is a highly heritable, childhood-onset neuropsychiatric disorder that causes substantial physical and psychosocial morbidity. Prior non-parametric linkage analyses of 771 individuals (213 affecteds) from 15 large, unrelated, multi-generational TS families of European ancestry identified a genome-wide significant linkage peak on chromosome 2p (Z= 5.2, p=9.8x10-8). The region of maximal linkage spanned 22 Mb, with the 95%CI extending across the entire 2p arm. Two additional regions on chromosome 6p and 17p achieved suggestive levels of significance. We used Beagle FastIBD to perform genotype phasing and subsequent IBD detection of Illumina 610Quad genotypes in 201 individuals (136 affected, 65 unaffected) from these 15 TS families. At each marker, we calculated the differential IBD rate (DIBDR) equal to the IBD rate of affected-affected cross-family pairs minus the corresponding value for affected-unaffected or unaffected-unaffected pairs. The strongest cross-family DIBDR peaks were observed on chromosomes 2 and 17, both within the previously identified linkage critical regions, and on chromosome 6, within the 95% CI for that linkage peak. Statistical significance was assessed by permutation tests. The obtained results confirm earlier findings, dramatically narrowing the region for these linkage peaks (1-4 Mb each) and indicate that apparently unrelated TS families may share common disease haplotypes. The method highlights a useful approach for transitioning from linkage data to targeted sequencing aimed at identifying the underlying susceptibility genes for non-Mendelian disorders.

A family-based association and brain expression analysis of the reading disabilities candidate gene DYX1C1. *C. Tran[1], K. Wigg[2], F. Yu[2], L. Gomez[2], B. De Souza[2], T. Cate-Carter[3], A. Pitch[3], E. Kerr[3], M. Lovett[3], L. Field[4], B. Kaplan[5], C.L. Barr[1, 2, 3, 6].* 1) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 2) Division of Genetics and Development, Toronto Western Hospital, Toronto, ON, Canada; 3) Program in Neurosciences and Mental Health, Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 5) Department of Pediatrics, University of Calgary, Calgary, AB, Canada; 6) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

Reading disabilities (RD) refer to a specific difficulty in learning to read despite normal intelligence and access to education. Family and twin studies have shown that RD have a significant genetic component while linkage studies have identified a susceptibility locus on chromosome 15q21. Dyslexia susceptibility 1 candidate gene 1 (DYX1C1), located in this region, has been proposed as a RD candidate gene based on a chromosomal translocation. However, subsequent association studies have yielded mixed results. This study investigated the role of DYX1C1 in RD through family based association and brain tissue expression analyses. In our sample of 441 families from Toronto, Ontario, each with at least one child exhibiting reading difficulties, 10 single nucleotide polymorphisms (SNPs) in DYX1C1 were genotyped. A replication sample of 100 sibling pair families from Calgary, Alberta was also genotyped for the 10 SNPs. Categorical, haplotype and quantitative analyses were performed using Haploview, Transmit and FBAT, respectively. To examine the association between DYX1C1 variants and expression levels, 40 post-mortem individuals were genotyped and real-time PCR was performed using tissues from the dorsolateral prefrontal cortex, caudate nucleus and hippocampus. In the categorical analysis of the initial sample, rs692691 showed a trend towards association with RD (p=0.058). However, this did not hold up after correction for multiple testing (p=0.334) and was not replicated in the additional sample. The -3A/1249G haplotype was significantly undertransmitted in the initial sample (p=0.007), differing from the haplotype results of previous studies. In the quantitative analysis, rs11629841 was associated with lower performance in expressive language (p=0.034), while rs1789126 was associated with receptive language (p=0.034) and phonological awareness (p=0.044). There was no correlation between the genotyped DYX1C1 variants and expression levels in the three brain regions. Our results do not provide strong evidence for DYX1C1 as a RD candidate gene. Although some markers showed a trend towards association, these were not the associated markers identified in previous studies. It is possible that the observed association may be a signal pointing to another susceptibility gene within the same region.

517T

Refinement of the chromosome 3p22 region of interest for bipolar affective disorder and identification of a putative candidate gene. *R. Secolin[1], L. F. B. Mella[2], M. L. Santos[1], P. Dalgalarrondo[2], C. E.M. Banzato[2], I. Lopes-Cendes[1].* 1) Medical Genetics Dept , University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Medical Psychology and Psychiatry Dept, University of Campinas - UNICAMP, Campinas, SP, Brazil.

Background: BPAD is a common psychiatric illness, with a prevalence of 0.8-2.6 % in the general population. Genetic factors are known to contribute to the etiology of BPAD. Several studies, including our own previous results, have point to a region on chromosome (ch) 3p22 as a candidate to contain a susceptibility gene for BPAD . **Objectives:** We aim to refine the region of interest on ch 3p22 by genotyping additional SNPs as well as to try to identify putative candidate genes for BPAD within this region. **Methods:** We evaluated 74 families, with a total of 411 individuals, including 96 patients who fulfilled clinical criteria for BPAD according to DSM-IV classification. We genotyped a total of 94 SNPs. Statistical power was verified by TDT POWER CALCULATOR. Genotyped data and minor allele frequency estimation were processed by JINGLEFIX program. Mendelian inconsistencies and Hardy-Weinberg equilibrium were evaluated by PEDCHECK and HAPLOVIEW softwares, respectively. Family based association analysis was performed by transmission disequilibrium test (TDT) using TDTAE software and statistical results were adjusted using Bonferroni correction. In addition, we performed gene expression analysis using peripheral blood samples from 12 probands with BPAD who had been previously genotyped for a SNP of interest. We used Kruskal-Wallis test to evaluate different gene expression among groups. **Results:** Our family sample showed statistical power higher than 80% to detect association. We found a single significant association signal for SNP rs166508 ($p_{corrected}$ = 0.0187). Since this SNP is located within an intronic region of integrin alpha 9 (*ITGA9*) gene, we evaluated *ITGA9* expression in BPAD probands showing the three rs166508 genotypes found. We observed an increased gene expression in patients with the *A/A* genotype (Kruskal-Wallis pvalue = 0.0339). **Conclusions:** We demonstrated that SNP rs166508, located within intron 15 of the *ITGA9* gene, is associated with BPAD. In addition, we detected an increased expression of *ITGA9* in patients with the *A/A* genotype, which is associated with an increased transmission of *A/A* genotype to patients in our family sample. *ITGA9* encodes a subunit of the alpha 9 integrin, an integral membrane glycoprotein which is a receptor for the nerve growth factor, neurotrophin 3 and brain-derived neurotrophic factor. Supported by FAPESP, São Paulo, Brazil.

SNPs genotyping and homozygosity mapping to identify candidate loci in a consanguineous family affected by a congenital muscular dystrophy with hyperlaxity (CMDH). *M. Tetreault[1], M. Vanasse[2], B. Brais[1].* 1) Laboratoire de neurogénétique de la motricité, Centre d'Excellence en Neuromique de l'Université de Montréal, CRCHUM, Montréal, Québec, Canada; 2) Clinique des maladies neuromusculaires, Centre de réadaptation Marie-Enfant, Hôpital Sainte-Justine Hospital, Montréal, Québec, Canada.

Over the past two decades, there have been major advances in defining the genetic bases of congenital muscular dystrophies (CMD). Genetic research has allowed the identification of more than 14 genes responsible for various forms of CMDs. Despite the great progress in this field, there are still a significant percentage of cases for which the mutated gene is unknown. This is particularly the case for milder forms. We recruited a consanguineous French-Canadian family from Southwestern Quebec affected by CMDH. A previous microsatellite genome wide-scan (GWS) has linked this family to 32cM region on chromosome 3p23-21. Most obvious candidate genes have been rule out in this region. A SNPs genome scan (Illumina OmniExpress) have identified six homozygous region shared by the two affected members. Among them, a 17Mb region on chromosome 3p24.3p21.3 was identified. We believe this study combine to a resequencing approach will enable us to identify a novel gene for CMDH. The uncovering of the genetic bases of muscular dystrophies serve as the essential original building blocks on which successful new therapeutic approaches can be designed.

519T

Identification of the tRNA methyltransferase gene NSUN2 as the gene for a new form of autosomal recessive intellectual disability. *J.B. Vincent[1], M.A. Khan[2], M.A. Rafiq[1], A. Noor[1], S. Hussain[3], V. Rupp[4], A.K. Vincent[1], J. Flores[3], G.E. Ishak[5], D. Doherty[6], R. Weksberg[7], M. Ayub[8], C. Windpassinger[4], S. Ibrahim[9], M. Ansar[2].* 1) Molecular Neuropsychiatry & Development Lab, Neurogenetics Section, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Department of Biochemistry, Quaid-I-Azam University, Islamabad, Pakistan; 3) Wellcome Trust Centre for Stem Cell Research Tennis Court Road Cambridge, CB2 1QR United Kingdom; 4) Institute of Human Genetics, Medical University of Graz, Graz, Austria;; 5) Department of Radiology, Seattle Children's Hospital, University of Washington, Seattle;; 6) Division of Genetics and Developmental Medicine, University of Washington, Seattle;; 7) The Centre for Applied Genomics & Program in Genetics and Genomic Biology, The Hospital for Sick Children, Toronto;; 8) Tees, Esk and Wear Valleys NHS Foundation Trust and School for Health and Medicine, University of Durham, United Kingdom;; 9) Dept. of Paediatrics, Aga Khan University, Karachi, Pakistan.

We have used genome-wide genotyping to identify a homozygosity-by-descent locus in a consanguineous Pakistani family with three intellectual disability (ID) plus distal myopathy to a 2.6Mb region on 5p15.32-p15.31, and have identified a missense mutation, Gly679Arg, at a conserved residue within the gene NSUN2. This gene encodes a methyltransferase that catalyzes formation of 5-methylcytosine at C34 of tRNA-leu(CAA), as well as functioning in spindle assembly during mitosis as well as chromosome segregation. The Gly679 residue in orthologous proteins is highly conserved across the animal kingdom. Analysis of the Gly679Arg mutation through Myc-tagged constructs carrying the mutation and overexpressed in HeLa, COS7 and HCC1954 breast cancer cells indicates that the effect of the mutation at the cellular level appears to be the prevention of NSUN2 localizing within the nucleolus, and occasionally the nucleus also. Thus it is likely that the role of NSUN2 within the nucleolus is crucial to normal neurodevelopmental processes.

520T

Serotonin gene expression significant changes could it be evidence for psoriasis related to depression? *S. Ghasemi[1], G. Ahangari[1], H. Mortazavi[2], R. Torabi[1], M. Mohamadian[1].* 1) Medical Biotechnology, National Institute of Genetic Engineering and Biotechnology, Tehran, Iran; 2) Department of Dermatology, Razi hospital, Tehran university of medical science, Tehran, Iran.

Serotonin (5HT) plays roles as a neurotransmitter and a neuromodulator which its modulation at synapses is thought to be a major action of several classes of pharmacological antidepressants. Serotonin receptor subtypes are related to depression and also have been shown to be present in certain cells of the immune system. Since serotonin also has a proliferate effect on various types of cells and psoriasis is a hyperproliferative inflammatory disease, we hypothesized that serotonin and its receptors are related to pathogenesis of psoriasis in this way serotonin can be a mediator between psoriasis, depression and stress. The aims of this study are evaluation of 5HT3a gene expression in peripheral blood mononuclear cells (PBMC) of psoriatic patients in comparison with normal individuals by Real-time PCR and finding the probable mutations in this gene via sequencing.

The PBMC was separated from whole blood by Ficoll-hypaque. The total cellular RNA was extracted and the cDNA was synthesized. This process was followed by real-time PCR using primer pairs specific for 5HT (3a) serotonin receptor mRNA and beta-actin as internal control. Our results show that relative expression of 5HT (3a) has significant decrease in psoriasis patients with comparison of healthy individuals. We are confirming our data by gathering more samples and sequencing the RNA obtained from the patients. In conclusion, 5HT3a significant decrease or any mutations on its gene can reveal an important role of this receptor in pathogenesis of psoriasis.

521T

A comprehensive nation-wide epidemiological survey for Pelizaeus-Merzbacher disease and associated disorders in Japan. *K. Inoue[1], Y. Numata[1], T. Ohkubo[1], E. Arima[1], A. Iwaki[2], K. Kurosawa[3], J. Takanashi[4], K. Deguchi[1,5], T. Yamamoto[6], H. Osaka[7].* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) Med Inst Bioregulation, Kyushu Univ, Fukuoka, Japan; 3) Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Pediatrics, Kameda Medical Center, Kamogawa, Japan; 5) Deguchi Pediatric Clinic, Ohmura, Japan; 6) TIIMS, Tokyo Women's Medical Univ, Tokyo, Japan; 7) Neurology, Kanagawa Children's Medical Center, Yokohama, Japan.

Purpose: Pelizaeus-Merzbacher disease (PMD) is the most common form of congenital hypomyelinating disorders (CHD) in the CNS, but the exact frequency of this group of diseases is currently unknown. In this study, we conducted a nation-wide epidemiological study in Japan to determine the prevalence and incidence of the CHD.

Methods: We enrolled all hospitals with pediatric neurology division and institutes for severely retarded children in Japan, the total of 918 institutions. The study was composed of primary and secondary surveys: the former was a brief questionnaire to determine the presence of patients with CHD in the past 1 year, and the latter was a detail survey to obtain clinical information of the CHD patients. This study was approved by IRB at National Institute of Neurology and Psychiatry, Japan.

Results: We identified 107 patients with CHD with detailed clinical information. The prevalence for CHD was 0.8 per 100,000 (0~20 y.o.) and the incidence was 1.6 per 100,000 live births. Male to female ratio was 5.7:1 and the average age of the patients was 11.8±9.9 y.o. The clinical diagnoses included PMD (63%) and Pelizaeus-Merzbacher-like disease (8%), while 18% remained undiagnosed. Molecular testing was performed on 75% of patients, of which 61% showed *PLP1* mutations, while 29% showed no detectable mutations. Together, the incidence of PMD with known *PLP1* mutation was at least 1.44 per 100,000 male live births. Clinically, 75% of the patients previously had nystagmus, which is currently present in 56%. Similarly, 72% had a previous history of hypotonia, of which only 54% are currently hypotonic. In contrast, spasticity was continuously present in 56% of the patients.

Discussion: Little etiological studies have been conducted for PMD and associated disorders. As far as we know, this is the first report to determine the prevalence and incidence of these disorders by a comprehensive nation-wide survey. The incidence of genetically confirmed PMD was approximately 20 times less than Duchenne muscular dystrophy. About 20% of the CHD remain undiagnosed, suggesting the presence of other disease-causing genes unveiled.

522T

A Deep Intronic Mutation In An Ataxia Telangiectasia Patient Identified By Genomic Resequencing Of The *ATM* Region. *S. Cavalieri[1], R.A. Gatti[2], A. Brusco[1,3].* 1) SCDU Medical Genetics S.Giovanni Battista Hospital, Torino, Italy; 2) UCLA School of Medicine Department of Pathology and Laboratory Medicine, Los Angeles,California; 3) Department of Genetics, Biology and Biochemistry, University of Torino, Italy.

Recent development of Next Generation Sequencing (NGS) techniques is changing the approach to search for mutations in human genetic diseases. We decided to apply NGS to study a patient affected by Ataxia Telangiectasia (A-T), in which one of the two expected mutations was not found after DHPLC, cDNA sequencing and MLPA screening. Linkage analysis showed the mutated unknown allele was maternally inherited. The entire *ATM* genomic region (160 Kb) was divided in 32 partially overlapping fragments of 4-6 kb and amplified by long-range PCR (Takara) in the patient and her mother. Fragments were quantified, pooled in equimolar amounts and sequenced by the Baseclear service using an IlluminaGAIIX platform. Raw data were analyzed by the CLC Genomics workbench software. Average coverage was 300X. Comparison between the mother and daughter sequences, allowed to identify six variants shared in heterozygosis by the two genomes and not reported in the SNP (ver 131) database. All were intronic, but only one c.1236-405C>T (coverage 670X), located in IVS11 was predicted to be pathogenic as it affected splicing (BDGP, www.fruitfly.org/seq). This mutation creates a novel donor splice site (score 0.22 wt to 1.00 mutated) in position -405 of intron 11 and as a result may activate an alternative acceptor splice site in position -619 of intron 11 (score 0.71). cDNA analysis in the patient using forward and reverse primers in exon 11 and 12, showed a normal band of 260 bp and a larger extra band of 472 bp. Sequence analysis showed that the larger band contained a “pseudoexon” of 212 bp, which used the alternative 5' and 3' splice sites at positions -619 and -405 of intron 11. This insertion results in a frameshift on the cDNA and premature stop codon. This approach based on resequencing of a genomic region is a powerful strategy to identify rare mutations that affect splicing, and it is suitable for a selected group of patients in which DHPLC or cDNA sequencing plus MLPA was unsuccessful. The identification of splicing variants is important for their possible therapeutic targeting using AMO (Antisense Morpholino Oligonucleotides).

Whole Exome Sequencing in First Degree Cousin Pairs with Early Age-at-onset Bipolar Disorder. *D. Chen, N. Akula, C.J.M. Steele, L. Kassem, F.J. McMahon, The Bipolar Genome Study (BiGS).* Human Genetics Branch, National Institute of Mental Health, Intramural Research Program, National Institutes of Health, Bethesda, MD.

Background: Though bipolar disorder is highly heritable, recent estimates of total genetic variance accounted for by common variants have been low. Identification of uncommon and rare variants may increase the total genetic variance explained. Methods: In this pilot study, we identified 4 first-cousin pairs with bipolar I disorder beginning before age 16. Cases were drawn from 4 distinct families of European-ancestry ascertained by the NIMH Genetics Initiative. Exome sequencing was performed with SOLiD technology. Fragment libraries were made with 5ug genomic DNA, followed by exome capture using the Agilent SureSelect Human All Exon 50MB kit. Between 95M and 120M single-end reads were generated per individual (4 exomes/SOLiD Quad). Of these, 65M-80M reads mapped to the reference genome (hg19). Duplicated reads were removed using PICARD, and non-duplicated reads were re-calibrated using GATK. Of 82K called SNVs, ~26K were filtered out due to quality control or minor allele frequencies greater than 10% in the 1000 Genomes Database. The remaining ~56K variants were then mapped to regions of the genome shared identical-by-descent (IBD) between cousin pairs, using BEAGLE IBD. Results: The proportion of single nucleotide variants shared by cousin-pairs exceeded the proportion of the genome shared IBD by 150 to 176%. Approximately 147 variants mapped within IBD regions in all 4 cousin pairs, 100% of which could be phased. One variant, predicted to be damaging by SIFT, was found to reside on the haplotype that was actually shared IBD within that cousin pair. Conclusions: High throughput sequencing of cousins with early onset bipolar disorder reveals an excess of single nucleotide variants within shared genomic regions. Uncommon and rare variants may provide new insight into the etiology of bipolar disorder.

Complete Screening of *GBA* mutations in Brazilian Parkinson's disease patients. *B.C. Guimarães[1], A.V. Santos[1], J.M. Santos[1], M. Campos Jr.[1], F.L. Santos[1], A.L.Z. Rosso[2], D.H. Nicaretta[3], J.S. Pereira[4], D.J. Silva[5], C.B. Santos-Rebouças[1], M.M.G. Pimentel[1].* 1) Genetics, State University of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil; 2) University Hospital Clementino Fraga Filho, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; 3) Gama Filho University, Rio de Janeiro, Brazil; 4) Faculty of Medical Sciences, Biomedical Center, State University of Rio de Janeiro, Rio de Janeiro, Brazil; 5) Neuroscience Nucleus, Hospital of Clinics, Federal University of Goias, Integrated Institute of Neuroscience, Goias, Brazil.

Parkinson's disease (PD) is a common progressive neurodegenerative movement disorder, being characterized by the selective degeneration of dopaminergic neurons within the substantia nigra pars compacta and the presence of intracellular protein inclusions called Lewy bodies in the surviving neurons. PD has a complex etiology which may involve gene-environment interactions and multiple susceptibility genes. In this context, loss-of-function mutations in the glucocerebrosidase gene (*GBA*) have been well-validated as susceptibility factors for PD. This gene is located on 1q21 and comprises 11 exons that encode the lysosomal enzyme glucocerebrosidase. The main objective of our study was to investigate if alterations in the GBA gene constitute a predisposing factor for the development of PD in the Brazilian population. For this, a Brazilian cohort of 126 unrelated PD patients (24 familial and 102 sporadic cases; mean age: 66.4 ± 11.4) were screened for *GBA* mutations by complete sequencing of the gene's exons. Three mutations and one recombinant allele, previously associated with PD, were detected (A456P, L444P, N370S and RecNciI), as well as, one newly identified variant (W378C), in a total of 8 patients (6.3%). In silico analysis on the effect of amino acid substitutions in the protein function, using the program PolyPhen-2, showed that W378C variant might have a pathogenic role. Our results, until now, have been strengthen the association between this gene and PD in the Brazilian population, in addition to supporting the hypothesis that alterations in the GBA gene represent a significant genetic susceptibility factor for the development of PD. However, it is still important to perform segregation analysis of the mutations identified in order to evaluate the penetrance of these mutations.

525T

Next-generation sequencing of known and putative susceptibility genes for schizophrenia and autism spectrum disorders to detect rare high-penetrant risk variants. *E.M. Kenny, S. Furlong, P. Cormican, C. Fahey, R. Anney, G. Donohoe, A.P. Corvin, L. Gallagher, M. Gill, D.W. Morris.* Neuropsychiatric Genetics Research Group, Dept. of Psychiatry and Institute of Molecular Medicine, Trinity College Dublin, Dublin, Ireland.

Schizophrenia (SZ) and autism spectrum disorders (ASD) are complex neurodevelopmental disorders that share certain phenotypes including cognitive deficits and some behavioural characteristics. Such similarities suggest that these disorders may share an underlying pathology and thus may share some genetic risk variants. This study involves next-generation sequencing of the exonic regions of 215 potential susceptibility genes in an Irish sample of 150 cases of ASD, 300 cases of SZ and 300 controls, in order to identify single nucleotide polymorphisms, indels and structural variants contributing to one or both disorders. A multiplex target enrichment method is used whereby DNA samples are multiplexed together using DNA indexes/barcodes and enriched for the exonic regions of these genes using the Agilent SureSelect target enrichment method. This is followed by 80bp paired-end sequencing in a single lane of an Illumina GAII. Gene selection comprised of five categories: 1) Interactors of NRXN1, 2) Interactors of DISC1, 3) Genes within the Glutamate Receptor Complexes; NMDA, mGluR5 and AMPA, 4) Cell adhesion molecules and 5) Functional and Positional Candidates. Analysis of the pilot set of samples indicates that the approach undertaken is successful with an even spread of sequence information for 24 indexed samples per lane, >8X coverage for 84% of target regions and overall SNP concordance with previous GWAS data (Affymetrix 6.0) of 99.3%. A preliminary SNP analysis of 219 SZ cases and 206 controls has identified an excess of rare (nonsense) mutations in cases. We are currently validating these findings using capillary sequencing and details of these analyses will be presented.

526T

Screening of *PARKIN* mutations in Brazilian patients with early onset Parkinson's disease. *K.V. Moura[1], M. Campos Jr.[1], F.C. Rodrigues[1], F.L. Santos[1], A.L.Z. Rosso[2], D.H. Nicaretta[3], J.S. Pereira[4], D.J. Silva[5], C.B. Santos-Rebouças[1], M.M.G. Pimentel[1].* 1) Genetics, State University of Rio de Janeiro, Rio de Janeiro, Rio de Janeiro, Brazil; 2) University Hospital Clementino Fraga Filho, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; 3) Gama Filho University, Rio de Janeiro, Brazil; 4) Faculty of Medical Sciences, Biomedic Center, State University of Rio de Janeiro, Rio de Janeiro, Brazil; 5) Neuroscience Nucleus, Hospital of Clinics, Federal University of Goias, Integrated Institute of Neuroscience, Goias, Brazil.

Parkinson's disease (PD) is one of the most common neurodegenerative disorders associated with aging, reaching 2% at age 70. It is a disease characterized by progressive degeneration of nigra dopaminergic neurons in the basal ganglia and the presence of cytoplasmic protein inclusions known as Lewy bodies and neurites in surviving neurons. The etiology of PD is complex, with the involvement of gene-environment interactions. Knowledge achieved in the last 13 years about the genetic basis of PD clearly shows that genetic factors play an important role in the etiology of this disorder. In the present study, we screened mutations in *PARKIN* gene, whose product acts as an E3 ubiquitin ligase and has a role in mitochondrial biogenesis, in 136 unrelated Brazilian patients with early onset PD, by direct sequencing of PCR products. The presence of sequence variants was evaluated in exons 1 to 12 of *PARKIN* gene, where were found seven missense variants: c.245C>A, c.434G>A, c.659A>G, c.1016C>T, c.1021C>T, c.719C>T (each one in a patient) and c.1310C>T (in two patients). Among the mutations that alter the amino acid sequence, four variants have never been described: c.434G>A, c.659A>G, c.1016C>T and c.1021C>T. The exon 4 c.434G>A variant was identified in a patient that is a compound heterozygote (PAR2391) who also had the polymorphism c.500G>A in the same exon of the *PARKIN* gene. The c.659A>G mutation was found in only one patient (PAR1459), a sporadic case of the disease, in a heterozygous state. We identified two new variants in *PARKIN* exon 9, the alteration c.1016C>T in a patient (PAR2384) that has a family history of PD and the mutation c.1021C>T in two patients (PAR2143 and PAR2256) that are isolated cases of the disease. In silico analysis on the effect of amino acid substitutions in the protein function, using the program PolyPhen-2, showed that between the seven missense mutations identified, c.434G>A, c.1016C>T, c.719C>T and c.1310C>T variants are probably deleterious. Our data show that *PARKIN* point mutations are common in Brazilian early onset PD patients and the frequency of missense variants observed by us (5,9%) was similar to others worldwide.

527T

Population-based association study of the Dopamine Receptor D4 (DRD4) gene in Attention Deficit Hyperactivity Disorder (ADHD) and response inhibition. *S-M. Shaheen[1], Sarah. Ickowicz[1], J. Crosbie[2], A. Paterson[1], R. Schachar[2], Bingbin. Li[1], P. Arnold[1,2].* 1) Genetics and Genomic Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Psychiatry,The Hospital for Sick Children, Toronto, ON, Canada.

ADHD is a common neurodevelopmental disorder characterized by inattention, impulsivity, and hyperactivity that commences in childhood and often persists throughout life (Gizer and Waldman, 2009). Dopamine receptor D4 (DRD4) gene polymorphisms have previously been associated with ADHD (Kim, 2009; Congdon, 2008), but few studies have examined the specific association between DRD4 and important endophenotypes of ADHD, including the stop signal task (SST). We hypothesized that in children and adolescents, polymorphisms of the DRD4 gene including single nucleotide polymorphisms (SNPs) and a widely studied variable number tandem repeat in exon 3 (VNTRIII) are associated with inhibitory control measured through the SST. DNA samples were extracted from saliva collected from participants aged 7 to 17 at the Ontario Science Centre, who completed an SST task and self-report questionnaire. 177 samples, comprising children with the highest and lowest SST scores, were genotyped on a genome-wide array. Two DRD4 promoter SNPs, rs3758653 and rs1800955, as well as the VNTRIII polymorphism were then directly genotyped in a larger sample of 364 children (182 high SST, 182 low SST). Samples successfully genotyped by both genome-wide and single SNP or VNTR genotyping showed complete concordance between methods. Association analysis was completed with Plink (Purcell, 2007) and Haploview (Barrett, 2005). The two DRD4 SNPs were not found to be significantly associated with SST performance. There was a trend for carriers of the 7-repeat allele of the exon III VNTR to perform better on the SST (p=0.06). Small sample size (n=364) may have limited the detection power for this study. Further research should be aimed at elucidating genetic relationships between variation in the DRD4 gene, response inhibition, and ADHD. Improved understanding of the genetic antecedents of ADHD will lead to alternative and effective strategies for treatment, early identification, and prevention of this common and debilitating childhood onset psychiatric disorder.

528T

A Genome-scan for Shared Autism Spectrum Disorder and Specific Language Impairment Loci. *C.W. Bartlett[1], L. Hou[1], J.F. Flax[2,3], Z. Fermano[3], A. Hare[3], S.Y. Cheong[1], S. Buyske[4], L.M. Brzustowicz[3].* 1) Battelle Ctr Mathematical Med, Columbus Children's Res Inst, Columbus, OH; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ;; 3) Department of Genetics, Rutgers University, Rutgers University, New Brunswick, NJ; 4) Department of Statistics, Rutgers University, Rutgers University, New Brunswick, NJ.

Background: The genetic basis of autism spectrum disorders (ASDs) is still largely unknown as is possible shared etiologies of ASDs and specific language impairment (SLI), a neurodevelopmental disorder of language that is not accounted by low IQ or other cognitive impairments. In order to elucidate shared loci, a genome scan was conducted on pedigrees ascertained using a novel sampling design - pedigrees that were ascertained for both ASD and SLI probands in each pedigree. Methods: Affymetrix Axiom Array SNP genotyping provided data for both linkage and association analysis on 51 families with both ASD and SLI (+27 families without an SLI proband). The posterior probability of linkage (PPL) framework was used. It is the only implementation of a joint categorical-quantitative analysis method that allows for persons with ASD to be coded as “affected due to being beyond a unknown threshold” while all other family members are analyzed using quantitative trait values on 3 factors scores derived from performance on 22 language and literacy tests. Analysis of language and reading impairment as categorical traits was also conducted. Results: Categorical trait analysis showed large peaks for both language and reading impairment on chromosomes 15 (PPL=55%, 78 Mb, build 37) and 16 (PPL= 37%, 20Mb, build 37), respectively. These results explicitly assume ASD is etiologically the same as language or reading impairment. Analysis of the 3 factors scores did not yield large linkage peaks, though GWAS of the same data did indicate strong evidence for LD (PPLD=81%, 184 Mb, build 37) on chromosome 4. Discussion: These data provide evidence for shared etiology of ASD and SLI since a lack of genetic overlap would be expected to reduce power due to the incorrect diagnostic classification of coding both ASD and SLI affected as done here. The peak locations are not known ASD or SLI loci, but this may be expected since this unique sampling design is most powerful where other studies are least powerful. Further mapping efforts are warranted to elucidate these loci and determine their effects in ASD alone, SLI alone and jointly.

529T

Smoothed functional principal component analyses of two independent GWA studies identify 67 genes significantly associated with schizophrenia. *X. Chen[1], Y. Zhu[2], J. Chen[1], M. Xiong[2].* 1) Department of Psychiatry and Virginia Institute for Psychiatric and Behavioral Genetic, Virginia Commonwealth University, Richmond, VA 23219; 2) Department of Biostatistics, University of Texas Health Science Center, Houston, TX.

Genome wide association (GWA) analysis is a powerful tool to identify risk genes for complex diseases. However, due to the testing of hundreds of thousands of markers GWA suffers considerable power loss and many risk genes with small to modest effects cannot be discovered. In recent literature, attention has been focused to develop methods to jointly analyze multi-marker associations where a combination of genetic variants from a gene or a genomic interval is taken as a unit of association analysis. Recently, we have developed a novel statistic based on smoothed functional principal component analysis (SFPCA) for testing the association between a gene and a disease, and now we apply it to two independent schizophrenia GWA datasets (MGS_GAIN and MGS_nonGAIN) obtained from dbGaP. The MGS_GAIN dataset includes 1,135 individuals diagnosed with schizophrenia and 1,362 controls with 727,479 typed SNPs. The MGS_nonGAIN dataset includes 1,089 schizophrenia subjects and 1,273 controls with typed 696,510 SNPs. Using SFPCA, we find that there are 56 and 38 genes respectively for the MGS_GAIN and MGS_nonGAIN datasets meeting genome-wide significance after Bonferroni correction. A Meta-analysis of the two datasets yields 67 genes meeting genome-wide significance. Among them, 10 genes have been reported to be associated with schizophrenia in the literature, and 7 genes are found to be differentially expressed in schizophrenia patients in an RNA-sequencing expression study using postmortem brain samples.

530T

Analysis of SNPs with an effect on gene expression identifies spermatogenesis-associated protein 7 (SPATA7) as a potential candidate gene for schizophrenia. *J. Chen[1], L. Liu[3], K. Kendler[1,2], X. Chen[1,2].* 1) Virginia Institute for Psychiatric and Behavioral Genetics, and Department of Psychiatry;; 2) Department of Molecular and Human Genetics; Virginia Commonwealth University, Suite 390A, 800 E. Leigh Street,Richmond, VA 23298, USA; 3) Shandong Mental Health Center, Jinan, Shandong, P.R. China, 250014;.

Recently we reported that two non-synonymous SNPs (rs2401751 and rs2274736) from the PTPN21 (protein tyrosine phosphatase, non-receptor type 21) gene were associated with schizophrenia. In the follow-up studies using the publicly available SNPExpress database (http://people.chgv.lsrc.duke.edu/~dg48//SNPExpress/index.php), we found that in both brain tissue and peripheral blood mononuclear cells (PBMC), these two SNPs are cis-acting elements influencing the expression of spermatogenesis-associated protein 7 (SPATA7) gene (In brain tissue, P = 1.24×10-3 and 1.21×10-3 for rs2401751 and rs2274736; in PBMC, both markers have the same P = 2.98×10-6). Using the same database, we also found that multiple SNPs, including two different non-synonymous SNPs from the SPATA7 gene, significantly affect the expression of SPATA7. The most significant SNP is rs3179969 (P = 2.75×10-4 in brain and 2.98×10-6 in PBMC). In order to test our hypothesis that those alleles that affect gene expression (eQTL) could more likely be schizophrenia susceptibility alleles, the 2 non-synonymous SNPs (rs4904448 and rs3179969) from SPATA7 were selected for association studies based on the analyses of the expression data and linkage disequilibrium (LD). In a meta-analysis of 8 independent samples including 6 European America (EA) and 2 African America (AA) samples with a total of 10,979 subjects, we found that rs3179969 is significantly associated with schizophrenia (P = 2.39×10-5), which remains significant after Bonferroni correction. While the SNP rs4904448 did not reach experiment-wide significance in the meta-analyses of all 8 samples (P = 0.034), it showed a marginal signal in the 6 EA samples (P = 0.013). Furthermore, in a meta-analysis of 3 other independent expression datasets from different brain regions, we found that these two SNPs show consistent association with the expression of SPATA7 (P = 8.79×10-5 and 1.53×10-12 for rs4904448 and rs3179969, respectively). From these data, we conclude that at least one of the two non-synonymous SNPs from the SPATA7 gene that affect the expression of SPATA7 is significantly associated with schizophrenia. These results show that eQTL-based pre-selection for follow-up is a useful approach for identifying risk loci from a moderately sized GWAS. Further investigation of this locus is warranted.

531T

A Genome-Wide Association Study of Autism Spectrum Disorders Incorporating Assessment Items from ADI-R, ADOS, and SRS. *J.J. Connolly[1], J.T. Glessner[1], H. Hakonarson[1,2].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department: Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Autism Spectrum Disorders (ASDs) represent a group of childhood developmental disorders defined by impaired social skills, communication deficits, and repetitive or stereotyped behaviors and interests. Efforts to understand the causes of ASDs have been hampered by the genetic complexity and heterogeneity of the disorders. A potentially productive strategy for reducing this complexity is to target endophenotypes, simpler biologically-based measures that may involve fewer genes and constitute a more homogenous sample. We present results of a genome-wide association study (GWAS) of 2,165 participants from the Autism Genetic Resource Exchange (AGRE), with the aim of identifying genes that correlate with items from the Autism Diagnostic Interview-Revised (ADI-R), Autism Diagnostic Observation Schedule (ADOS), and Social Responsiveness Scale (SRS). We identify a number of genes known to be involved in neurodevelopment that correlate significantly with assessment items. These include KCND2 (overly serious facial expressions), NOS2A (loss of motor skills), and BIN1 (association of loss with physical illness). These findings may help prioritize study design and directions for future genomic efforts.

532T

Genome-wide association analyses using cerebrospinal fluid tau and phospho-tau and Aβ_{42} levels as endophenotypes for Alzheimer 's disease. *C. Cruchaga[1, 5], J.S.K. Kauwe[6], D. McKean[6], M. Bailey[6], D. Patty[6], K. Mayo[1], S. Bertelsen[1], A. Hinrichs[1], E.R. Peskind[7,8], G. Li[7,8], J.B. Leverenz[7,8,9], D. Galasko[10], A.M. Fagan[2,4,5], D.M. Holtzman[2,3,6,5], A.M. Goate[1,2,3,4,5], Alzheimer Disease Genetic Consortium (ADGC), and the Alzheimer's Disease Neuroimaging Initiative.* 1) Psychiatry, Washington University, St Louis, MO; 2) Neurology; 3) Developmental Biology; 4) Knight Alzheimer's Disease Research Center; 5) Hope Center for Neurological Disorders; 6) Department of Biology, Brigham Young University, Provo, UT, USA; 7) Departments of Psychiatry and Behavioral Sciences; 8) Veterans Affairs Northwest Network Mental Illness Research, Education, and Clinical Center, Seattle, WA; 9) Neurology, University of Washington School of Medicine; 10) Department of Neurosciences, University of California San Diego, La Jolla, CA.

Cerebrospinal fluid (CSF) Aβ_{42}, tau and tau phosphorylated at threonine 181 (ptau) are promising biomarkers for Alzheimer Disease. In this study we have performed a genome-wide association study using CSF Aβ_{42} and ptau levels as endophenotypes to identify additional genetic factors implicated in AD pathogenesis. CSF Aβ_{42} and ptau were measured in 957 European American samples. 356 samples were enrolled in longitudinal studies at the WU-ADRC, 391 in ADNI and 210 in studies at the University of Washington. The samples were genotyped using Illumina chips. The 1000 genome data and MACH software were used to impute 6 million SNPs. The normalized CSF ptau values were tested for association using an additive model in PLINK. Age, gender, site, and principle components were included as covariates. As CSF Aβ_{42} levels are not normally distributed and absolute levels of the measurements differed between samples we analyzed each series separately. Series specific analyses were performed using linear regression with age, principle components from stratification analyses and/or APOE genotype as covariates. Empirical P-values for each SNP were generated using ten million permutations. All association analyses were performed using PLINK. Metaanalysis of the three series incorporating sample size and effect direction was performed using METAL. For CSF Aβ_{42} two SNPs in the APOE-TOMM40 gene region showed genome-wide significant association (rs2075650 $p=2.6x10^{-16}$; rs157580 $p=4x10^{-08}$). Inclusion of APOE e4 presence/absence as a covariate drastically reduces the strength of association for these SNPs indicating that these associations may be due to LD with the APOE e4 allele. These results provide further evidence that genetic variation in the APOE region is strongly associated with CSF Aβ_{42} and tau levels. For CSF ptau levels, only SNPs in the APOE-TOMM40 region showed genome-wide significant association with ptau levels (rs2075650; $p= 1x10^{-9}$). Rs2075650 still showed strong association when CSF Aβ42 levels but not APOE genotype were included as a covariate ($p= 1.34x10^{-7}$). This result may indicate that APOE genotype or other SNPs in LD could affect tau pathology independently of the Aβ pathology. We found more p-values in the range 10^{-5} to 10^{-7} than would be expected by chance for both analyses. This could indicate that true positive results have not reached genome-wide significance levels due to lack of statistical power and that a larger sample is required.

533T

Genome-Wide Study and Whole-Exome Sequencing for Dementia in the Amish. *A.C. Cummings[1], L. Liang[1], D. Velez Edwards[2], R. Laux[1], L.L. McFarland[1], L. Caywood[3], L. Reinhart-Mercer[3], D. Fuzzell[1], C. Knebusch[3], C.E. Jackson[4], W.K. Scott[3], M.A. Pericak-Vance[3], J.L. Haines[1].* 1) CHGR, Vanderbilt University, Nashville, TN; 2) Vanderbilt Epidemiology Center, Vanderbilt University Medical Center, Nashville, TN; 3) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 4) Scott & White, Temple, TX.

To aid in our ability to identify late-onset Alzheimer disease (LOAD) risk genes, we are studying the genetically isolated and well-defined Amish populations of middle Ohio and northern Indiana. To date we have enrolled over 2300 Amish individuals with 135 of these having either probable or possible dementia. Through the use of the Anabaptist Genealogy Database, we have accurately defined the kinship coefficients and the family structure among our collected individuals. We performed a genome-wide study (Affymetrix Human SNP Array 6.0) and successfully genotyped 830 Amish individuals (125 with LOAD) and are following up this study with whole-exome sequencing. Following extensive QC procedures for the genome-wide SNP study, 614,957 SNPs were analyzed. Using more computationally tractable sub-pedigrees, we conducted parametric multipoint linkage analysis (Merlin) in regions in which a 2-pt lod score ⁄ 3 was calculated. Because of the relatedness of these individuals, we employed the MQLS test for association, which uses kinship coefficients to correct for relatedness. The highest multipoint peak (HLOD=6.14, (=0.39, recessive model) was calculated at 2p12. Six genes lie within the 1-LOD-unit interval, none of which have previously been associated with LOAD. The lowest MQLS p-value ($1.29x10^{-4}$) under this peak is at rs2974151 located in *CTNNA2*, catenin alpha 2 isoform 1, encoding a neuronal-specific catenin. Three additional regions had a multipoint lod score >3: 3q26 (HLOD=5.27, (=0.49, dominant model), 9q31 (HLOD=4.44, (=0.34, dominant model), and 18p11 (HLOD=4.42, (= 0.21, recessive model). These results indicate heterogeneity within the Amish population and suggest novel non-*APOE* genetic effects for LOAD with the most compelling evidence for *CTNNA2*. The best approach to exhaustively explore the coding sequence of *CTNNA2* and the other significant linkage regions is whole-exome sequencing. Therefore, using the Agilent SureSelect Human All Exon 50Mb Kit, we are sequencing ~110 AD affected and unaffected close relatives, which will allow us to also investigate the rest of the exome for LOAD variants. We will verify variants with Sanger sequencing and/or genotyping. Verified variants will also be tested for in an outbred LOAD dataset to see the extent of the effect of those variants in other populations.

534T

Genome-wide association analysis localizes a QTL influencing serum brain-derived neurotrophic factor levels in a single large extended pedigree. *V.P. Diego[1], S. Kumar[1], J.W. Kent Jr.[1], T.D. Dyer[1], S.L. Santangelo[2], D.C. Glahn[3], J.L. VandeBerg[1], J. Blangero[1], S. Williams-Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX 78227; 2) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research, Massachusetts General Hospital Simches Research Building 185, Cambridge St, CPZN 6-256, Boston, MA 02114; 3) Department of Psychiatry, Yale University School of Medicine, New Haven, CT 06511.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, is involved in regulating neuronal survival, differentiation, and outgrowth. It is expressed in the central nervous system, and in a diversity of peripheral tissues, including primary and secondary lymphoid tissues. BDNF appears to play important roles in neurodegenerative disease, psychiatric disorders, and neuroinflammatory pathology. Recent work in mental disorders indicates that serum/plasma levels of BDNF are lowered in individuals with alcohol dependence, autism, bipolar disorder, major depression and schizophrenia. To gain a better understanding of the genetics of this complex neuropeptide, we performed the first genome-wide association (GWA) analysis of quantitative serum BDNF levels to search for causal quantitative trait loci (QTLs). Serum levels of BDNF were measured using a commercial ELISA assay on blood samples obtained from 1070 individuals of the Jirel population, a well-studied genetic isolate living in eastern Nepal. All Jirels can be assigned to a single large complex pedigree. The size and complexity of this pedigree can substantially complicate genetic analyses. However, we have recently developed a novel fast exact maximum likelihood variance component-based algorithm that provides speeds of likelihood calculations equivalent to those observed for unrelated individuals, thus making genome-wide exact analyses feasible for even the largest pedigrees. Variance component analysis (allowing for covariates such as sex, age, and population structure-related principal components of random SNPs) revealed that serum BDNF level exhibits a large highly significant heritability of 0.61 ($p = 4.6 \times 10^{-47}$) in this isolated population, documenting that BDNF levels are substantially influenced by genetic factors. GWA analysis of 513,073 SNPs identified at least one SNP showing evidence of genome-wide significant association (our empirical genome-wide significance threshold = 1.3×10^{-7}). This SNP, rs2065615 ($p = 5 \times 10^{-8}$), is located on chromosome 20q13 near C20orf85 and accounts for nearly 4% of the variance in BDNF in this sample. Another association near the KIF26B gene at 1q44 nearly reached genome-wide significance ($p = 5 \times 10^{-7}$). Our results show that serum BDNF is highly heritable and amenable to QTL localization. Given that BDNF levels appear to be altered in efficacious psychiatric treatment, identification of causal genes may lead to novel drug targets.

535T

Genome-wide Association Study of Symptomatic Dimensions of Schizophrenia. *A. Fanous[1,2], B. Zhou[3], S.E. Bergen[4], S.H. Aggen[16], R.L. Amdur[1], J. Duan[5], A.R. Sanders[5], J. Shi[3], B.J. Background: Family, twin, linkage, and association studies provide convergent evidence that variation in clinical features of schizophrenia is in part due to genetic factors. Genome-wide association studies of such phenotypes have yet to be published. However, these dimensions of the illness mediate its morbidity, including functional disability. **Methods**: Exploratory Factor Analysis (EFA) of the Lifetime Dimensions of Psychosis Scale was performed in the Molecular Genetics of Schizophrenia (MGS) sample, which had been previously genotyped using the Affymetrix 6.0 genotyping array (Shi et al., *Nature*, 2009). PLINK was used to implement a test of linear regression for allelic effects on three quantitative symptomatic dimensions in the European-American sample (N=2,445). **Results**: EFA extraction indicated three phenotypic dimensions: Positive, Negative, and Affective symptoms. No SNP was associated at a genome-wide significance level. Fourteen SNPs within 50kB of a gene were moderately associated ($P<1 \times 10^{-5}$) with one of the factors, as were 20 intergenic SNPs. Associated genes included the following: CTDP1, ADAMTS6, CXCL12, PCDH20 and ZFYVE28 (Positive); GNAL, FAM38B, HLA-DQB1, and RORA (Negative); KIF26B, NLRC5, and CTNND2 (Affective). Only one such SNP was even nominally associated with schizophrenia. **Discussion**: While no single SNP was significant genome-wide, several genes with moderate association have functions with previous evidence of involvement in schizophrenia pathogenesis. These included brain development (CXCL12, PCDH20, GNAL, and CTNND2), dopaminergic transmission (GNAL), and autoimmunity (HLA-DQB1). RORA has been implicated in autism, which has strong phenomenological overlap with negative symptoms, in both human and animal studies. CTDP1 variants cause demyelinating Charcot-Marie -Tooth Disease, and several lines of evidence support defective myelination as a pathogenic process underlying schizophrenia. Finally, some members of the ADAMTS family promote neurite extension. Therefore, the genes implicated herein should be studied more thoroughly in larger samples with the same phenotypes. This is planned in the Psychiatric GWAS Consortium. Genetic variants predisposing to the illness, and those that modify it, are likely to be distinct.

536T

Genetics of Susceptibility to Multiple Sclerosis. *G. Hellenthal, International Multiple Sclerosis Genetics Consortium and Wellcome Trust Case Control Consortium 2.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom.

Multiple sclerosis (MS) is the most common neurological disease affecting young adults, estimated to affect over 2 million people worldwide with peak incidence occurring in individuals aged 30-40. Previous studies have established a strong genetic component to MS susceptibility, with variation within the Major Histocompatability Complex (MHC) exerting the greatest individual effect on risk. However, there is remaining controversy over more substantive details of disease etiology, such as which alleles in the MHC are important. Furthermore while inflammatory and neurodegenerative disease mechanisms are implicated, there is debate on whether these occur in sequence, inflammation determining secondary neurodegeneration or vice versa, or exert fully independent effects through clinical course. We report the results of the largest genome-wide association study (GWAS) to date exploring MS susceptibility. In particular we test for associations using data from 475,806 Single-Nucleotide-Polymorphisms (SNPs) genotyped in 9,772 affected individuals and 17,376 healthy controls sampled from 15 populations (plus replication data from 4,218 affected individuals and 7,296 controls). Novel statistical methodologies were developed to cope with complex population structure in GWAS collections such as ours where not all case samples have controls available from the same population, a scenario that may become more routine as study sizes increase. We utilized recently developed statistical methods for imputing classical Human Leukocyte Antigen (HLA) types from SNP data to examine in detail the landscape of genetic risk in the MHC, revealing that four mutations (DRB1*15:01, HLA-A*02:01, DRB1*03:01, DRB1*13:03) with effects modelled in a simple multiplicative manner within and across loci are sufficient to account for most of the risk attributable to the MHC. Outside of the MHC, we replicate 23 of the 26 previously suggested MS susceptibility loci and report the discovery and replication of at least 29 new genetic loci. Just over a third of the identified loci overlap with regions already confirmed as associated with at least one other autoimmune disease. Using pathway analysis, we show definitively that genes located in these association regions are highly enriched for cell-mediated immune mechanisms, rather than directly implicating neurodegeneration. We conclude that the critical disease mechanisms of multiple sclerosis primarily involve immune dysregulation.

Genome-wide association study for Parkinson's Disease in the mid-western US Amish. *L. Jiang[1], M.F. Davis[1], A.C. Cummings[1], D. Velez Edwards[2], R. Laux[1], L.L. McFarland[1], L. Reinhart-Mercer[3], D. Fuzzell[1], C. Knebusch[3], C.E. Jackson[4], W.K. Scott[3], M.A. Pericak-Vance[3], S.L. Lee[5], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Vanderbilt Epidemiology Center, Vanderbilt University Medical Center, Nashville, TN; 3) Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 4) Scott & White, Temple, TX; 5) Dartmouth College, Hanover, NH.

Parkinson's Disease (PD) is the second most common neurodegenerative disorder of adults. Previous evidence has shown that PD has a heritable component. Mutations in five known genes [(-synuclein (PARK1, PARK4), Parkin (PARK2), PINK1 (PARK6), DJ-1 (PARK7), and LRRK2 (PARK8)] cause Mendelian inheritance of PD and consensus regions from genome-wide linkage and association studies of the more common non-Mendelian forms of PD implicate MAPT and SNCA. Other genes have been associated with PD but the functional variants responsible are unknown. Genetic heterogeneity complicates the verification of likely genes and the identification of other susceptibility genes. Our approach to overcome the problem of heterogeneity is to study a population isolate, the Amish communities of Indiana and Ohio. We have enrolled over 2200 Amish individuals with 32 of these diagnosed with PD. In this dataset we see a higher average kinship coefficient among our cases (.016) compared to the rest of our dataset (.012), suggesting that PD is heritable in the Amish. We have undertaken a genome-wide association study (Affymetrix Genome-Wide Human SNP Array 6.0) and genotyped 900 Amish individuals (including all individuals with PD). Using the Anabaptist Genealogy Database, we determined the family structure connecting all individuals with PD. Following QC, 614,957 SNPs and 830 individuals were analyzed. SNPs were analyzed by linkage and association analysis. Linkage analysis was conducted using Merlin after cutting the pedigree into 10 computationally feasible sub-pedigrees using PedCut. Each sub-pedigree contained at least 3 individuals with PD. Three regions generated a hlod score⁄ 3 in 2-pt linkage analysis on chromosomes 5 and 10 under a recessive model. Association analysis was conducted using MQLS, which takes into account the relatedness of the individuals. Five SNPs reached genome-wide significance (p-value ≤ 1 × 10-7). Two SNPs are located in genes (COL13A1, TMC3) and the other SNPs are located in close proximity to one another in an intergenic region on chromosome 19. We further investigated to see if the 2-pt linkage and association results overlap. Ten SNPs are suggestively linked and associated with hlod ⁄ 2 and p-value ≤ 1 × 10-4. These data suggest that there are likely multiple loci within the Amish, likely representing a subset of all the PD loci segregating in the Caucasian population and will be followed up with multipoint linkage analysis.

538T

Genome-Wide Association Study of Treatment Refractory Schizophrenia in Han Chinese. *M. Lee[1], H. Wang[1], Y. Liou[2], Y. Chen[1], C. Hong[2], J. Wu[1].* 1) National Genotyping Ctr, IBMS, Academia Sinica, Taipei, Taiwan; 2) Department of Psychiatry , Taipei Veterans General Hospital, Taipei, Taiwan.

Purpose: Schizophrenia is a severe psychiatric disorder with a prevalence estimated to be approximately 1% in the world and 0.6% in Taiwan. Its clinical manifestations are characterized by distortion of reality, delusions, hallucinations, altered emotional reactivity, disorganized behavior, social isolation and cognitive impairment. In addition, schizophrenia is a heterogeneous disorder. Reducing the heterogenetity through subphenotyping or stratification might reduce the background in the genetic study for complex disorders. Methods: Antipsychotic medication is the major treatment for schizophrenia. However, one fifth to one third of schizophrenic patients do not respond to antipsychotic treatments. These patients with treatment refractory schizophrenia (TRS) have persistent psychotic symptoms combining with poor social/work function in spite of administering at least two trials of sufficient antipsychotic doses and adequate treatment duration. Therefore, TRS may be a distinct and homogenous subgroup of schizophrenia. To identify the genetic variants susceptible for schizophrenia, we performed the first genome-wide association study focusing on TRS, a relatively homogenous subtype of schizophrenia, in 522 Han Chinese individuals with TRS and 806 controls. Results: Four loci showed suggestive significant association with TRS were identified. These loci include: rs4699030 (P = 8.41 x 10-7) and rs230529 (P = 1.07 x 10-6) are located in the gene nuclear factor of kappa light polypeptide gene enhancer in B-cells 1 (NFKB1); rs10218843 (P = 6.73 x 10-6) and rs11265461 (P = 5.90 x 10-6) are adjacent to signaling lymphocytic activation molecule family member 1 (SLAMF1); rs739617 (P = 1.46 x 10-5), rs17158926 (P = 3.99 x 10-5) and rs17158930 (P = 3.08 x 10-5) cluster in dedicator of cytokinesis 4 (DOCK4); and rs13049286 (P = 1.23 x 10-5) and rs3827219 (P = 1.23 x 10-5) fall in receptor-interacting serine/threonine-protein kinase 4 (RIPK4). Five isolated SNPs with P values less than 10-5 were also identified to be associated with TRS. The -94delATTG allele (rs28362691) located in the promoter region of NFKB1 was identified by resequencing and was found to associate with TRS (P = 4.85 x 10-6). The promoter assay demonstrated that the -94delATTG allele had a significant lower promoter activity than the -94insATTG allele in the SH-SY5Y cells. This study suggests that rs28362691 in NFKB1 might be involved in the development of TRS.

Parkinson disease (PD) is the second most common adult-onset neurodegenerative disorder worldwide. Several studies have utilized genome-wide association (GWAS) methods to identify genes contributing to PD with growing evidence for the role of SNCA, MAPT, GAK/DGKQ, and the HLA region in disease susceptibility. There is evidence that there are additional loci yet to be identified. To maximize the power to detect additional risk factors having small to modest effects on PD susceptibility, we combined data from multiple GWAS. A two stage design was used to identify SNPs associated with the risk for Parkinson disease (PD). First, we combined individual level genotypic data from five recently completed GWAS of PD (Discovery Sample: 4,238 PD cases and 4,239 controls). Following imputation, a logistic regression model was employed in each dataset to test for association with PD susceptibility and the results from each dataset were meta-analyzed. Genome-wide significance was reached for SNPs in SNCA (odds ratio (OR)= 1.37; p=9.3 x 10^{-21}), MAPT (OR=0.77; p=1.5 x 10^{-10}), GAK/DGKQ (OR= 1.35; p=8.2 x 10-9/ OR=1.35; p=2.0 x 10-9), and the HLA region (OR=0.83; p=1.2 x 10^{-8}), which have been previously established in PD susceptibility. In the second stage we genotyped 768 SNPs in an independent Replication Sample of 3,738 cases and 2,111 controls. These SNPs included 100 ancestry informative markers (AIMs) and 686 SNPs that tag the LD blocks with the most extreme p-values from the meta-analysis. The Replication Sample confirmed the previously identified associations with SNCA, MAPT, and the HLA region and confirmed association with GBA (E326K OR=1.71; p=5 x 10^{-8} Combined Sample) (N370 OR=3.08; p=7 x 10^{-5} Replication sample), which had been previously associated with PD. We also replicated a novel PD susceptibility locus, RIT2, on chromosome 18 (rs12456492; p=5 x 10^{-5} Discovery Sample; p=1.52 x 10^{-7} Replication sample; p=2 x 10^{-10} Combined Sample). Conditional analyses within each of the replicated regions identified distinct SNP associations within GBA and within SNCA, suggesting that there may be more than one risk alleles within these genes. In summary, we have identified a novel PD susceptibility locus, RIT2, replicated several previously identified loci, and identified more than one risk allele within SNCA and GBA. These results have important implications as studies are being designed to identify all potentially functional disease-associated variants.

540T

Significant Association of Coding (Missense) SNPs with Familial LOAD Based on a Functional Genome-Wide Association Screen. *A.R. Parrado[1], K. Mullin[1], B. Hooli[1], L. Gotta[1], L. Bertram[2], C. Lange[3], R.E. Tanzi[1].* 1) Genetics and Aging Research Unit, Mass General Institute for Neurodegenerative Disease (MIND), Department of Neurology, Massachusetts General Hospital, Charlestown, MA, USA; 2) Max-Planck Institute for Molecular Genetics, Berlin, Germany; 3) Department of Biostatistics, Harvard School of Public Health, Boston, MA, USA.

Late-onset Alzheimer's disease (LOAD) genome-wide association study's (GWASs) have yielded novel AD candidate genes beyond APOE including CLU, CR1, PICALM, BIN1, ABCA7, MS4A6A/MS4A4E, EPHA1, CD2AP, all of which have been replicated in independent samples (www.alzgene.org). Our recent family-based GWAS also yielded novel AD candidate genes exhibiting genome-wide association, including ATXN1, GWA14q31, and CD33, of which CD33 has been confirmed. We set out to identify coding changes and particularly missense substitutions that associate with risk for LOAD. For this purpose, we performed a GWAS on the NIMH Genetics Initiative Family Sample using the Affymetrix 20K cSNP panel. To optimize statistical power, age of onset and AD affection status were tested together, as a combined phenotype, by use of the multivariate extension of the FBAT method, FBAT-GEE. In addition to the traditional p-values we report p-values from the Liptak test statistic, which utilizes all available information. The Liptak method attains higher power levels, than the FBAT-GEE approach, by combining the Z-statistics that correspond to the p-values of the family-based test (the within family information) with the rank-based p-values for population-based analysis (the between family information). Three genes contained cSNPs that exhibited previously unreported association with LOAD at a genome-wide significance level of 0.05 (Bonferroni correction, 4x10-6). These genes included: NMS, OR51F1, and AQP9(p = 3x10-7, 3x10-6, and Liptak p = 3x10-7, respectively). Additional genes containing cSNPs with suggestive evidence of association with LOAD (Liptak p ≤ 10-5) included: ZNF214, KRT7, and KLK3. This study represents the first comprehensive genome-wide screen for cSNPs associated with LOAD. The strongest evidence for association with LOAD was observed for a missense substitution in AQP9, encoding aquaporin-9. An edema model in rat brain suggests that the regulation of AQP9 expression may play a vital role in brain homeostasis via regulation of water channel activity. Aquaporin-9 has also been suggested to regulate immunological responses to bactericidal activity indicative of a role in the innate immune system. Interestingly, other recently reported AD candidate genes, e.g. CD33 and CR1, have also been implicated to play roles in the innate immune system. Replication analysis to confirm these initial findings is planned in a large independent collection of families with over 4,000 subjects.

541T

Genetics of cortical thickness in 822 twins. *A.S. Quiggle[1,2], N.K. Hansell[1], K.A. Johnson[1,2], G.A. Blokland[1,3], K.L. McMahon[2], G.W. Montgomery[4], P.M. Thompson[5], N.G. Martin[1], G.I. de Zubicaray[3], M.J. Wright[1,3].* 1) Genetic Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia; 2) Centre for Advanced Imaging, University of Queensland, Brisbane, Australia; 3) School of Psychology, University of Queensland, Brisbane, Australia; 4) Molecular Epidemiology, Queensland Institute of Medical Research, Brisbane, Australia; 5) Laboratory of Neuroimaging, UCLA School of Medicine, Los Angeles, CA.

Cortical thickness measurements have gained recent interest for being a potential brain-based endophenotype for a whole host of psychiatric illnesses and cognitive measures. Studies have shown patterns of cortical thinning to be associated with schizophrenia, major depressive-disorder, autism, Alzheimer's, and cardiovascular health. Despite previous research showing the brain to be widely heritable, little is still known about the genetic underpinnings of the cerebral cortex and about which genes are likely to be involved. We acquired 3D T1-weighted structural images of 822 twins and siblings of twins (121 MZ and 162 DZ pairs, mean age 22.7 ± 3.2 SD) using a 4 Tesla scanner, and extracted cortical thickness measures in 56 *a priori* regions-of-interest (ROIs), making our study one of the largest neuroimaging studies to date. We estimated the heritability of each ROI by performing a univariate Cholesky decomposition. We then performed the first genome-wide association study (GWAS) on cortical thickness to our knowledge (n= 704, after accounting for family structure). Variance component analysis showed cortical thickness heritability to vary widely: there was no significant genetic component of the right uncus, whereas a genetic component accounted for as much as 67% of variance in the left postcentral gyrus. Our analysis revealed substantially larger common environmental factors than previous estimates, probably due to an increase in power from a larger number of DZ twins. Although the GWAS revealed no individual single nucleotide polymorphisms (SNPs) of genome-wide significance ($P=5 \times 10^{-8}$), we found, in the medial frontal gyrus, a series of SNPs in a gene at a schizophrenia susceptibility locus that, in a gene-based association test which corrects for gene-size and linkage disequilibrium between SNPs, lay just under significance ($P=3 \times 10^{-6}$ compared to gene-based significance $P=2.8 \times 10^{-6}$). More intriguing still, the significance of these SNPs in other ROIs reflected the phenotypic correlations between these gyri and the medial frontal gyrus, making it a potential genetic marker. Results and significance levels are likely to change as our sample size increases. We are in the process of finding a replication sample in order to validate these results.

Genetics of cerebral asymmetry in the caudate nucleus. *M.E. Renteria[1,3], J.L. Stein[5], K. Johnson[1], S.E. Medland[1,3], K.L. McMahon[4], G.I. de Zubicaray[4], G. Montgomery[2], P.M. Thompson[5], N.G. Martin[1,3], M.J. Wright[1,3].* 1) Genetic Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 2) Molecular Epidemiology Laboratory, Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 3) School of Psychology, University of Queensland, Brisbane, Queensland, Australia; 4) Center for Advanced Imaging, University of Queensland, Brisbane, Queensland, Australia; 5) Laboratory of Neuroimaging, University of California Los Angeles, Los Angeles, California, USA.

The two hemispheres of the human brain exhibit anatomical and functional asymmetries across different brain regions. These differences arise from a combination of genetic and environmental factors and are thought to underlie the functional lateralization of brain function. While there is normal individual variation in asymmetry, evidence suggests that atypical symmetry or asymmetry at particular regions might lead to either superior performance or disease. In this study, we investigate the genetics of asymmetry of the caudate nucleus, a sub-cortical structure that plays roles in learning and memory and the control of voluntary movement. We obtained whole-brain MRI scans of 526 (325 females and 201 males) Australian twins. Images were processed and volumetric measures for caudate nucleus were extracted using the FSL/FIRST suite. An asymmetry index was calculated for each individual and the OpenMX structural equation modelling package was used to estimate the heritability of the trait. We then conducted a gene-based association analysis with the Versatile Gene-based Association Study (VEGAS) method, finding a statistically significant association with a gene on chromosome 14 (p-value: 2.0e-06), which is significant at the gene-based level (significance cut-off value after multiple testing correction is 2.8e-06). Our results provide a genetic association for cerebral asymmetry.

543T

Japanese subsequent GWAS identifies strong association at a novel risk locus and MCCC1 for Parkinson's disease. *W. Satake[1], K. Yamamoto[2], Y. Nakabayashi[1], M. Kubo[3], T. Morizono[3], T. Kawaguchi[3], T. Tsunoda[3], H. Tomiyama[4], M. Yamamoto[5], N. Hattori[4], M. Murata[6], Y. Nakamura[3,7], T. Toda[1].* 1) Div Neurol/Mol Brain Sci, Kobe Univ Grad Sch Med, Japan; 2) Div Genome Analysis, Medical Instit of Bioregulation, Kyushu Univ, Fukuoka, Japan; 3) Center for Genomic Med, RIKEN, Japan; 4) Dept Neurol, Juntendo Univ Sch Med, Japan; 5) Dept Neurol, Kagawa Pref Cen Hsp, Japan; 6) Dept Neurol, Natl Center Hsp Neurol and Psy, Japan; 7) Human Genome Center, Univ Tokyo, Japan.

Parkinson's disease (PD) is one of the most common neurodegenerative diseases worldwide. We reported a genomewide association study (GWAS) in a total of 2,011 cases and 18,381 controls from the Japanese (Satake W et al, Nat Genet 2009). In that GWAS, we selected 337 most associated SNPs (P <0.00054) from genome-wide 435,470 SNPs, conducted two subsequent replication studies, and detected 4 susceptibility loci for PD consequently. In the present study, we re-analyzed our genotyping data of 988 cases in the previous GWAS using more control data in order to obtain more accurate allele frequencies in controls. We subsequently genotyped and tested association for second hit more than ~9000 SNPs. Although genotyping is still underway, we have so far genotyped 1,948 cases and 28,990 controls in total and tested for association between each SNP and PD using Cochran-Armitage trend test with 1 d.f. We identified a novel susceptibility locus on chromosome 1 with P <5 x 10^{-8}. We also detected strong association at MCCC1 on 3q27 (rs10513789, P = 1 x 10^{-7}) that was identified in a recent Caucasian meta-GWAS (IPDGC, Lancet 2011). Our results identify a new PD susceptibility locus and confirmed MCCC1 in the Asian population.

544T

Genome-wide association study of narcolepsy with cataplexy in Japanese population. *H. Toyoda[1], T. Miyagawa[1], S. Khor[1], M. Kawashima[1], M. Yamasaki[1], A. Koike[2], Y. Honda[3], M. Honda[3,4], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Central Research Laboratory, Hitachi, Ltd. Tokyo, Japan; 3) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 4) SLEEP control project, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Narcolepsy with cataplexy is a sleep disorder characterized by excessive daytime sleepiness and cataplexy. The prevalences of narcolepsy with cataplexy have been reported to be 0.02-0.18% in Japan, US and Europe, whereas 1-2% of first-degree relatives of patients develop narcolepsy, indicating genetic predispositions influence the development of narcolepsy. Several studies have showed a strong association with a specific HLA allele. Most of the patients (88-100%) with narcolepsy-cataplexy are HLA-DQB1*0602 positive whereas only 10% of healthy people possess the HLA allele. However, HLA can explain only a part of genetic contribution to the disease. We have performed the first SNP-based genome-wide association study (GWAS) in Japanese (Miyagawa et al. Nat. Genet. 2008), and participated in international GWAS (Hallmayer et al. Nat. Genet. 2009; Kornum et al. Nat. Genet. 2011). Now, we conducted an expanded GWAS using the Affymetrix Genome-Wide Human SNP 6.0 on 425 Japanese patients with narcolepsy-cataplexy compared to 1626 Japanese healthy controls.

Extensive quality control tests were performed to ensure the integrity of the data, including sample filters (total call rates／ 95%), SNP filters (SNP call rates／ 97%, MAF／ 5%, deviations from HWE in controls (P／ 0.001)), and EIGENSTRAT method to correct for population stratification. The final post-QC discovery set comprised 409 cases and 1,562 controls, and a total of 545,140 SNPs passed the quality control criteria. The estimated inflation factor (λ) on the basis of the median $\chi 2$ test was 1.03 after the quality control. Each SNP was tested for association by allelic, dominant/recessive, genotype and trend test. HLA region were excluded from further analysis. We detected 48 SNPs in 20 different regions with P < 1.47E-05, except for HLA regions. The top SNP showed P = 6.27E-06 in trend test and P = 4.92E-06 in EIGENSTRAT-adjusted model. The candidate regions were further subjected to imputation of missing genotypes to increase SNP coverage. Imputation was performed with MACH 1.0, IMPUTE v2 and PLINK 1.07 softwares using reference haplotypes from HapMap 3 (JPT+CHB). There were no SNPs that showed markedly stronger associations than genotyped SNPs in each region, even though some SNPs were found to be suggestively significant. Replication study of the top-ranking SNPs found in the discovery phase is in progress using independent sample sets.

545T

CDH13: GWAS, brain distribution and mouse model studies support roles in addiction and ability to quit smoking. *G. Uhl[1], J. Drgonova[1], D. Walter[1], B. Ranscht[2].* 1) Dept Molec Neurobiology, NIDA/NIH, Baltimore, MD; 2) Sanford-Burnham Institute, LaJolla, Calif.

Classical human genetic studies suggest that vulnerability to dependence on addictive substances shares genetic determinants with ability to quit, and with its common comorbidities, including attention deficit/hyperactivity disorder (ADHD). Genome wide association (GWA) datasets for dependence-related phenotype and abilities to quit smoking have repeatedly identified a number of genes in the following way: they contain clusters of nearby SNPs whose case vs control differences reach nominal statistical significance. The cell adhesion molecule cadherin 13/T cadherin/H cadherin (CHD13) is identified in this way in 15 of 17 independent genome wide datasets for dependence-related phenotypes or quit success. About one in 10exp12 genes of this size would be expected to be identified this frequently by chance. In most samples, clustered association signals are found in the first several CDH13 introns. These CDH13 introns also identified in metaanalyses of ADHD GWA data. CDH 13, and most of other genes identified in the same way, is expressed in both developing and adult brain. This gene, and more than ½ of the other genes identified in the same fashion, is expressed in dopaminergic and noradrenergic neurons implicated in rewarding effects of addictive substances of a variety of different classes and in regulation of locomotion. This gene and more than ½ of other genes identified in the same fashion, is also expressed in large striatal cholinergic interneurons. Searching databases of genes subjected to cis-regulation in lymphoblastoid cell lines fail to identify CDH13; these databases identify about as many “addiction/quit success” genes as expected by chance. Levels of CDH13 mRNA expressed in postmortem cerebral cortical samples from > 100 individuals also fail to provide any strong association with CDH13 SNPs in these first introns. CDH13 KO mice reveal robust influences on mouse models of drug reward/memory, some effects on models for quit success, and differences in stimulant-induced locomotion. Variations in CDH 13 are thus strong candidates to provide polygenic contributions to development of dependence on an addictive substance and for perhaps for individual differences in abilities to quit smoking Support: NIH IRP (NIDA).

Investigating the association between the glutamate system genes *SLC1A1*, *DLGAP3*, and *GRIN2B* and sub-phenotypes of obsessive compulsive disorder. *P.D. Arnold[1], B.T. Doan[2], J. Beneteau[3], S. Taillefer[4], S. Shaheen[1], S.E. Stewart[5], J.L Kennedy[6], M.A. Richter[7], OCD Mini-Collaborative.* 1) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 2) Faculty of Nursing, University of Toronto, Toronto, ON, Canada; 3) Department of Psychology, Simon Fraser University; 4) Department of Psychology, Ryerson University; 5) Department of Psychiatry, University of British Columbia; 6) Centre for Addiction and Mental Health, Toronto; 7) Sunnybrook Health Sciences Centre, Toronto.

Obsessive-Compulsive Disorder (OCD) is a disabling heritable neuropsychiatric condition affecting 1 to 3% of the population. The phenotype of OCD is highly heterogeneous, which may reflect underlying genetic heterogeneity. There is growing evidence for glutamate dysfunction in OCD, and three main glutamate genes have been investigated by our group and others: *SLC1A1*, *GRIN2B*, and *DLGAP3*. This study examined these three genes as candidate genes for OCD, and attempted to reduce heterogeneity by subgrouping based on gender and predominant symptoms. Subjects were 252 OCD-affected probands and their first degree relatives (N=453 total) collected in a specialized OCD clinic in Toronto and genotyped as part of a larger collaborative study. Tag single nucleotide polymorphisms (SNPs) were selected using publicly available databases (dbSNP, HapMap) and the Haploview program. Genotyping was performed on the Sequenom iPlex platform (http://www.sequenom.com). Markers with genotyping success rates less than 90%, with minor allele frequency less than 0.05, and with greater than 10 Mendelian errors were excluded. In total, 36 single nucleotide polymorphisms (SNPs) were investigated for *DLGAP3*, 32 for *SLC1A1*, and 10 for *GRIN2B*. The association between OCD diagnosis and candidate genes was tested using the Family Based Association Test (FBAT); haplotype analysis was also performed. In addition, FBAT was used to test for association when the sample was stratified by gender or by symptom type (five groups identified using factor analysis). Variants in the glutamate genes *DLGAP3* and *SLC1A1* were significantly associated with OCD diagnosis. These genes showed specific associations with male gender (p = 0.04) and with the hoarding subgroup (p=0.03), which has been identified in multiple previous studies as having distinct clinical and neurobiological characteristics. *GRIN2B* did not show a significant association with OCD diagnosis or specific sub-phenotypes. Although limited by sample size and requiring replication, these results provide further evidence that *DLGAP3* and *SLC1A1* may be associated with susceptibility to OCD, particularly in males and individuals with primary hoarding symptoms. In concordance with basic neuroscience and clinical neuroimaging studies, these results provide further support for the presence of glutamatergic neurotransmission abnormalities in OCD.

547T

The Catechol-O-methyltransferase Val158Met polymorphism and the decision making in bipolar disorder. *S.B. CAMPOS[1], D.M. MIRANDA[1], M.A. ROMANO-SILVA[1], F.S. NEVES[1], F.M. PASSOS[1, 2], L.F. MALLOY-DINIZ[1, 2], H. CORREA[1].* 1) Mental Health, Universidade Federal de Minas Gerais , Belo Horizonte, Minas Gerais, Brazil; 2) Psychology, Universidade Federal de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil.

Catechol-O-methyltransferase (COMT) is one of several enzymes that degrade cathelocamines. The Val158Met (rs4680) polymorphism, located in exon 4 (codon 158) of the human COMT gene, has been widely researched and associated with several cognitive and behavioral phenotypes in psychiatric disorders. In this polymorphism occurs a change of a valine for a methionine at position 158. The Met variant is associated to a reduce in the enzymatic activity. The Val homozygotes catabolizes dopamine at up four times relative to Met alleles, resulting in lower prefrontal dopamine (DA) levels, that is also associates to a poorly development on neuropsychological task. Considering the relationship between COMT and executive function, we launched an investigation into the relationship between the Val158Met polymorphism and the performance in decision making. We administered a Brazilian version of Iowa Gambling Task (IGT), a neuropsycological test, to bipolar patients to measure their levels non-planning impulsivity. After the task we extract blood samples. Our sample of 64 bipolar patients, with mean age 42,6 ± 11,4 years, was selected from the psychiatrical division, Hospital das Clínicas, Belo Horizonte, Brazil. Genomic DNA was extracted from blood using the high salt method. We analyzed COMT functional polymorphism (Val158Met) selected from the International HapMap Project. Markers used were correspondent to the polymorphisms rs4680. Genotyping was performed using a PCR-Realtime in the allelic discrimination mode (Strategene Mx3005 - MxPro) using the TaqMan Genotyping Master Mix (Applied Biosystems). After genotyping, the subjects were grouped according to the presence or absence of Met allele (Val/Val x Val/Met + Met/Met). The two groups were compared using the Mann-Whitney test and results were considered statistically significant when $p < 0.05$. We found significant differences in the measures of nonplanning impulsivity of the two groups. COMT-Val homozygote performed more poorly on IGT-Br. This difference is significantly worse than individuals in the Val/Met + Met/Met group (U=248,5; Z=-2,906).

A homopolymer polymorphism in the TOMM40 gene contributes to cognitive performance in aging. *O. Chiba-Falek[1, 2, 3], J.M. McEvoy[1], C. Linnertz[1], D. Attix[2, 4], M. Kuchibhatla[5], A.M. Saunders[2, 6], M.W. Lutz[6], K.A. Welsh-Bohmer[3, 4], A.D. Roses[1, 2, 6], K.M. Hayden[3, 4].* 1) Institute for Genome Sciences & Policy, Duke University, Durham, NC 27708, USA; 2) Division of Neurology, Department of Medicine, Duke University Medical Center, Durham, NC 27710, USA; 3) Joseph and Kathleen Bryan Alzheimer's Disease Research Center, Duke University, Durham, NC 27705, USA; 4) Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC 27710, USA; 5) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC 27710, USA; 6) Deane Drug Discovery Institute, Duke University Medical Center, Durham, NC 27710, USA.

A highly polymorphic T-homopolymer was recently discovered to be associated with late onset Alzheimer's disease (LOAD) risk and age of onset. The objective of this study was to explore the effects of the polymorphic polyT tract (rs10524523, referred as `523') on cognitive performance in cognitively healthy elderly. Over 180 participants were recruited from local independent-living retirement communities. Informed consent was obtained and participants completed demographic questionnaires, a conventional paper and pencil neuropsychological battery, and the computerized Cambridge Neuropsychological Test Automated Battery (CANTAB). Saliva samples were collected for determination of the TOMM40 `523' (S, L, VL) and the APOE (, 2, 3, 4) genotypes. Comparison of the `523' genotype frequencies between participants aged 80+ to those under 80 showed no difference. Multinomial logistic regression was used to evaluate performance on the various neuropsychological tests as predictors of `523' genotypes, adjusted for age, sex, education, depression, APOE status, and mental status score. Significant differences were found in a measure of free recall with the S heterozygotes group recalling fewer correct items than the S homozygotes group. Follow-up analysis in a sample restricted to APOE, 3 homozygotes only showed significant differences between S/S and VL/VL groups; the VL/VL group performed significantly worse on measures of episodic memory (CANTAB Paired-Associate learning OR 2.84, 95% CI 1.12-8.07), attention (Trail Making Test, Part A OR 2.64, 95% CI 1.23-6.13), and executive function (CANTAB measures of intra-extradimensional set shifting OR 9.27, 95% CI 1.66-64.06). In conclusion, our results suggest important APOE -independent associations between the TOMM40 `523' polymorphism and specific cognitive domains of memory and executive control in cognitively normal aging subjects. Interestingly, these specific cognitive domains are preferentially affected in early stage AD. It will be very important to assess the association of the `523' polymorphism in other large elderly cohorts from which neuropsychological data is available in order to get a better understanding of the genetic factors that contribute to successful cognitive aging.

549T

Calcium-channels are implicated in human episodic memory: Evidence from a pathway analysis in healthy individuals. *A. Heck[1], M. Fastenrath[2], L. Gschwind[2], C. Vogler[1], S. Ackermann[1], K. Spalek[2], D. DeQuervain[2], A. Papassotiropoulos[1].* 1) University of Basel, Molecular Neuroscience, Basel, Switzerland; 2) University of Basel, Cognitive Neuroscience, Basel, Switzerland.

Genome-wide association studies (GWAS) are a potent tool for the unbiased search for single marker associations with a specific trait. By reporting the best single p-values meeting the genome-wide level of significance, GWAS ignores effects possibly acting in combination, which results in restricted insight in the biological background of a phenotype. Based on the assumption that genes exert their influence within complex functional systems rather than in isolation, prior biological knowledge is of special value and can be used to inform pathway analyses used to identify combinations of genes implicated in the trait of interest. Statistical methods originating from gene expression analysis have been modified to identify genetic pathways in GWAS data. Among these methods, gene enrichment scores analysis (GSEA) (i.e. testing the overrepresentation of test statistics of functionally related genes against the distribution of all p-values) have become increasingly important. Here we performed a GSEA for an episodic memory task in 1'166 healthy Swiss individuals. We observed 12 pathways significant at the genome level (pFDR<0.05) in the screening sample. Seven pathways replicated in a second sample, including genes involved in calcium-channel activity, cell-adhesion molecules and cation transport processes. On a single marker level of replication (identical SNP, same direction of effect) we observed associations for three SNPs within the calcium channel acticty pathway (gene ontology: GO:0005262) showing robust effects on episodic memory performance. In further analyses we will use functional imaging data and correlate an additive multilocus score of these beneficial alleles with activity in memory-related brain regions.

550T

A preliminary study of genotype-phenotype correlations for rare copy number variants in children with Obsessive-Compulsive Disorder. *B. Li[1], M. Marshall[2], A. Lionel[2], S-M. Shaheen[1], S.W. Scherer[2], G.L. Hanna[3], J.L. Kennedy[4], D.R. Rosenberg[5], P.D. Arnold[1].* 1) Genetics and Genome Biology, Sickkids Research Institute, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, Sickkids Research Institute, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Michigan, Ann Arbor, Michigan, US; 4) Psychiatric Neurogenetic Section, Centre for Addiction and Mental Health, Toronto, Ontario Canada; 5) Department of Psychiatry and Behavioral Neurosciences, Wayne State University, Detroit, Michigan, US.

Background: Obsessive-Compulsive Disorder is a common, highly heritable and genetically heterogeneous psychiatric disorder. Recent studies on the role of rare copy number variants (CNVs) have demonstrated that specific CNVs may be involved in various psychiatric disorders such as autism, schizophrenia and ADHD. However, their role in OCD is not established. This pilot study aims to identify rare CNVs in children with OCD and attempts to correlate rare CNVs with phenotypic data from these patients, including clinical information and brain imaging data. **Methods:** A total of 181 OCD patients aged 7 to 17 were genotyped on the Illumina 610K array and the intensity data was used to predict CNV regions based on two programs, PennCNV and iPattern. Rare CNVs were identified by comparing the CNV calls validated by both programs to the Database of Genomic Variants. CNVs with <1% population frequency on the database were considered rare in the general population and subjected to further annotation to determine their potential relevance to OCD. Detailed clinical information was obtained for all patients and Magnetic Resonance Imaging (MRI) and Magnetic Resonance Spectroscopy (MRS) data was available for a subset of 20 patients. Based on this information, we reviewed the possible correlation between the identified rare CNVs and available phenotypic data. **Results:** A total of 387 novel or rare CNV calls were identified in our 181 patients. Six CNV regions were found to be disrupting exons in functionally relevant genes involved in neurobiological processes, including NRXN1, SLC2A3, PRODH, CAPN14, ADRA2B2, NOTCH4 and PLXNA3. A patient with a deletion in NRXN1, a gene previously implicated in autism and schizophrenia, showed very early onset of severe OCD symptoms at 4 years of age. Another patient with a deletion in SLC2A3, a neuronal glucose transporter, showed very low glutamatergic concentrations (an OCD-associated phenotype) across all examined brain regions. **Conclusion:** We identified two rare CNVs present in genes previously associated with other psychiatric disorders in our patients. Data from another set of 81 probands have been genotyped and will have been analyzed by the time of presentation (total N=262) including an additional 30 subjects with brain imaging data (total N=50). It is hoped that an increased sample size in this ongoing study will help us find more CNVs in genes relevant to the etiology of OCD and more recurrent CNV-phenotype associations.

Association of multiple sclerosis risk variants of *IRF5* with cerebrospinal fluid levels of the putative prognostic marker CXCL13. *M. Lindén, M. Khademi, I. Lima Bomfim, J. Hillert, T. Olsson, I. Kockum.* Karolinska Institutet, Stockholm, Sweden.

Multiple sclerosis (MS) is a multifactorial disease where both genes and environmental factors affect susceptibility. The strongest genetic association is in the *HLA* locus but several non-*HLA* genes have been confirmed as risk genes for the disease. To predict individual patient prognosis and treatment protocol is challenging. Increased levels of the B-cell chemokine CXCL13 correlate to a worse clinical course, and may represent a prognostic marker, and any genetic correlation to CXCL13 may indicate effects on MS severity. Here, we investigate a possible correlation between CXCL13 levels in cerebrospinal fluid (CSF) and some of the non-*HLA* gene variants showing association with MS. CXCL13 levels in CSF from 420 individuals (including CIS, MS and other neurological diseases) were measured using ELISA. SNPs associated with MS were genotyped in the following genes: *CD226, CD6, CLEC16A, EVI5, IL2RA, IL7R, IL12A, IL21R, IRF5, IRF8, PTGER, RBM17, RGMA, RGS1, SH2B3, STAT3, TNFAIP3, TNFRSF1A, TYK2, VAV1*. The Wald test was used for a quantitative trait association analysis of MS risk genes against levels of CXCL13 in CSF. rs3807306 and rs4728142 in *IRF5* showed significant association with CXCL13 levels ($p<0.001$ for both). Both SNPs are included in a risk haplotype associated with MS in Spanish, Finnish and Swedish populations (Kristijansdottir et al, 2008, Lima Bomfim et al, unpublished data) and are in high LD with each other ($r^2=0.95$). Therefore, and for the sake of simplicity only results for rs3807306 will be shown here. We stratified all individuals by genotype and performed t-tests with Welch's correction to test for differences in mean CXCL13 levels in the different genotype groups. Individuals carrying the risk genotype associated with MS, rs3807306-TT, had significantly higher levels of CXCL13 compared with those carrying the rs3807306-GG genotype ($p=0.0017$). The Jonckheere-Terpstra test showed an effect of allelic dosage of the rs3807306 risk allele on CXCL13 levels (J=23421.5, p=1.10-3), where an increasing number of T alleles correlates with increasing CXCL13 mean levels. IRF5 is a transcription factor that induces antiviral and inflammatory responses. The role the MS-associated *IRF5* variants in MS pathogenesis and disease progression is not known. These results suggest that elevated levels of CXCL13 in CSF are in part determined by SNPs in *IRF5* but further research on their function and possible impact on pathways regulating CXCL13 is needed.

Allelic Differences between Han Chinese and Europeans for Functional Variants in ZNF804A and Their Association With Schizophrenia. *B. Su[1], M. Li[1,2], X. Luo[1], X. Xiao[1], L. Shi[1,2], X. Liu[3], L. Yin[3], H. Diao[4].* 1) Kunming Inst Zoology, Chinese Academy Sci, Kunming, China; 2) Graduate School of Chinese Academy of Sciences, Beijing, China; 3) The Second People's Hospital of Yuxi City, Yuxi, China; 4) Yunnan Mental Health Hospital, Kunming, China.

ZNF804A is a recently identified schizophrenia risk gene by GWAS as well as subsequent replications. Although the results are consistent among studies in European populations, there have been conflicting reports in Chinese populations. We conducted both association and functional analyses to test whether ZNF804A is a risk gene for schizophrenia in Chinese populations. We recruited two independent Han Chinese case-control samples (a total of 2,207 subjects) from southwestern China. A total of 6 single nucleotide polymorphisms (SNPs) were tested including the key SNP (rs1344706) showing significant association with schizophrenia in European populations and the other 5 promoter SNPs of ZNF804A. Based on the results of the association analysis, we performed two functional assays to test the impact of the risk SNP on transcriptional factor binding affinity and promoter activity. Our results showed that rs1344706 was not associated with schizophrenia in either of the two Han Chinese samples, and this result was confirmed by meta-analysis in five Han Chinese samples. However, we identified two ZNF804A promoter SNPs significantly associated with schizophrenia in both samples, and the significance were strengthened in the combined samples (rs359895, p=1.0×10-5 and rs1021042, p=3.0×10-6), and further supported by the haplotype analysis (global p<1.0×10-8). The functional assays demonstrated that the risk SNP (rs359895) can influence the Sp1 binding affinity, resulting in a higher promoter activity of the risk allele. We propose that ZNF804A is a common risk gene for schizophrenia in world populations, and the newly identified functional SNP (rs359895) is likely a risk SNP for schizophrenia.

Using Cluster Analysis to Identify Homogenous Subgroups Within the Autism Spectrum. *O.J. Veatch[1], B.L. Yaspan[1], N. Schnetz-Boutaud[1], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Ctr Human Gen, Vanderbilt Med Ctr, Nashville, TN; 2) J.P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Autism Spectrum Disorders (ASD) are developmental neuropsychiatric syndromes characterized by impaired social interaction, language/communication deficits and restricted, repetitive behavioral patterns. Previous studies established a strong influence of genomic variation in the etiology of ASD. While associated genomic regions have been identified, estimated effect sizes are small and the combined evidence from numerous analyses does not explain the highly heritable nature of the disorder. Disorders diagnosed within the autism spectrum are very heterogeneous with regard to phenotypic presentation. This wide variability in clinical manifestation has been cited as an explanation for difficulties in identifying common genetic variation associated with ASD and suggests that the clinical variability may be explained in large part by underlying genetic heterogeneity. We chose to use clustering methodology to explore ASD data in an attempt to uncover highly similar genetic subgroups. Single Nucleotide Polymorphism (SNP) data from Caucasian families in the publicly available Autism Genetic Research Exchange (AGRE) dataset was previously evaluated using a pathway-based approach in the Pathway Analysis by Incorporating Structure (PARIS) program. Published results identified 17 biological pathways which met the significance threshold of $p < 0.05$. We further analyzed these pathways to identify risk SNPs driving the associations. We identified a total of 895 SNPs, following pruning for linkage disequilibrium (LD), located in pathways of interest which significantly increased ASD risk ($p < 0.05$). Individuals were scored based on presence of these risk alleles to create a genotype risk score. Clustering was initially done using solely the presence of risk alleles at each locus to identify genetically homogenous groups. In order to identify sub-phenotypes related to underlying genetic risk, we then included available Autism Diagnostic Interview-Revised (ADI-R) scores, Autism Diagnostic Observation Schedule (ADOS) scores, Vineland Adaptive Behavior Scale (VABS) scores and head circumference data in the clustering analysis. Unique clusters of ASD cases are currently being assessed. This approach to ASD gene discovery allows effective evaluation of a broad array of data and enables a more complete phenotype definition thereby increasing power to detect genetic factors influencing risk in subsets of individuals with ASD.

554T

Chromosome 9p21 is associated with frontotemporal lobar degeneration in Finland. *A.E. Renton[1], A.M. Remes[2], A.-L. Kaivorinne[2], T. Peuralinna[3], P.J. Tienari[3], B.J. Traynor[1].* 1) Neuromuscular Diseases Research Group, Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD; 2) Department of Clinical Medicine, Neurology, University of Oulu, Oulu, Finland; 3) Department of Neurology, Helsinki University Central Hospital and Molecular Neurology Programme, Biomedicum, University of Helsinki, Helsinki, Finland.

We recently completed a genome-wide association study (GWAS) of amyotrophic lateral sclerosis (ALS) in Finland, which identified a highly significant association peak on chromosome 9p21. All of the Finnish ALS patients associated with this locus shared a 42-SNP haplotype spanning 232 Kb, strongly suggesting a founder effect in this population. Some of the SNPs in this haplotype were also marginally associated with frontotemporal lobar degeneration (FTLD) in an independent GWAS. Furthermore, unpublished data suggest that Finland has a high rate of FTLD, and clinical, neuropathological and epidemiological studies suggest that ALS and FTLD are part of the same neurodegenerative disease spectrum. Given these observations, we hypothesized that the chromosome 9p21 locus may also be responsible for a proportion of FTLD in the Finnish population. To test this, we selected nine SNPs that tagged the original 42-SNP haplotype identified at this locus, genotyped them in 80 Finnish FTLD patients, and compared the haplotype frequency with previously-generated Finnish control data. Overall, 22.5% of these FTLD cases carried the same chromosome 9p21 risk haplotype as the ALS patients. This carrier frequency was similar to that observed previously in Finnish ALS patients. The 9p21 risk haplotype was significantly overrepresented in FTLD compared to controls ($p = 9.22\text{x}10^{-11}$, odds ratio = 7.7). Our results suggest that the chromosome 9p21 locus accounts for a high percentage of Finnish FTLD cases, and confirm that this risk haplotype can clinically present as either ALS or FTLD. It is possible that the chromosome 9p21 locus also accounts for a sizeable proportion of FTLD in other parts of Scandinavia, such as the Lund focus of cases in the south of Sweden.

Genome-wide scan suggested novel Alzheimer disease susceptibility genes by factoring influence of *APOE*. *J. Buros[1], G. Jun[1,2,3], B.N. Vardarajan[1], K.L. Lunetta[3], R. Mayeux[4,5], J. Haines[6], M.A. Pericak-Vance[7], G. Schellengberg[8], L.A. Farrer[1,2,3,9,10], The Alzheimer Disease Genetics Consortium.* 1) Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA; 2) Ophthalmology, Boston University School of Medicine, Boston, MA; 3) Biostatistics, Boston University School of Public Health, Boston, MA; 4) The Taub Institute on Alzheimer's Disease and the Aging Brain and The Gertrude H. Sergievsky Center, College of Physicians and Surgeons, Columbia University, New York, NY; 5) Epidemiology, Mailman School of Public Health, Columbia University, New York, NY; 6) Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 7) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 8) Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA; 9) Epidemiology, Boston University School of Public Health, Boston, MA; 10) Neurology, Boston University School of Medicine, Boston, MA.

The *APOE* , 4 allele is the most significant genetic risk factor for late-onset Alzheimer's disease (LOAD). We investigated interaction of *APOE* with other loci on a genome-wide level to identify novel LOAD susceptibility genes. A sample of 11,641 AD cases and 11,341 cognitively normal controls from the Alzheimer Disease Genetics Consortium (ADGC) were evaluated for 2,312,972 genotyped and imputed SNPs. Association of each SNP with LOAD was examined separately in subgroups of subjects with *APOE* genotypes , 3/, 3 and , 3/, 4 using logistic regression adjusting for age and sex. Top-ranked SNPs were further examined within categories of other *APOE* genotypes and by tests of interaction with , 4. All analyses were conducted within constituent ADGC datasets and the results were combined using meta-analysis. Among 10,083 , 3/, 3 subjects (37% cases), the most significant results were obtained for three previously identified AD loci (*BIN1*, *ABCA7*, and *CD33*) and one novel locus near *PTK2B* (rs17447007; P = 1 x 10^{-7}; other *APOE* genotypes: P > 0.50). Among 8,102 , 3/, 4 subjects (70% cases), SNPs in four novel genes (*PRDM12, EXOC5, METTL19* and *SMAD3*) showed strong evidence for association (P < 10^{-5}). The most significant result was observed for SNP rs12899234 near *SMAD3* (P = 8 x 10^{-7}; other *APOE* genotypes: P > 0.29). Analysis of a full model that included terms for this SNP, *APOE* and an interaction term was very significant (interaction term P = 9 x 10^{-6}). This study suggests that there are several novel genes for LOAD whose effects on LOAD risk are either independent of or through interaction with *APOE* genotype.

556T

Identification of Novel Schizophrenia Loci by Homozygosity Mapping Using DNA Microarray Analysis. *N. Kurotaki[1], H. Mishima[2], S. Ono[1], A. Imamura[1], S. Tasaki[1], T. Kukuchi[1], N. Nishida[3], K. Tokunaga[3], KI. Yoshiura[2], H. Ozawa[1].* 1) Department of Neuropsychiatry, Nagasaki University, Nagasaki, Japan; 2) Department of Human Genetics, Nagasaki University, Nagasaki, Japan; 3) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

The recent development of high-resolution DNA microarrays, in which hundreds of thousands of single nucleotide polymorphisms (SNPs) are genotyped, enables the rapid identification of susceptibility genes for complex diseases. Clusters of these SNPs may show runs of homozygosity (ROHs) that can be analyzed for association with disease. An analysis of patients whose parents were first cousins enables the search for autozygous segments in their offspring. Schizophrenia (SCZ) is categorized as a severe chronic debilitating psychosis that affects approximately 1% of the global population. Although genetic factors are reported to contribute to the disease and multiple responsible loci have been identified from linkage analysis and case-control association studies, there have been few reproducible results to date. Some reports suggested that homozygosity mapping is a powerful tool not only for investigating single gene defects but also for rare genomic variants in complex traits. They observed homozygous deletions in patients with autistic disorders and concluded that genomic alterations might be a subset of disease-causing mutations in chromosomal regions. The increased susceptibility to SCZ observed in consanguineous families suggests that genomic recessive variations may be involved in its etiology. Considering this and other results, we hypothesized that homozygosity mapping, including identical by descent (IBD) analysis, would be a highly constructive method for identifying the loci responsible for SCZ. Here, using the Affymetrix® Genome-Wide Human SNP Array 5.0 to determine ROHs, we genotyped 9 individuals with schizophrenia (SCZ) whose parents were first cousins. We identified overlapping ROHs on chromosomes 1, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 16, 17, 19, 20, and 21 in at least 3 individuals. Only the locus on chromosome 5 has been reported previously. The ROHs on chromosome 5q23.3-q31.1 include the candidate genes histidine triad nucleotide binding protein 1 (HINT1) and acyl-CoA synthetase long-chain family member 6 (ACSL6). Other overlapping ROHs may contain novel rare recessive variants that affect SCZ specifically in our samples, given the highly heterozygous nature of SCZ. Analysis of patients whose parents are first cousins may provide new insights for the genetic analysis of psychiatric diseases.

Association Study of Cathepsin D Gene Polymorphism with Alzheimer's Disease. *M. Noruzinia[1], A. Sayad[1], M. Zamani[2], M. Harirchian[3], A. KazemNezhad[4], E. ShahsavandAnanloo[5].* 1) Department of Medical Genetics, Tarbiat modares university, Tehran, tehran, Iran; 2) Department of Neurogenetics, Iranian Centre of Neurological Research, Tehran University of Medical Sciences, Tehran, Iran; 3) Department of Neurology, School of Medicine, Tehran University of Medical Sciences, Tehran, Iran; 4) Department of Biostatistics, Faculty of Medical Science, Tarbiat Modares University, Tehran, Iran; 5) Department of Genomic Psychiatry (DGP), Roozbeh Psychiatric Hospital.

One of the most prevalent forms of dementia is Alzheimer's disease (AD). Complex inheritance and multi-factorial patterns of late-onset Alzheimer's disease (LOAD) along with its heterogeneity are due to the presence of different AD predisposing genes with different influence on disease development among various populations. A key event in the pathogenesis of AD is the deposition of beta amyloid peptide, which is derived from the amyloid precursor protein by beta and gamma secretases. Cathepsin D (CTSD) is an acid protease with) and . secretases-like features in vitro. An exonic C→T polymorphism at position 224 of the CTSD gene has shown to be associated with the enzyme function of CTSD and to Alzheimer's disease. Two studies in German population reported a strong association of this polymorphism with an increased risk of developing AD, while other studies did not confirm this observation. We tested for this association in a case control study in 100 Iranian LOAD patients based on diagnostic criteria DSM-IV-TR and NINCDS-ADRDA and 100 normal controls without any personal and family history of Alzheimer's disease of other related dementias. PCR-RFLP was set up to detect this polymorphism. Our study demonstrated that T carrying genotype frequency in AD patients is significantly higher than in controls and there was 2.5 fold increased risk for developing AD in T carrying genotype compared to C/C genotype(OR=2.5, 95%CI: 1.2-5.1, P=0.01). Our results indicate that CTSD genotype is associated with the disease and significantly alter the risk for developing AD.

Intersecting copy number variants and whole exome sequencing for diagnosis of *FA2H* mutations. *D.R. Simeonov, M. Sincan, T.C. Markello, D.A. Adams, C. Toro, G. Golas, C.F. Boerkoel, W.A. Gahl, T. Pierson.* Undiagnosed Diseases Program, National Institutes of Health, Bethesda, MD.

The spastic paraplegias are a genetically heterogenous group of disorders that overlap clinically. This clinical overlap confounds directed molecular testing. To circumvent this, the NIH Undiagnosed Diseases Program has been evaluating a combination of genomic tools for diagnosis of such genetically heterogeneous diseases. Exemplifying this, we present 10-year-old boy born to healthy unrelated parents who presented with spastic paraplegia, cerebellar ataxia, and cognitive deficits. At age 3, he developed progressive leg spasticity, ataxia, postural instability, impaired eye movements, and dysarthria. Extensive genetic and molecular testing did not reveal a definitive diagnosis. Muscle, skin, and nerve biopsies were unrevealing. MRI imaging of the brain showed non-specific T2 deep-white-matter hyper-intensity consistent with demyelination and evidence of mineralization of the globus pallidi. A sural axonal neuropathy was also present. Exome sequencing and SNP analysis identified two novel *FA2H* mutations: a paternally inherited c.707T>C (p.F236S) and maternally inherited hemizygosity for exons 3-7. FA2H encodes the enzyme fatty acid 2-hydroxylase and is important for CNS myelination. Fatty acid 2-hydroxylase deficiency causes fatty acid hydroxyl associated neurodegeneration (FHAN). In summary, we expand the clinical phenotype of FHAN, report the first instance of FHAN arising in a non-consanguineous family and show the CNV deletions can uncover recessive mutations in SPG-associated genes.

559T

Exome re-sequencing in familial hemiplegic migraine with linkage to 14q32. *M. VILA-PUEYO[1], E. CUENCA-LEON[1], I. GARCIA-MARTÍNEZ[1], F. CASTRO[2], I. GUT[2], M. BAYES[2], B. CORMAND[3], A. MACAYA[1].* 1) PEDIATRIC NEUROLOGY, INSTITUT DE RECERCA HOSPITAL VALL D'HEBRON, BARCELONA, BARCELONA, Spain; 2) CENTRO NACIONAL DE ANÁgLISIS GENÓMICO, BARCELONA, SPAIN; 3) DEPARTMENT OF GENETICS, FACULTY OF BIOLOGY, UNIVERSITY OF BARCELONA, SPAIN.

Familial hemiplegic migraine (FHM) is a rare and severe monogenic variant of migraine with aura, with an estimated prevalence of 1/10.000. Mutations in three genes, CACNA1A, SCN1A and ATP1A2, have been linked to both familial and sporadic hemiplegic migraine. However, genetic heterogeneity appears to be high and a substantial number of cases do not harbour mutations in any of these three genes, including families with known linkage to other chromosomal loci. We have previously reported a multigenerational family with FHM and MA following a dominant inheritance pattern, where a genome-wide linkage analysis mapped the disease-causing gene to a 4.15Mb locus on chromosome14q32 with a maximum two-point LOD score of 3.11 (Cuenca-León et al., Neurogenetics 2009). Direct sequencing of three candidate genes in the region (SLC24A4, ATXN3 and ITPK1) did not uncover pathogenic mutations. To further analyze the linkage region, in the present study we performed exome sequencing of the FHM index case. The Nimblegen SeqCap EZ Exome Library SR was used for exome enrichment. The capture library was sequenced on a Illumina Genome Analyzer IIx instrument using paired-end 75 bp reads. We attained a mean coverage depth of x15 for ~82% of the primary target (26.7 Mb). Under a dominant inheritance model, preliminary whole exome analysis identified 22,131 variants. After filtering through the dbSNP, 1000G and CNAG in-house databases, 156 predicted damaging variants were left, including those in several genes with known brain expression. However, none of them was found within the linkage critical interval on chromosome 14. We then focused on the 4.15 Mb linkage locus and identified 62 variants, although only one of them was not present in dbSNP or 1000G and it was not predicted to be damaging. We are currently inspecting the variants identified in the linkage region and in the rest of the exome to list a selection of plausible candidates for Sanger sequencing validation and for testing cosegregation with the disorder in the whole pedigree.

560T

Association of CNTNAP2 with specific language impairment related phenotypes. *S. Cheong[1], L. Hou[1], J. Flax[2,3], S. Petrill[1,4], P. Tallal[2], L. Brzustowicz[3], C. Bartlett[1].* 1) The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 3) Department of Genetics, Rutgers University, Rutgers University, New Brunswick, NJ; 4) Department of Human Development and Family Science, The Ohio State University, Columbus, OH.

Background. Specific Language Impairment (SLI) is a developmental failure to develop normal language in the absence of intellectual disability or other cognitive/medical explanations. With a prevalence of 7%, it has been associated with later academic difficulty/failure. In previous sibling studies a gene replicated as being involved in autism, CNTNAP2, was associated with SLI specifically with regard to phonological short-term memory (PSTM). In order to replicate and extend this finding, a series of extended pedigrees with SLI were assayed and assessed for association between CNTNAP2 and SLI phenotypes. **Methods.** The sample consisted of 17 US and Canadian extended families with multiple cases of SLI that were genotyped with Illumina SNP arrays (one of: Omni Express, 660W, or Omni 1M). A total of 133 SNPs in CNTNAP2 were used for linkage and association analysis to 8 reading and language phenotypes (categorical: language impairment, reading impairment; quantitative: PSTM, rapid auditory processing, reading comprehension, decoding, expressive language, and receptive language). For each phenotype we analyzed linkage and linkage disequilibrium using the program Kelvin's posterior probability of linkage/linkage disequilibrium. Phenotypic effects of CNTNAP2 were further characterized in a regression framework. **Results.** Three phenotypes (decoding, expressive language, and receptive language) show strong LD with CNTNAP2 (PPLDs > 60% for SNPs rs17586018, rs347180, and rs347223). Additionally, rs1608629 yielded a PPL of 10% with PSTM in line with previous findings. Phenotypes were regressed onto associated SNPs in a model selection framework including possible covariates for age, age2, sex, and performance IQ (PIQ). Variance accounted for by these models ranged in R2 from 0-14% when performing backward selection of hierarchical models assuming additive genotypic effects and accounting for multiple testing. The 3 SNPs associated with language accounted for as much variance in rapid auditory processing and decoding as the language measures (R2=4-9%). Additionally, genotypes at rs1608629 account for 14% of the variance in PSTM. **Conclusions.** CNTNAP2 shows equally strong genetic associations with expressive and receptive language abilities as well as decoding though regression models assuming additive effects also indicate an important role for rapid auditory processing. Additionally, additive effects of CNTNAP2 on PSTM are quite large in this sample.

Association of 18q22.1 with Specific Language Impairment Susceptibility. *N. Li[1], L. Hou[1], J. Flax[2,3], S. Petrill[1,4], P. Tallal[2], L. Brzustowicz[3], C. Bartlett[1].* 1) 1The Battelle Center for Mathematical Medicine, The Research Institute at Nationwide Children's Hospital and Department of Pediatrics, The Ohio State University, Columbus, OH; 2) Center for Molecular and Behavioral Neuroscience, Rutgers University, Newark, NJ; 3) Department of Genetics, Rutgers University, Rutgers University, New Brunswick, NJ; 4) Department of Human Development and Family Science, The Ohio State University, Columbus, OH.

Background Specific Language Impairment (SLI) is a neurodevelopmental failure to develop normal language without explanatory factors such as low IQ or inadequate environment. Affecting ~7% of children entering school, it is associated with poor academic outcomes. To date, 4 SLI-associated genes have replicated. In order to discover additional genetic risk factors, genome-wide linkage and follow-up association analysis of a single extended pedigree was conducted. Methods A single large Caucasian pedigree consisting of 61persons from the US (phenotypic N=41, genotypic N=36) was genotyped at > 600,000 single nucleotide polymorphisms (SNPs) using the Illumina SNP arrays. Primary linkage analysis of 6 phenotypes (categorical: language impairment, reading impairment, quantitative: reading comprehension, expressive language, receptive language, non-word reading) were included in the primary analysis. Linkage was conducted using a modified version of McLink. Peak regions were included in an association analysis using all genotyped SNPs from the array including an additional 7 SLI extended pedigrees for follow-up linkage disequilibrium analysis in the program Kelvin. Additional genotype-phenotype characterizations were conducted by regression analysis. Results Four linkage peaks were detected including a PPL of 14.3% in 18q22.1 with the reading comprehension measure. Several SNPs showed linkage disequilibrium in the pedigree (highest PPLD=26%) Those SNPs were entered as independent variables in a regression analysis of reading comprehension. SNP rs957789 accounted for 7% of the variance in reading comprehension in discovery extended pedigree and 2.6% of the variance in reading comprehension for 7 independent SLI pedigrees from a replication analysis. In both cases, the A allele is associated with lower mean reading comprehension scores. This SNP is located in a miscellaneous RNA (miscRNA) transcriptional unit, which we found is expressed in an adult human brain cDNA library. Discussion This is the first report of a risk factor for language impairment in this region of chromosome 18. Further elucidation of the transcriptional system may provide possible mechanistic insights for further cognitive neuroscience studies. Key Words: genome-wide linkage study; language; reading abilities; specific language impairment (SLI).

562T

Linkage and candidate gene analysis identifies a rare variant in NRG1 associated with cannabis dependence in African-Americans. *S. Han[1], J. Gelernter[1,2], H. Kranzler[3,4], B. Yang[1].* 1) Department of Psychiatry, University School of Medicine, New Haven, CT 06511 and VA CT Healthcare Center 116A2; 950 Campbell Avenue; West Haven, CT 06516, USA; 2) Departments of Genetics and of Neurobiology, Yale University School of Medicine, New Haven, CT 06511, USA; 3) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 4) VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, Pennsylvania.

Cannabis is the most commonly used illicit drug in the world. A genetic contribution to cannabis dependence (CaD) has been established from family and twin studies. The objective of the current study was to use linkage and candidate gene analyses to identify genetic variants associated with CaD. We first performed nonparametric linkage analysis for CaD in 384 African-American (AA) and 385 European-American (EA) families ascertained on the basis of sibling pairs affected with cocaine and/or opioid dependence. We then used the SAGE GWAS dataset to investigate the association between single nucleotide polymorphism (SNPs) in the region of the linkage peak and CaD, adjusting for sex, age, and population stratification principal components in AAs and EAs separately. In AAs, we identified genomewide suggestive evidence for linkage on chromosome 8p21.1 at 54.9 cM (lod=2.9, pointwise P = 0.00013, empirical genomewide P = 0.097). Weak linkage evidence was detected at the same location in EAs (lod= 0.62, pointwise P = 0.05). In the association analysis in the region of the linkage peak (2601 SNPs) in the SAGE sample, we identified three SNPs nominally significantly associated with CaD in both AAs and EAs. However, only one SNP (rs17664708), located at NRG1, which encodes neuregulin 1, variation in which has been implicated in risk of schizophrenia, showed consistent direction of effect in both AAs (minor allele frequency (MAF) = 0.02, OR=2.7, 95% CI=1.33-5.49, P=0.006) and EAs (MAF=0.098, OR=1.4, 95% CI=1.06-1.86, P=0.017). We replicated the association of rs17664708 with CaD in an independent AA sample (MAF=0.012, OR=2.76, 95% CI= 1.20-6.35, P=0.0085), but not in EAs (MAF=0.12, OR=0.99, 95% CI=0.73-1.35, P=0.96). The joint analysis of the two AA sample sets (SAGE and ours) demonstrated strong association between rs17664708 and CaD (OR= 2.86, 95% CI=1.73-4.75, P=1.3E-5). In conclusion, our study shows, for the first time, that NRG1 is probably a susceptibility gene for cannabis dependence, based on convergent evidence of linkage and replicated association in two independent samples of AAs. Further replication studies using a high density SNP panel or deep sequencing are necessary to confirm the role of NRG1 in CaD.

563T

Cytochrome P450 downregulation in Niemann-Pick disease type C. *C.V.M. Cluzeau[1], N. Al Eisa[2], D.E. Watkins-Chow[3], R. Fu[1], B. Borate[4], M.K. Dail[1], C.A. Wassif[1], F.M. Platt[2], W.J. Pavan[3], F.D. Porter[1].* 1) Program in Developmental Endocrinology and Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, Bethesda, MD; 2) Department of Pharmacology, University of Oxford, UK; 3) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, MD; 4) Molecular Genetics Section, Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, MD.

Niemann-Pick disease type C (NPC) is a lethal autosomal recessive neurodegenerative disorder, resulting from mutations in *NPC1* and *NPC2* genes, with no FDA approved therapy. Cholesterol and sphingolipids are trapped in late endosomes/lysosomes, resulting in liver disease and progressive neurodegeneration. Presenting signs and symptoms are nonspecific, and the diagnosis is frequently difficult and delayed. Despite intensive work, the pathological mechanisms leading to both brain and liver dysfunctions have not been fully defined. In order to identify functional pathways responsible for the NPC pathology, we carried out gene expression profiling in a murine *Npc1*$^{-/-}$ model, which closely recapitulates the human disorder. We isolated liver RNA for microarray analysis to compare gene expression in mutant and control females (N=4), at multiple pre-symptomatic (1-, 3- and 5-week old) and post-symptomatic ages (7-, 9- and 11-week old). Using this approach, we identified 222 significantly altered pathways, including many corresponding to metabolic processes, immune response and developmental signaling. We focused initially on 155 genes that were differentially expressed at all time points. Among these, 10 genes in the cytochrome P450 family were surprisingly downregulated in the mutant mice. This microarray result was validated by qPCR. Cytochrome P450 enzymes are involved in the metabolism of drugs and endogenous compounds, such as arachidonic acid (AA). AA metabolites include the pro-inflammatory molecules prostaglandins (PG) and leukotrienes (LT). The downregulation of cytochrome P450 family members, together with the upregulation of two major enzymes in PG synthesis, led us to hypothesize that dysregulation in AA metabolism may contribute to the inflammation observed in NPC. Cytochrome P450 enzyme downregulation is also a significant pharmacogenetic finding, since impaired P450 activity may result in altered drug metabolism by NPC patients and thus require alteration in medication dosing. Our preliminary data in the murine and feline NPC models showed a marked reduction in cytochromes P450 activity. Microarray analysis also identified 103 differentially expressed genes encoding secreted proteins, including 12 with a modified expression at all time points. These genes represent important candidate biomarkers to facilitate diagnosis or development of therapeutic trials. Analysis of these potential biomarkers in a 56-patient natural history trial is in progress.

564T

Age-dependent Parkinson disease risk assessment for GBA mutation carriers. *H.Q. Rana[1], M. Balwani[1], L. Bier[1], R.N. Alcalay[2].* 1) Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Movement Disorders Division, Department of Neurology, Columbia University Medical Center, New York, NY.

Background: The association between GBA mutations and Parkinson disease (PD) is well established; however, the age-dependent risk for PD among mutation carriers is unknown. In the general population, PD risk by age 65 is estimated to be 1-1.5%. Objective: To obtain age-related history of PD in parents and children of Gaucher disease (GD) patients, who are obligate carriers of GBA mutations and who were not ascertained by PD history. Methods: We approached all previously genotyped GD patients evaluated at MSSM from 2009-2011. A validated family history of PD questionnaire was administered to GD patients; their parents' and children's age, history of PD, age-at-onset of PD, and ethnic background were obtained. Results: Of 106 GD patients with whom we established contact, 104 (98%) agreed to participate in the study. Mean age was 47.4 years (range 2-93 years old), 53 participants (51%) were male, 66 (63.5%) were N370S homozygotes, and 71 (69%) patients were on enzyme replacement therapy (ERT). One study participant, genotype N370S/L444P, who was diagnosed with GD at age 55 and started ERT at the same time, reported a personal history of PD diagnosed at age 63. Of the 206 parents of GD patients, (mean age 68.7, SD 15.9.), four were reported to have a definitive diagnosis of PD and one had Lewy body dementia (2.4%). The mean age of disease onset was at 64 years old. None of the children of GD patients (N=162, mean age 24.2 years, SD 16.6), were reported to have PD. Conclusion: While GBA mutations may increase the age-dependent risk for PD, the vast majority of GD patients and heterozygous mutation carriers may not develop the disease. Further studies are needed to assess PD risk among GBA mutation carriers in order to provide accurate genetic counseling.

565T

Endophenotype-based discovery of a novel risk locus for alcoholism: *CYP7B1*. *L. Almasy[1], M.A. Carless[1], R. Olvera[2], J. Kent[1], T.D. Dyer[1], M.P. Johnson[1], J.E. Curran[1], E.K. Moses[1], H.H.H. Göring[1], R. Duggirala[1], J. Blangero[1], D. Glahn[3].* 1) Texas Biomedical Research Institute, San Antonio, TX; 2) University of Texas Health Science Center at San Antonio, San Antonio, TX; 3) Yale University, New Haven, CT.

The maximum number of drinks an individual has ever consumed in a 24-hour period (maxdrinks) is highly correlated with risk for alcohol dependence and has been utilized in genetic studies of alcoholism, including successful gene localizations via linkage. However, this important endophenotype has yet to be studied using modern methods of genome scanning that take advantage of high density SNP data.

Maxdrinks was assessed in 1195 Mexican American participants in extended pedigrees from the San Antonio Family Study, along with lifetime history of abuse or dependence derived from the MINI-Plus psychiatric screening questionnaire. Participants were genotyped for approximately one million SNPs on Illumina microarrays. After removal of monoallelic SNPs and SNPs with low call rates, 931,219 markers remained. Genome-wide association analyses were conducted using an additive measured genotype model, correcting for the non-independence among family members.

The heritability of maxdrinks was 0.33 and its genetic correlation with lifetime history of alcohol abuse or dependence was 8_g=0.98 ($p=1.4\times10^{-10}$). The environmental correlation was 8_e=0.48 ($p=3.1\times10^{-9}$), implying that both shared genetic and shared environmental factors influence lifetime risk for alcoholism and maxdrinks. Genome-wide association identified one significant signal for max-drinks on chromosome 8 at rs17293712 ($\chi2$=29.5, $p=5.0\times10^{-8}$, MAF=0.096) which also showed nominal evidence of association with lifetime history of alcohol abuse (p=0.018). This SNP is located in the intron of the cytochrome P450, family 7, subfamily B, polypeptide 1 (CYP7B1) gene, which encodes a member of the cytochrome P450 superfamily. The cytochrome P450 proteins are monooxygenases that catalyze reactions involved in drug metabolism and synthesis of cholesterol, steroids and other lipids. Although *CYP7B1* has not previously been associated with alcoholism, it is highly expressed in human hippocampus, a brain region altered in individuals at risk for alcoholism. In addition, a closely related gene, *CYP2E1*, has been implicated in alcohol dependence in candidate gene studies. We are currently conducting sequencing studies in a subset of these families to identify putative functional variants in and around *CYP7B1*.

566T

Association between the *COL25A1* gene and anti-social personality disorder (ASPD) co-morbid with drug dependence. *D. Li[1], H. Zhao[2,3], HR. Kranzler[4,5], D. Oslin[4,5], RF. Anton[6], LA. Farrer[7], J. Gelernter[1,3,8,9].* 1) Department of Psychiatry, School of Medicine, Yale University, New Haven, CT; 2) Department of Epidemiology and Public Health, School of Medicine, Yale University, New Haven, CT; 3) Department of Genetics, School of Medicine, Yale University, New Haven, CT; 4) Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, PA; 5) VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 6) Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, Charleston, SC; 7) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Genetics & Genomics, Biostatistics, and Epidemiology, Boston University Schools of Medicine and Public Health, Boston, MA; 8) VA CT Healthcare Center, West Haven, CT; 9) Department of Neurobiology, Yale University School of Medicine, New Haven, CT.

Antisocial Personality Disorder (ASPD) is a psychiatric disorder characterized by a long-term pattern of manipulating, exploiting or violating the rights of others. Subjects ascertained for genetic studies of drug addiction and diagnosed with ASPD and co-morbid drug dependence were included in a two-stage genetic association study. Selected single nucleotide polymorphisms (SNPs) mapped to 258 candidate gene loci were genotyped in a case-control cohort and family-based cohort at the discovery stage. After stringent quality control, one SNP, rs13134663, mapped to the collagen XXV alpha 1 gene (*COL25A1*), was significantly associated with ASPD in both African-Americans (AAs) and European Americans (EAs) (smallest *P* values were 0.0002 and 0.0004, respectively). The findings were further observed by including family samples using a unified association approach. Evidence of association with the same SNP was also revealed in independent case-control replications in both AA and EA subjects with co-morbid alcohol dependence (AD), cocaine dependence (CD), and marijuana dependence (MjD) (*P* = 0.035 and 0.033, respectively). Analysis of the combined set of case-control subjects including both AAs and EAs (in both the discovery and replication stages) yielded an allelic *P* value of 9×10^{-6} [odds ratio (95% confidence interval) = 1.3 (1.16, 1.47)]. The association was more significant in the AA subjects with co-morbid drug dependence. The *COL25A1* gene, located at chromosome 4q25, encodes the collagen-like Alzheimer amyloid plaque component precursor, a type II transmembrane protein specifically expressed in neurons; it co-localizes with A) in senile plaques in Alzheimer disease brains. This SNP maps to the transcription factor binding site and is conserved in 17 vertebrates, including mice and rats. Our findings suggest that the *COL25A1* gene may also be associated with ASPD, especially when it co-occurs with AD, CD and/or MjD. Further investigation of the gene using other methods is warranted.

567T

Genomic Characterization of Schizophrenia Candidate Gene Regions. *A. Nato[1], X. Kong[1,2], B. Byrne[3], J. Naus[4], D. Gordon[1], S. Buyske[1,4], L. Brzustowicz[1], T. Matise[1].* 1) Dept Genetics, Rutgers Univ, Piscataway, NJ; 2) GlaxoSmithKline, King of Prussia, PA; 3) Informatics Inst, UMDNJ, Piscataway, NJ; 4) Dept Statistics and Biostatistics, Rutgers Univ, Piscataway, NJ.

Schizophrenia (SZ) is a debilitating mental disorder with a lifetime prevalence of ~0.55-1%. Family, twin, and adoption studies have revealed that SZ has a genetic component. In this study, we extracted and analyzed data from the 47 published independent genomewide linkage scans for SZ between 1994 and 2010. We defined 22 schizophrenia candidate gene regions (SCRs) by employing three methods: single significant hit approach, disjoint approach, and smoothing method. For the single significant hit approach, an SCR was defined by the presence of a significant hit by extending 10 cM upstream and downstream of that hit. For the disjoint approach, we identified criteria-events based on clustering of hits within small regions by using a sliding window approach. For the smoothing method, we imputed a randomized range of p-values ($0.001697\leq p<1$) for the genome scans without a suggestive or significant result at each 0.1 cM interval. We combined these p-values with the genome scan results using three methods: geometric mean method, Fisher's method, and Stouffer's method. We characterized each SCR by identifying genes and genomic elements such as structural variations, regulatory elements, and functional noncoding RNAs. Total SCR coverage is 880 cM with SCR sizes ranging from 18 cM to 87 cM. There are 5,482 known genes, 1,954 SD pairs, 16,176 CNVs, and 24 rearrangement hotspots within these SCRs. SCRs with multiple peaks were divided into smaller subregions. We developed a ranking system to identify and prioritize SZ candidate genes by assigning weights to each of the following criteria: (a) located within SCRs that are weighted based on maximum -log10(p-values), (b) annotated in SZ association studies, microarray analyses, and meta-analyses, (c) associated with phenotypes or diseases, and (d) located within or near other genetic elements. We identified pathways that were most significantly associated with the top 10% of candidate genes after prioritization by utilizing the Ingenuity® Pathways Analysis (IPA). We generated an interactome for SZ based on the SZ candidate genes. Our procedure, which provides a novel approach to identify and prioritize candidate gene regions and genomic elements, is applicable to other complex diseases.

568T

Next generation sequencing follow-up study on the Late-Onset Alzheimer Disease susceptibility gene *MTHFD1L*. *J.R. Gilbert[1], M.A. Kohli[1], A.C. Naj[1], A.J. Griswold[1], J.M. van Baaren[1], T.E. Plitnik[1], P.L. Whitehead[1], G.W. Beecham[1], E.R. Martin[1], M.L. Cuccaro[1], C.B. Wright[1], E. Crocco[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL, USA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN, USA.

Genome-wide association studies (GWAS) have identified many common variants with reproducible associations to a multitude of human complex diseases, however the underlying functional variant or molecular mechanism often remains undiscovered. Next generation sequencing (NGS) promises comprehensive variant discovery in a genomic region of established genetic association to human disease. We used long-range PCR to capture a 50 kb region on chromosome 6q25.1 for NGS on a Genome Analyzer II from Illumina. The selected region comprises a linkage disequilibrium (LD) block harboring rs11754661, a single nucleotide polymorphism (SNP) for which we previously reported genome-wide statistical significance in a GWAS on Late-onset Alzheimer's disease (LOAD) and subsequently replicated in a much larger GWAS. The SNP rs11754661 is an intronic SNP with a low minor allele frequency (MAF) of 0.07 in Caucasians, and is located in the 5' region of the 236-kilobasepair gene *MTHFD1L*, which is involved in the folate pathway and represents an interesting LOAD candidate since it may influence homocysteine levels, a significant risk factor for LOAD. We re-sequenced 50 LOAD cases and 34 age-matched cognitively normal controls all heterozygous for rs11754661 to increase the likelihood of also detecting rare LOAD relevant variants. We generated ultra-deep sequencing data and used MAQ for sequence read alignment and variant calling. We detected 264 putative variants which were all intronic or mapped 5' of *MTHFD1L*. Genotypes of 234 variants were clustered according to expected allelic read ratios and examined: 29% were novel (not in dbSNP132 annotation) and 55% were rare (MAF < 0.05). Excluded variants were shown to be false positives by Sanger sequencing mainly due to falling in repetitive regions. Examining single marker case-control data, several associations were observed, including rs4869953 (P=0.033), 151234519_A>G (P=0.048), and rs7765521 (P=0.049). Pooled rare variant case-control associations are currently being examined. In summary, NGS data provide a comprehensive catalogue of SNPs throughout the target region with reliable individual genotypes after filtering. Several challenges remain, including insertion-deletion genotype calling and finding functional candidate variants to explain the GWAS association, the latter of which may require analysis of resequencing data of the whole *MTHFD1L* gene region in more individuals, which is ongoing.

569T

Identification of autism risk variants through targeted next generation sequencing in a 1000 case and 1000 control cohort. *A.J. Griswold[1], D. Hedges[1], R. Chung[1], J. Rantus[1], P. Whitehead[1], I. Konidari[1], W. Hulme[1], S. Slifer[1], J. Jaworski[1], S.M. Williams[2], R. Menon[3], M.L. Cuccaro[1], E.R. Martin[1], J.R. Gilbert[1], J.L. Haines[2], J.P. Hussman[4], M.A. Pericak-Vance[1].* 1) University of Miami, Miami, FL; 2) Vanderbilt University, Nashville, TN; 3) Emory University, Atlanta, GA; 4) Hussman Foundation, Ellicott City, MD.

Genome-wide association studies (GWAS) and copy number variation screens have suggested roles for hundreds of genes in autism susceptibility. Since disease causing variants likely have not been genotyped, sequencing of associated regions to identify rare or low frequency variants contributing to autism is essential. To identify functional variants associated with autism, we are sequencing candidate regions in 1000 unrelated cases with autism and 1000 unrelated controls. Candidate regions were chosen from our recent analysis of two autism datasets which employed the GWAS noise reduction method in conjunction with prioritization of haplotype blocks based on the Truncated Product Method (TPM) (Hussman et. al., 2011). We designed an Agilent SureSelect probe set covering 17Mb corresponding to: 1) exons of 689 genes overlapping blocks with TPM p-values < 0.05 2) evolutionarily conserved regions in those genes plus 5kb from their transcriptional starts and ends 3) evolutionarily conserved regions within non-genic significant blocks 4) the entire blocks with TPM p-values < 0.01. Cases meet DSM-IV and ADI-R criteria for autism; controls were obtained from a cord blood bank or saliva samples from pediatric non-autistic individuals. The cases and controls are matched across three self-reported ethnicities, confirmed by Eigenstrat analysis, into 700 non-Hispanic Caucasians, 200 Hispanics, and 100 African Americans in each set. Sample preparation and capture hybridization of 96 samples is concurrently performed on the Caliper Sciclone G3 and sequenced on the Illumina HiSeq2000. Data are analyzed with a pipeline consisting of BWA alignment, variant calling with the GATK Unified Genotyper, and annotation using publicly available tables. Preliminary analysis of 214 sequenced samples (112 cases and 102 controls) reveal complex libraries with 4.8% ± 2.3 library duplication and 64.1% ± 5.1 of bases on target. 87.5% ± 4.3 of our targeted bases are covered at least 8X allowing for robust variant identification. We identified an average of 32685 ± 3226 single nucleotide variants per individual including 30084 ± 2785 variants in dbSNP version 132 or 1000-Genomes and 2601 ± 878 novel variants, including 54 ± 19 novel non-synonymous nonsense and missense or splice site mutations. This sequencing will provide a vast compendium of variation in autism associated genomic regions and allow for discovery of new variants in genes and genetic networks contributing to autism risk.

Deep sequencing of the LRRK2 gene in 14,002 individuals to guide the clinical development of LRRK2 inhibitors. *J.P. Rubio[1], S. Topp[1], L. Warren[2], P.L. St Jean[2], J. Shen[2], D. Kessner[3], J. Novembre[3], D. Fraser[2], J. Aponte[2], K. Nangle[2], L.R. Cardon[4], M.G. `Ehm[2], S.L. Chissoe[2], J.C. Whittaker[1], M.R. Nelson[2], V.E. Mooser[4].* 1) Genetics, R&D, GlaxoSmithKline, Stevenage, Hertfordshire, United Kingdom; 2) Genetics, R&D, GlaxoSmithKline, Research Triangle Park, NC, USA; 3) Ecology and Evolutionary Biology, UCLA, Los Angeles, CA, USA; 4) Genetics, R&D, GlaxoSmithKline, King of Prussia, PA , USA.

Both rare and common genetic variation in the LRRK2 gene can predispose to Parkinson Disease (PD). The former observation set in motion discovery efforts for inhibitors of LRRK2 for the treatment of PD. LRRK2 has pleiotropic functions and is genetically associated with autoimmune diseases, so LRRK2 inhibitors may be indicated or contraindicated for non-PD conditions. In an attempt to answer these questions and guide the development of LRRK2 inhibitors, we applied the principle that natural variations within the drug target gene may be used as surrogates for pharmacological modulation of LRRK2 in humans. To that end, we deep-sequenced the 51 protein-coding exons of LRRK2 in 12 case collections (n = 9,582) including Alzheimer's disease, bipolar disorder, coronary artery disease, chronic obstructive pulmonary disease , dyslipidemia, epilepsy, irritable bowel syndrome, multiple sclerosis, osteoarthritis, rheumatoid arthritis, schizophrenia and unipolar depression, and in 4,420 population-based controls. We identified 739 single nucleotide variants (SNVs), one every 20 bp on average, including 260 non-synonymous (NS) variants and five nonsense mutations. In Europeans, 62% of SNVs were private to a single individual, whereas 6% had a minor allele frequency (MAF) ⁄ 1%. For the enzymatic domains of LRRK2 we found greater conservation across mammalian species and evidence of purifying selection against potentially damaging NS variants in humans. Case-control association analysis for 12 diseases identified 17 suggestive associations (P≤0.05) of small-modest effect that will require independent replication. We also identified 98 carriers (0.7%) of previously reported PD-associated variants amongst 14,002 individuals, including 31 carriers (0.22%) of pathogenic mutations. In conclusion, this study provides the most comprehensive evaluation of LRRK2 variation to date and provides important insights into evolutionary and population genetic aspects of LRRK2. Genetic association analysis in 12 non-PD common human diseases did not strongly point towards new opportunities for re-purposing of LRRK2 inhibitors, or any particular safety concerns.

571T

Whole-Exome Sequencing of 40 Obsessive-Compulsive Disorder Patients. *D. Trujillano[1], S. Ossowski[1], C. Tornador[1], P. Alonso[2], M. Gratacòs[1], X. Estivill[1].* 1) Genes and Disease Program, Center for Genomic Regulation (CRG-UPF), Barcelona, Catalonia, Spain; 2) Psychiatry Department, Bellvitge University Hospital, Barcelona, Catalonia, Spain.

Introduction: Fast progress in sequencing capacity focused on the coding regions (the exome) that occupy 2% of the genome has provided enormous possibilities to identify new disease genes. Obsessive-compulsive disorder (OCD) is a severe mental disorder characterized by unwanted and intrusive thoughts, images, or impulses (obsessions) and/or repetitive behaviors or mental acts (compulsions). OCD is recognized by the World Health Organization as a major cause of disability. However, little is known about its neurobiology and research still needs to study the genetic factors underlying this complex and heterogeneous disorder. **Methodology:** To reach this goal we carried out whole-exome sequencing of 40 OCD patients. Our heterogeneous cohort included patients with family history of OCD, early age at onset, severe cases, and also patients with good prognosis. The high depth of sequencing achieved by using the SureSelect Human All Exon Kit (Agilent) and sequencing using paired-end sequencing on a single lane of the Illumina GAIIX sequencer allowed us to confidently mine the data for single nucleotide variants (SNV) of interest and for novel SNV and short InDel discovery. **Results:** We identified potentially pathogenic variants in our cohort of patients, where further functional testing is necessary. Correlations are being sought between the different mutated genes and the clinical phenotypes of the patients. **Conclusions:** Whole-exome sequencing of OCD patients provides a high level of resolution of SNV and InDel discovery to dissect the molecular basis of OCD. Replication of SNV and InDel in additional patients should further substantiate these results. We expect that results from this project will contribute to design new strategies for treatment of OCD.

572T

Difficulties in prenatal Diagnosis of Metachromatic Leukudystrophy. *E. Khalili[1&2], M. Hooshmand[1&2], O. Aryani[1].* 1) National Institute for Genetic Engineering and , Tehran, Iran; 2) Genetic Dep. Special Medical Center, Tehran, Iran.

Two siblings of consanguinous parents were noted to have a neurologic syndrome marked by regression of psychomotor performance from the first year, marked spasticity and progressive central nervous system degeneration (clinical manifestation was like late infantile Metachromatic Leukodystrophy.) Markedly delayed nerve conduction times were evident. Brain MRI showed diffuse white matter lesions without involvement of subcortical U-fibers., activity of arylsulfatase A white blood cells and cultured skin fibroblasts were below 5%. Molecular investigation of ARSA gene showed a homozygote DNA alteration in A905G position in exon 5 which changes amino acide Lys302Arg. The parents were heterozygote for this alteration. Because of some problem with prenatal diagnosis with enzyme assay such as: 1) The presence of aryl sulphatase C in chorionic villi, an isoenzyme which may interfere in assays of aryl sulphatase A. 2) The presence of maternal enzyme in chorionic villus material illustrated by the detection of the A isoenzyme of B-hexosaminidase in chorionic villus from a pregnancy affected with Sandhoff's disease. 3) The finding of falsely normal levels of -iduronidase in chorionic villus samples from a pregnancy affected with Hurler's disease, probably due to contamination with maternal tissue which has relatively high levels of this enzyme compared with fetal chorionic material. 4) The inadequacy of indirect assays of incorporation of radiolabel into macromolecules using chorionic villi, for example propionate incorporation for prenatal diagnosis of methylmalonic aciduria. 5) Multiple sulfatase deficiency and their combination with other diseases. Molecular diagnosis according to sequencing finding was done for this family. Prenatal Diagnosis was done for this family and fetus was heterozygot for this mutation. This child was affected according to enzyme assay after birth. Molecular investigation for multiple sulfatase deficiency and Saposin B deficiency were negative in this family. Thus, we believe these patients may represent a new form of ARSA deficiency.

Impaired FLNA expression disrupts radial glia functions leading to periventricular heterotopia in rats and humans. *A. Carabalona[1,2], S. Beguin[1,2], E. Pallesi-Pocachard[1,2], E. Buhler[1,2,3], C. Pellegrino[1,2], K. Arnaud[1,2], P. Hubert[4], M. Oualha[5], S. Khantane[1,2], I. Coupry[6], C. Goizet[6], A. Bernabe Gelot[7], A. Represa[1,2], C. Cardoso[1,2].* 1) INMED, INSERM U901, Parc Scientifique de Luminy, Marseille, France; 2) Université de la Méditerranee, Marseille, France; 3) Plateforme postgénomique INMED, INSERM, Parc Scientifique de Luminy, Marseille, France; 4) Université Paris Descartes, 12 rue de l'Ecole de Medecine, Paris, France; 5) Service de réanimation pédiatrique et de néonatologie, Hôpital Necker Enfants Malades, 149 rue de Sèvres Paris, France; 6) Laboratoire de Génétique Humaine, Université Victor Segalen Bordeaux 2, Bordeaux, France; 7) Département de Neuropathologie, Service d'Anatomie et Cytologie Pathologiques, Hôpital A. Trousseau, Paris, France.

Periventricular heterotopia (PH) is a brain malformation caused by defective neuronal migration that results in ectopic neuronal nodules lining the lateral ventricles beneath a normal appearing cortex. Most affected patients have epilepsy, with normal to borderline cognitive function. Mutations in the Filamin-A (FLNA) gene are the main cause of PH. However, the lack of FlnA animal models that mimic PH has delayed our understanding of the underlying pathological mechanisms. Here, we show that in utero RNA interference-mediated knockdown of FlnA expression leads to the genesis of PH in the developing rat brain. FlnA-knockdown disrupts the organisation and polarity of radial glia as revealed by the altered distribution of vimentin and) 1-integrin at the ventricular zone. The resultant defects alter cell cycle progression and delay migration of cortical neurons. We found similar alterations of radial glia in the post-mortem brain of a PH patient harboring a novel FLNA frameshift mutation (R2103QfsX56). Altogether, these findings highlight the critical role of FLNA in radial glia organization and function for neurogenesis and migration. We propose that alterations of these functions contribute to PH formation. Finally, FlnA-knockdown rats showed increased susceptibility to pentylenetetrazol-induced seizures thus providing a unique opportunity to investigate PH pathogenesis.

Deep sequencing in mental retardation. *M. Gratacos[1], J. González[1], I. Madrigal[2], L. Rodríguez[2], M. Milà[2], X. Estivill[1], R. Rabionet[1].* 1) Genes and Disease, Center for Genomic Regulation, Barcelona, Spain; 2) Genetics Service, Hospital Clínic i Provincial de Barcelona, Barcelona, Spain.

Intellectual disability (ID) is a genetically heterogeneous disorder affecting 1-3% of the population. There are both syndromic and non-syndromic forms of ID, and although there is an elevated proportion of sporadic cases, it can also be inherited in both autosomal dominant and autosomal recessive forms. About 30% of cases of ID can be explained by large structural variants, visible either cytogenetically or by microarray, and over 100 genes have been implicated in its pathophysiology. Nevertheless, about 60% of the cases remain unexplained. A recent study has shown that *de novo* point mutations are a frequent cause of ID, which would make next generation sequencing technologies extremely powerful tools to identify rare *de novo* genetic causes of mental retardation. We recruited 37 cases of sporadic idiopathic mental retardation without dysmorphic features, all of them negative for the fragile X expansion and without cytogenetically visible abnormalities. We performed array comparative genomic hybridization (aCGH) in order to detect smaller structural variants potentially causing the ID, and we identified large sturctural variations (SV) in approximately 20% of the cases. We further performed long-insert mate pair sequencing in 15 cases in order to compare the results with aCGH. Samples negative for SV by aCGH or next generation sequencing were selected for exome sequencing. The exome was captured with Agilent sure select technology, multiplexed, and sequenced in an Illumina HISeq2000 lane. Potential damaging variants were detected by an in-house developed pipeline. Finally, the identified variants were tested in parental DNA to confirm that they were true *de novo* events and thus considered as potentially involved in the susceptibility to develop ID.

575T

Parent-child trio exome sequencing in non-syndromic intellectual disability. *F.F. Hamdan[1], H. Daoud[2], A. Dionne-Laport[2], D. Spiegelman[2], S. Dobrzeniecka[2], E. Henrion[2], O. Diallo[2], J.M. Capo-Chichi[1], S.L. Girard[2], G.A. Rouleau[2], J.L. Michaud[1].* 1) Centre of Excellence in Neuroscience of Université de Montréal (CENUM), Centre de Recherche du CHU Sainte-Justine, Montréal, Quebec, H3T1C5, Canada; 2) Centre of Excellence in Neuroscience of Université de Montréal (CENUM) and Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), and Department of Medicine, Université de Montréal, Montreal, Quebec, Canada, H2L 4MI.

Non-syndromic intellectual disability (NSID) is defined by the absence of associated morphologic, metabolic, or radiologic abnormalities. Recent studies suggest that de novo mutations are responsible for a large fraction of sporadic NSID cases. We have launched a project that aims to identify these mutations by performing exome sequencing in sporadic NSID cases and in their parents. We capture exomes with the Agilent SureSelect all exon capture kit (50Mb) and sequence them on SOLiD or Illumina HiSeq platforms. Stringent criteria are used for calling variants. After applying a series of variant filters to exclude synonymous, inherited and common variants, the remaining candidate amino-acid altering or splicing de novo variants are validated by Sanger sequencing. This analytic pipeline typically leads to the identification of less than 10 candidate variants per trio. As a proof of principle, we have identified a de novo truncating mutation (p.R157X) in the transcription factor gene *TCF4* in a female with NSID using this approach. Heterozygous truncating point mutations in *TCF4* have been previously reported in patients with Pitt-Hopkins syndrome (PHS), which is characterized by specific facial dysmorphism, severe intellectual disability, epilepsy, and intermittent hyperventilation. In contrast, our patient shows mild-to-moderate NSID without epilepsy or breathing abnormalities. Our finding shows for the first time that *TCF4* truncating point mutations can cause NSID, expanding the phenotypical spectrum associated with this gene. At this point in time, we have completed the sequencing in 11 other trios and are currently processing the datasets. We will discuss these results and provide an analysis of the yield of our approach.

576T

Mutations in SPTAN1 in intellectual disability and pontocerebellar atrophy. *J.L. Michaud[1], H. Saitsu[2], K. Nishiyama[2], J. Gauthier[3], S. Dobrzeniecka[3], D. Spiegelman[3], J.C. Lacaille[4], J.C. Décarie[5], N. Matsumoto[2], G.A Rouleau[3], F.F. Hamdan[1].* 1) Centre of Excellence in Neuroscience of Université de Montréal (CENUM), Centre de Recherche du CHU Sainte-Justine, Montréal, Quebec, H3T1C5, Canada; 2) Department of Human Genetics, Yokohama City University Graduate School of Medicine, 3-9 Fukuura, Kanazawa-ku, Yokohama 236-0004, Japan; 3) Centre of Excellence in Neuroscience of Université de Montréal (CENUM) and Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), and Department of Medicine, Université de Montréal, Montreal, Quebec, Canada, H2L 4MI; 4) Le Groupe de Recherche sur le Système Nerveux Central, Department of Physiology, Université de Montréal, Montréal, H3C 3J7, Canada; 5) Department of Medical Imaging, CHU Sainte-Justine, Montréal, Quebec, H3T1C5, Canada.

Heterozygous in-frame mutations in the (-II subunit of spectrin (SPTAN1) were recently identified in 2 patients with intellectual disability (ID), infantile spasms, hypomyelination and widespread brain atrophy (Saitsu et al., 2010 *AJHG*). By screening *SPTAN1* in 95 patients with idiopathic ID, we found 2 novel de novo mutations. The first is an in-frame mutation, p.Q2202del, found in a patient with a milder phenotype than that found in the previously described patients, including less severe cognitive impairment, well-controlled generalized epilepsy and pontocerebellar atrophy. Expression of this mutant form of (-II spectrin in primary neurons resulted in the formation of aggregates containing) -II and) -III spectrin subunits in 20 percent of cells, whereas the previously described in-frame mutations induced aggregation in most cells. The milder phenotype of our patient thus correlates with the decreased ability of the mutation p.Q2202del to induce spectrin aggregations. The second de novo mutation is a missense, p.R566P, found in a patient with mild non-syndromic ID. The sister of this second patient was also diagnosed with non-syndromic ID but lacked p.R566P in her blood DNA, suggesting that she is a phenocopy or that p.R566P is not responsible for her brother's condition. The p.R566P mutant induced aggregates in a small number of neuronal cells (<5 percent). Double immunostaining revealed that these aggregates were composed of the) -II but not of the) -III spectrin subunit. This work indicates that in-frame mutations in the C-terminus of SPTAN1 cause a core set of manifestations that include severe ID, generalized epilepsy and pontocerebellar atrophy. Although it is unclear whether p.R566P is pathogenic, we found that this mutation induces a distinct pattern of spectrin aggregation. The study of spectrin aggregation in cultured cells provides a paradigm to validate candidate variants and to establish correlations between genotypes and phenotypes.

577T

Mutations in the *SHANK3* gene in Japanese autistic patients with severe delayed speech development and mental retardation. *C. Waga[1,2], N. Okamoto[3], H. Asano[1], Y. Goto[2], S. Uchino[1], S. Kohsaka[1].* 1) Department of Neurochemistry, National Institute of Neuroscience, Kodaira, Tokyo, Japan; 2) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, Kodaira, Japan; 3) Department of Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan.

The 22q13.3 deletion syndrome (Phelan-McDermid syndrome, PMS) is characterized by a significant delay in language development, mental retardation, hypotonia, and autistic features. Cumulative evidence has shown that haploinsufficiency of the *SHANK3* gene is a major cause of the neurological symptoms of the 22q13.3 deletion syndrome. Shank3, a multidomain protein containing the SH3 and PDZ domains, is located in the postsynaptic density and interacts with various synaptic molecules including PSD-95 and glutamate receptors. It is therefore thought that the Shank3 plays an important role in the formation and function of synapses. The *SHANK3* gene consists of 22 exons and has five CpG islands (CpG island-P, -2, -3, -4, -5) whose methylation is thought to be involved in regional- and temporal-specific expression of *SHANK3* gene. In this study, we initially analyzed the *SHANK3* gene in 128 autistic patients with manifestations similar to those seen in the 22q13.3 deletion syndrome and identified two novel heterozygous mutations; an 18 bp (6-amino acid) deletion upstream of the SH3 domain (1 patient) and the insertion (3 patients) or deletion (1 patient) of a repeated 10-bp GC sequence located 9-bp downstream from the 3' end of exon 11. None of these mutations was found in 288 control subjects. Since these mutations were located within an intragenic CpG island-2 (vicinity of exon11 encoding SH3 domain), we next examined the methylation of CpG island-2 in the developing mouse neocortex. The results showed that the methylation rate of CpG island-2 increased from birth until postnatal day 14, thereafter decreased gradually. Furthermore, we identified intragenic promoters whose activity was regulated by DNA methylation, and found the expression of several *SHANK3* transcripts. To clarify the effect of mutations of *SHANK3* gene in autistic patients on DNA methylation and promoter activity and elucidate the role of novel Shank3 transcripts in the developing brain, further study is now on going. This study was approved by the ethics committees in National Center of Neurology and Psychiatry and in Osaka Medical Center and Research Institute for Maternal and Child Health.

578T

Genomic methylation profile in peripheral blood DNA of Autism Spectrum Disorder (ASD): A case-control study. *A. Homs Raubert[1], I. Cusco[1,2], L.A. Perez-Jurado[1,2].* 1) Unitat de Genetica, DCEXS, Universitat Pompeu Fabra, Barcelona, Spain; 2) Centro de Inevstigacion Biomedica en Red de Enfermedades Raras, CIBERER, ISCIII, Spain.

Autistic Spectrum Disorders (ASD) are a group of neurodevelopmental conditions characterized by a triad associating impairments in social interactions, communication problems and restricted range of interests. ASD prevalence is apparently increasing, affecting nowadays 1/150 newborns, being a relevant Public Health burden. Despite strong evidence for a genetic basis and recent findings of single gene mutations, copy number changes and double hit combinations, only a small proportion of cases have a defined etiology. MZ twin concordance is less than 90%; with variable expressivity suggesting environmental factors are also important. To explore a possible role of epigenetic abnormalities in ASD, we have quantified global 5mC content by HPLC-MS and SssI/dam methylase assays and established genomic methylation patterns with the Illumina Human Methylation 450K array platform in blood DNA from ASD patients (n=34, males, 2-15 year old) and age and gender-matched controls (n=10). All patients had a diagnosis of idiopathic ASD after extensive clinical and genomic studies. We found that the genomic content of 5mC was significantly reduced in ASD with respect to age-matched controls (2.62±0.4 vs 4.06±0.16). After extensive filtering and statistical analysis of array data, we observed 293 genes containing differentially methylated CpGs (p-value<0.01; SD in controls<0.025, present at least in 2 samples and with no SNPs in the CpG), mostly showing relative hypomethylation (82%), in agreement with 5mC quantification. Functional annotation by enriched gene ontology-based analysis performed with the top 20 differential methylated genes revealed a primary role in regulation of brain development, organization and synaptic assembly (*CTNNA2*, *WNT7B* and *NCOR2* genes). Moreover, among the 293 loci, 21 lie in genes previously associated with ASD through different genetic or genomic rearrangements (mostly de novo events), further reinforcing their putative role in the disease. Replication in a larger cohort by scalable techniques is in process, along with expression studies in several samples and additional tissues, including brain. Our data suggest that epigenetic abnormalities may be pathogenically related with ASD in a significant proportion of cases.

579T

DNA methylation landscapes of the human brain in Alzheimer's disease. *S. Iraola-Guzman[1], R. Rabionet[1], M. Montfort[2], F. Mancuso[3], G. Roma[3], E. Martí[1], I. Ferrer[4], X. Estivill[1].* 1) Genes and Disease Program, Center for Genomic Regulation (CRG), and Pompeu Fabra University (UPF), Barcelona, Spain; 2) Genotyping Unit, CeGen-ISCIII, Center for Genomic Regulation (CRG), and Pompeu Fabra University (UPF), Barcelona, Spain; 3) Bioinformatics Unit, Center for Genomic Regulation (CRG), and Pompeu Fabra University (UPF), Barcelona, Spain; 4) Anatomo-pathological Clinical Service, Hospital of Bellvitge and Biomedical Research institute of Bellvitge (IDIBELL), Barcelona, Spain.

Alzheimer's disease (AD) is a neurodegenerative disorder with an estimated worldwide prevalence of 30 million people. Most patients with AD develop the disease after age 60, and are considered “late-onset AD” (LOAD). Several genes have been described as risk factors for LOAD (*APOE, CLU, CR1, PICALM and MTHFD1L*), but the variants in these genes explain a small proportion of the genetic component of the disorder. Alterations in the DNA methylation (DNAm) profile have been related to several diseases, and it has been proposed that they may play an important role in age-related diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. We have attempted the evaluation of the DNAm profile of human brain samples in patients affected by LOAD. For this purpose, we selected four brain areas that are target regions for LOAD (cortex, hippocampus, amygdala and cerebellum), belonging to 40 individuals affected and non-affected with LOAD. To assess the DNAm status of more than 450,000 CpG sites (CpGs) we used the Humanmethylation450K Beadchip Illumina array, containing CpGs in coding and non-coding CpG islands (CGIs), CGIs shores, non-CGIs regions and miRNAs. We performed hierarchical clustering based on methylation values by Principal Component Analysis (PCA), which confirmed the previously reported clustering of all the cerebellum samples, in addition to a clustering by gender within each branch, probably due to X-chromosome inactivation. A second PCA, after removing the cerebellum samples and the CpG sites located in the X-chromosome, showed a trend to cluster by brain area (cortex, hippocampus and amygdala). Next, we assessed the feasibility to correlate DNAm values with either brain area or disease status, using Linear Discriminant Analysis (LDA), finding: 1) a combination of 38 CpGs that group all samples according to brain area; and 2) a different combination of 60 CpGs that differentiate unaffected and affected samples, even discriminating between the various stages of the disease. Finally, we performed differential analysis, finding 123 CpGs with DNAm values significantly altered in the cerebellum samples of LOAD-affected vs. unaffected individuals (p<0.05). Our findings strongly support the hypothesis of an epigenetic involvement in LOAD, and encourage further studies in this and other neurodegenerative disorders.

580T

Association analysis of polymorphisms in DNA MethylTransferase(DNMT) genes with Schizophrenia in a South Indian population. *K.R. SARADA LEKSHMI[1], N.V NEETHA[1], BALAN. SHABEESH[1], NAIR. CHANDRASEKHARAN[2], M.A PRIYA[3], K.R INDU[3], M. BANERJEE[1].* 1) HUMAN MOLECULAR GENETICS, RAJIV GANDHI CENTRE FOR BIOTECHNOLOGY, THIRUVANANTHAPURAM, KERALA, INDIA; 2) NAIRS HOSPITAL, COCHIN, KERALA,INDIA; 3) MENTAL HEALTH CENTRE, THIRUVANANTHAPURAM, KERALA, INDIA.

Schizophrenia is a complex biopsychosocial disorder affecting about one percent of world population. It encompasses severe mental disorders that result in loss of contact with reality along with major personality derangements. The etiology is complex involving a major genetic contribution as well as environmental factors interacting with the genetic susceptibility. Epigenetic processes may contribute to environmentally induced phenotypic variation by modifying gene expression. The capacity to respond to environmental cues is often heritable, indicating a genetic basis for epigenetic modifications. DNA methylation is the most common epigenetic modification and aberration that have been implicated in the pathophysiology of various complex disorders including schizophrenia. These variations might be due to extrinsic factors like diet, age etc or due to intrinsic variations in the genes involved in maintainance of DNA methylation.DNA methytransferases are a group of enzymes which catalyses the transfer of methyl group from S-Adenosyl methionine to the cytosine residue of DNA. The objective of the study was to investigate the role of polymorphisms in DNMT genes (DNMT1, DNMT2, DNMT3A, 3B and 3L) and their association with schizophrenia in a south Indian population and its effects in global methylation levels. Methodology: DNA was isolated from 250 patients and 250 healthy controls after obtaining informed consent. Only patients suffering from schizophrenia diagnosed by DSM-IV/ICD 10 have been enrolled for this study. Symptom severity was rated using BPRS-E and PANNS. Age, Sex and ethnicity matched controls were recruited for the study. We selected 19 polymorphisms from DNMT genes based on their functional relevance and tagging status. Samples were genotyped using allele specific amplification followed by fluorescence detection (KASPar) and PCR-Sequencing. Global DNA methylation levels were analysed using Methylamp™ Global DNA Methylation Quantification Kit from Epigentek. Statistical analysis was done using COCAPHASE and SPSS. Results: DNMT1 was found to be significantly associated with schizophrenia in our population. The rs 2114724 and rs 2228611 were associated with allelic, genotypic and haplotypic combinations. Global DNA methylation level was found to be higher in patients compared to controls.

Schizophrenia (SCZ) is a highly heritable complex disorder for which disease liability is poorly explained by known genetic variation. To better elucidate the biology of SCZ we are implementing a transcriptional approach to cognitive endophenotypes within large, multigenerational, multiplex SCZ pedigrees. We have a cohort of 677 samples from 42 families with 2 or more cases of SCZ or schizoaffective disorder, depressed type (SAD) and 273 healthy controls. We performed preliminary gene expression analysis on 158 individuals (23 SCZ/SAD, 122 unaffected family members, 13 healthy controls) using Illumina microarrays; 15,278 probes were tested against nine cognitive trait scores. Most notably, expression of *QSOX2* withstood Bonferroni correction for correlation with sensorimotor dexterity (SD, $p=1.72\times10^{-6}$). *QSOX2* plays a role in catalyzing oxidation of sulfhydryl groups in peptide and protein thiols, and is suggested to be a positive mediator of programmed cell death. We also saw suggestive significance for correlation between *CCNG1* expression and abstraction and mental flexibility (ABF) efficiency ($p=8.8\times10^{-4}$). *CCNG1* is located within a chromosome 5 linkage region that we had previously implicated in ABF in this cohort. It is involved in cell cycle regulation and expression differences have been demonstrated in hippocampus and inferior parietal lobule of individuals with mild cognitive impairment. Further, gene enrichment analyses indicated that related cyclin-dependent kinase inhibitors (CDKN, empirical $p=6.0\times10^{-3}$) were enriched for association with ABF. We also examined miRNA expression using the Illumina GA*IIx* next-generation sequencing platform; a total of 480 miRNAs were tested against cognitive traits. *miR-1248* withstood Bonferroni correction for correlation with ABF ($p=4.9\times10^{-5}$) and has many predicted target sites, including those within cell cycle regulatory genes (*CCND2*, *CDK2*). Other miRNAs showed suggestive significance with a number of traits, including *miR-505* with emotion ($p=5.9\times10^{-4}$), *miR-339-3p* with SD ($p=1.3\times10^{-4}$), *miR-4517* with facial (1.4×10^{-3}) and spatial ($p=6.1\times10^{-4}$) memory and *miR-182* with verbal memory ($p=8.8\times10^{-4}$). Our preliminary results suggest that gene and miRNA transcripts play an important role in cognitive deficits in schizophrenia, particularly with regard to cell cycle regulation in ABF. We are currently analyzing the full cohort to identify additional genes and miRNAs that may play a role in the etiology of schizophrenia.

MicroRNA expression profile in mesial temporal sclerosis provides insight into underlying mechanisms. *D.B. Dogini[1], C.S. Rocha[1], C. Yassuda[2], H. Tedeschi[2], E. Oliveira[2], C.V. Maurer-Morelli[1], F. Cendes[2], I. Lopes-Cendes[1].* 1) Dept Medical Genetics, FCM - UNICAMP, Campinas, Sao Paulo, Brazil; 2) Dept Neurology, FCM - UNICAMP, Campinas, Sao Paulo, Brazil.

The main purpose of this study was to investigate the possible role of microRNA (miRNA) gene regulation in temporal lobe epilepsy (TLE) with mesial temporal sclerosis (MTS). MTS is mainly characterized by selective neuronal loss and gliosis of specific regions of hippocampus. Total RNA was isolated from hippocampal tissue of 4 patients who underwent selective resection of the mesial temporal structures for the treatment of clinically refractory seizures. In addition we used control samples from autopsy (n= 4) for comparison. RNA samples were used in real-time PCR reactions with the Human Panel Early Access™ kit (Applied Biosystems) to quantify 157 different miRNAs. Bioinformatic analyzes identified three miRNAs, which were differently expressed in patients as compared to controls: let-7d and miR-29b were over expressed in patients; whereas, miR-30d was down-regulated in patients. A possible target gene for let-7d is Nme6 which we also found to be down- regulated in patients. In addition, Mcl-1, the putative target gene of miR-29b was also down-regulated in patients. Mcl-1 is a potent multidomain anti-apoptotic protein of the Bcl-2 family and its tight regulation of protein levels is necessary, because insufficient Mcl-1 can result in inappropriate cell death. Nme6 belongs to NME (nm23 /nucleoside diphosphate kinase) gene family in humans and act as an inhibitors of p53-induced apoptosis. In conclusion, we have identified three miRNAs differently expressed in hippocampal tissue from patients with TLE and MTS. At least 2 of the genes regulated by these miRNAs play an important role in apoptosis.

583T

Transcriptional and posttranscriptional regulation of *SPG4*, encoding Spastin, the most frequently mutated gene in hereditary spastic paraplegia. *B.J. Henson[1], W. Zhu[2], K. Hardaway[1], J.L. Rupert[1], M. Stefan[1], K.M. Albers[3], R.D. Nicholls[1,2].* 1) Dept Pediatrics, Children's Hospital of Pittsburgh, Rangos Research Center, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Medicine, University of Pittsburgh, Pittsburgh, PA.

Hereditary spastic paraplegia (HSP) refers to a group of neurodegenerative disorders that display progressive spasticity of the lower extremities, due to axonal degeneration of the corticospinal motor tracts. HSP is both clinically and genetically heterogeneous. Clinically, HSP can be pure or present as complex forms that have other neurological or non-neurological features. HSP shows autosomal dominant inheritance in ~70-80% of cases, with additional cases being recessive or X-linked. To date, 48 chromosomal loci have been linked to pathogenesis in HSP, with the causal genes identified for half of these. The most common form of HSP arises from mutations in the *SPG4* (*SPAST*) gene, which occurs in ~40% of dominantly inherited cases and ~10% of sporadic cases. *SPG4* encodes Spastin, which possesses microtubule-severing ability and is a member of the AAA (ATPases Associated with diverse cellular Activities) protein family. Both loss of function and dominant-negative mutations in *SPG4* have been described, suggesting that precise or stoichiometric levels of Spastin are necessary for biological function. Therefore, we hypothesized that transcriptional and post-transcriptional regulatory mechanisms controlling expression of *SPG4* are important and presently unknown determinants of Spastin biology. We used phylogenetic methods to identify highly conserved transcription factor (TF) binding sites and miRNA targeting sequences in the *SPG4* promoter and 3'-UTR, respectively. Using chromatin immunoprecipitation (ChIP), luciferase reporter assays (with mutations in the TF binding sites), siRNA knockdown of TFs, and TF overexpression, we demonstrate that *SPG4* transcription is positively regulated by NRF1, SOX11, and Sp1. Indeed, our data shows that NRF1 regulates about one-third of known HSP loci. Furthermore, we show that miR-182 and miR-96 negatively regulate *SPG4* via effects on both mRNA stability and protein translation. Intriguingly, our data indicate that miR-182 and miR-96 also regulate *NRF1*, *SOX11*, and several other spastic paraplegia gene products, suggesting that these miRNAs play critical roles in the regulation of corticospinal neuronal functions. In conclusion, we have identified major transcriptional and miRNA regulatory mechanisms for Spastin synthesis. These regulatory elements provide new functional sequences for mutation screening in HSP. *Supported by the Spastic Paraplegia Foundation and NIH.*.

miRNAs and Polyamine Gene Expression in the Brains of Suicide Completers. *J.P. Lopez[1,2], L.M. Fiori[2,3], V. Yerko[3], G. Turecki[1,2,3].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 3) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada.

MicroRNAs (miRNAs) are small, non-coding RNA molecules that play an important role in the posttranscriptional regulation of mRNA. These molecules have been the subject of growing interest as they are believed to control the regulation of a large number of genes, including those expressed in the brain. Evidence suggests that miRNAs could be involved in the initiation and progression of neuropsychiatric disorders. Alterations in metabolic enzymes of the polyamine system have been reported to play a role in predisposition to suicidal behavior, and we have previously shown the expression of the polyamine genes SAT1 and SMOX to be down-regulated in the brains of suicide completers. We hypothesize that the dysregulation of these genes in suicide completers could be influenced by miRNA posttranscriptional regulation. Using five miRNA target prediction programs, we identified several miRNAs that target the 3' untranslated region (UTR) of SAT1 and SMOX. We profiled the expression of 10 miRNAs in the prefrontal cortex (BA44) of suicide completers (N=15) and healthy controls (N=15) using quantitative real-time polymerase chain reaction (qRT-PCR). We found that four miRNAs showed significant up-regulation in the prefrontal cortex of suicide completers compared to healthy controls: hsa-miR-139-5p (fold change: 1.84; $p < 0.01$), hsa-miR-195 (fold change: 1.68; $p < 0.05$), hsa-miR-34c-5p (fold change: 2.56; $p < 0.01$) and hsa-miR-320c (fold change: 1.95; $p < 0.01$). Furthermore, we demonstrated a significant correlation between these miRNAs, SAT1 and SMOX expression. Our results suggest a relationship between miRNAs and polyamine gene expression in suicide behaviors and postulate a mechanism for SAT1 and SMOX down-regulation by posttranscriptional activity of miRNAs. Ultimately, our results provide new evidence for the role of miRNAs in neuropsychiatric disorders.

585T

Identification of miRNAs associated with mood disorders using next-generation sequencing. *J.L. Neary[1], D.C. Glahn[2], M. Zlojutro[1], T.D. Dyer[1], J.E. Curran[1], L. Almasy[1], R. Duggirala[1], J. Blangero[1], M.A. Carless[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Psychiatry, Yale University, New Haven, CT.

MicroRNAs (miRNAs) are a family of short non-coding RNAs which post-transcriptionally modulate gene expression, and several have been proposed as viable targets for mood stabilizing medications. However, miRNA expression in affected individuals and the relationship between miRNA expression and neurophenotype have not been well-studied. Our GOBSF (Genetics of Brain Structure and Function, ~1,300 individuals within ~50 families) and GOBD (Genetics of Bipolar Disorder, ~100 individuals) studies collect blood samples and extensive neuroanatomical and neurocognitive data for all subjects, as well as measures of depression, anxiety, and substance abuse. Here we present preliminary results associating miRNA expression to neurocognitive and neuroanatomical measures of mood disorder.

For a subset (n=126) of individuals with complete phenotypic data, we employed multiplex-based NGS sequencing (Illumina TruSeq platform) to ascertain whether quantitative variations in lymphocyte-derived miRNA levels correlate to mood disorder endophenotypes. Several miRNAs were associated with major depressive disorder (MDD), recurrent MDD (rMDD) and the Beck Depression Inventory (BDI) at a nominal p-value of 0.05. For example, hsa-miR-1282 ($p=0.021$, $p=0.0015$, $p=0.045$), hsa-miR-486-3p ($p=0.023$, $p=0.0028$, $p=0.036$), and hsa-miR-1231 ($p=0.035$, $p=0.0023$, $p=0.040$) were associated with all three measures of depression respectively. Another miRNA, hsa-miR-4690-3p, was strongly associated with lifetime MDD ($p=0.0075$) and recurrent MDD ($p=0.00028$). In these cases, higher levels associated with increased risk. We also identified several miRNAs with evidence of decreased expression in bipolar disorder and some suggested targets of mood stabilizers. For example, hsa-miR-27b shows altered expression in bipolar disorder, MDD ($p=0.021$), and recurrent MDD ($p=0.045$). Although no associations met correction for multiple testing, we anticipate that expansion to a larger cohort will yield more powerful results, particularly for miRNAs that demonstrate consistency across multiple measures of depression or have prior evidence of affiliation with mood disorders.

Identification of miRNAs and target mRNAs with deregulated expression in schizophrenia and bipolar brains. *B. Sadikovic, R. Pearson, L. Meng, A. Beaudet.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

While miRNA expression could play a role in the etiology of schizophrenia and bipolar disorder, current literature is limited and conflicting. The objective of this study was to identify deregulated miRNAs in the prefrontal cortex of schizophrenia and bipolar subjects, and analyze expression of their mRNA targets. Postmortem samples of BA8 region from 30 control, 22 schizophrenia, and 20 bipolar subjects were analyzed with the Agilent miRNA Microarray (V3) for >950 miRNAs. We identified 25 and 24 significantly deregulated miRNAs in schizophrenia and bipolar samples respectively, whose expression signature allowed robust clustering of disease vs. control brains. Validation of 20 candidate miRNAs with qRT-PCR across all samples confirmed the array findings in 17 miRNAs, with 13 showing significance ($p < 0.05$). These included miRNAs 223, 142-3p, 19b overexpressed, and 129-5p, 212, 181a, 132 26a, 24, and 487a underexpressed in schizophrenia, and 223, 7-1*, 454 overexpressed, and 26a, 29c, 22, and 1973 underexpressed in the bipolar samples. Bioinformatic analysis of binding sites identified significant enrichment for brain and neuron-specific genes as putative targets for schizophrenia miRNAs, and included AFF2, SEMA6A, CDK5R1, BPTF, and MAPT genes. Expression analysis using qRT-PCR showed significant increase in expression in all these genes in schizophrenia brains. In a concurrent set of experiments using qRT-PCR and Northern analysis, we show evidence of differential degradation of snoRNAs (that are often used to normalize miRNA data) relative to endogenous miRNAs in post-mortem brains, which create normalization artifacts, and may provide explanation for some of the discrepancies in current schizophrenia miRNA literature. In conclusion, these data provide the most thorough and comprehensive assessment of miRNA expression in schizophrenia to date and identify disease-specific miRNA signatures. In silico integration of miRNA and mRNA targets allowed us to predict and validate multiple brain-specific and neurodegeneration-related genes with increased expression in schizophrenia brains.

Differential analysis of microRNAs expression profile between PBMCs from primary progressive and relapsing remitting multiple sclerosis patients for the identification of novel targets. *M. Sorosina[1], P. Brambilla[1], C. Fenoglio[2], G. Giacalone[1], D. Scalabrini[2], F. Esposito[1], M. Serpente[2], C. Cantoni[2], E. Venturelli[2], M. Rodegher[1], L. Moiola[1], B. Colombo[1], M. De Riz[2], V. Martinelli[1], E. Scarpini[2], G. Comi[1], D. Galimberti[2], F. Martinelli Boneschi[1].* 1) Institute of Experimental Neurology (INSPE), and Department of Neurology, Division of Neuroscience, San Raffaele Scientific institute, Milan, Italy; 2) Dept. of Neurological Sciences, "Dino Ferrari" Center, University of Milan, Fondazione Cà Granda, IRCCS Ospedale Maggiore Policlinico, Milan, Italy.

Multiple Sclerosis (MS) is a chronic autoimmune disease of the central nervous system, characterized by the loss of myelin and axonal degeneration. Identification of novel targets and biomarkers of MS could be extremely helpful to better understand the mechanisms underling the pathogenesis of the disease. About 85% of the MS patients experience the relapsing-remitting MS (RRMS) disease course, characterized by phases with neurological deficits followed by remission. The more severe form of MS is the primary progressive (PPMS), characterized by a progression of the neurological impairment from the onset. MicroRNAs (miRNAs) are single-stranded non-coding RNA molecules of 20-25 nucleotides involved in the fine regulation of the gene expression at the post-trascriptional level. They act binding specific 3'UTR sequences of target miRNAs leading to their down-regulation. By using an hypothesis-free approach, we tested the expression profile of 1146 miRNAs in peripheral blood mononuclear cells (PBMCs) of 7 PPMS patients and 6 RRMS patients using the Illumina® BeadArray Technology. We observed 64 differentially expressed miRNAs (FDR corrected $p \leq 0.05$ and Fold Change ≥ 2 or ≤ -2) between the two variants of MS: 30 and 34 miRNAs were respectively up- and down-regulated in PPMS. According to the microRNA.org database we downloaded a list of 37 predicted target genes (mirSVR score$\leq$-1) common to the top five upregulated miRNAs and a list of 159 target genes (mirSVR score$\leq$-1) common to the top five downregulated miRNAs. Subsequently we looked at the expression profile of these target genes obtained from a HumanHT-12 v.3 BeadChip microarray Illumina experiment performed on PBMCs from 13 PPMS and 12 RRMS patients. Among all the predicted common target genes, 10 genes satisfied either conditions: (i) they were significantly differentially expressed ($p \leq 0.05$) between PPMS and RRMS and (ii) they showed an opposite expression levels compared to those of the miRNAs they were targeted by. One gene (PRIC285) resulted downregulated in PPMS, and 9 genes (AP3M1, ATXN1, CGGBP1, DENND4C, EIF5, PRDM2, SPRED1, TMED7, UBE4A) were observed to be upregulated. Despite the limited sample size, we believe that this pilot study could suggest the presence of fine regulation mechanisms, carried out through miRNAs differentially expressed between PPMS and RRMS patients, toward common target mRNAs. Deeper analyses are needed to evaluate the role of these target genes in the two forms of MS.

588T

Mitochondrial genetics: Identification of variants in subjects with mood disorders and schizophrenia. *F. Mamdani[1], P.A. Sequeira[1], M.V. Martin[1], B. Rollins[1], E.A. Moon[1], W.E. Bunney[1], F. Macciardi[1], C. Magnan[2], M. van Oven[3], P. Baldi[2], M.P. Vawter[1].* 1) Psychiatry & Human Behavior, University of California, Irvine, Irvine, CA; 2) Computer Science, University of California, Irvine, Irvine, CA; 3) Forensic Molecular Biology, Erasmus MC, University Medical Center Rotterdam, The Netherlands.

The human mitochondrial DNA genome (mtDNA), independent from the nuclear genome, has been shown to accumulate mutations in the brain during the lifespan that can lead to biochemical dysfunctions and observable phenotypic changes. Mitochondrial diseases often are characterized by the presence of psychiatric symptoms suggesting a link between mutations in the mtDNA and the susceptibility to psychiatric disorders. Several lines of evidence support a role of mitochondrial dysfunction in mood disorders and schizophrenia, including postmortem brain, imaging and, genetic studies. Mitochondrial DNA (mtDNA) somatic and common polymorphisms were investigated in schizophrenia (SZ), bipolar disorder (BD), major depressive disorder (MDD) and controls using the Illumina GAII platform, as well as Affymetrix SNP 6 arrays. Previously, we compared a 4977 base pair mtDNA common deletion between SZ and controls, in eleven brain regions and in peripheral blood. This investigation was further extended to assess levels of the deletion in the dorsolateral prefrontal cortex (DLPFC) in a sample of 12 BD, 14 SZ, 15 MDD and 35 controls. We found the presence of the common deletion to be highly variable across the 11 brain regions; however, minimal differences were seen in peripheral blood. Instances of the common deletion in the DLPFC sample were increased in BD ($p=0.022$) compared to controls, but not in the other disorders. Full mtDNA genome resequencing identified 12 novel homoplasmic mutations in the haplogroups mtDNA of 23 subjects. Currently, we are conducting further experiments to confirm and reinforce our findings through sequencing of 40 additional subjects (10 BD, 10 SZ, 10 MDD, 10 controls) for DLPFC and investigating the common deletion across 11 brain regions from these same 40 subjects. This study reinforces that the brain shows an increased accumulation of mitochondrial structural variants in brain tissue within psychiatric populations compared to controls.

589T

Regulators of expression of heroin-dependence candidate genes and their association with gene networks involved in mouse opioid-induced behavioral changes. *R.F. Clark, E.O. Johnson.* RTI International, Research Triangle Park, NC.

Differences in gene expression in the brain influence behavior and disease susceptibility, yet the contribution of single genes to complex behavioral phenotypes is usually small. Describing such phenotypes in terms of networks of interacting genes is desirable but challenging in humans due to the low availability of appropriate tissues. Thus, a systems biology approach to linking human candidate genes with publicly-available large-scale gene expression data in mice may be a useful technique for identifying networks of co-expressed genes that may influence complex human phenotypes. In this study we used in silico systems genetics tools to identify genes that are co-regulated with mouse homologues of 20 human heroin-dependence candidate genes and to evaluate their overlap with genes associated with >100 opioid-induced behavioral changes in mice. We used expression-QTL mapping to identify the sources of variation in gene expression in the mouse hippocampus and nucleus accumbens (NA), and to enable global mapping of factors regulating such transcriptional responses. We investigated natural genetic variation in gene expression levels of >39,000 transcripts in related mouse strains in two RI panels of C57BL/6J and DBA/2J to gain insights into molecular networks that might alter the transcription of the candidate genes. We found that the expression of >18 genes proximal to Oprm1 (an important gene involved in opioid-dependence) on chromosome 10 in mice are coordinately expressed and cis-regulated (LRS > 20). We also found that several other candidate genes (e.g., Comt, Myocd, etc.) have statistically significant trans- QTL loci (LRS > 20). Some of these loci are found proximal to loci of genes within gene networks associated with several opioid-induced behaviors, such as differential morphine response to locomotion in an open field. These analyses suggest that we have found several good candidate genes for regulating hippocampal/NA expression of opioid-induced behavioral genes in mice (and potentially heroin-dependence in humans). All genes are highly expressed in the hippocampus/NA, as well as in several other brain regions. Furthermore, these genes are novel candidates for involvement in human heroin addiction pathways. These findings emphasize the utility of a systems biology approach to analyze complex data to model interacting biological processes.

590T

Access to Genetically Engineered Mouse Models. *S. Rockwood, C. Lutz, M. Sasner, L. Donahue.* Gen Res Sci, The Jackson Laboratory, Bar Harbor, ME.

Genetically modified mice have greatly contributed to our understanding of basic biology and disease processes. In order to facilitate access to these mice, the Mouse Repository at The Jackson Laboratory was established to serve as a centralized resource for the archiving and distribution of genetically engineered mice at a high health status. As the number and complexity of alleles increase, so does the importance of providing adequate information to facilitate their selection and use by researchers. New mouse strains with applications in a wide range of disciplines (immunology, neurology, metabolism, etc) continue to be made available to the scientific community through an easy to use, online database. Newly available strain types generally reflect the most compelling human disease concerns. New to the immunological class of mutants are *Batf3* knockout mice which feature an impaired development of splenic CD8($^+$ conventional dendritic cells. Conditional mutants continue to represent a significant portion of the new alleles reposited; a floxed Rptor strain makes possible the examination of a central node of the mammalian pathway that coordinates cell growth and availability of nutrients, energy and growth factors. Serving as companion strains to floxed models are a wide range of cre recombinase expressing strains; newly added is a transgenic line expressing cre under the direction of an *Adipoq* promoter, allowing researchers to control cre-mediated recombination effectively in white and brown adipose tissues. Another knock-in model at the *Sst* locus expresses cre in dendritic inhibitory interneurons, such as Martinotti cells and Oriens-Lacunosum-Moleculare (O-LM) cells. Numerous tool strains are available as well, such as a growing number of strains that incorporate channelrhodopsin technology, and the "R26R-Confetti" mice which serve as a stochastic multicolor Cre recombinase reporter of multiple fluorescent proteins expressed from a single genomic locus. Donating a strain to the Repository fulfills the NIH's requirements for sharing of mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains at: www.jax.org/donate-a-mouse.

591T

Evaluating Genetic Markers and Neurobiochemical Analytes for Antidepressant Response Using a Panel of Inbred Mouse Strains. *T. Wiltshire[1], C. Santos[1], B.H Miller[3], S. Skewerer[2], J.S. Marron[2], O. Suzuki[1], M. Pletcher[4].* 1) Sch Pharmacy, Univ North Carolina, Chapel Hill, NC; 2) Department of Statistics and Operations Research, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) Department of Neuroscience, The Scripps Research Institute, Florida, Jupiter, FL, USA; 4) Compound Safety Prediction, Pfizer Global Research and Development, Groton, CT, USA.

Identification of biomarkers that can establish diagnosis or treatment response is critical to the advancement of research and management of patients with major depressive disorder. Biomarkers can be used objectively to evaluate clinical progression and response to antidepressant therapy. To identify genetic and neurobiochemical biomarkers of antidepressant response, we compared behavior, gene expression, and levels of thirty-six neurobiochemical analytes proposed to affect anxiety and mood disorders between water and fluoxetine-treated mice in a panel of genetically diverse mouse inbred lines. While responses in the open field (OF) and tail suspension test (TST) both contribute to baseline inter-strain differences, chronic fluoxetine treatment predominantly affected behavior in the TST, indicating that the TST is sensitive to the antidepressive effects of fluoxetine. We found that levels of glyoxylase1 (GLO1) and guanine nucleotide binding protein (GNB1) account for most of the covariance in baseline anxiety-like and depressive-like behavior. Overall difference in neurobiochemical levels were observed for positive and negative responders. Biochemical alterations following chronic fluoxetine treatment discriminated positive responders, while baseline neurobiochemical differences differentiated negative responders. Results from partial least squares (PLS) and distance weighted discrimination (DWD) analyses show that levels of S100) , GFAP, GSK3) , and HDAC5 contributed most to variable antidepressant response. These proteins are linked within a cellular growth/proliferation pathway, suggesting that positive responses to antidepressants are likely due to increased cellular genesis. In addition, a candidate genetic locus that associates with baseline depressive-like behavior contains a gene that encodes for cellular proliferation/adhesion molecule (Cadm1), supporting a genetic basis for the role of neuro/gliogenesis in depression.

Pre-diagnostic parent experiences in Duchenne and Becker muscular dystrophies, congenital muscular dystrophies, and spinal muscular atrophies: A survey of the National Task Force for the Early Identification of Childhood Neuromuscular Disorders. *H. Peay[1], K. Mathews[2], National Task Force for the Early Identification of Childhood Neuromuscular Disorders.* 1) Parent Project Muscular Dystrophy, Richmond, VA; 2) University of Iowa Children's Hospital, Iowa City, IA.

Objective: Describe the pre-diagnostic experiences of parents of children with Duchenne, Becker, congenital muscular dystrophies and spinal muscular atrophy, including parents' descriptions of their earliest concerns. Background: We know little about how parents describe first concerns of neuromuscular disorders. Studies utilizing chart reviews indicate that childhood NMDs are often diagnosed well after symptoms emerge, and after parents express concerns to a clinician. Design/Methods: Cross-sectional, retrospective survey distributed electronically to parents of children diagnosed between ages 6m-9y. Analyses include chi-squared, T tests, ANOVA, correlation, and thematic coding. Results: Data were analyzed from 1087 parents: 651 DMD (60%), 244 SMA (22%), 105 CMD (10%), 87 BMD (8%). Quantitative data largely support published data and clinical experience. There were no significant differences between those with a positive family history and those without regarding whether parent had concerns before diagnosis (Chi-Square = 0.528, p-value = 0.467) or who had first concerns (Chi-Square = 2.035, p-value = 0.362). Parents with a family history reported significantly less time between first telling doctor about their worry and age at diagnosis (t = -2.171, p-value = 0.030). Analysis of open-ended questions about words parents use to describe concerns identified themes of milestone-associated concerns, comparing to siblings/peers, and non-specific intuition statements. Concerns clustered in infant/young child (SMA and CMD) and preschool/school age (B/DMD). We report specific words parents use to describe weakness, hypotonia, coordination, muscle hypertrophy, difficulty rising from floor, and others. Conclusions: These data support the previously reported diagnostic delay. The fact that there is a significantly shorter time between sharing concerns with providers and diagnosis in those with a family history suggests that providers are (rightly) taking family history into account when evaluating development. The effect of birth order may reflect a greater focus on motor milestones among first-born children and disinclination by parents, and/or dissuasion by providers, to compare the development of siblings. Unlike chart reviews, we report parents' words to describe their concerns as one step in facilitating earlier diagnosis. Funding Source: This survey was funded by the Centers for Disease Control and Prevention.

Molecular analysis of *FA2H* gene mutations in patients with spastic paraplegia and thin corpus callosum. *D. Di Bella[1], E. Sarto[1], M. Plumari[1], S. Caldarazzo[1], B. Castellotti[1], M. Panzeri[1], A. Erbetta[2], L. Nanetti[1], C. Mariotti[1], F. Taroni[1].* 1) Unit of Genetics of Neurodegenerative & Metabolic Diseases, IRCCS Istituto Neurologico C Besta, Milan, Italy; 2) Unit of Neuroradiology, IRCCS Istituto Neurologico C Besta, Milan, Italy.

Hereditary spastic paraplegias (HSP) are a clinically and genetically heterogeneous group of neurodegenerative disorders. Pure and complicated forms of the disease have been described. Autosomal recessive HSP (AR-HSP) with thin corpus callosum (TCC) is a distinct form of familiar spastic paraplegia linked to the SPG11, SPG15, SPG21 and SPG5 loci. SPG35 is an AR-HSP caused by mutations in the gene encoding fatty-acid 2-hydroxylase (*FA2H*), an enzyme that produces free 2-hydroxy fatty acids. *FA2H* mutations have recently been associated not only with complicated forms of spastic paraparesis characterized by TCC and white matter abnormalities on MRI, but also with leukodystrophy and neurodegeneration with brain iron accumulation (NBIA). Eleven Italian HSP index patients, including 7 sporadic patients and 4 AR patients, were investigated for SPG35 mutations by direct sequencing and quantitative Real-Time PCR of the *FA2H* gene. All the patients have thin corpus callosum and are negative for mutations in SPG11, SPG15, SPG21 and SPG5 genes. Results: Two novel missense FA2H mutations (Y34C, T207M) were detected in one family, with 2 affected sibs carrying both variations and 2 healthy brothers heterozygous for the Y34C only or homozygous for the normal allele, respectively. These sequence variants were not found in 300 unrelated control chromosomes. The 2 affected brothers presented with slowly progressive adult-onset HSP (at 32 and 40 yrs) and manifested, a few years later, speech impairment and cognitive decline. Neurological examination at age 48 and 51 demonstrated severe lower-limb spasticity, Babinski sign, pes cavus, distal muscle weakness, dysarthria, ophthalmoplegia, and dementia. Electroneurography showed normal conduction velocities. MRI demonstrated prominent global atrophy (including cerebellum, brainstem, cerebral hemispheres, and corpus callosum) with enlarged ventricles. No micro-rearrangements in *FA2H* gene were identified. Conclusions: We have identified compound heterozygosis for two missense FA2H mutations in one AR-HSP family. This is the first report of FA2H mutations in adult-onset patients with a complicated form of HSP characterised by TCC in early phases, cognitive decline and profound pancerebral atrophy after 10 years of disease. Although SPG35 represents a rather rare form, our findings suggest that it should be considered in the diagnosis of complicated AR-HSP phenotypes with TCC, negative for other AR-HSP gene mutations.

594T

Analyses of compound heterozygous rearrangements of *parkin*. *M. Funayama[1, 2], H. Kusaka[2], H. Yoshino[1], Y. Li[1], K. Ogaki[2], H. Tomiyama[2, 3], N. Hattori[1, 2, 3].* 1) Research Institute for Disease, Graduate School of Medicine, Juntendo University, Tokyo, Japan; 2) Department of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 3) Department of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan.

Background and Purpose: Parkinson's disease (PD) is one of the most common neurodegenerative disorders affecting approximately 1.39 million people in Japan. Mutations in *parkin* are the most frequent cause of early onset autosomal recessive parkinsonism. Exonic rearrangements in *parkin* are frequently reported in Asian populations. In general, gene dosage analysis by quantitative PCR (qPCR) is used to detect exonic rearrangements. However, there is a problem with the method of qPCR, because compound heterozygous mutations for deletion and duplication in the same allelic exon could be determined to be normal. To verify the problem, we investigated parkin mutations of a Japanese family with early onset parkinsonism by detailed genetic analyses. **Methods:** A patient with early onset parkinsonism and the parents were investigated by qPCR using TaqMan probe, semi-qPCR and haplotype analysis using microsatellite, and RT-PCR. **Results:** None of point mutations or homozygous exonic deletions were found in any of the three family members. Heterozygous duplication of exon 6 and 7 (EX6-7 dup) of *parkin* was detected in the patient with parkinsonism by qPCR. However, the parents did not have the same mutation. Comparison of the peak height of each allele and genotyping results showed that the patient's mutation pattern seemed to be compound heterozygous with EX3-7 dup and EX3-5 del. RT-PCR and direct-sequencing were revealed that the patient had two of abnormal alleles (EX 3-7dup and EX3-5 del) which were inherited from the parents. We detected a sequence of the duplicated break point in the patient and father, and exon skipping was observed at the transcript level in the patient and mother. **Discussion:** In this study, we demonstrated the pseudo-heterozygous rearrangement mutation of *parkin* using qPCR assay due to the combination of duplication and deletion in the same allelic exons. It is difficult to avoid this erroneous decision by examining gene dosage in only patients with parkinsonism. **Conclusion:** In conclusion, to execute the correct decision for rearrangement mutation, we should examine the mutation analysis not only in the patient but also in the patient's family members and/or breakpoint analysis in genomic DNA and transcript level.

Luquin[1,2], J. Perez-Tur[6], J.A. Obeso[1,2,4], P. Pastor[1,2,4].* 1) Neurogenetics Laboratory, Division of Neurosciences, Center for Applied Medical Research (CIMA), University of Navarra, Pamplona, Spain; 2) Department of Neurology, Clínica Universidad de Navarra, University of Navarra School of Medicine, Pamplona, Spain; 3) Parkinson's Disease and Movement Disorders Unit, Neurology Service, Institut Clínic de Neurociències, Hospital Clínic de Barcelona, Spain; 4) CIBERNED, Centro de Investigación Biomédica en Red de Enfermedades Neurodegenerativas, Instituto de Salud Carlos III, Spain; 5) Division of Neurogenetics, Department of Neuroscience, Mayo Clinic, 4500 San Pablo Road, Jacksonville, FL, USA; 6) Unitat de Genètica Molecular, Institut de Biomedicina de València-CSIC, Valencia, Spain.

Background and objective. Mutations in the *LRRK2* (Leucine-rich repeat kinase 2) gene at chromosome 12q12 are the most common genetic cause of sporadic and familial Parkinson's disease (PD). Our aim was to identify novel *LRRK2* mutations in late-onset PD (LOPD) families. **Design.** We analyzed chromosome 12p11.2-q13.1 haplotypes in 14 families with LOPD, none of whom carried the most common *LRRK2* mutations (p.G2019S, p.R1441G or p.R1441C). **Results.** Haplotype analysis identified 6 LOPD families in which the affected subjects shared chromosome 12p11.2-q13.1 haplotypes, and 6 families in which *LRRK2* haplotype-sharing among affected individuals was uncertain. Sequencing of the entire *LRRK2* encoding gene region in the probands of these 12 LOPD families led to the discovery of a novel co-segregating mutation in the *LRRK2* COR domain in Family 1256. No mutations in the *LRRK2* coding region were detected in the other 11 LOPD families. The novel *LRRK2* mutation is located within a highly conserved region of the COR domain, and could potentially deregulate LRRK2 kinase activity. The novel mutation was also detected in 2 out of 2501 unrelated PD subjects, but not in 2491 healthy controls analyzed. Mutation carriers developed levodopa-responsive asymmetrical parkinsonism, with variable age at onset (range: 37-72 years) suggesting age-dependent penetrance. **Conclusions.** These findings support that haplotype-sharing analysis is an efficient tool to identify infrequent *LRRK2* mutations causing familial LOPD.

596T

Identification of schizophrenia-associated *NPAS3* and *COMT* exonic variants in a pre-onset aged population. *L. Luoma[1], G. Macintyre[1], D. LaFreniere[2], A. Beierbach[2], F. Berry[1,3], S. Purdon[2], P. Tibbo[2,4], D.W. Cox[5].* 1) Dept Med Gen, Univ Alberta, Edmonton, AB, Canada; 2) Department of Psychiatry, University of Alberta, Edmonton, AB, Canada; 3) Department of Surgery, University of Alberta, Edmonton, AB, Canada; 4) Department of Psychiatry, Dalhousie University, Halifax, NS, Canada; 5) Department of Medicine, University of Alberta, Edmonton, AB, Canada.

Schizophrenia (SZ) is a psychotic disorder with an incidence of approximately 1% worldwide. SZ is contributed to by endogenous (biochemical, developmental, neurological, etc.) and exogenous (environmental) factors, both of which are influenced by genetic factors. Treatment response is similarly heterogenous and is more effective when implemented early in the course of psychosis. Identification of specific sub-clinical quantifiable phenotypes (endophenotypes) of genetic variants is critical to understanding SZ pathology and developing methods to identify at-risk individuals to maximize outcomes.

Variants in catechol-O-methyltransferase (COMT), an enzyme involved in the metabolism of catecholamines are associated with SZ, and have been shown to affect synaptic dopamine, cortical thickness and working memory. NPAS3 (neural PAS-domain containing 3) is a SZ-associated transcription factor implicated in neurodevelopment and adult neurogenesis in mice, and cross-disorder plieotropic effects in humans. Endophenotypes of the SZ-associated SNPs in *NPAS3* have yet to be determined. We hypothesize that we will identify an increased frequency of SZ-associated SNPs in *COMT* and *NPAS3* in our pre-onset aged population with a range of psychosis risk relative to a selected control population of neurologically normal adults.

Eighty-seven healthy teenagers (16-19 years) were recruited for volumetric MRI, MRS, neuropsychological and genetic analyses to identify endophenotypes of one *COMT* and three *NPAS3* SNPs. *COMT* rs4680 allele and genotype frequencies are in agreement with the HapMap CEU population (minor allele frequency [MAF] 0.48, $\chi 2$ P=0.80; genotype $\chi 2$ P=0.68). The allele frequency of *NPAS3* SNP rs12434716 differs from the reported frequency (normal control MAF=0.096; current cohort MAF=0.17; $\chi 2$ P=0.0016) likely due to the cohort being of pre-onset age. The genotype frequencies of SNPs rs12434716, rs10141940, rs10142034 are in agreement with those previously reported (Fisher's Exact P=0.10, 0.38 and 0.38). There is no association between rs4680 and any *NPAS3* SNP (Fisher's Exact P=0.31, 0.82 and 0.82). The variability observed in *NPAS3* and *COMT* allows for additional research to correlate putative biological and psychological endophenotype markers for psychosis. This information may be useful for identifying at-risk individuals and lead to earlier diagnosis and treatment.

Background and Purpose: Mutations in the microtubule-associated protein tau (*MAPT*) cause frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). We investigated the genetic and clinical features in familial and sporadic patients with *MAPT* mutation. Methods: All exons were sequenced and multiplex ligation-dependent probe amplification (MLPA) was performed in *MAPT* in 75 Japanese patients suspected of FTDP-17; frontotemporal dementia (FTD), FTD with motor neuron disease, FTD with parkinsonism, primary progressive aphasia, progressive supranuclear palsy (PSP), corticobasal syndrome, dementia with Lewy bodies and Parkinson's disease, including consideration for family history. Patients with mutations underwent single photon emission computed tomography. Results: We identified 4 *MAPT* mutations in 6 families. The gene dosage of *MAPT* by MLPA study was normal. The frequency of *MAPT* mutation was 9.0%. All 6 patients with PSP phenotype and characteristically abnormal eye movements (such as visual grasping, oscillopsia with congenital nystagmus, and tonic upward fixation after eye closure) had *MAPT* mutations. Comparison of 3D-stereotactic surface projection images of *MAPT*-positive PSP phenotype patients with these distinct eye movements and duration-matched PSP patients lacking these distinct eye movements showed hypoperfusion in bilateral Brodmann area 8. Conclusions: *MAPT* should be analyzed when clinicians see patients with PSP suspected of having FTDP-17 (*MAPT*), after carefully examining the clinical presentation, especially characteristically abnormal eye movements. The distinct eye movements and hypoperfusion of Broadmann area 8 might be new hallmarks of FTDP-17 (*MAPT*).

To identify, validate and characterize the gene on 18p which is responsible for causing Myoclonus-Dystonia. *M. Vanstone[1,2], T. Read[1,2], F. Han[1,2], D.A. Grimes[1], D. Bulman[1,2].* 1) Regenerative Medicine, Ottawa Hospital Research Institute, Ottawa, Ontario, Canada; 2) Biochemistry Dept, University of Ottawa, Ottawa, Ontario, Canada.

Myoclonus-Dystonia (MD) is an inherited, rare, autosomal dominant movement disorder characterized by quick, involuntary muscle jerking or twitching (myoclonus) and involuntary muscle contractions that cause twisting and pulling movements, resulting in abnormal postures (dystonia). The onset of symptoms usually occurs within the first two decades of life. People with MD also have an increased risk of developing psychological conditions such as depression and anxiety. The first MD locus was mapped to 7q21-q31 and called DYT11; this locus corresponds with the *SGCE* gene. We have identified a second MD locus (DYT15) in a large kindred spanning 5 generations, which maps to a 3.18 Mb region on 18p11. The coding regions and intron-exon boundaries of all known REFSEQ genes in the critical region were sequenced and did not yield the causative mutation. In total, 110 kb of the critical region was sequenced and we identified 358 novel SNPs and insertion/deletions, all of which have been detected in control samples. Large deletions, duplications and inversions have been excluded as a cause of MD in our family. Two meiotically distant patients from our family were chosen to undergo next-generation sequencing. First, NimbleGen Sequence Capture technology was used to enrich for DNA from the chr18:4,619,674-7,800,480 critical region plus 50 kb flanking, then Roche 454 sequencing technology was used to sequence the targeted region on 18p11. We obtained >97% coverage of our critical region with an average depth of coverage >50 per patient. Using NextGENe™ software from SOFTGENETICS, we have identified 2,413 shared novel variants within the critical region. I have assigned a priority to this list of variants and am currently attempting to exclude candidates by confirming each one by Sanger sequencing and validating their disease-causing potential by testing for their occurrence in control patients. To date, 2,325 candidate variants have been excluded and 88 remain, one of which will be the causative mutation of MD in our family.

Genetic analyses of myotonic dystrophy in Malaysia. *M.K. Thong[1], I. Taufik[1], K. Ambrose[2], L.H. Lian[2], A.A. Azlina[2], K.J. Goh[3], K.T. Wong[4].* 1) Dept Pediatrics, Univ Malaya Med Ctr, Kuala Lumpur, Malaysia; 2) Dept Molecular Medicine, Univ Malaya Med Ctr, Kuala Lumpur, Malaysia; 3) Dept Medicine, Univ Malaya Med Ctr, Kuala Lumpur, Malaysia; 4) Dept Pathology, Univ Malaya Med Ctr, Kuala Lumpur, Malaysia.

Introduction: Myotonic dystrophy (DM1) is an autosomal dominant condition characterized by progressive muscle weakness and myotonia. The congenital form leads to neonatal death. DM1 results from an unstable trinucleotide repeat (CTG) expansion in the DMPK gene. The age of onset and phenotypic severity correlates with the CTG expansion size. In Malaysia, molecular diagnosis of DM1 is not available. Objective of this study is to develop a polymerase chain reaction (PCR) analysis and Southern transfer approach to diagnose DM1 Method: Analysis of the CTG repeat length was carried out via polymerase chain reaction (PCR) and later confirmed with sequencing and Southern-blot. When an individual demonstrates two different normal size alleles on PCR, DM1 is excluded. The presence of a single band may indicate CTG expansion or an unaffected individual homozygous for a given normal allele. Therefore, Southern blotting test is performed. We determined the heterozygosity of DM1 alleles and the frequency distribution of various CTG repeats in normal Malays and optimized Southern blotting to determine the CTG repeats in affected families. Results: In 120 normal Malays, 58% were heterozygous while 42% were homozygous for the DM1 alleles. Amongst 240 normal chromosomes, a total of 14 alleles with different CTG lengths from 5 to 28 were found. The frequency of CTG > 18 alleles was 3.3%. We successfully determined the number of CTG repeats in two families who had several affected individuals. Conclusion: We developed an effective strategy to screen patients for DM1 using PCR analysis. To the best of our knowledge, this is the first study on the molecular genetics of DM1 in the Malay population. Individuals with DM1 homozygous alleles were subjected to Southern transfer for ascertainment of CTG repeats. Genetic counseling was provided for affected families.

Prader-Willi Syndrome due familial paternal 224 Kb interstitial deletion upstream to SNORD108A. *M. Albalwi[1,2,4], I. Al Abdulkareem[2,4], B. Almuzaini[2], M. Almoalami[2], N. Alatawi[1,4], W. Eyaid[3], M. Aljumah[2,4].* 1) Div Molec Path & Lab Med, National Guard Hosp, Riyadh, Saudi Arabia; 2) King Abdullah International Medical Research Center, Molecular Biology, King Abdulaziz Medical City, Riyadh, Saudi Arabia; 3) Pediatric department, King Abdulaziz Medical City, Riyadh, Saudi Arabia; 4) King Saud bin Abdulaziz University for Health Sciences, College of Medicine, Riyadh, Saudi Arabia.

Prader-Willi syndrome is a neuro developmental disorder due to a number of different genetic mechanisms. All involve lacking of paternal genes expression within 4 Mb of chromosome 15q11q13. Recent studies narrowing PWS to the critical region involving cluster of imprinting SNORD16 gene. Although rare cases of PWS are reported due to inherited familial interstitial deletion compared to the majority of PWS sporadic cases. Here we report a baby girl clinically diagnosed with PWS. DNA Methylation studies and high resolution karyotyping analysis were normal. FISH analysis revealed presence of a dim florescent signal in both daughter and her father. High-resolution oligonucleotide array-CGH revealed approximately 224 Kb interstitial deletion upstream to SNORD108A paternally inherited. This deletion was further validated by Multiplex Ligation-dependent Probe Amplification (MLPA) assay. Using such advance molecular technology will provide better understanding of familial genetic alteration as well as providing better counseling for family with high recurrence risk of having PWS offspring.

601T

Custom capture in a large Primary Lateral Sclerosis family. *V. Belzil[1], S. Girard[1], H. Daoud[1], M. Sabbagh[1], C. André-Guimont[1], D. Spiegelman[1], P. Valdmanis[1], J. St-Onge[1], I. Bachand[1], P. Provencher[2], N. Dupre[2], P. Dion[1], G. Rouleau[1].* 1) Medicine Department, CHUM Research Centre, Univ Montreal, Montreal, Canada; 2) Neurosciences Department, CHAUQ Enfant-Jesus, Univ Laval, Quebec, Canada.

Background: Primary Lateral Sclerosis (PLS) is a neurodegenerative disease of upper motor neurons characterized by progressive spinal and bulbar spasticity. The lower limbs are generally first affected, followed by the upper extremities and the bulbar muscles. The average disease duration is 20 years, and its prevalence is 1 per 10 million. The average age of onset is 50 years old. PLS cases are mostly sporadic. We first identified in 2007 one French-Canadian family with twelve individuals displaying a PLS phenotype which segregates in an autosomal dominant fashion. A 550 marker genome scan was performed and a locus on chromosome 4 between the telomere and marker D4S2928 was identified (PLS1 locus). Twelve members of the family share the same haplotype. This region spans 10.2 Mb and encompasses 130 genes. We then identified a second small French-Canadian family with three members having the same haplotype found to be shared between the affected members of the first family. The two families actually shared the same ancestor three generations before; thus, the same mutation must cause the disease in the two pedigrees. Objectives: Identify the mutation responsible for the PLS phenotype in this large French-Canadian family, in order to better understand the pathological pathway involved in the degeneration of upper motor neurons. Methods: The UTRs and coding regions of the 14 most interesting candidate genes were sequenced and no causative mutation was identified. Also, no major deletion or duplication was identified after performing a copy number variant test. DNA extracted from blood from two patients of the first pedigree and one patient from the second pedigree was used to capture the 10.2Mb region of interest. The Agilent custom capture SureSelect XT kit (13.6 Mb) was selected to sequence the entire PLS1 locus; extra bates were also used to increase the coverage. Library preparation, capture and sequencing were performed at the Genome Quebec Innovation Centre (Montréal, Québec, Canada) using Illumina Hiseq Paired-end sequencing. Results: A list of variants was generated for each three affected members of the PLS family. The variants shared between the three patients were validated by Sanger sequencing and segregation in the two pedigrees was verified. Discussion/Conclusions: The analysis of variants found is undergoing.

602T

Analysis of Lysosomal Storage Disorder Genes in Lewy Body Disorders. *L. Clark[1], N. Park[2], M. Verbistky[1], A. Brown[1], JP. Vonsattel[3], K. Marder[3], L. Honig[3], J. Lee[2].* 1) Dept Pathology & Taub Inst, Columbia Univ, New York, NY; 2) Gertrude H. Sergievsky Center, Columbia Univ, New York, NY; 3) Dept Neurology, Columbia Univ, New York, NY.

Objective To determine the relationship of lysosomal storage disease (LSD) gene mutations to Lewy Body (LB) and Alzheimer disease (AD) pathology. Background: Mutations in the LSD gene, glucocerebrosidase (GBA), are associated with LB disorders. We hypothesized that other LSD genes in the same biochemical pathway may also represent susceptibility genes for LB. Methods: Brain tissue from 243 autopsies from the NYBB at Columbia University included: 128 brains with primary neuropathological diagnoses of LB disorders with or without AD changes, 79 brains with AD without significant LB pathology, and 36 control brains with neither LB or AD pathologies. To capture rare variants (MAF<1%), four LSD genes were sequenced, including GBA and 3 non-GBA genes: hexosaminidase A (HEXA), sphingomyelin phosphodiesterase 1 (SMPD1), and mucolipin 1(MCOLN1). Rare variant analysis was performed using the CCRaVAT. The CRaVAT program used a collapsing method that investigates a combined multiple variant alleles in our case-control study. Results: We found non-GBA variants in 103 (42.4%) brains (HEXA n=42 (17.3%), SMPD n=37 (15.2%), MCOLN1 n=67 (27.6%), of which 33 (13.6%) and 5 (2.1%) brains had variants in 2and 3 of the genes, respectively. Several of the variants that we identified including, c.1278insTATC (HEXA), c.672+30T>G (HEXA), S3S (HEXA), P330R (SMPD1) and E515V (SMPD1) have been reported previously as mutations in patients with lysosomal storage disorders. GBA, as previously reported was in 34 (16.9%) brains (23 without and 11 with non-GBA mutations). We showed an association of GBA mutations with presence of LB particularly cortical LB: OR=6.48, 95%CI, 2.45-17.6, p<0.001 adjusting for sex, death age, and ApoE4 status. At least one mutation in SMPD and MCOLN1, non-GBA gene, were significantly associated with LB.or LB with AD pathology. Multiple variants in SMPD and MCOLN1 were significantly associated with LB and LB with AD (p range: 0.01 - 0.0078. Conclusion: We showed that GBA mutations and at least one mutation in SMPD and MCOLN1 were significantly associated with LB or LB with AD pathology. This work shows evidence suggesting that the mutations in the lysosomal pathway may be associated with LB pathology. Funding: This study was funded by National Institutes of Health grants R21NS050487 (LNC), R01NS060113 (LNC), R01NS36630 (KM), UL1RR024156 (KM), R37AG15473 (RM) and P50AG08702 (M. Shelanski), the Parkinson's Disease Foundation (LNC, KM).

Clinical features of four familial cortico-basal degeneration (CBD) and progressive supranuclear palsy (PSP) in south Fukuoka prefecture, Kyushu island in Japan. *H. Furuya[1], A. Watanabe[1], H. Arahata[1], Y. Kawano[1], E. Araki[1], H. Kumazoe[2], N. Fujii[1].* 1) Department of Neurology, National Omuta Hospital, Omuta, Fukuoka, Japan; 2) Department of Radiology, National Omuta Hospital, Omuta, Fukuoka, Japan.

Objective: We evaluate clinical features and genetic analysis for four unrelated familial CBD and PSP pedigrees in south Fukuoka prefecture. **Background:** Although, it is considered that 10-15% of Parkinson disease (PD) is familial, familial PSP and CBD is very rare. Recently, a decrease in myocardial uptake of meta-iodobenzylguanidine (MIBG), an analogue of norepinephrine, has been reported in PD and dementia with Lewy body disease (DLB) but not in PSP and CBD. This imaging approach is thought to be of significance in the diagnosis and characterization of akinetic-rigid syndromes with high sensitivity and specificity especially for PD and DLB, which infer the involvement of postganglionic sympathetic nerves failure in the heart caused by (-synucleopathy. **Methods:** We describe four unrelated families of CBD and PSP in this region with clinical feature and result of gene analysis (PARK 1, 2, 6, 7, 8 and MAP) and MIBG myocardial scintigraphy. **Results:** In this region, 18.5% (15/81) of PD and DLB, 16.7% of PSP and CBD (4/24) are familial. L-dopa was not effective in these four families and genetic analysis exclude the possibility of PARK 1, 2, 6, 7, 8 and MAP related PD. The myocardial uptake of MIBG is decreased only in one case. Heterogenous clinical phenotypes in these pedigrees are also observed. **Conclusions:** The incidence of familial CBD and PSP are higher in this region. Cardiac sympathetic denervation due to (-synucleopathy occurs rare in familial CBD and PSP.

Novel microRNA and novel predicted gene targets in sporadic form of Creutzfeldt-Jakob disease (CJD). *D. Glavač, E. Bostjančič, M. Ravnik-Glavač, M. Popovič.* Department of Molecular Genetics, Faculty of Medicine, Vrazov trg 2, 1000, Ljubljana, Slovenia.

Prion diseases are a related group of rare, fatal brain diseases in humans and animals, also known as transmissible spongiform encephalopathies (TSE).The most common human prion disease is the sporadic form of Creutzfeldt-Jakob disease (CJD). MiRNAs are effectors of brain function with roles in ischemia and injury, neuroprotection and neurodegeneration. Compelling evidence also links miRNAs to the control of neuronal development and differentiation. We used a co-ordinated approach to integrate miRNA and mRNA profiling and bioinformatic predictions in order to profile miRNA expression changes in human brains during sporadic CJD.Total RNA was isolated from the brain tissue of 8 patients with diagnosed CJD and the brain tissue of 7 healthy individuals. Expression analysis was performed using hybridization to μParaflo microfluidics micorarrays in the Sanger miRBase database version Release 10.1. Our analysis revealed over one hundred differentially expressed (up- or down-regulated) miRNAs. Sixteen of them showed similar dysregulation in experimental animals, in brains of mice infected with mouse-adapted scarpie and in the brains of BSE-infected cynomolgus macaques as a model for CJD. In addition, we selected 15 miRNAs for microarray validation using real-time PCR. MiRNA miR-342-3p, which showed up-regulation in our microarray experiment, was also up-regulated in the brains of BSE-infected macaques. Neuronal-specific miRNA, miR-124a, was also up-regulated in our experiment; this miRNA is believed to have constant expression in adult neurons. Neuronal death would therefore have some impact on miR-124a expression. Other up-regulated miRNAs, miR-16 and miR-98, are involved in apoptosis as pro-apoptotic miRNAs, with miR-16 believed to be involved in the apotosis of developing neurons. Neuronal autophagy and apoptosis are mechanisms of programmed cell death. Since there is some information that autophagy and apoptosis are processes naturally occurring in experimentally induced scrapie and CJD, we believe that miRNAs regulating apoptosis may also play a role in transmissible spongiform encephalopathies. Computational analysis predicted numerous potential gene targets of these miRNAs, including some genes previously identified as being also de-regulated in mouse scrapie. In conclusion, we detected several novel miRNAs and novel predicted gene targets and confirmed their down-regulation in human CJD brain tissue.

Hereditary spastic paraplegias (HSP) constitute a heterogeneous group of neurodegenerative disorders characterized at least by slowly progressive spasticity of the lower limbs. Mutations in REEP1 were recently associated with SPG31, a pure dominant HSP. We recently identified 12 different heterozygous mutations in REEP1 by screening 175 unrelated HSP index patients from kindreds with dominant inheritance (AD-HSP), associated with either a pure or a complex phenotype. The overall mutation rate in our clinically heterogeneous sample was 4.5% in French families with AD-HSP. The phenotype was restricted to pyramidal signs in the lower limbs in most patients but 9 had a complex phenotype. Interestingly, we evidenced abnormal mitochondrial network organization in fibroblasts of patients from two families in addition to defective mitochondrial energy production in both fibroblasts and muscle, but whether these anomalies are directly or indirectly related to the mutations remains to determine.

606T

Exome sequencing reveals mutations in VPS35, encoding a subunit of the retromer complex, as cause for Parkinson's disease. *E. Graf[1], A. Zimprich[2], A. Benet-Pagès[1], W. Struhal[3], S.H. Eck[1], M.N. Offman[4], D. Haubenberger[2], S. Spielberger[5], E.C. Schulte[1,6], P. Lichtner[1], S.C. Rossle[4], N. Klopp[7], E. Wolf[5], W. Pirker[2], S. Presslauer[8], R. Katzenschlager[10], T. Parkinson's disease is the second most common neurodegenerative disorder affecting 1%-2% of the population above the age of 60. It is characterized by degeneration of dopaminergic neurons in the nigrostriatal pathway and other monoaminergic cell groups in the brainstem leading to bradykinesia, resting tremor, muscular rigidity, and postural instability as well as non-motor symptoms. By exome sequencing, we identified a single mutation, D620N, in VPS35, encoding a subunit of the retromer complex, in an Austrian family with 16 affected individuals. The mutation co-segregated with the disease in all seven affected family members that are alive. This is, after *LRRK2* and *SCNA*, the third gene in which mutations provide a high risk for late-onset PD. By screening additional PD cases, we saw the same variant co-segregating with the disease in an autosomal dominant mode with high penetrance in two further families with five and ten affected members, respectively. Genotyping showed that the shared haplotype extends across 65 kilobases around *VPS35*. Screening the entire *VPS35* coding sequence in 860 cases and 1014 controls by dye-binding/high-resolution DNA melting curve analysis revealed six further non-synonymous missense variants. Three were only present in cases, two only present in controls, and one present in cases and controls. D620N and a further variant detected in a PD case, R524W, were predicted to be damaging by sequence-based and molecular dynamics analysis. VPS35 is a component of the retromer complex which mediates retrograde transport between endosomes and the trans-Golgi network and which has recently been described to be involved in Alzheimer's disease.

Development of high throughput targeted resequencing array for the diagnosis of hereditary neuropathie. *O. Jarinova[1], J. Warman[1,2], C. Goldsmith[1,2], N. Carson[1], E. McCready[1], G. Yoon[3], S. Baker[4], A.M. Innes[5], K. Boycott[1].* 1) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, K1H 8L1; 2) Division of Neurology, Department of Medicine, The Ottawa Hospital, K1H 8L6; 3) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, M5G 1X8; 4) Department of Medicine, Divisions of Physical Medicine and Rehabilitation, McMaster University, Hamilton, L8N 3Z5; 5) Department of Medical Genetics, Faculty of Medicine, University of Calgary, Alberta, T2N 4N1.

Hereditary neuropathies comprise a distinct group of inherited disorders in which peripheral nerves undergo progressive degeneration leading to significant physical disability of the hands and lower legs. Causative mutations can reside in any of a number of genes responsible for various aspects of maintenance of peripheral nerves and result in an overlapping clinical spectrum for these disorders. Currently available molecular technologies only allow the sequential genotyping of these genes and determining genetic cause for most cases is often time consuming and expensive.

We have developed a high-throughput cost-effective method of molecular detection to facilitate the diagnosis of inherited neuropathies (`Neuropathy Chip') based on the Affymetrix resequencing platform. The Neuropathy Chip v1.0 is primarily designed to discern genetic changes in the coding sequences of 42 genes. In addition, we targeted 18 regions of potential clinical importance residing in close proximity to coding sequences of genes that are most commonly altered in hereditary neuropathies, i.e. *PMP22*, *MPZ*, *GJB1* and *MFN2*. These regions exhibit sequence conservation in human, mouse and opossum and may contain yet uncharacterized exonic sequences and/or regulatory elements. Combined, Neuropathy Chip v1.0 interrogates over 167 kb of unique sequence with call rates above >98% for successfully hybridized amplicons and effectively detects point mutations and provides clues towards identifying insertion and deletions.

Resequencing data were obtained for 13 affected individuals with known mutations and 19 affected individuals with unknown molecular etiology. Generated resequencing data will be examined and detected variants of potential/established clinical significance will be confirmed by Sanger sequencing. Efficiency, performance and clinical validity of the assay will be assessed and results from this analysis will be presented.

We estimate that the cost for testing of all the genes associated with hereditary neuropathies in any given patient would be close to the fee currently charged for analysis of only one gene. Furthermore, this approach has a potential to discover novel causative mutations and establish missing heritability in neuropathy patients with unknown molecular etiology.

608T

Rare genetic variants in APP, PSEN1, PSEN2, GRN, APOE and MAPT are associated with familial and sporadic Early and Late-Onset Alzheimer's disease. *S. Jin[1], S. Cervantes[2], B. Benitez[1], P. Pastor[2], A. Goate[1], C. Cruchaga[1].* 1) Psychiatry, Washington University in St. Louis, St. Louis, MO; 2) Center for Applied Medical Research, University of Navarra, Spain.

It has been suggested that the combined effects of rare variants could explain a large proportion of the genetic susceptibility to Alzheimer's disease (AD). Early studies showed that mutations in APP, PSEN1, and PSEN2 contribute to early-onset familial AD. Mutations in GRN and MAPT have been found in clinically diagnosed AD cases. We have used next-generation sequencing to identify rare variants implicated in both early and late onset AD. Pooled-sample sequencing was performed in 141 individuals with sporadic early-onset AD, 48 with familial early-onset AD, and 47 with late-onset AD. The pooled PCR products were sequenced on Illumina HiSeq 2000. Sequencing reads were mapped back to the sample and the reference sequence by gapped alignment. The SPLINTER program was used not only to predict and quantify short insertions, deletions, and substitutions but to predict rare allele frequencies. SIFT2 was then used to predict the effect of variants on protein structure. Variants identified by next-generation sequencing were confirmed by direct genotyping using Sequenom technology. Novel variants were tested for segregation in the familial cases and were also genotyped in 1000 controls. A total of 40 coding variants were identified out of 357 non-intronic variants in the genes encoding APP, PSEN1, PSEN2, GRN, APOE, and MAPT. Among these 40 variants, 19 are non-synonymous variants, 19 are synonymous variants. Out of 19 non-synonymous, 8 are predicted to be tolerated and 11 damaging. Out of 357, there are 43 (12%) novel variants. Comparing to 1000 Genomes data and the AD & FTD Mutation Database, 4 non-synonymous variants are predicted to be novel and damaging and 3 novel and tolerated. In addition, we find 6 known non-causative variants in PSEN1 and MAPT, and 2 known where pathogenicity is unknown in pooled-sample. These results highlight the necessity of additional sequencing in these genes, because new pathogenic variants are still to be discovered.

609T

A Japanese hereditary spastic paraplegia patient with BSCL2 gene mutation. *M. KOHDA[1], K. ITOKAWA[2], T. HIRATA[1], N. ARAKI[2], Y. OKAZAKI[1].* 1) Division of Translational Research, Saitama Medical University, Japan; 2) Department of Neurology, Saitama Medical University, Japan.

OBJECTIVE AND BACKGROUND: Hereditary spastic paraplegia (HSP) is a neurodegenerative disorder defined clinically by progressive lower limb spasticity and weakness. HSP is a genetically highly heterogeneous condition with at least 46 gene loci identified so far, involving X-linked, autosomal recessive and autosomal dominant inheritance. For correct diagnosis molecular testing is essential since clinical parameters by themselves are not reliable enough to differentiate HSP types. Here we report a two-generation family with six patients in which the inheritance pattern is consistent with an autosomal dominant model. We performed a homozygosity haplotype method (HH) in all affected/unaffected family members followed by exome sequencing to find the causative mutation in this family. METHODS: We used the HH approach to identify shared chromosomal segments derived from a common ancestor, who had the causative mutation. The HH represents haplotypes of both copies of homologous autosomes, allowing for direct comparisons of the autosomes among multiple patients and enabling the identification of the shared segments. Then we performed exome sequencing which is capable of resequencing nearly a complete set of coding exons in an individual. RESULTS: HH analysis identified a certain amount of shared regions that segregated with spastic paraplegia in this family. We performed exome sequencing on single affected individuals to investigate causal nonsense variants. Using a combination of sanger sequencing of candidate genes and next-generation exome sequencing, we identified one mutation in BCSL2 (N88S), which lied in one of the shared region. This variant had been reported previously as pathogenic in SPG17 with incomplete penetrance. Sanger sequencing confirmed the co-segregation between disease-phenotype and this mutation. CONCLUSION: The HH successfully detected the shared segments from members of a family with spastic paraplegia, which is an autosomal dominant disease. Exome sequencing has greatly impacted the speed at which new disease genes are identified. Our strategy to identify causative disease genes using the HH followed by exome sequencing provides an efficient and effective approach in identifying potential disease linked region and causative mutation.

610T

Evaluation of Parkinson Disease Risk Variants as Expression-QTLs. *J.C. Latourelle[1], A. Dumitriu[1], T.C. Hadzi[1], T.G. Beach[2], R.H. Myers[1].* 1) Department of Neurology, Boston University School of Medicine, Boston, MA; 2) Civin Laboratory for Neuropathology, Banner Sun Health Research Institute, Sun City, AZ.

The recent Parkinson Disease GWAS Consortium (PDGC) meta-analysis and replication study reports association at several previously confirmed risk loci at *SNCA*, *MAPT*, *GAK/DGKQ*, and *HLA* and identified a novel risk locus at *RIT2*. None of the findings represents coding variation and most of the regions encompass many genes. We sought to examine modification of gene expression by the associated SNPs to identify the genes responsible for association. In this study, we examine the association between Parkinson Disease (PD) risk SNPs identified by the PDGC and gene expression levels in prefrontal cortex brain samples. 33 pathologically confirmed PD cases and 29 controls were run on an Agilent 60-mer Microarray. The samples were genotyped in the PDGC replication sample using a custom Illumina array including all top association results from the discovery meta-analysis. Twelve samples were removed after evaluation of microarray and genotyping QC, leaving 26 cases and 24 controls for the eSNP analysis. We selected for evaluation as potential eSNPs 92 SNPs, from 19 different loci, that showed nominal association to PD ($p<0.05$) in the PDGC replication sample. Association between the eSNPs and expression levels was evaluated using a 2df test of association between genotype and expression and difference in association between cases and controls, adjusted for relevant covariates. SNPs at each of the 19 loci were tested for cis-acting association to all probes within 250 kb of the most proximal and distal SNPs for each locus. As a secondary analysis, trans-effects of the SNPs on the 39,122 probes passing all QC on the microarray were also examined. From the cis analysis, several SNPs in the *MAPT* region show significant association to multiple nearby probes, including two strongly correlated probes, targeting the gene *LOC64424* and the duplicated genes *LRRC37A* and *LRRC37A2*, and a third uncorrelated probe targeting the gene *DCAKD*. Significant cis-associations were also observed between SNPs and two probes targeting genes in the *HLA* region on chromosome 6. Expanding the association to examine trans effects revealed an additional 20 SNP-probe associations reaching statistical significance ($p<1.9\times10^{-8}$) including SNPs from the *SNCA* and *RIT2* regions. These findings suggest that genes other than *MAPT* may be responsible for the SNP association to PD observed at 17q21 and give additional insight into which genes are responsible for association in ambiguous GWAS implicated regions.

Comparison of pathway analysis approaches using lung cancer GWAS data sets. *G. Fehringer[1], G. Liu[2], L. Briollais[1], P. Brennan[3], C.I. Amos[4], M.R. Spitz[4], H. Bickeböller[5], H.-E. Wichmann[6], A. Risch[7], R.J. Hung[1].* 1) Prosserman Centre for Health Research, Samuel Lunenfeld Research Institute, Toronto, Ontario, Canada; 2) Department of Medicine and Medical Biophysics, Ontario Cancer Institute/Princess Margaret Hospital, Toronto, Ontario, Canada; 3) International Agency for Research on Cancer (IARC), Lyon, France; 4) Department of Epidemiology, The University of Texas M. D. Anderson Cancer Center, Houston, Texas, U.S.A; 5) Department of Genetic Epidemiology, University Medical Center, University of Goettingen, Goettingen, Germany; 6) Institute of Epidemiology, GSF-National Research Center for Environment and Health, Neuherberg, Germany; 7) Division of Epigenomics and Cancer Risk Factors, German Cancer Research Center, Heidelberg, Germany.

Pathway analysis has been proposed as a complement to single SNP analyses in GWAS. This study compared pathway analysis methods using two lung cancer GWAS data sets based on four studies: one a combined data set from Central Europe and Toronto (CETO); the other a combined data set from Germany and MD Anderson (GRMD). We searched the literature for pathway analysis methods that were widely used, representative of other methods, and had available software for performing analysis. We selected the programs EASE, which uses a modified Fishers Exact calculation to test for pathway associations, GenGen (a version of Gene Set Enrichment Analysis (GSEA)), which uses a Kolmogorov-Smirnov-like running sum statistic as the test statistic, and SLAT, which uses a p-value combination approach. We also included a modified version of the SUMSTAT method (mSUMSTAT), which tests for association by averaging χ^2 statistics from genotype association tests. There were nearly 18,000 genes available for analysis, following mapping of more than 300,000 SNPs from each data set. These were mapped to 421 GO level 4 gene sets for the pathway analysis. Among the methods designed to be robust to biases related to gene size and correlation among pathway SNPs (GenGen, mSUMSTAT and SLAT), mSUMSTAT identified the most significant pathways (9 in CETO and 1 in GRMD). This included a highly plausible association for the acetylcholine receptor activity pathway in both CETO (FDR ≤0.001) and GRMD (FDR=0.005). Few other replicated associations were found using any of these methods. Difficulty in replicating associations hindered our comparison, but results suggest mSUMSTAT has advantages over the other approaches. This method may be a useful pathway analysis tool that could be used alongside other methods such as the commonly used GSEA (GenGen) approach. Acknowledgements: D. Identification of genetic factors that mediate inter-individual differences in the gut microbiome. *J.K. Goodrich[1], J. Bell[2], T. Spector[2], A.G. Clark[1], R.E. Ley[1].* 1) Cornell University, Ithaca, NY; 2) King's College, London, U.K.

Using fecal samples from the TwinsUK study cohort, we quantify the magnitude of heritable, inter-individual differences in microbiome composition. Next generation sequencing was applied to generate 16S rRNA gene sequences of microbes in the fecal samples of 128 dizygotic and 110 monozygotic twin pairs, with each sample yielding an average of ~6,000 quality-filtered sequence reads. These rRNA sequence data were used to catalog and quantify inter-individual variability in microbiota and produce a phylogenetic representation of the microbiome species composition. Multiple metrics to characterize the microbiome were examined, including representation of all universally-shared taxa, and proportional representation of some of the major phylogenetic groups (e.g. Firmicutes). Monozygotic twin samples and repeated measures of some individuals were used to quantify environmental stability of each microbiome metric. Using whole-genome SNP genotypes, we applied allele-sharing methods to identify DZ twin pairs that shared 0, 1, or 2 alleles Identical-by-Descent (IBD) for each segment of the genome. This information was used to test the null hypothesis that each genome segment had zero effect on each of the microbiome metrics. Significant rejections of this hypothesis establish a statistical association between regions of the human genome and the composition of the gut microbiome, indicating that genetic factors may in part be responsible for gut microbiome dysfunction.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: High Imputation Coverage of Low Frequency Variants using Dense Genotyping Arrays. *T.J. Hoffmann[1], M.N. Kvale[1], Y. Zhan[2], S. Hesselson[1], P. Kwok[1], C. Schaefer[3], N. Risch[1,3].* 1) University of California, San Francisco, San Francisco, CA; 2) Affymetrix Incorporated, Santa Clara, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Resource on Adult Health and Aging has assayed 675,000+ SNPs on each of 100,000 participants. With this unprecedented number of subjects, it is possible to have adequate power to detect disease/trait associations even for SNPs with low minor allele frequency (MAF) not assayed on the array via imputation of missing genetic variants. It has been previously shown that larger reference sample sizes increase the accuracy of imputing genetic variants, especially rare variants. However, these analyses have not directly addressed the question of how well imputation can predict variants as a function of their population frequency. The ability to impute a low frequency variant is likely to be a function of both its general population frequency as well as its representation in the reference sample, and possibly by other sample characteristics. Here we report results of analyses intended to explore the determinants of imputation accuracy for low MAF variants, stratifying these analyses by various different metrics. For these analyses, we use the SNP content of a European-ancestry array designed specifically for the Kaiser Permanente/UCSF project. For reference data, we use various subsets of recently released sequence data from the 1000 Genomes Project. For determination of MAF, we use a sample independent of the reference sample on which the imputation is based, to disentangle the confounding between minor allele count and MAF. We find that the primary determinant of imputation ability for low frequency variants is the minor allele count in the reference sample. For a given minor allele count, imputation accuracy is only modestly influenced by minor allele frequency and overall reference sample size (or major allele count). For MAF down to 2%, we project high imputation accuracy provided a sufficiently large reference sample is available. However, for detecting associations of variants with frequencies below this level, because of possible ethnic variation and mutational heterogeneity, direct sequencing will likely be preferable. Finally, we use these results to determine the average power of our project to detect associations for rare alleles given a large reference data set for imputation. For a SNP with MAF of 2%; or greater that contributes 0.1%; of the variance of a quantitative trait, for our sample of 100,000 individuals the power is greater than 90%; at a P-value of 10^-8.

614T

A meta-analysis of 16 genome-wide association studies identifies genetic variation in the *LEP* gene to be associated with blood leptin levels independent of body mass index. *T.O. Kilpeläinen[1], Q. Background: Leptin is in adipocyte-derived hormone of which the circulating levels correlate closely with body fat. Leptin acts as a chronic signal to inform the brain about the stored body fat and as such it is involved in the regulation of long-term energy homeostasis. Complete leptin deficiency due to mutations in the leptin (*LEP*) gene causes severe obesity. We aimed to identify genetic variants regulating leptin levels in the general population. **Methods:** We performed a meta-analysis of associations between ~2.5 million SNPs and blood leptin levels from 24,778 individuals of white European descent using additive genetic model while adjusting for age, in men (n=9,835) and women (n=14,943) separately. To identify loci associated with leptin levels independent of body fatness, we performed an additional meta-analysis with adjustment for BMI. Both meta-analyses were performed in all individuals and in men and women separately. **Results:** Five independent loci reached $P<10^{-6}$ for their association with leptin. In the BMI-unadjusted analysis, variants in the *COBLL1* ($P=2x10^{-7}$) and *FTO* ($P=5x10^{-7}$) genes and near the *SLC19A3* gene ($P=6x10^{-7}$) showed association with leptin in all individuals, and variants in the *SLC2A2* gene showed association with leptin in men ($P=4x10^{-7}$). In the BMI-adjusted analysis, variants in the *LEP* gene showed genome-wide significant association with leptin in all individuals ($P=6x10^{-9}$). The associations of all 32 previously established BMI loci with leptin in the BMI-unadjusted analysis were directionally consistent with their known associations with BMI. **Conclusions:** Genetic variation in the *LEP* gene is associated with blood leptin levels irrespective of the overall body fatness. The association of variants in *FTO*, *COBLL1*, *SLC2A2*, and near *SLC19A3* with leptin may be dependent on BMI. While *FTO* is a well-known adiposity gene and is likely associated with leptin due to its effect on body fatness, the *COBLL1*, *SLC2A2*, and near-*SLC19A3* loci have not been linked with adiposity and may affect leptin levels through other mechanisms. The *COBLL1* gene is involved in neuronal development, and the *SLC2A2* and *SLC19A3* genes encode transmembrane transporters for glucose and thiamine, respectively. The replication of all loci reaching $P<10^{-6}$ for the association with leptin is underway. The identification of loci regulating leptin levels may provide new insights into the genetic regulation of appetite and obesity.

615T

Replication of GWAS signals and association of novel functional variants for serum uric acid and total serum bilirubin levels in an Irish population. *Y. Kim[1], C.D. Cropp[1], A.M. Molloy[2], J.L. Mills[3], P.N. Kirke[4], J.M. Scott[2], L.C. Brody[5], J.E. Bailey-Wilson[1], A.F. Wilson[1].* 1) Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD, USA; 2) School of Immunology and Biochemistry, Trinity College, Dublin, Ireland; 3) Division of Epidemiology, Statistics, and Prevention Research, NICHD, NIH, Bethesda, MD, USA; 4) Child Health Epidemiology Unit, Health Research Board of Ireland, Dublin, Ireland; 5) Genome Technology Branch, NHGRI, NIH, Bethesda, MD, USA.

Background: The measurement of blood and serum metabolites can provide insight into the metabolic processes underlying the variation of traits related to many diseases. The catabolic products of purine and hemoglobin metabolism can directly cause disease and serve as pathologic markers of several disease states. In order to better understand the genetic determinants of the product of these pathways, we measured serum uric acid (URIC, mmol/L) and total serum bilirubin (TBIL, umol/L) in a healthy, young population. Blood and dietary information were collected and metabolites were measured in 2490 healthy students at Trinity College Dublin in Ireland. **Methods:** URIC was adjusted for age, sex, and BMI, and log-transformed TBIL was adjusted for age and sex. High density genotyping was performed with the Illumina 1M HumanOmni1-Quad chip. After quality control assessment 2232 unrelated individuals and 757,533 SNPs were retained for association testing. Tests of association were performed with simple univariate linear regression, regressing each marker on each trait, assuming an additive genetic model as implemented in PLINK v1.0.7. Locus-specific heritability (h2) for the effect size of each SNP on phenotypic variation was calculated using R v2.12.1. **Results:** For URIC, we replicated previously reported SNPs in *SLC2A9* (rs6449213, h2 = 10%), *WDR1* (rs717615, h2 = 3%), and *ABCG2* (rs2199936, h2 = 2%) at genome-wide significance levels (p-value ≤ 5e-08). Additional SNPs were significant in these 3 reported candidate genes and *ZNF518B*. The most significant results were from rs13111638 (p-value = 4e-24, h2 = 9.5%) in an intronic region and in two coding SNPs in *SLC2A9* (rs10939650 and rs13113918 (p-value = 2e-22, 1e-21; h2= 4.4%, 5.6% respectively). For TBIL, strong *UGT1A* gene family signals were found including replication of rs887829 (p-value = 4e-156, h2=28%). Additionally, two non-synonymous SNPs (rs6431631 and rs1500480 (p-value = 3e-09, 2e-08 respectively) were found to be associated in *LOC339766*. However, there were no genome-wide significant signals in *SLCO1B1* a known candidate gene for TBIL (minimum p-value = 7e-07). **Conclusion:** Previously published common variants associated with URIC and TBIL levels with high h2 were replicated and additional new coding genetic variants were found in this healthy, young Irish population. These findings provide additional evidence for future analyses to identify the mechanism of genetic contributions to these phenotypes.

Exploration of pleiotropic effects of inflammation-related disease GWAS SNPs with C-reactive protein levels in the PAGE study. *J.D. Kocarnik[1], S.A. Pendergrass[2], C. Carty[1], J. Pankow[3], F. Schumacher[4], I. Cheng[5], P. Durda[6], N. Cook[7], S. Liu[8], J. Wactawski-Wende[9], A. LaCroix[1], B. Jackson[10], T. Manolio[11], D. Crawford[2], M. Gross[12], U. Peters[1] on behalf of the PAGE Consortium.* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology, University of Minnesota, Minneapolis, MN; 4) Keck School of Medicine, University of Southern California, Los Angeles, CA; 5) University of Hawaii Cancer Center, Honolulu, HI; 6) Department of Pathology, University of Vermont, Burlington, VT; 7) Department of Epidemiology, Brigham & Women's Hospital, Boston, MA; 8) Department of Epidemiology, University of California Los Angeles, Los Angeles, CA; 9) Department of Social and Preventive Medicine, University at Buffalo, Buffalo, NY; 10) Department of Internal Medicine, Ohio State Medical Center, Columbus, OH; 11) Office of Population Genomics, NHGRI, NIH, Bethesda, MD; 12) Masonic Cancer Center, University of Minnesota, Minneapolis, MN.

Introduction: Inflammation is an important health measure related to many common complex diseases. C-reactive protein (CRP) is a circulating biomarker indicative of systemic inflammation. Genome-wide association studies (GWAS) have successfully identified several loci important to inflammation-related diseases including cardiovascular disease (CVD), diabetes and obesity. However, the associations between these variants and CRP have not been fully explored. We evaluated whether CRP levels are associated with previously identified variants from GWAS of inflammation-related diseases, and whether such associations differ by race. Methods: We included 9088 participants of the Women's Health Initiative who had baseline high-sensitivity CRP measurements and were genotyped as part of the Population Architecture using Genomics and Epidemiology (PAGE) Consortium: 6309 White, 1564 Black, 714 Hispanic, 418 Asian/Pacific Islander, and 83 American Indian women. We evaluated 95 single nucleotide polymorphisms (SNPs) previously shown to be associated with inflammation-related diseases. We used linear regression stratified by race to evaluate the association between serum CRP level and each SNP, using an additive genetic model adjusted for age and global ancestry, using the first two principal components from ancestry informative markers. We corrected for multiple comparisons using Bonferroni adjustment ($p<5.3x10-4$). Results: Three SNPs had statistically significant positive associations with CRP: rs429358 T allele (APOE) in Whites ($p=1.2x10-20$), Blacks ($p=2.6x10-7$), and Hispanics ($p=3.3$ x10-7); rs4420638 A allele (APOC1) in Whites ($p=7.7x10-14$) and Hispanics ($p=8.7$ x10-5); and rs1260326 T allele (GCKR) in Whites ($p=6.2$ x10-6). No SNPs were significantly associated with CRP in Asian/Pacific Islanders or American Indians, though sample sizes were small. Conclusions: This preliminary analysis indicates that several SNPs previously associated with inflammation-related disease are also associated with circulating CRP levels, which appear to differ by race/ethnicity. Future efforts will include incorporating data from the other three studies of PAGE, to further detect and replicate and SNP-inflammation associations in each ethnic group. PAGE includes the Multiethnic Cohort (MEC), Epidemiologic Architecture of Genes Linked to Environment (EAGLE), and the CALiCo Consortium (see pagestudy.org).

Two-stage multi-locus association analysis - collapsing variants with the adjustment for effect directions. *C. Kuo, D. Zaykin.* Biostatistics Branch, National Institute of Environmental Health Sciences, Durham, NC.

Complex diseases are likely to be influenced by multiple genetic loci among which the majority are undetectable using single-locus approaches, due to small marginal effects. Multi-locus approaches jointly modeling several loci at a time may capture gene-gene interactions but most of them have low power to detect joint effects of rare variants. A number of approaches have been proposed, based on the idea of adding up the number of rare alleles for each individual and using the resulting “allelic score” in an association test. However, such approaches implicitly assume that susceptibility of an allele is inversely related to its frequency. To avoid this assumption while maintaining statistical power, we introduce a two-stage analysis. In the first stage, we use a portion of the data to compute an overall P-value of association (P1) while recording effect directions for each variant. In the second stage, we compute a one-sided P-value (P2) from the “allelic score”, with possibly corrected effect directions, based on what have been observed in the first stage. Finally, we combine P1 and P2 in a weighted manner. We conduct simulations by considering a variety of genetic models with different patterns of linkage disequilibrium (LD). When the number of variants increases and a substantial portion of them are either causal variants or indirectly associated with the disease due to the LD, the two-stage analysis using ~30% of cases and controls for the first-stage has similar or higher power than a test based on the total sample.

Optimal test for rare variant effects in sequencing association studies. *S. Lee[1], M. Wu[2], X. Lin[1].* 1) Biostatistics, Harvard School of Public Health, Boston, MA; 2) Biostatistics, University of North Carolina, Chapel Hill, NC.

With development of massively parallel sequencing technologies, rare variants association tests are increasingly conducted. Burden tests, which assume all rare variants in the target region have effects on the phenotype in the same direction and of similar magnitude, are not powerful if there are many non-causal rare variants, or if there exist variants with different association directions. Recently proposed Sequence Kernel association Test (SKAT) (Wu, Lee, et al, AJHG, 2011) provides a robust test and is particularly powerful in the presence of protective and deleterious variants and null variants. However, SKAT is less powerful than burden tests when a large number of variants in a region are causal and in the same direction. It is hence of substantial practical interest to develop a test that is optimal for both scenarios. In this paper, we generalize SKAT by incorporating a correlation structure of variants effects through a particular family of kernels. The generalized SKAT includes burden tests as a special case when the effects of variants are perfectly correlated. Based on this new family of kernels, we have developed the optimal testing procedure (SKAT-O) by estimating the correlation parameter to maximize the power. We show that SKAT-O outperforms burden tests and SKAT in a wide range of scenarios. The results are illustrated using simulation studies and triglyceride data from the Dallas Heart Study.

HLA-DRB1 gene and type 1 diabetes: meta-analysis. *Y. Lee[1,2,4], C. Huang[2], W. Ting[2], F. Lo[3], T. Chang[1].* 1) Dept Med Res, Mackay Memorial Hosp, Tamshui District, New Taipei City, Taiwan; 2) Dept Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Dept Pediatrics, Chang Gung Memorial Hospital, Taoyuan, Taiwan; 4) Dept Pediatrics, Taipei Medical University, Taipei, Taiwan.

The concordance rate of type 1 diabetes (T1D) is ~50%; in monozygotic twins but only ~5%; in dizygotic twins. These observations suggest that genetic factors are important in the pathogenesis of T1D. The DRB1 gene in the HLA complex has been found to be associated with T1D. However, there are wide discrepancies among different ethnic groups. Therefore a meta-analysis on the gene may help know the reasons. **Materials and Methods** We searched the PubMed database for all genetic association studies of DRB1 and T1D using search terms “Diabetes Mellitus, Type 1”[Mesh] AND “DRB1”. The references of all identified publications were also searched for additional studies. According to the MOOSE (Meta-analysis Of Observational Studies in Epidemiology) guidelines, authors' names, year of publication, ethnicity of the study subjects, region/country where the study subjects resided, numbers of patients and controls, age at diagnosis of T1D for patients and at sampling of DNA for controls, manner in which the controls were selected, and number of subjects with each genotype or allele in both cases and controls were extracted. A meta-analysis was by Comprehensive Meta-Analysis Version 2. All P values are two-tailed and significant if <0.05. **Results** The literature search yielded 101 eligible articles. The meta-analysis revealed that risk factors are DRB1*04 and *03 in Africans and African Americans; *03 and *04 in Arabs; *03, *04 and *09 in Asians; and *03 and *04 in Caucasians. Protective factors are DRB1*11 in Africans; *15 in African Americans; *14, *13, *15 and *11 in Arabs; *12, *10 and *15 in Asians; and *15, *07, *11 and *14 in Caucasians. **Conclusions** The alleles in the DRB1 gene conferring susceptibility to or protection against T1D vary in different ethnic populations. The results of a case-control study in a population might not be completely replicated in another populations with different ethnicities.

620T

The role of cis-acting genetic modifiers in phenotypic variability of familial amyloid polyneuropathy FAP ATTRV30M. *C. Lemos[1,2], T. Coelho[3], J.L. Neto[1], J. Pinto-Basto[1,2], J. Sequeiros[1,2], I. Alonso[1,2], A. Sousa[1,2].* 1) UnIGENe, IBMC, Porto, Portugal; 2) Unidade Clínica de Paramiloidose, Centro Hospitalar do Porto (CHP), Porto, Portugal; 3) ICBAS, Instituto Ciências Biomédicas Abel Salazar, Univ. Porto Portugal.

Familial amyloid polyneuropathy (FAP) ATTRV30M is an autosomal dominant systemic amyloidosis, due to a point mutation in the transthyretin (TTR) gene. More than 100 mutations have been found in the TTR gene but V30M is by far the most common. The initial description of Portuguese cases (Andrade, 1952) characterized FAP as a disease of the young adult (onset 25-35yrs). A much wider variability in age-at-onset (AO) of FAP has been uncovered, including among Portuguese patients [17-80yrs]. So far, very few consistent results have been produced to explain that variability and most of the approaches have compared early (≤30) and late-onset (⁄ 50) as two separate groups. However, early and late-onset cases are not separate entities, since they often coexist in the same family, with offspring showing a much earlier AO than their affected parent - anticipation. Late-onset parents remain asymptomatic for several years and often have offspring with early onset, while the reverse has never been observed. Focusing on variation between generations of the same family and identifying genetic modifiers associated with variability in AO may have important clinical implications and is a very promising avenue. Our aim is to identify genetic modifiers within or closely linked to the TTR locus. Haplotype analysis families may indicate the presence of modifiers in TTR neighbourhood. Haplotype analysis is on-going in 100 families, using intragenic SNPs and flanking STRs for extended haplotypes. Sixteen tagging SNPs were selected based on a data dump from the HapMap Project (www.hapmap.org) and using Haploview v4.1, with a minor allele frequency (MAF) of 0.1% and covering 60 Kb around the TTR locus. SNP genotyping is currently underway by SNaPshot, using a multiplex approach. Eight microsatellite markers were also selected, encompassing 11.4 Mb. STRs genotyping is being performed by PCR, using fluorescent-labelled primer pairs and genotypes will be determined using GeneMapper version 4.0 software. Haplotypes will be constructed in informative families and inferred, using PHASE v2.1, when the phase cannot be directly determined. Some variants or regions that may confer protection to a number of generations (in families with late-onset patients or aged asymptomatic carriers) are expected to be found which when lost (by recombination or mutation) result in early onset in the offspring and therefore, may explain part of the variability of age-at-onset observed in FAP ATTRV30M.

621T

Differential call rates in genotype imputation and their effect on genetic association studies. *N. Liu, B. Zhang.* Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL.

Genotype imputation is the process of inferring genotypes that are not directly genotyped in a cohort of individuals. Imputation offers a promising way to infer untyped genotypes in genetic studies and has been widely adopted to boost power, fine-map associations, and synchronize the genotype data from studies using different platforms. However, the quality of the imputed data is vital to the downstream analyses and is largely ignored. One of these issues is the differential call rates among the imputed genotypes: AA, Aa, and aa (assuming a is the minor allele at a locus). In this work, we compare the call rates among the genotypes from imputation and evaluate the effect of differential call rates on genetic associate studies. We further provide guideline for genetic association studies when imputation is used. Our analysis based on the WTCCC and HapMap data indicates that the call rates for Aa and aa can be as low as 33% and 35% of that for AA when the minor allele frequency (MAF) is low. MAF is the major cause of such difference, although other factors such as untype rate, homogeneity of study samples, and threshold for accepting the “calling” from imputation can also affect the call rates. Simulation studies show that the differential call rates can considerably lower the power of the association test by 66% when background prevalence, MAF, and sample size are small. Relative risk of the disease, untyped rate and threshold for accepting an imputed genotype can also affect the power. We suggest that a study should balance between the sample size, untyped rate, and threshold used for imputation. For rare variants less than 5%, a study may consider a combined genetic score instead of using single marker for association test.

622T

A Nonparametric Approach to Population Based Association Tests. *S.M. Lutz[1], W. Yip[3], J. Hokanson[2], N. Laird[3], C. Lange[3].* 1) Biostatistics Dept, University of Colorado at Denver, Aurora, CO; 2) Epidemiology Dept, University of Colorado at Denver, Aurora, CO; 3) Biostatistics Dept, Harvard School of Public Health, Boston, MA.

In population-based genetic association studies, the standard approach is to model the phenotype of interest as a function of the offspring genotype. We propose an alternative approach based on conditional score-tests that treats the genetic information as the random variable and conditions upon the phenotypic information. The flexible structure of the approach enables the straight-forward application to standard and complex phenotypes. By treating the phenotype data as deterministic, the validity of the approach does not depend on the correctness of any assumptions about the phenotype. This makes the approach especially suitable for complex phenotypic models and the analysis of secondary phenotypes in studies that applied ascertainment conditions to the primary phenotype. If both phenotypes are correlated, the ascertainment conditions can cause a perturbation of the distribution of the secondary phenotypes. Based on theoretical considerations and on simulation studies, we show that our approach is robust against mis-specification of phenotype assumptions and, at the same time, achieves the same or higher power level as standard genetic association tests for population-based designs.

623T

Comparing the statistical power of joint and meta-analysis association testing with rare variants. *C. Ma, M. Boehnke, L.J. Scott.* Biostatistics, University of Michigan, Ann Arbor, MI.

Meta-analysis has become the standard approach to combine GWAS information across multiple studies, allowing simple sharing of results and study-specific covariate adjustment. For association testing of common genetic variants, Lin and Zeng (2010) showed that using meta-analysis to combine results from multiple studies has comparable power to joint analysis of the complete individual-level data. However, it is unclear whether meta-analysis remains statistically efficient compared to joint analysis for variants with small per-study minor allele counts (MAC). To address this question, we compared the power of joint and meta-analysis for disease-marker association testing of less common variants (minor allele frequency [MAF] < .05). We simulated datasets with 10000 cases and 10000 controls, assuming a single multiplicative causal genetic variant with varying expected MAC and a binary covariate. We analyzed the data using (1) logistic regression (LR), (2) Fisher's exact test (FET) with covariate stratification, and (3) exact logistic regression (ELR). We performed (a) joint analysis of the complete dataset and (b) meta-analysis of results from the same dataset partitioned and analyzed as 10 equal-sized sub-studies.

For common variants (per sub-study MAC ⁄ 400; MAF ⁄ .1), both joint and meta-analysis had near nominal type I error and equivalent power. However, for less common variants (MAC ≤ 40; MAF ≤ .01) and for all analysis methods, type I error for joint and meta-analysis was conservative but more conservative for meta-analysis. Furthermore, power was greater for joint analysis than meta-analysis. For example, for variants with MAC = 4 (MAF = .001) and genotype odds ratio = 5, power estimates were: 83% joint vs. 38% meta (ELR), 82% joint vs. 19% meta (FET), and 55% joint vs. 2% meta (LR). Overall, exact-inference tests (ELR and FET) had greater power than asymptotic tests (LR) for both joint and meta-analysis. Without covariate adjustment, ELR and FET had similar power for both joint and meta-analysis, but with covariate adjustment, ELR had greater power. For each test, meta-analysis has lower power and type I error due to the smaller number of possible statistically-significant configurations for the small number of alleles per sub-study. Since ELR can directly adjust for covariates and handle imputed allelic dosages, we recommend ELR for testing low frequency variants, preferably using joint analysis over meta-analysis.

Genome-wide association analysis of rare variants with Crohn's disease. *R. Magi, A.P. Morris.* Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Genome-wide association studies have been successful in identifying novel Crohn's disease (CD) susceptibility loci. However, the joint effects of common variants account for no more than 23% of the heritability of the disease. The aim of this study was to assess the evidence for association of CD with rare genetic variation, defined here to have minor allele frequency (MAF) less than 1%, through imputation up from a scaffold of existing GWAS genotyping data.

We performed imputation in 1,748 CD cases and 2,940 controls of European descent, genotyped using the Affymetrix GeneChip 500K Mapping Array Set by the Wellcome Trust Case Control Consortium. Imputation was undertaken using IMPUTEv2 and the European reference panel from the 1000 Genomes Project (August 2010 release). We tested for association of CD with accumulations of minor alleles at rare variants within genes using GRANVIL software, which models disease status as a function of the proportion of rare variants at which an individual carries at least one minor allele in a logistic regression framework.

The strongest signal of association of rare variants with CD was observed for *PTGER4* ($p=1.3x10^{-6}$, genome-wide significant correcting for 30,000 genes). This gene contains common variants that have been previously associated with CD and plays an important role in immune response. The gene contained 28 rare variants (mean MAF = $4.9x10^{-3}$), with odds ratio of 0.73 (0.64-0.83) per minor allele. Strong evidence of association of rare variation with CD ($p<10^{-5}$) was also observed for *CD247* ($p=2.5x10^{-6}$). Defects in the gene are a primary cause of primary T-cell immunodeficiency and common variants have been previously associated with systemic sclerosis. The gene contained 19 rare variants (mean MAF = $5.7x10^{-3}$), with odds ratio of 1.23 (1.13-1.34) per minor allele.

Our analysis has highlighted strong evidence of association of Crohn's disease with rare variation in 2 genes which warrant follow-up in independent cohorts. Our results highlight the potential for the identification of rare variant associations using existing GWAS genotyping data, supplemented with imputation from publicly available high-density reference panels, without the need for costly re-sequencing experiments.

Transferability of European Fasting Glucose Quantitative Trait Loci to African American Populations: the Candidate Gene Association Resource (CARe). *J.B. Meigs[1], C.T. Liu[2], J. Dupuis[2], A. Adeyemo[3], S. Bielinski[4], I. Borecki[5], B. Cade[6], Y.I. Chen[7], M. Fornage[8], M.O. Goodarzi[7], S.F.A. Grant[9], X. Guo[7], T. Harris[10], L. Kao[11], E. Kabagambe[12], J.R. Kizer[13], Y. Liu[14], J. Nettleton[8], M. Ng[14], J. Pankow[15], S. Patel[16], E. Ramos[3], L. Rasmussen-Torvik[17], S.S. Rich[18], C. Rotimi[3], D. Siscovick[19], J. Zmuda[20], J.C. Florez[1], J.G. Wilson[21], D.W. Bowden[14].* 1) Massachusetts Gen Hosp, Boston, MA; 2) Boston University School of Public Health, Boston, MA; 3) National Institute of Health, Bethesda, MD; 4) Mayo Clinic, Minneapolis, MN; 5) Washington University, St. Louis, MO; 6) Harvard Medical School, Boston, MA; 7) Cedars Sinai Medical Center, Los Angeles, CA; 8) University of Texas Health Science Center at Houston, Houston, TX; 9) Children's Hospital of Philadelphia, Philadelphia, PA; 10) National Institute on Aging, Bethesda, MD; 11) Johns Hopkins University, Baltimore, MD; 12) University of Alabama, Bimingham, AL; 13) Weill Cornell Medical College, New York, NY; 14) Wake Forest University, Winston-Salem, North Carolina; 15) University of Minnesota, Minneapolis, MN; 16) Brigham and Women's Hospital, Boston, MA; 17) Northwestern University, Chicago, IL; 18) University of Virginia, Charlottesville, VA; 19) University of Washington, Seattle, WA; 20) University of Pittsburgh, Pittsburgh, PA; 21) University of Mississippi Medical Center, Jackson, MS.

Background: Hyperglycemia disproportionately affects African Americans (AfA). Genetic variants associated with glycemic traits in European Ancestry (EuA) populations may be the same in AfA. We investigated population differentiation, evidence for selection, transferability and fine-mapping in the AfA CARe cohorts for loci previously associated with fasting glucose (FG) in EuA genome-wide association studies. Methods: We meta-analyzed (inverse-variance weighting approach) genome-wide single nucleotide polymorphism (SNP) associations with FG in 5,984 non-diabetic AfA from 5 CARe cohorts: ARIC, CARDIA, CFS, JHS, MESA. We tested transferability of 16 Index EuA FG-associated SNPs (from MAGIC, Dupuis et al 2010) in AfA using the meta-analysis results by 1) calculating allele frequency differences (|EuA-AfA/EuA|), fixation index (Fst) and integrated haplotype scores (iHS) in EuA and AfA, 2) testing directly 16 EuA index SNPs and 3) interrogating SNP-FG associations within ±250kb flanking regions around each index SNP to account for differences in LD structure. Significant evidence of transferability for index SNPs was defined as the same direction of effect and a P value adjusted for the effective number of independent tests. Results: Index SNP frequencies in each group differed by 2% (0.28 AfA, N=5,984 vs. 0.29 EuA, N=46,186; TCF7L2) to 77% (0.87 AfA vs. 0.49 EuA, CRY2). Fst was >0.15 at 1/16 loci in CARe but 6/16 loci in HapMap 2, indicating modest population differentiation, and all iHS were <2, suggesting no recent major selection at any locus. Only 3/16 EuA index SNPs (at G6PC2, GCK and MTNR1B) were nominally associated with FG in AfA (13 SNP associations were P>0.05). However, after accounting for LD differences, 15 SNPs flanking EuA loci were directionally consistent and nominally significantly associated with FG (P<0.05), with three which were multiple-test-adjusted significantly associated (at GCK, P=5.8x10-8, MTNR1B, P=8.5x10-9, FADS1, P=2.2x10-4). At each locus the SNP in AfA was only weakly correlated (r2 <0.3) with the EuA index SNP. Conclusions: Despite substantial allele frequency variation and modest index SNP transferability, after accounting for LD differences most FG-associated loci showed at least nominal evidence of similarity in AfA and EuA, with 4 loci (G6PC2, GCK MTNR1B, FADS1) associated with FG in both AfA and EuA. Accounting for varying LD across ancestral groups identified signals that may aid functional variant fine-mapping.

The lipid-associated rs4846914 GALNT2 gene variant confers a highly elevated risk for type 2 diabetes. *B. Melegh[1], P. Kisfali[1], A. Maasz[1], E. Baricza[1], B. Duga[1], M. Mohas[2], I. Wittmann[2], N. Polgar[1].* 1) Department od Medical Genetics, University of Pecs, Pecs, Hungary; 2) 2nd Department of Internal Medicine and Nephrology Center, University of Pecs, Pecs, Hungary.

The UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 2 (GALNT2) is indirectly contributing to plasma triglyceride level modifications as it has been recently implicated in the modulation of antgiopoietin-like protein - 3 (ANGPTL3) activity via O-glycosylation and ANGPTL3 is an inhibitor of lipoprotein lipase, the enzyme responsible for triglyceride hydrolysis. In addition, recent genome-wide association studies found GALNT2 variant rs4846914 to be associated with blood lipid level alterations. As the GWAS studies do not provide functional information, we studied the possible association of this variant in type 2 diabetes mellitus (T2DM) and metabolic syndrome (MS) patients. A total of 308 type 2 diabetic patients, 394 metabolic syndrome patients and 246 healthy controls were genotyped by PCR-RFLP method. A significantly higher ratio of GG homozygotes was detected among both T2DM and MS patients compared to controls. Furthermore, in multiple regression analysis adjusted for body mass index, triglyceride as well as age and sex, the GG genotype was found to be associated with the development of type 2 diabetes, with an unusually high odds ratio of 5.218 (CI 95%: 2.811-9.683; p<0.001), while carriers of the G allele demonstrate a lower risk for T2DM (OR 1.659 [CI 95%: 1.027-2.678], p=0.038). The results revealed a differentiated risk nature of the lipid profile modifying GALNT2 natural gene variant rs4846914, as in our cohort the variant did not show an association with metabolic syndrome, but seems to confer an exceptionally high risk for type 2 diabetes, which strong association has not been reported in the literature available.

627T

Coexpression network analysis in abdominal and gluteal adipose tissue reveals regulatory genetic loci for metabolic syndrome and related phenotypes. *J.L. Min[1], G. Nicholson[2], I. Halgrimsdottir[2], K. Almstrup[3], A. Petri[3], P. Keller[3], A. Barrett[4], M. Travers[4], N.W. Rayner[1,4], R. Mägi[1], F.H. Pettersson[1], J. Broxholme[1], M.J. Neville[4,5], Q.F. Wills[2], J. Cheeseman[4], The. GIANT Consortium[6], The. MolPAGE Consortium[7], M. Allen[4], C.C. Holmes[1,2], T.D. Spector[8], J. Fleckner[3], M.I. McCarthy[1,4,5], F. Karpe[4,5], C.M. Lindgren[1], K.T. Zondervan[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, Oxford, United Kingdom; 3) Department of Molecular Genetics, Novo Nordisk A/S, Maaloev, Denmark; 4) Oxford Centre for Diabetes, Endocrinology & Metabolism, Churchill Hospital, Oxford, United Kingdom; 5) NIHR Oxford Biomedical Research Centre, ORH Trust, Churchill Hospital, Oxford, United Kingdom; 6) The GIANT Consortium; 7) The MolPAGE Consortium; 8) Twin Research Unit, King's College London, London, United Kingdom.

Metabolic Syndrome (MetS) is a highly prevalent disorder with considerable public health concern, but its underlying genetic factors remain elusive. To identify gene networks involved in its pathogenesis, we conducted whole-genome expression and genotype profiling on abdominal (ABD) and gluteal (GLU) adipose tissue, and whole blood (WB), from 29 MetS cases and 44 controls. Co-expression network analysis for each tissue independently identified nine, six and zero MetS-associated modules of coexpressed genes in ABD, GLU and WB, respectively. Of 8,992 probesets expressed in ABD or GLU, 685 (7.6%) were expressed in ABD and 51 (0.6%) in GLU only. Differential eigengene network analysis of 8,256 shared probesets detected 22 shared modules with high preservation across adipose depots, ($D_{ABD-GLU}$=0.89), seven of which were associated with MetS (FDR P<0.01). The strongest associated module, significantly enriched for immune response related processes, contained 109/620 (18%) genes with inter-depot differences. In an independent cohort of 145/141 twins with ABD and WB longitudinal expression data, median variability in ABD due to familiality was greater for MetS-associated vs un-associated modules (ABD: 0.48 vs 0.18, P=0.08; GLU: 0.54 vs 0.20, P=0.002); median variability due to shared hospital visits was greater in WB than in ABD (0.34 vs 0.15, $P=1.9*10^{-6}$). *Cis*-eQTL analysis of probesets associated with MetS (FDR P<0.01) and/or inter-depot differences (FDR P<0.01) provided evidence for 32 eQTLs. Corresponding eSNPs were tested for association with MetS-related phenotypes in two GWAS of >100,000 individuals; rs10282458, affecting expression of *RARRES2* (encoding chemerin), was associated with body mass index (BMI) ($P=6.0*10^{-4}$); rs2395185, affecting inter-depot differences of *HLA-DRB1* expression, was associated with high-density lipoprotein ($P=8.7*10^{-4}$) and BMI-adjusted waist-to-hip ratio ($P=2.4*10^{-4}$). Since many genes and their interactions influence complex traits such as MetS, integrated analysis of genotypes and coexpression networks across multiple tissues relevant to clinical traits is an efficient strategy to elucidate their pathogenesis.

Pleiotropic Relationships among Measures of Body Composition in Afro-Caribbeans from Tobago. *R.L. Minster[1], A.L. Kuipers[2], C.M. Kammerer[1], A.L. Patrick[3], V.W. Wheeler[3], J.M. Zmuda[1,2].* 1) Dept of Human Genetics, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 2) Dept of Epidemiology, University of Pittsburgh, Pittsburgh, Pennsylvania, USA; 3) Tobago Health Studies Office, Scarborough, Tobago, Trinidad and Tobago.

Covariation between bone, muscle and fat tissue could be due to developmental, homeostatic, mechanical or geriatric processes, some of which may be due to pleiotropy. Little is known about such pleiotropic effects or the specific genes involved. In this study we explored the pleiotropic relationships among 22 measures of arm and leg bone mineral density and geometry, arm and leg lean mass and arm and leg fat mass using data from two populations of Afro-Caribbeans from the island of Tobago: a population sample of 1,937 unrelated men aged ⁄ 40 years and a set of 470 men and women aged > 18 years in seven extended pedigrees (mean family size = 67; 4,206 relative pairs). We first characterized phenotypic relationships via hierarchical clustering (HC) and then derived composite traits using principal components (PC) analyses. Subsequently, we estimated residual heritabilities (h_r^2) for the individual and composite traits, estimated genetic correlations (δ_G) among the 22 individual traits, and conducted genomewide linkage analysis using data on 1,516 autosomal SNPs (median spacing: 1.92 cM). HC and PC analysis revealed that the traits fall into three groups: (1) a “geometry group” that comprises mostly bone geometry traits and lean mass (PC1); (2) a “density group” that comprises mostly bone mineral density traits (PC2); and (3) a “fat mass group” that comprises measures of fat mass (PC3). Estimates of h_r^2 ranged from 0.206 to 0.763 (all $p < 0.007$) for all individual and composite traits. Genetic correlations were high among measures of lean mass and fat mass (δ_G: 0.43-0.84) and among measures comprising PC1 (δ_G: 0.36-0.89). Linkage analysis revealed significant evidence for QTLs on two chromosomes: (1) a QTL for PC1 that overlapped with a QTL for tibial periosteal circumference on 10q (LOD = 3.45 and 3.12 respectively) and (2) a QTL for PC3 that overlapped with a QTL for arm fat mass on 21q (LOD = 2.82 and 3.66 respectively). Leg fat mass and arm and leg lean mass also showed peaks on 21q (LOD < 2.5). Bivariate linkage analysis of arm and leg fat mass demonstrated suggestive linkage at this locus (LOD = 2.65) as did arm lean mass and arm fat mass (LOD = 2.92). The current analyses present evidence for specific QTLs with pleiotropic effects on multiple body composition traits. Additional mapping of variation in these regions could reveal genes that jointly influence susceptibility to osteroporosis, sarcopenia and obesity.

629T

Association Tests for Rare and Common Variants: an approach based on Genotypic and Phenotypic Measures of Similarity between Individuals. *I. Mukhopadhyay[1], J. Zhao[2], A. Thalamuthu[2].* 1) Human Genetics Unit, Indian Statistical Institute, 203 B T Road, Kolkata 700108, India; 2) Human Genetics, 60 Biopolis Street 02-01, Genome Institute of Singapore, Singapore 138672.

Gene-based association tests are gaining importance for the analysis of Genome-wide Association Studies (GWAS) because it reduces multiple testing burdens and also provides directions for future functional studies. The common variants used in GWAS account only for a small fraction of phenotypic variance or heritability. Along with the common variants, many rare variants are also identified through next generation sequencing technology. These rare variants are expected to have significant effects in the disease pathogenesis and may contribute significantly to the fraction of heritability that is still unexplained. So, within a gene or any genomic region of interest, testing of the joint association of both rare and common variants would be of utmost importance to determine their synergistic effects. Based on the idea of our recently proposed kernel based association test (KBAT) for binary trait, here we propose powerful methods to test such joint association. The association test for quantitative trait is based on both genotypic and phenotypic measures of similarity between individuals. We also have developed a modified version of KBAT for rare variants association. In fact, this method also has the potential to combine both rare as well as common variants to see whether any gene is associated with the disease etiology. The basic idea is to construct a number of groups of individuals depending on the similarity (phenotypic and / or genotypic) score between two individuals and test whether the group specific effects are same for these groups. Thus the usual idea of analysis of variance (ANOVA) technique is used here with careful modification. However, in contrary to ANOVA, we have shown that the proposed test statistics do not follow any known probability distribution, even when the null hypothesis of absence of association is true. Hence we use extensive simulation and permutation based type I error rate and power to evaluate the performance of the tests, under several genetic models. Our newly proposed approach seems to be very robust and can be extended in various directions.

The effect of plasma fibrinogen on the risk of venous thromboembolism among African American and White women using oral contraceptives. *C.S. Neal[1], F.D. Mili[2], W.C. Hooper[2], C. Lally[3], H. Austin[3].* 1) Pediatric Genetics Team, National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, Georgia, USA; 2) Research Laboratory Branch, Division of Blood Disorders, National Center on Birth Defects and Developmental Disabilities, Centers for Disease Control and Prevention, Atlanta, Georgia, USA; 3) Department of Epidemiology, Emory University Rollins School of Public Health, Atlanta, Georgia, USA.

Venous thromboembolism (VTE) is a condition that includes deep vein thrombosis and pulmonary embolism and has both hereditary and acquired risk factors. A strong association between Factor V Leiden mutation and VTE has been shown to exist in individuals of European descent. The mutation is uncommon and therefore of lesser importance in individuals of African descent and, to date, few genetic risk factors for VTE have been defined in this population. Data from the Genetic Attributes and Thrombosis Epidemiology (GATE) study, a matched case-control study conducted in Atlanta, Georgia, provided evidence that oral contraceptive (OC) use increased the risk of VTE in African American women and that the increased risk was even greater among African American women with sickle cell trait. Levels of plasma fibrinogen have a major genetic component and previous studies have suggested that high plasma fibrinogen (equal to 3g/L or above) was associated with increased risk for VTE. We sought to investigate the effect of plasma fibrinogen on the association between OC use and unprovoked, first VTE among African American versus White American women between 18 and 49 years of age. We defined unprovoked VTE as an episode of VTE where certain factors known to promote VTE (such as surgery or prolonged immobility) were absent. We analyzed data from the GATE study, and calculated odds ratios (OR) and 95% confidence intervals (CI) using conditional logistic regression adjusted for income and age. Our analysis included 269 African American women, [63 case patients (with VTE) and 206 control patients (without VTE)] and 192 White American women [43 case patients and 149 control patients]. Our findings indicated that the association between OC use and unprovoked, first VTE was stronger in African American women with high plasma fibrinogen (OR=5.5, 95% CI 1.7—18.0; P= 0.005) compared to those with normal fibrinogen levels (OR= 0.89, 95% CI 0.13—6.0; P=0.90). However, the association between OC use and VTE was not significantly different between White American women with high and normal plasma fibrinogen (OR=1.2 vs. OR=0.56, respectively). The P for interaction between African American women with high fibrinogen levels versus White American women with high fibrinogen levels was statistically significant at 0.037. Our preliminary results indicated that high fibrinogen levels might put African American women at a significantly greater risk for VTE from OC use.

Improving discrimination of true associations from tracking associations: a test using simulated disease data structured by real genomic data. *G. Nelson[1], P. An[2], C.A. Winkler[2].* 1) BSP/CCR Genetics Core, SAIC Frederick, NCI-Frederick, Frederick, MD; 2) Basic Research Laboratory, SAIC-Frederick, NCI-Frederick, Frederick, MD.

Successful genetic association searches, e.g. GWAS, commonly lead to identification of a region of association or a set of associated polymorphisms. If multiple polymorphisms are associated they will probably be in strong linkage disequilibrium (LD), making it difficult or impossible to distinguish factors functionally associated with disease from factors tracking the functional polymorphism by LD. Multivariate regression is a standard approach for finding the best association among correlated variables, but is strongly subject to noise when the explanatory variables are highly correlated, leading to instability in the results: small changes in the data can flip the results, so that a factor strongly associated in one analysis can lose all association in an analysis with slight changes in the data. This instability is heightened when automatic variable selection is used. We considered that bootstrapping might improve the stability and the accuracy of this analysis by partially suppressing the effect of noise. The chemokine receptor cluster on chromosome 3 contains a number of identified polymorphisms affecting AIDS progression, along with additional candidate polymorphisms for an influence on AIDS. As many of these are in strong LD, this region illustrates the association analysis problem. To test the ability of alternate methods in the context of a real pattern of LD, we combined real genomic data for polymorphisms in this receptor cluster with simulated AIDS progression data, generated assuming a Weibull distribution for genetic effects on AIDS progression. We show that bootstrapped forward automatic variable selection of the Cox model regression is the most successful strategy, among 6 bootstrapped and non-bootstrapped approaches, at correctly distinguishing the simulated associated factor or factors from the tracking factors. This contradicts a prevalent judgment that backward selection is preferable in epidemiological analysis, but is plausible for genetic factors, most of which will have no real association with the disease being studied.

632T

Japanese Population Structure Estimated from the Japanese Multi-institutional Collaborative Cohort (J-MICC) Data. *T. Nishiyama[1], N. Hamajima[2], S. Suzuki[3], H. Kishino[4], the Japan Multi-institutional Collaborative Cohort (J-MICC).* 1) Clinical Trial Management Center, Nagoya City University Hospital, Japan; 2) Departments of Preventive Medicine/Biostatistics and Medical Decision Making and Public Health/Health Information Dynamics, Nagoya University Graduate School of Medicine, Japan; 3) Department of Public Health, Nagoya City University Graduate School of Medicine, Japan; 4) Laboratory of Biometry and Bioinformatics, Graduate School of Agriculture and Life Sciences, University of Tokyo, Japan.

Background: Because population structure can cause spurious association in case-control studies, clarifying the population structure is important. The previous study of Japanese population with the use of genome-wide SNPs (Yamaguchi-Kabata et al, 2008) revealed that Japanese individuals fell into two main clusters, called as Hondo and Ryukyu. In this study, we examined Japanese population structure, using the Japanese Multi-institutional Collaborative Cohort (J-MICC) Data. Our main focus is to determine to which cluster Amami islands belong, because Amami islands is located just midway between regions covered by two clusters.

Methods: 234 SNPs in 4514 Japanese individuals from J-MICC were analyzed using principal-component analysis (PCA). We also used the multi-dimensional scaling (MDS) method to examine relatedness among individual using PLINK (Purcell et al, 2007).

Results: The PCA plot with the first and second components showed no separated cluster. The MDS method also indicated no separation in this sample.

Conclusions: These results have suggested that Amami islands midway between two sub-populational regions belong to the Hondo cluster, which includes most of the individuals from the main islands in Japan. Therefore, population stratification is unlikely to cause confounding in case-control analyses of J-MICC data.

Purpose: The aim of this project was to define genes associated with childhood blood pressure (BP) so as to better understand key biological pathways potentially related to hypertension in adulthood. **Methods:** Sex-stratified cross-sectional GWAS were conducted on children of European descent from the EAGLE Consortium across three pre-defined time frames; pre-pubertal [4-7 years], pubertal [8-12 years] and post-pubertal [13-19 years]. Each cohort created a Z-score for systolic and diastolic blood pressure (SBP and DBP) by removing the first BP measure and averaging the remaining at each time point, three models (M1-M3) were analysed. All models adjusted for age and assumed an additive model for SNP based main effects (M1). M2 additionally adjusted for height and weight. M3 additionally adjusted for birth weight and weight. Preliminary meta-analyses (in METAL(www.sph.umich.edu/csg/abecasis/metal)) using GWA data from studies; Raine, GenerationR, Young Finns Study and Lisa Plus are presented here. Avon Longitudinal Study of Parents And Children, Australian Twin Study and Spanish INMA will be contributing their GWAS analyses. The Netherlands Twin Register and Northern Finnish Birth Cohort will also supply genetic data for the purpose of replication. **Results:** A number of SNPs reached had a p-value of at least p≤1x10-5 across all models analysed (M1-M3). ***Males*** Pre-pubertal analyses revealed three SNPs in ARHGAP42 and one in SEL1L3 that were associated with SBP and DBP respectively. Pubertal analyses revealed two SNPs in HIVEP3 that were associated with SBP. Three SNPs in PAPPA2 were associated with DBP. Post-pubertal analyses revealed two SNPs in LINGO2 that were associated with DBP. ***Females*** Pre-pubertal analyses revealed a SNP in CDC45 was associated with SBP. Two SNPs in AFF3 and five SNPs in CSMD1 were associated with DBP. Pubertal analyses revealed a SNP in AKAP13 was associated with DBP. Post-pubertal analyses revealed a single SNP in both LPAR1 and SNX31 was associated with DBP. **Conclusion:** The findings were consistent within each time frame but not across time frames, supporting the concept that complex gene-environment interactions underlie the developmental origins of hypertension. Future studies with larger sample sizes will be required to replicate these findings (and in adult consortium: Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE)) to identify further biological pathways related to hypertension.

Atopic dermatitis (AD), or eczema, is one of the most common chronic skin diseases with a high heritability, complex mode of inheritance and an unclear genetic relationship with other atopic conditions such as asthma. Apart from filaggrin (*FLG*), the genes that underlie susceptibility to AD are largely unknown. In a large international consortium, the EAGLE Eczema Consortium, we conducted a genome-wide association meta-analysis on 5,606 Caucasian cases and 20,565 Caucasian controls from 16 population-based cohorts from across Europe, North America and Australia. Each contributing study conducted a case control genome-wide analysis of ~2.5 million imputed SNPs and we then used inverse-variance fixed effects meta-analysis (in METAL) to test for the associations in the overall study population. The ten most strongly associated novel markers were tested in a further 5,419 cases and 19,833 controls from 14 replication studies. Two variants were associated with AD susceptibility with genome-wide significance in the discovery sample (rs7000782 on chromosome 8q21·13, near the zinc finger and BTB domain containing ten gene *ZBTB10*, $p=1{\cdot}6x10^{-8}$ and rs9050 on chromosome 1q21·3, near the trichohyalin gene *TCHH*, $p=1{\cdot}9x10^{-8}$). Analysis adjusting for FLG null mutations suggested that the association of rs9050 was driven by these *FLG* variants and so rs9050 was excluded from further analyses. The locus reported to be associated in the only other GWAS on AD to date (11q13·5) showed nominal association in our meta-analysis (rs7927894, p=0·008), but of the 15 loci reported to be associated with asthma or total serum IgE levels in a recent GWAS, only two showed nominal association (5q13·1 *IL13*: rs1295685, p=0.0008; 12q13·3 *STAT6*: rs167769, p=0·0379). Of the ten SNPs taken through to replication, three showed association in the replication stage and reached genome-wide significance in the combined analysis: rs479844 on chromosome 11q13·1, near *OVOL1* (OR=0·88, $p=1{\cdot}1x10^{-13}$); rs2164983 on chromosome 19p13·2, near *ACTL9* (OR=1·17, $p=2{\cdot}4x10^{-10}$); rs2897442 on chromosome 5q31·1, in *KIF3A* (OR=1·10, $p=3{\cdot}0x10^{-8}$). We have identified three novel genetic loci associated with AD. The implicated genes for these associations underline the importance of epidermal barrier function in AD pathogenesis.

Segregation Analysis of Isolated Cleft Lip in a high-prevalence cluster of South America: uncommon high-risk allele and implications for genetic association studies. *F.A. Poletta[1,2,3], E.E. Castilla[1,2,3,4], I.M. Orioli[3,5], J.C. Mereb[6], F.M. Carvalho[3,5], C.A. Brandon[7,9], J.M. Resick[7,9], A.R. Vieira[7,8,9], M.L. Marazita[7,9], J.S. Lopez-Camelo[1,2,3,10].* 1) ECLAMC (Estudio Colaborativo Latino Americano de Malformaciones Congénitas) at CEMIC (Centro de Educación Médica e Investigaciones Clínicas-CONICET), Buenos Aires, Argentina; 2) CONICET (National Research Council of Argentina); 3) INAGEMP (Instituto Nacional de Genética Médica Populacional); 4) ECLAMC at Laboratório de Epidemiologia de Malformações Congênitas, Instituto Oswaldo Cruz, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil; 5) ECLAMC at Laboratório de Malformações Congênitas, Departamento de Genética, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; 6) ECLAMC at Hospital Zonal El Bolson, El Bolson, Rio Negro, Argentina; 7) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 8) Department of Pediatric Dentistry, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 9) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 10) IMBICE: Instituto Multidisciplinario de Biologia Celular (CIC-CONICET), La Plata, Argentina.

The genetic contribution to the etiology of orofacial clefts especially cleft lip and cleft palate (CL/P) is complex and heterogeneous. An area with high prevalence of CL/P was previously identified in Argentine Patagonia, probably associated with Amerindian ancestry and low socioeconomic status. The aim of this work was to estimate the mode of inheritance and the number of loci involved in CL/P families from Patagonia prior to planned for linkage/association studies. The sample included 117 extended pedigrees (2,835 total people) ascertained from CL/P probands registered by ECLAMC (The Latin-American Collaborative Study of Congenital Malformations) hospitals in Patagonia. Family Risk Ratios (FRR) were estimated for first-, second-, and third-degree relatives of CL/P probands, and Complex Segregation Analyses (CSA) were conducted using Pointer and SAGE software. CSA excluded the Sporadic, Environmental and Multifactorial threshold models, and provided evidence that CL/P is most likely determined by a dominant major gene with incomplete penetrance and with residual familial effects on affection status. Furthermore, FRR for relatives equate well with a major gene (or multiple additive or independent loci). One or two loci interacting epistatically with an poligenic background was also shown to be a plausible alternative. The high-risk allele frequency estimates of 1 to 9% have important implications with regards to the feasibility of identifying causative loci in this population through the typical commercial platforms and methods used in genome-wide association studies. Newer methodological approaches including customized genotyping platforms and analysis methods for association involving rare variants should be taken into account for future association studies to be conducted in this population. The identification of susceptibility genes associated with the occurrence of oral clefts in this high-prevalence cluster will eventually provide practical advice for genetic counseling of these families that will be more accurate than the current empiric recurrence risk estimates used. Support: DE016148.

Classification of anthropometric validated associations from GIANT using effects on childhood growth. *R.M. Salem[1,2,3], J.N. Hirschhorn[1,2,3], Early Growth Genetics (EGG) Consortium.* 1) Broad Institute, Cambridge, MA; 2) Children's Hospital Boston, Boston, MA; 3) Harvard Medical School, Boston, MA.

Background: The recent GIANT consortium meta-analysis recently revealed many validated loci associated with height (180 loci) and BMI (32 loci). Some of these variants have been shown to have effects on childhood traits (birth weight, birth length and puberty timing), but it is not clear whether the associated loci have similar effects on childhood growth, or show distinct patterns of association. We hypothesized that the pattern of associations across multiple traits can be used to classify the height- and BMI-associated loci into different groups representing different biological processes. **Methods:** Association data for the validated height and BMI associations from GIANT was provided by the EGG consortium for birth length and birth weight, and by REPROGEN for age at menarche. Cluster analysis was performed using a multivariate vector consisting of beta values or beta z-scores (beta / SE) for each childhood trait, in addition to GIANT height and BMI values. Heatmaps and dendrogram plots were generated to review clustering pattern and determine the number of clusters. Pathway analysis was performed using GRAIL. **Results:** The BMI SNPs clustered into two groups and the height SNPs into 11 groups (1-51 SNPs) based on review of heatmap and dendrogram plots. The two BMI clusters were differentiated most strongly by SNP effect on height (increasing and decreasing betas). The height clusters were more complicated, with varying patterns of effects across the traits. The subgroups identified by clustering fell into distinct pathways as noted with GRAIL pathway analysis, such as growth-hormone related genes, hedgehog- related genes, etc. Suggesting that cluster analysis across phenotypes can be used to identify SNPs that mark nearby genes that fall into distinct biological pathways, though GRAIL p values were generally not improved by division of the loci into subgroups. **Conclusion:** Association data for childhood traits could be used to classify the height- and BMI-associated SNPs into groups. Classifying variants by their effects on multiple traits might be a useful method to disentangle the genetic architecture of complex traits, and may inform pathway analysis to identify loci that play important roles in different biological processes.

637T

Imprinting and maternal genotype effects of 4q35 genetic variants on combined asthma-plus-rhinitis phenotype. *C. Sarnowski[1,2,3], G. Malerba[4], C. Laprise[5], K. Rohde[6], M. Moffatt[7], P. Jeannin[1,2,3], M-H. Dizier[1,2,3], P.F Pignatti[4], W.O.C Cookson[7], M. Lathrop[8], F. Demenais[1,2,3], E. Bouzigon[1,2,3].* 1) INSERM, U946, PARIS, France; 2) Univ Paris Diderot, Sorbonne Paris Cité, Institut Universitaire d'Hématologie, Paris, France; 3) Fondation Jean Dausset-Centre d'Etude du Polymorphisme Humain (CEPH), Paris, France; 4) Section of Biology and Genetics, Department of Mother and Child, and Biology-Genetics, University of Verona, Verona, Italy; 5) Université du Québec à Chicoutimi, Chicoutimi, Canada; 6) Max-Delbrück-Center for Molecular Medicine (MDC), Berlin, Germany; 7) National Heart Lung Institute, Imperial College, London, UK; 8) CEA-CNG, Evry, France.

A previous genome-wide linkage scan conducted in 640 families from European ancestry (French, British and Italian) detected linkage of 4q35 to a combined phenotype asthma-plus-rhinitis, with increased evidence when taking into account imprinting (LOD=3.14, $P=2.5x10^{-5}$). We investigated further this region by genotyping a panel of 3,000 SNPs (spanning 20Mb) in 161 families (206 offspring) from the French EGEA study (Epidemiological study on the Genetics and Environment of Asthma). To test for association between these SNPs and asthma-plus-rhinitis phenotype, we used two different methods aiming to detect parent-of-origin and/or maternal genotype effects: 1) the Monte-Carlo Pedigree Parent-Asymmetry-Test (MCPPAT) and 2) the Parent-of-origin-Likelihood ratio Test (PO-LRT). Irrespective of the method used, we identified 50 markers associated with asthma-plus-rhinitis with P-value < 0.005. These associations were replicated in 245 French Canadian families (Saguenay-Lac-Saint-Jean) for four SNPs with P-values ranging from 0.06 to 0.005 under the same model as in the discovery set. The combination of P-values (P_{comb}) from the EGEA and SLSJ samples using Fisher's method enhanced the evidence for association of asthma-plus-rhinitis with SNPs in two genes. The most significant SNP in one gene had $P_{comb}=2x10^{-4}$ under a parent-of origin effect model while the best SNP in the other gene had $P_{comb}=5x10^{-4}$ under a maternal genotype effect model. This study highlights that taking into account complex mechanisms, such as imprinting and maternal genotype effect, facilitates the identification of new susceptibility genes. The Kaiser Permanente Research Program on Genes, Environment and Health: A Resource for Genetic Epidemiology Research Linking Electronic Health and Environmental Risk Data to Genomics Data in a Large Cohort Based in a Health Plan. *C. Schaefer[1], S. Rowell[1], L. Walter[1], C. Somkin[1], S. Van DenEeden[1], C. Quesenberry[1], L. Croen[1], L. Kushi[1], R. Whitmer[1], C. Iribarren[1], M. Henderson[1], D. Smethurst[1], M. Sadler[1], D. Ranatunga[1], L. Shen[1], S. Sciortino[1], D. Ludwig[1], D. Olberg[1], K. Lapham[2], J. Lin[2], S. Miles[1], S. Hesselson[3], T. Hoffman[3], M. Kvale[3], E. Blackburn[2], P. Kwok[3], N. Risch[1,3].* 1) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 2) Dept. of Biochemistry and Biophysics, UCSF, San Francisco, CA; 3) Institute for Human Genetics, UCSF, San Francisco, CA.

Over the past decade, we have developed the Research Program on Genes, Environment, and Health (RPGEH), a large, population-based resource for genetic epidemiologic research based within the Kaiser Permanente Northern California (KPNC) membership of 3.3 million. The objective of the RPGEH is to facilitate research on determinants of disease and treatment response by linking information from comprehensive electronic medical records, genomic data from biospecimens, and environmental exposure data from surveys and geographic information system (GIS) databases on 500,000 broadly consented KP members. Over 430,000 adults have completed a survey that ascertained health-related behaviors and other risk factors. To date, we have obtained approximately 170,000 biospecimens (primarily saliva) from RPGEH survey participants. In 2009, we received a Grand Opportunity award from the NIH to perform genome-wide genotyping and telomere length analysis of 100,000 RPGEH participants, which we have now successfully completed. The sample is approximately 25% minority and 75% white. The mean age of participants is 65 years, and 51% have been KPNC members for 20 years or more. In addition to the genotype and telomere data, there is extensive health, environmental exposure, demographic and behavioral data on the cohort of 100,000. A unique feature of this resource is the comprehensive and longitudinal clinical, laboratory, radiology, pharmacy and other health data on all participants, beginning in 1995 and continuously updated as the cohort ages. The health data include many repeated measures of standard risk factors such as body mass index, blood pressure, lipid panels and other tests, as well as large numbers of subjects with a variety of chronic as well as infectious diseases with concomitant pharmacy and treatment data. GIS databases are available to map participants to environmental data such as air pollution and pesticide exposures, as well as the built environment. The resource will provide countless unique opportunities to advance knowledge of genetic and environmental predictors of disease and treatment response. Because a sizeable proportion (14%) are age 80 years and older, this cohort also provides unique opportunities to understand the factors underlying age-related disease and the processes of aging. To ensure best use of this resource, the RPGEH will provide collaborative access through application procedures or through dbGaP.

Rare variants in *ANKRD31* and *CXADR* are associated with blood pressure in African-Americans. *P.B. Shetty[1], H. Tang[2], T. Bamidele[3], A.C. Morrison[4], C.L. Hanis[4], D.C. Rao[5], R.S. Cooper[3], N. Risch[6], X. Zhu[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 3) Department of Preventive Medicine and Epidemiology, Loyola University of Chicago Stritch School of Medicine, Chicago, IL; 4) Division of Epidemiology, Human Genetics and Environmental Sciences, The University of Texas Health Science Center School of Public Health, Houston, TX; 5) Division of Biostatistics, Washington University in St. Louis School of Medicine, St. Louis, MO; 6) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA.

Background: Common genetic variants for hypertension have been identified through genome-wide association studies, but they are associated with modest effect sizes. Some of the missing heritability in hypertension may be attributed to rare variants of larger effect sizes, as they are expected to be functionally important. To address this, we assessed rare variants for association with blood pressure and body-mass-index (BMI).

Methods: We genotyped functional SNPs identified from a public database in genes in regions on chromosomes 5, 6, 8 and 21 where association evidence for hypertension or BMI was identified in our previous admixture mapping studies. We conducted gene based association analysis for systolic blood pressure (SBP) and diastolic blood pressure (DBP) adjusted for treatment and BMI in 1735 unrelated African-Americans. We collapsed the minor alleles of each rare functional SNP in a gene and conducted regression analyses. We adjusted for age, age^2, sex, and BMI, as applicable. To address population stratification, we adjusted for an individual's African ancestry estimated from 2,507 ancestry-informative markers. We corrected for multiple comparisons by adjusting for the number of genes in each region using the Bonferroni correction.

Results: Rare variants in *ANKRD31* were associated with SBP and DBP (nominal p = 0.0011 and 0.0001, respectively). Rare variants in *CXADR* were associated with SBP and DBP (nominal p = 0.0002 and 0.0008, respectively).

Discussion: The result in *CXADR* seems consistent with published findings that this gene plays a role in electrical conduction of the heart, and it is also associated with viral myocarditis and subsequent dilated cardiomyopathy [1, 2]. In *ANKRD31*, 3 of the 4 SNPs are non-synonymous, so they may result in functional changes. These two genes may be important in predicting the risk of hypertension, so future replication and functional analyses are warranted.

Gene-based tests that account for covariates and pedigree: The GLOGS / ACR pipeline for GWAS of complex traits. *S. Stanhope, M. Abney.* Department of Human Genetics, The University of Chicago, Chicago, IL.

In most GWAS, associations between markers and a trait are evaluated individually. Corrections for multiple comparisons are based on the number of markers, and after a significant association is obtained the chromosomal region containing the associated marker is studied. Presumably it contains a coding gene, with other markers in the region also showing association with the trait due to LD. We suggest that the analysis of individual markers is wasteful in terms of power. An approach that analyzes genes directly is preferable and more easily interpreted.

We describe a computational pipeline for gene-wise GWAS of complex traits in populations with arbitrary kinships and non-genetic risk factors. Our approach uses GLOGS (Genomewide LOGistic regression-Score test) to score associations between individual markers and the trait, and a novel code, ACR (Aggregation-Covariance estimation-Randomization test) that 1) aggregates marker scores, which are chi-squared distributed under the null hypothesis of no association with the trait, into gene scores; 2) calculates intra-marker score covariances due to LD, kinships, and the sensitivity of marker scores to changes in genotypes; and 3) performs randomization tests of the null hypothesis of no association between any marker in a gene with the trait. These tests utilize the fact that under the null the gene score is a function of covarying chi-squared random variables, and so its distribution may be sampled.

Using the GLOGS / ACR pipeline, we investigate the type I error, power, and sensitivity to misspecification in estimated intra-marker score covariances of several gene scoring methods. Although all methods yield correct type I error, there are differences in power with respect to the proportion of non-null markers within a gene, and in the sensitivity of a scoring method to covariance misspecification. In timing tests, we show that GLOGS / ACR, which is implemented for use on cluster, multi-core and GPGPU systems, is computationally tractable - a GWAS can be completed in under two hours. We conclude with gene-wise GWAS of several phenotypes in the Hutterites. We show that gene-based analyses can reveal associations between genes and traits that would be missed in marker-based GWAS, and that these associations can replicate those observed previously.

Clinical and epidemiological analyses of nonsyndromic craniosynostosis. *C.G. Stevens[1], G. Yagnik[1], L. Qi[2], E. Cherkez[1], P.A. Sanchez-Lara[3], V. Kimonis[4], J. Stoler[5], M. Cunningham[6], J.M. Graham[7], S.A. Boyd[1].* 1) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA 95817; 2) Division of Biostatistics, Department of Public Health Sciences, University of California Davis, Davis, CA 95616; 3) Division of Genetics, Department of Pediatrics, Children's Hospital of Los Angeles, University of Southern California, Los Angeles, CA 90027; 4) Division of Genetics, Department of Pediatrics, University of California Irvine, Irvine, CA 92697; 5) Division of Genetics, Children Hospital Boston, Harvard University, Boston, MA 02115; 6) Division of Craniofacial Medicine, Department of Pediatrics, University of Washington, Seattle, WA 98195; 7) Division of Clinical Genetics and Dysmorphology, Medical Genetics Institute, Cedars Sinai Medical Center, Los Angeles, CA 90048.

Craniosynostosis is the premature fusion of one or more cranial sutures. It is a common malformation (3 to 5 per 10,000 live births) and may present as an isolated anomaly (nonsyndromic) or with associated defects (syndromic). Through the International Craniosynostosis Consortium (genetics.ucdmc.ucdavis.edu/icc.cfm), we enrolled 699 families with at least one individual affected with craniosynostosis and collected clinical and epidemiological data using a 10 page self-administered bilingual (English/Spanish) survey. Of the families that provided sufficient information, 429 were found to have a proband with nonsyndromic craniosynostosis. Our primary aim was to characterize the clinical features of these affected individuals and to screen for potential causative environmental factors. We analyzed parental data, teratogenic exposures, pregnancy complications, indicators of fetal constraint, and associated congenital anomalies and developmental delays. Results were compared to National Vital Statistics data to determine if any of the above factors showed significant deviation from the control population. All factors were assessed statistically for the entire study cohort, as well as within suture-specific subgroups. We observed an association with advanced parental age (maternal, p=4.8 x 10-5; paternal, p=8.3 x 10-4) as well as with plurality (p=6.1 x 10-6). The latter may indicate intrauterine constraint as a risk factor for the malformation.

Descriptive analysis of skeletal dysplasias in the Utah population. *D. Stevenson[1], J.C. Carey[1], J.L.B. Byrne[1,2], S. Srisukhumbowornchai[3], M.L. Feldkamp[1,3].* 1) Dept Pediatrics, Univ Utah, Salt Lake City, UT; 2) Dept Obstetrics and Gynecology, Univ Utah, Salt Lake City, UT; 3) Utah Birth Defect Network, Utah Department of Health, Salt Lake City, UT.

The Utah Birth Defect Network (UBDN) collects population-based data for Utah on births from all resident women. Our aims were to investigate the prevalence of skeletal dysplasias and perform a descriptive analysis of affected pregnancies/infants within the Utah population. Cases categorized as a skeletal dysplasia from all live births, stillbirths, and pregnancy terminations (TAB) between 1999-2008 were reviewed by 3 clinical geneticists. After case review, 153 were included for analysis (88% live births, 3% stillborn, 9% TAB). Cases were categorized by individual diagnosis and by etiologic groups (2010 Nosology and Classification of Genetic Skeletal Disorders). Epidemiologic characteristics/outcomes (e.g. death, prenatal diagnosis, family history, genetic testing) were evaluated. The overall prevalence for skeletal dysplasia was 3.0/10,000 births. The prevalence for skeletal dysplasia for stillbirths was 20.0/10,000 stillbirths. The most common diagnoses were osteogenesis imperfecta (OI) (n=40; 0.79/10,000), thanatophoric dysplasia (n=22; 0.43/10,000), achondroplasia (n=18; 0.35/10,000), and cleidocranial dysplasia (n=6; 0.12/10,000). The most common etiologic groups were the FGFR3 chondrodysplasia group (n=41; 0.81/10,000), the OI/decreased bone density group (n=40; 0.79/10,000), and the type 2 collagen group (n=10; 0.2/10,000). Prenatal diagnosis was made in 53.6% (mean gestational week of diagnosis = 23 weeks). Of those deceased, 88% were prenatally diagnosed; of those alive 29% prenatally diagnosed. Paternal age was increased compared to the general population (mean 30.5 yrs; $p<0.05$). Cesareans were performed in 44%. 53% of mothers living in rural areas delivered at an urban hospital. Only 16% of cases were transferred to a different facility. Age of death for live born individuals: thanatophoric dysplasia (median 1.5 days; n=16 live births), OI type 2 (median 1 day; n= 6 live births). Of those deceased, 78% had a known lethal diagnosis. Median age of postnatal diagnosis was 30 days (range 1-2162). Postnatal genetic consult was obtained in 30% with and 55% without a prenatal diagnosis. Previously reported prevalence rates of skeletal dysplasia vary, but our data provide a population based approach not limited to the perinatal/neonatal period. OI was the most common skeletal dysplasia, differing from other epidemiologic studies. This investigation also provides data on outcomes and associated evaluation and referral patterns for skeletal dysplasias.

Association testing for rare variants via pooled design. *I. Tachmazidou[1], M. De Iorio[2], M. Falchi[2].* 1) The Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Imperial College, London, United Kingdom.

It is thought that much of the genetic susceptibility to complex diseases is due to rare variants. Next generation sequencing in large populations facilitates the detection of rare variants association to disease risk. Although sequencing costs have dropped, they are still high for large-scale studies. DNA pooling could prove a cost effective approach for identifying associations between rare variants and disease.

In this work, we propose to use pooled DNA samples to estimate allele and haplotype frequencies for rare SNPs, and we investigate the performance of collapsing methods in the context of a binary trait. In particular, we consider haplotype-based association tests and collapsing methods based on estimated allele frequencies. We use the EM algorithm of Yang et al 2003 to estimate haplotypes from pooled DNA, and we use a logistic regression framework to model the case/control outcome as a function of i) the presence or absence of a minor allele at any causal variant (RVT1, Li and Leal 2008, Morris and Zeggini 2009), and ii) the proportion of causal variants at which a minor allele is present (RVT2, Morris and Zeggini 2009). This approach is compared to the collapsing method (as described in Li and Leal 2008) with the estimated allele frequencies in an extended simulation study of N individually genotyped subjects versus N*K pooled subjects, where K is the pool size and N is the number of pools. We also introduce error in the allele and haplotype frequency estimates due to unequal amounts of probe material.

We find the allele frequency test to be more powerful than the haplotype-based tests even in the presence of high LD. The differences in power become smaller as N and/or the genetic signal increases. Moreover, the two collapsing haplotype-based methods perform similarly with RVT2 having a slight advantage. The methods also seem robust to pooling error. In conclusion, next generation sequencing of DNA pools provides a cost-effective approach for studying association of disease with rare SNPs, offering an advantage in terms of ability of detecting rare variants and power for association testing over individual DNA sequencing.

Additive polygenic effects on longevity and their functional meaning. *S.V. Ukraintseva[1,2], D. Wu[1], K.G. Arbeev[1], A.I. Yashin[1,2].* 1) Center for Population Health and Aging, Duke University, Durham, NC; 2) Duke Cancer Institute, Duke University, Durham, NC.

Recently we have shown that a substantial portion of genetic influence on lifespan can be explained by joint genetic effects involving large numbers of common SNP alleles, each with small and/or low significant effect (Yashin et al. 2010). Using various statistical approaches to selecting individual pro-longevity alleles from data on genome-wide genotyping of 550K SNPs in Framingham Study participants we identified a core set of 27 SNP alleles that manifest both substantial and significant additive influence on life span, regardless of statistical method used for their selection. This suggests potentially important functional roles of respective SNPs for achieving longevity. We found that majority of these SNPs (74%) are located within genes, compared to only 40% SNPs in the original 550K set, and most of them are intronic, which may also indicate functional significance of the selected SNPs such as in regulating protein concentrations, rather than in changes in protein structure. We performed trough search of literature (200+ relevant research papers) and online information data bases, to investigate functional properties of genes closest to 27 longevity SNPs. We found that these genes are largely involved in cell proliferation, apoptosis, cell adhesion, and brain information processing, as well as in cancer and brain disorders. Cell proliferation, apoptosis, and cell adhesion are also major outcomes of both aging and cancer pathways. The results indicate that the aggregate effect of aging and cancer related cell responses in body is essential for determining lifespan. We have also shown that “longevity” or “aging” genes identified in other studies often represent the same cell responses/pathways as genes in our study. E.g., a SNP linked to longevity in Newman et al. (2010) is near MINPP1 gene, which is involved in regulating cell proliferation, same as five genes from our study; one of longevity SNPs from our study is in CDH4 cell adhesion gene, and SNP in the same gene was linked to brain aging in Seshadri et al. (2007). This indicates that it may be reasonable to address replication of gene-longevity associations on the level of pathways and their outcomes rather than on the level of individual SNPs.

Association of a TOMM40 Variable-length Polymorphism with Risk and Age at Onset of Alzheimer Disease is not Independent of APOE. *B.N. Vardarajan[1], G. Jun[1,2,3], J. Buros[1], L. Cantwell[10], K.L. Lunetta[2], T. Foroud[6], R. Mayuex[7], J. Haines[8], M.A. Pericak-Vance[9], G. Schellenberg[10], L.A Farrer[1,2,3,4,5], Alzheimer Disease Genetics Consortium.* 1) Department of Medicine, Boston University, Boston, MA; 2) Department of Biostatistics, Boston University, Boston, MA; 3) Department of Ophthalmology, Boston University, Boston, MA; 4) Department of Epidemiology, Boston University, Boston, MA; 5) Department of Neurology, Boston University, Boston, MA; 6) Department of Medical and Molecular Genetics, Indiana University, Indianapolis, IN; 7) Taub Institute on Alzheimer's Disease and the Aging Brain, Department of Neurology, Columbia University, New York, NY; 8) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 9) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 10) Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, PA.

The APOE , 4 allele is the strongest and most consistently replicated genetic risk factor for Late-Onset Alzheimer Disease (LOAD). Recently, a repeat-length polymorphism (poly-T), rs10524523, in the translocase of outer mitochondrial membrane 40 homolog (TOMM40) gene located in the APOE region was associated with age-at-onset (AAO) of LOAD, and this association was independent of the effect of APOE. We examined the association of the poly-T variant with risk and AAO of in 3 Caucasian cohorts containing 1,258 AD cases and 1,715 age-matched cognitively normal controls. One dataset is almost exclusively comprised of younger autopsy-confirmed cases and age-matched controls (mean age=74.3±8). The other two datasets contain relatively older clinically-confirmed AD patients (mean age=81.7±5.9). The poly-T repeat lengths were grouped into three classes based on the number of T residues: Small (S) =14-16, Long (L) = 19-30 and Very Long (VL) =30-36. Models including covariates for age, sex and population substructure were evaluated in each cohort and the results were combined using an inverse-variance meta-analysis approach. The dosages of the S, L and VL variants were very significantly associated with AD (p= 5.9e-08, 3.87e-33 and 1.86e-08 respectively). However, when adjusted for the number of APOE , 4 alleles, only the L variant revealed marginal association with AD (p=0.87 for S, p=0.02 for L and p=0.35 for VL). Similarly, none of the poly-T variants was associated with AAO after adjusting for , 4 status (p=0.87 for S, p=0.21 for L and p=0.63 for VL). Within the subgroup of APOE , 3/3 subjects, there was no evidence of association with AD or AAO with any of the TOMM40 variants. Among subjects with at least one , 4 allele, AD was associated with the S (p=0.002) and L (p=2.47e-06) variants. We tested the association of the APOE , 4 allele in subjects stratified by presence and absence of the L form of TOMM40 to determine whether the effect of TOMM40 is independent of APOE. , 4 was strongly associated (p= 3.7e-06) with AD in subjects with the TOMM40 L variant. The correlation of the dosages of , 4 and the L allele is more than 90%in the three datasets. Our results indicate that the association of the TOMM40 poly-T polymorphism with AD risk and AAO is indistinguishable from the effect of APOE probably because of strong linkage disequilibrium between these loci. Functional studies are needed to demonstrate a role of TOMM40 in AD pathogenesis.

646T

Review and re-analysis of all schizophrenia multiplex families in the NIMH repository substantially alters overall linkage findings. *K.A. Walters[1], K. Tobin[2], M. Azaro[2], T. Lehner[3], L.M. Brzustowicz[2], V.J. Vieland[1].* 1) Battelle Center for Mathematical Medicine, Research Institute Nationwide Children's Hospital, Columbus, OH; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Genomics Research Branch, NIH/NIMH, Bethesda, MD.

We have undertaken an exhaustive review of all available genome-wide schizophrenia data in the NIMH Human Genetics Initiative (HGI) (1,417 multiplex families from 6 studies) and analyzed the newly cleaned data using the PPL statistical framework, which is uniquely designed to accumulate genetic information across multiple sets of potentially heterogeneous data. Our results differ from previously published results for these data sets as well as from meta-analysis across the studies. Differences include substantial reductions in previously reported linkage peaks; large newly observed peaks; and substantial shifts in localization for previously detected loci. Here we examine the causes of differences in results: whether cleaning genotypes (GT-clean), cleaning phenotypes (PT-clean), and/or changing statistical methods (METHOD) had the greatest effects on results. Data cleaning included: review and correction of family structures based on genotypes; application of various filters including markers < 10%; missingness and individuals < 20%; missingness; and construction of by-study marker maps and allele frequency estimation. Phenotypes were carefully reviewed and in a large number of cases revised. We required at least one person affected with schizophrenia (SZ), one additional person affected with SZ or schizoaffective disorder (SA), classified families clinically based on presence/absence of SA, and used sequential updating to accumulate evidence across studies and clinical groups. In all we filtered out 27%; of families (N= 1,029 families in “clean” analyses). Here we compare 4 versions of the data: RAW (original data, N=1,417 families), GT-clean (PT-raw), PT-clean (GT-raw), CLEAN (N=1,029 families with PT- and GT-clean); and we compare the PPL with previously reported methods (primarily NPL) and meta-analysis (GSMA). The results illustrate specific ways in which any one of the cleaning steps or METHOD can substantially affect results, and show that in aggregate the overall picture of the SZ genome that emerges is substantially different from what would be gleaned from a review of the previous literature on these studies. This work underscores that revisiting retrospective data with the benefit of hindsight for purposes of cleaning data and applying new statistical techniques can extract important new genetic information from existing data resources.

Study design and power considerations for exome sequencing of near-Mendelian traits. *M.E. Weale, M.A. Simpson, R.C. Trembath.* Department of Medical & Molecular Genetics, King's College London, London, United Kingdom.

Exome sequence scans have successfully identified the causal variants of many simple dominant Mendelian disorders. However, a causal variant will not be unique to all cases if its variant-specific `homogeneity' (defined as one minus genocopy/phenocopy rate) is <1, and will not be excluded from screened controls if its penetrance is <1. Even for `near-Mendelian' traits (where homogeneity and penetrance are close but not equal to one), simple filtering and sharing approaches to variant discovery are likely to fail. This problem is exacerbated when considering unscreened controls, recessive inheritance, and protocol-specific sequencing errors between cases and controls.

Here we investigate the use of simple exact tests for gene-level rare variant burden in cases and controls, thus avoiding a heavy dependence on variant filtering. We perform empirically-based power calculations to define the success space of exome scans for near-Mendelian traits. We compare the use of only 1000 genomes data for controls against a combined 1000 genomes + additional exome data (sequenced at King's College London using an Agilent capture + Illumina sequencing protocol) to correct for protocol-specific sequencing errors. We show that with a case exome pool of 10, power to detect a genome-wide significant signal is greater than 80% provided penetrance >0.5 and gene-level homogeneity >0.75. This provides reassurance that some near-Mendelian traits will be mapped by a modest increase in exome sequencing effort.

Manifold learning and causal inference in genome-wide integrated genetic and epigenetic analysis. *M. Xiong, Y. Zhu.* Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX.

Understanding cause-effect relationships between genotype and phenotypes is of primary interest in unraveling mechanism of diseases. Usually intervention is used to discover cause-effect relationships. Unfortunately, in human genetics experimental intervention is infeasible. The goal of this report is to infer cause-effect from high dimensional observed genetic and phenotype data. We present a novel semiparametric method to estimate causal effects of genetic variants. Specifically, a variant to be examined for causal effects is taken as a primary variable and modeled as a linear relationship between the variants and a phenotype in a semiparametric model. All remaining genetic variants in high dimensional space which include confounding factors will be projected into a low dimensional space while preserving neighborhood structure among genetic variants by manifold learning which will be modeled as a nonlinear function. These confounding variables can be viewed as nuisance variables. A novel inference procedure and new test statistic will be developed to estimate the direct causal effect of the primary variable while removing the correlation between the primary variable and confounding variables from the primary variable. To evaluate its performance, we first compare the proposed method with the sparse graphical model for causal inference by extensive simulations. The simulation results show that the genetic causal effects on phenotypes can be consistently estimated by two approaches. The proposed method is then applied to two TCGA datasets: Glioblastoma Multiform dataset with expressions of 12,042 genes and 470 miRNA and typed 561,278 SNPs in 198 tumor samples, and ovarian cancer dataset with expressions of 12,042 genes and 799 miRNA, and typed 906,600 SNPs in 512 tumor samples. Multi-level networks with gene co-expression networks, miRNA co-expression networks, miRNA target networks, quantitative trait networks as its components and their consensus network in two datasets were identified. The causal effects were estimated. The results demonstrate that the network structure is stable in bootstrap analysis and their causal effects are quite different from regression analysis. Finally, our experience in simulations and real data analysis demonstrates that the proposed manifold learning combined with inference on the primary variables in the semiparametric model is more computationally fast than sparse graphical approach.

Simultaneous association testing of genome-wide genes using sequence data. *H. Xu.* Dept Biostatistics, Georgia Health Sciences University, Augusta, GA.

Sequence data have been increasingly available for population-based association studies to investigate the genetic basis of complex diseases. Association methods have been developed to handle the vast majority of rare genetic variants in sequence data, for example, by combining information in a genomic region. However, for multi-factorial complex diseases, it is preferable to test the association for the genes across the genome simultaneously. We developed such an approach based on supervised principal component analysis. We compared its performance with the LASSO based approach through simulations. Results show that it has smaller error rate and better power than the LASSO based approach. It is also robust with respect to missing data and sequencing errors. Our method has great potential in genome-wide association studies using (re)-sequencing data.

Do endothelial NOS haplotypes influence neonatal respiratory distress in premature infants? *K. Yanamandra[1], S.A. Ursin[1], H. Chen[1], J.A. Bocchini Jr.[1], R. Dhanireddy[2].* 1) Pediatrics, LSU Health Sciences Center, Shreveport, LA; 2) Pediatrics, UT Health Science Center, Memphis, TN.

Apnea and ineffective respiration are common clinical findings in preterm infants and infants who have experienced a peripartum hypoxic insult. Failure to clear fluid from the lungs delays normal cardiopulmonary transition and may result in Transient Tachypnea of the Newborn (TTN). Another risk for neonatal respiratory distress is the Persistent Pulmonary Hypertension of the Newborn (PPHN), a common pathophysiologic pathway in many diseases that compromise the pulmonary and cardiac systems of newly born infants. Asphyxia occurs when there is impairement of function within the lungs. In the fetus, asphyxia results from decreased placental blood flow or maternal hypoxia. Asphyxia occurs either when there is alveolar hypoventilation or impaired pulmonary blood flow. The initial response to hypoxemia includes a vigorous effort to breathe with preservation of heart rate and blood pressure. It is important to recognize that the sequence of these events begin in utero and continue after delivery. Several genetic factors including gene polymorphisms have been implicated in neonatal respiratory distress. Our laboratory has been studying endothelial nitric oxide synthase (eNOS) gene polymorphisms in premature neonates in the etiology of sepsis, retinopathy of prematurity (ROP), and necrotizing enterocolitis (NEC) for the past several years. In the present investigation we studied 169 premature infants with respiratory distress and 114 without the condition for the association of haplotypes in the eNOS gene (T-786C in the promoter region, 27-bp VNTR b/a in intron 4, and G894T in exon 7) with respiratory disease using microplate PCR-RFLP genotyping methods and Allele specific PCR methods. Mutant haplotype C-a-T frequency was represented significantly higher in infants with respiratory distress as compared to controls in Caucasian infants (odds ratio 2.2, CI 1.6-3.1, pValue <0.00001). The findings were similar in African American infants. Earlier data have shown that the mutant eNOS genotypes result in decreased levels of nitric oxide. Based on our data we conclude that the endothelial NOS haplotypes, dictating endogenous nitric oxide production, have a significant role in the development of the neonatal respiratory system. Stratified data and statistics with various genotypes, ethnicities, and disease condition will be presented.

A Genome-wide association (GWA) study of Cloninger's Temperament and Character Inventory (TCI): Do genetic variants influence personality? *S. Yang[1], M. Lee[1], D.H. Lee[1], J.H. Kim[2], H.L. Kim[5], H.N. Kim[5], Y.M. Song[3], K. Lee[4], J. Sung[1].* 1) Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health Seoul National University,Korea; 2) Department of Psychiatry, Samsung Medical Center, Sungkyunkwan University, School of Medicine , Seoul, Korea; 3) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, SungKyunKwan University School of Medicine, Seoul, Korea; 4) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea; 5) Department of Biochemistry, School of Medicine, Ewha Womans University, Seoul, Korea.

Whether or not, and what extent of, human personality is influenced by genes, have been a question. Previous research has demonstrated that genes accounted for 30%~60% of variation in personality measurements. A report from a consortium identified genes related to domains of human character measured by Big 5 (RASA1, KATNAL2). A previous GWA study on TCI has identified potential associated SNPs, but none established genome-wide significance with four temperament domains. Specific aims of this study are to estimate overall genetic contribution to human character measured by TCI's seven dimensions: Novelty seeking (NS), Harm Avoidance (HA), Reward Dependence (RD), Persistence (PE), Self-Directedness (SD), Cooperativeness (CO), Self-Transcendence (ST), and to identify genetic variants explaining TCI. A total of 3079 individuals (1217 men) including 661 families, in the Healthy Twin Study in Korea: a twin-family cohort, were involved in this study. Heritability of each dimensions of TCI was estimated using the variance component method. The Affymetrix (1 million SNPs) platform was used for generating genetic marker information. The GWA study was conducted by combining transmission test (FBAT) and population mean effects of founders (PLINK). Heritability of the each seven dimension of TCI ranged 0.25~0.40 (ACE Model). Several genes were replicated with previous GWA study on TCI; BTBD3 on 20p12.2 (“PE”, p=4.80E-4), NCALD on 8q22.2 (“HA”, p=2.20E-3), DENND1A on 9q33.3 (“PE”, p=6.3E-3), SUCLG2 on 3p14.1 (“PE”, 7.2E-3). A GWA result measured by Big5 was also compared. A correlation between Openness to Experience in Big5 measured in subsample (n=349) and “PE” in TCI was significant (r^2=0.2 p= 0.0001). RASA1 gene on 5q14.3, which is associated with Openness to Experience of Big5, was replicated with “PE” domain (p=2.8E-3, 5.0E-3 etc.) Some novel genetic variants were also identified; ATP2B4 on 1q32.1 (“RD”, p=8.9E-6), CACNB2 on 10.q12.33 (“SD”, p=1.2E-6). Also seven SNPs within MAP4K3 on 2p22.1 (rs10865149, p=1.7E-6, rs3770670, p=1.7E-6, etc.) were found to have high association to “CO”. Our findings suggest that Temperament and Character dimensions are genetically influenced. Also novel GWA findings suggest several candidate genes that can be associated to personality. This suggests that genetic component may contribute to personality trait variations, and determine one's personality.

GWAS for childhood tooth decay implicates novel genes for pit and fissure and smooth surfaces. *Z. Zeng[1], J.R. Shaffer[1], X. Wang[2], M. Lee[2], K.T. Cuenco[2], M.M. Barmada[1], D.E. Polk[3], R.J. Weyant[3], R. Crout[4], D.W. McNeil[5], D.E. Weeks[1], E. Feingold[1], M.L. Marazita[1,2].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV.

Dental caries (i.e. tooth decay) is one of the most common chronic diseases in children. Caries contributes to several associated health and social problems including chronic pain, tooth loss, difficulty hearing, eating, and sleeping, failure to thrive, poor school performance, poor social relationships, and decreased success later in life. As a multi-factorial disease, it is the result of a complex interplay of genetic and environmental factors. Despite the high heritability (30-60%) of caries, few specific risk genes have been identified. A genome-wide association study (GWAS) was conducted to explore the role of genes on dental caries in the primary dentition (i.e. “baby” teeth). Carious lesions on pit and fissure (PF) and smooth (SM) tooth surfaces were investigated separately. 596 self-reported whites were included for analysis of dental caries on SM surfaces (ages 3 to 12 years); 572 were included for PF surfaces (ages 4 to 14 years). 589,735 SNPs were genotyped on the Illumina Human610-Quadv1_B BeadChip and used to impute additional markers based on the HapMap Phase III reference panel. A total of 1.4 million SNPs were tested for association with separate counts of the number of carious SM and PF surfaces. All analyses were adjusted for age and age^2 effects. Genomic inflation factors (λ) calculated from all the 1.4 million SNPs were 1.10 for SM carious surface counts and 1.08 for PF. For SM caries, two SNPs passed the genome-wide significance threshold: rs7523195 on chromosome 1 (p = 2.16E-9) located in a “gene desert” and rs16867579 (imputed) on chromosome 8 (p = 1.11E-9) near *ZHF706*, *GRHL2*, and pseudogene *NACAP1*. These genes have no previously known role in cariogenesis. Several plausible caries genes were identified near “suggestive” association signals (i.e. p < 10E-6), including *PLUNK*, *BPIL1*, *BPIL3*, and *BASE* genes (involved in defense against pathogens in oral and nasal cavities) on chromosome 20q11, *PERP* (a regulator of tooth enamel formation) on chromosome 6q23, and *TRAF4* (involved in odontogenesis in mouse) on chromosome 17q11. For PF caries, no genome-wide significant associations or suggestive associations near plausible caries genes were observed. In conclusion, our GWAS discovered significant associations of a number of novel genes and loci with SM caries in the primary dentition. Replication studies in other samples are underway. Candidate pathway based analysis for cleft lip with or without cleft palate. *T. Zhang, I. Rucinski, T.H. Beaty, International Cleft Consortium.* Johns Hopkins University, Baltimore, MD.

Objectives: The objective of this research was to identify potential biological pathways associated with non-syndromic cleft lip with or without cleft palate (NSCL/P), and to explore the potential biological mechanisms underlying these associated pathways on risk of NSCL/P. Methods: This project was based on the dataset of a previously published genome-wide association (GWA) study on NSCL/P (Beaty et al. 2010). Case-parent trios used here originated from an international consortium (The Gene, Environment Association Studies consortium, GENEVA) formed in 2007. A total of 5,742 individuals from 1,908 CL/P case-parents trios (1,591 complete trios and 317 incomplete trios where one parent was missing) were collected and genotyped using the Illumina Human610-Quad. The main procedure of pathway-based analysis is based on the algorithm gene set enrichment assessment (GSEA) and candidate pathways were selected from gene list of 356 genes that may be related to oral clefts. We conducted a permutation-based test to assess the statistical significance of the nominal p-values of 42 candidate pathways. Results: In total, 42 candidate pathways, which included 1,707 genes and 42,919 SNPs were tested. Pathway-based analysis revealed several pathways yielding nominally significant p-values. However, after estimating the family wide error rate (FWER), none of these pathways could retain statistical significance. Nominal p-values of these pathways were concentrated at the lower tail of the distribution, with more than expected low p-values. A permutation based test for examining this type of distribution pattern was yielded an overall p-value of 0.029. Conclusion: We successfully examined a set of 42 pathways to assess their possible roles in the etiology of NSCL/P yielded intriguing evidence of association. Careful analysis of the top six most significant pathways indicated some genes in these top pathways, including PCDH18, ARHGAP8, EPHA3, and TP63 may be causally related to NSCL/P. Further development of pathway based approaches may help to incorporate and weigh tests of association to reflect prior biological knowledge and lead to the identification of novel susceptibility genes and mechanisms to NSCL/P.

A combined principal components analysis and propensity score approach for population stratification adjustment in genome-wide association. *H. Zhao[1, 2], N. Mitra[1], T. Rebbeck[1].* 1) Biostatistics & Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Westat, Rockville, MD.

In population based genetic association studies, confounding due to population stratification (PS) arises when differences in both allele and disease frequencies exist in a population of mixed racial/ethnic subpopulations. Propensity scores are often used to address confounding in observational studies. However, they have not been adapted to correct bias due to PS in genetic association studies. Currently, genomic control, structured association, principal components analysis, and multidimensional scaling approaches have been proposed to address this bias using genetic markers. We propose a genomic propensity score approach to correct for bias due to PS that considers both genetic and non-genetic factors such as patient characteristics. We further propose an extended genomic propensity score approach that allows one to estimate a genotype effect under various genetic models in candidate gene studies. Finally, we propose a new approach that combines principal components analysis and the propensity score (PCAPS) to correct for bias due to PS in genome-wide association studies (GWAS). Simulations show that our approach can adequately adjust for bias due to confounding and preserve coverage probability, type I error and power. We illustrate these approaches in a case-control GWAS of testicular germ cell tumors. We provide a novel and broadly applicable strategy for obtaining less biased estimates of genetic associations.

Genetic architecture of biochemical markers for disease. *B. Benyamin, RP. Middelberg, GW. Montgomery, PM. Visscher, NG. Martin, JB. Whitfield.* Queensland Institute of Medical Research, Brisbane, Australia.

Biochemical markers measured in blood are widely used indicators of a current disease or predictors of disease risk. Genetic factors are significant sources of individual difference in biochemical markers with heritability ranging from 25 to 75%. Genome-wide association studies (GWAS) have identified a number of single nucleotide polymorphisms (SNPs) associated with biochemical markers. However, the genetic architecture of the biochemical phenotypes remains poorly understood. The aims of this study are to: 1) assess the spectrum of allelic effect sizes; 2) assess the contribution from SNPs whose associations do not reach genome-wide (GW) significance; 3) compare the sum of SNP-associated effects against heritability; 4) contrast the results across phenotypes. We analysed 16 biochemical markers measured in serum from ~11,000 individuals from QIMR twin and family studies, in which genome-wide (~2.4 million) SNPs data were available. These include markers for cardiovascular disease, such as triglycerides, LDL- and HDL- cholesterol. For most biochemical markers, GWAS found several GW-significant SNPs that in total account for <5% of the phenotypic variance. For some phenotypes, including bilirubin, cholinesterase, transferrin and uric acid, GW-significant SNPs explain between 10 to 20% of the phenotypic variance. On the other hand, no GW-significant SNPs were identified for alanine aminotransferase, total protein or albumin. By considering all SNPs simultaneously (Yang et al Nat Genet 42:565-9, 2010), we found that common SNPs account for 20 - 80% of the heritability (except for albumin where common SNPs do not explain any of the heritability). For most phenotypes there is still some `heritability gap' - presumably due to incomplete LD between causal variants and tagging SNPs.

Schlessinger[6].* 1) Center for Statistical Genetics, Ann Arbor, University of Michigan, MI, USA; 2) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, 09042, Italy; 3) Michigan Center for Genomics & Public Health, Ann Arbor, University of Michigan, MI, USA; 4) Universita' degli Studi di Sassari, Dipartimento Scienze Biomediche, Sassari, 07100, Italy; 5) CRS4, Laboratorio di Genomica, Parco tecnologico della Sardegna, Pula; 6) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA.

Age is associated with decline in many physiological functions eventually leading to increased susceptibility to diseases. The rate of aging varies among individuals. This study aims to quantify variation associated with aging by comparing an individual's chronological age to a predicted age, based on health indicators from the SardiNIA/Progenia longitudinal cohort study, which was designed to explore both gene-finding and longitudinal analyses of age-associated conditions. The cohort contains data on approximately 6,400 individuals, including 711 family units. Longitudinal data has been collected in excess of 100 quantitative traits, of which 46 were chosen for this analysis. Employing a mixed linear regression, accounting for pedigree structure of the data, a parsimonious predictive model for age was determined. The model accounted for ~64% of the variation in age within our sample. We then considered the difference between the predicted age (based on physiological indicators) and chronological age as a quantitative trait. This difference between predicted and chronological age was significantly heritable, with an estimated heritability of 29%. We are currently performing a genome-wide analysis study (GWAS) for this trait using ~13M genotyped or imputed SNPs.

657T

Meta-analysis of 15 genome-wide association studies with ~8,000 cases and ~50,000 controls identified multiple novel loci associated with age-related macular degeneration. *W. Chen[1], L.G. Fritsche[2], Y. Yu[3], M. Schu[4], B.L. Yaspan[5], AMDGene Consortium.* 1) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Institute of Human Genetics, University of Regensburg, Regensburg, Germany; 3) Ophthalmic Epidemiology and Genetics Service, Department of Ophthalmology, Tufts Medical Center, Boston, MA; 4) Department of Medicine Biomedical Genetics, Boston University School of Medicine, Boston, MA; 5) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration (AMD) is the leading cause of irreversible vision loss in the elderly population in Western countries. Several genes and pathways have been discovered to be associated with the disease through linkage and genome-wide association studies (GWAS). However, individual GWAS does not have sufficient power to detect genetic variants with small effect size or low minor allele frequency. We conducted a meta-analysis of ~ 2.5 million imputed HapMap SNPs in 15 GWAS worldwide with a total of 7,650 cases and 51,844 controls from European and Asian ancestries. For our primary study outcome of advanced AMD, we confirmed eight previously identified loci including *ARMS2/HTRA1* ($p<10^{-308}$), *CFH* ($p<10^{-289}$), *C2/CFB* ($p<10^{-54}$), *C3* ($p<10^{-26}$), *CFI* ($p<10^{-9}$), *TIMP3* ($p<10^{-12}$), *CETP* ($p<10^{-11}$), and *LIPC* ($p<10^{-8}$). Five additional loci on chromosomes 3 ($p=6\times10^{-10}$), 6 ($p=9\times10^{-12}$), 8 ($p=7\times10^{-10}$), 19 ($p=4\times10^{-15}$) and 22 ($p=3\times10^{-8}$) reached genome-wide significance. Some of the top loci fit with ease into known pathways mediating AMD pathogenesis, whereas the biological role of others remains to be determined. For example, the top hit on chromosome 6 is near *VEGFA*, a gene that influences vascular permeability and vasculogenesis, confirms the importance of new vessel formation in advanced AMD. For secondary outcomes of specific AMD lesions, including large drusen (LD), geographic atrophy (GA) only, and choroidal neovascularization (CNV) only, we identified a number of gene loci which were close to genome-wide significance level, indicating possibly different roles they play in the etiology of AMD. Replications of these new findings are currently underway with ~15,000 cases and ~8,200 controls mainly from European ancestry. Our data strongly support a multigenic hypothesis for AMD pathogenesis and may provide new insights into the biology of the retina.

A novel analysis method based on gene-gene interactions in pathways defined by protein-protein interaction networks. *R.H. Chung[1,2], W.K. Scott[1,2], J.M. Vance[1,2], E.R. Martin[1,2].* 1) John P. Hussman Inst for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, FL.

Pathway analysis in GWAS has become increasingly popular under the premise that collectively testing a set of genes with individual modest effects might increase the power for identifying disease genes. Current pathway analysis methods mostly focus on testing for main effects in a set of genes on disease. However, for complex diseases, gene-gene interactions might play an important role in disease etiology. Identifying gene-gene interactions in GWAS is difficult because of the multiple testing burden. Because protein products of genes within a pathway often interact, testing for gene-gene interactions in gene sets created using protein-protein interaction (PPI) information offers an informed way to reduce the number of gene pairs tested and may reveal associations missed by approaches focused only on main effects of genes. We developed the Pathway analysis method Using Protein-Protein Interaction network for case-control data (PUPPI). PUPPI computes the PLINK fast-epistasis statistics for a pair of genes if (a) the two genes are in the same pathway, (b) public PPI databases indicate the protein products of the two genes interact and (c) the two genes are on different chromosomes or are more than a pre-defined distance apart on the same chromosome. The maximum test statistic from all pairs of SNPs between the two genes is used as the score for the gene pair and the score is adjusted for gene size by correcting for the effective number of SNPs tested. The PUPPI statistic for a pathway is the sum of the scores of gene pairs in the pathway producing p-values less than a pre-specified threshold. A permutation procedure is used to approximate the distribution of the PUPPI statistic. We used simulations to demonstrate that PUPPI has correct type I error rates and high power under different disease models. We applied PUPPI to data from a Parkinson disease (PD) GWAS (Edwards et al 2010), consisting of 1,752 cases with PD and 1,745 controls and 443,234 autosomal SNPs. We tested 208 KEGG pathways. Interestingly, the top pathway (hsa05012) is the PD pathway defined by KEGG (PUPPI p-value=0.0005). The significance is mainly derived from interactions between nuclear-encoded NADH dehydrogenase subunits that localize to the mitochondrial membrane. Our analyses demonstrate that pathway analysis using only gene-gene interaction information can be powerful for identifying disease pathways and reveal gene-gene interactions that may not be detected at a genome-wide level.

659T

Use of posterior probability of linkage in weighted false discovery rate analysis of cleft lip with or without cleft palate (CL/P) families. *M. Govil[1], N. Mukhopadhyay[1], T.H. McHenry[1], T.H. Beaty[2], J.C. Murray[3], M.L. Marazita[1].* 1) University of Pittsburgh, Department of Oral Biology, Pittsburgh, PA; 2) Johns Hopkins University, School of Public Health, Baltimore, Maryland, USA; 3) The University of Iowa, Department of Pediatrics, Iowa City, IA.

Non-syndromic CL/P is a common birth defect with a complex etiology. In the past several years, our group and others have done much to shed light on a variety of aspects of CL/P including heterogeneity of the phenotype and its refinement to include sub-clinical phenotypes, identification of environmental factors influencing risk, and accumulating evidence for the role of genes in CL/P etiology, including IRF6, FOXE1, MSX1, and TGFA. Concurrently, a variety of sophisticated statistical methods for both linkage and association have been developed to improve our ability to map such complex traits. The weighted false discovery rate (w-FDR) utilizes evidence for linkage as a prior probability to weight association p-values. DATA and METHODS: The posterior probability of linkage (PPL) is a class of likelihood-based, model-free statistics to measure of the strength of evidence for/against linkage. PPLs were pulled from a 10 cM, 401 marker genome scan (Govil et al, 2005) carried out on 487 multiplex CL/P families drawn from 7 countries. Association p-values were generated for 1,028 trios from 7 ethnicities, using 589,945 GWAS SNPs described earlier (Beaty et al, 2010). For each of these analyses, the families were divided into two groups: Asian (A) and European (E). The PPL was sequentially updated by population within each group. The w-FDR p-values were then generated for the entire marker panel using the PPLs as user-defined weights. RESULTS: The original sequentially updated PPLs had identified multiple regions of linkage, with peak scores for Asians on chr. 6 and Europeans on chr. 9. These results corresponded to previous multipoint HLOD results for the same data (Marazita et al, 2009). The original GWAS, with a different set of families, identified regions primarily on chr. 1, 11 (A) and 8 (E), with a peak on chr 6 (A) ~63 Mb from the linkage peak, but found no significant results on chr. 9. Using the PPL as a user-defined weight in w-FDR, additional SNPs on both chr. 6 (A) and 9 (E) approached the w-FDR corrected genome-wide significance levels (2.71e-6, A; 3.42e-6, E) with p-values<3.6e-5 for SNPs under the linkage peak. While we continue to refine this method, our results show the potential power of this approach to identify genes associated with complex traits. Detecting Genetic Association with Rare Variants in Admixed Populations. *X. Mao[1], Y. Li[2], M. Li[1].* 1) Departments of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA 19104, USA; 2) Department of Genetics, Department of Biostatistics, University of North Carolina, Chapel Hill, North Carolina 27599-7264, USA.

Recent studies suggest that rare variants play an important role in the etiology of many traits. Analysis of rare variants holds the promise of explaining some of the missing heritability left from GWAS. Although a number of methods have been developed for genetic association analysis of rare variants, all assume a relatively homogeneous population under study. Such an assumption may not be valid for samples collected from admixed populations as various studies have shown that there is a great extent of local variation in ancestry in admixed populations. While such variation may be useful for admixture mapping, it imposes a challenge for the analysis of rare variants because rare variants are more likely to be influenced by distinct local genetic background. To ensure valid and more powerful rare variant association tests performed in admixed populations, we have developed a local-ancestry-based weighted dosage test for the analysis of rare variants. Our test shares similarity with WHaIT, a recently developed method for the analysis of rare variants, in that both take into account of the direction of association by allowing for risk and protective alleles. The key difference between our method and WHaIT is that we are able to adjust the weighted dosage score by local ancestry. In our earlier publication, we have shown that regardless of the mechanism of population stratification, whether it is due to local or global ancestry difference, adjustment of local ancestry is sufficient to remove the effect of population stratification. Through extensive simulations, we confirm that our proposed test has controlled type I error rates when population stratification is induced by local ancestry difference among study subjects, whereas naïve application of existing rare variants tests leads to inflated type I error rates. When there is moderate population stratification such as 80%-20% admixture in case samples vs 75%-25% admixture in control samples, the existing rare variants tests without adjusting for ancestry has type I errors of 22% while our proposed test has a type I error under 5% (both at 5% level). Our results suggest that it is important to appropriately control for potential population stratification induced by local ancestry difference in the analysis of rare variants in admixed populations.

To date, there have been relatively few GWAS for longitudinal data phenotypes. Yet, knowledge of genes that influence longitudinal patterns may inform about disease course and offer the ability to predict disease progression. We have developed a systematic GWAS procedure for testing association between SNP genotypes and longitudinal phenotype data. We used growth mixture models (GMMs) to fit longitudinal data to a small number of estimated trajectory curves. We determined Bayesian posterior probabilities of belonging to specific trajectory curves and used these probabilities as the values for quantitative trait loci. We then tested for genome-wide association with SNPs. We evaluated the type I error and power of our method using data that was simulated as a function of multiple parameters under null and alternative scenarios. Our alternative scenarios mimicked different modes of inheritance including single disease marker at full penetrance, a single disease marker at reduced penetrance under both a dominant and multiplicative model, and multiple disease loci. We also performed association tests under alternative scenarios for different minor allele frequencies and variances. Our principal findings are: (i) our method maintains the correct empirical type I error rate for all simulations and (ii) most of our alternative simulations produce ~ 95 - 100% power. For example, we observe a type I error rates of 0.0101, 0.0496, 0.0931, and 0.1398 for (= 0.01, 0.05, 0.1, and 0.15, respectively. We also observed 100% power for the single marker full penetrance and the multi-locus model at all (. In addition, 94-98% power was obtained for the dominant reduced model and 97-99% power for the multiplicative reduced model. Thus, we conclude that our method is effective for identifying allelic association with disease for multiple genetic modes of inheritance using longitudinal data. We believe that this method is clinically significant as it may allow doctors to predict disease progression based on genotype and alter treatment accordingly.

Genome-wide linkage and association analyses reveal quantitative trait loci that influence thyroid-related hormones. *J. Singh[1], L. Yerges-Armstrong[2], J.R. Shaffer[1], J. Curran[3], M. Carless[3], S. Cole[3], J. Kent[3], T. Dyer[3], L. Almasy[3], M. Mahaney[3], J. Blangero[3], C.M. Kammerer[1], P.B. Samollow[4].* 1) University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 2) University of Maryland School of Medicine, Baltimore, MD; 3) Texas Biomedical Research Institute, San Antonio, TX; 4) Texas A&M University, College Station, TX.

Thyroid hormones play major roles in the regulation of protein synthesis, basal metabolism, lipid metabolism, and higher order characteristics such as neural and skeletal development, cardiac output, thermogenesis, and other traits that are critical to health; but the genetic basis of normal thyroid hormone regulation is not well known. In this study, we performed genome-wide linkage (GWL) and association (GWA) analyses to detect quantitative trait loci (QTLs) influencing six thyroid hormone related traits: free and total thyroxine (FT4 & TT4), total triiodothyronine (TT3), thryoxine-binding globulin (TBG), thyrotropin (TSH), and thyroglobulin (TG). Phenotypic and genotypic data were available on 1002 euthryroid individuals (420 males and 582 females) from 35 Mexican-American families collected as part of the San Antonio Family Heart Study. Prior to performing GWL and GWA analyses, effects of significant environmental components (e.g., sex, age, diabetes status, alcohol consumption, physical activity and smoking habits) were identified and removed. GWL revealed a QTL influencing TG on chr 2 at location 160cM pter (LOD=5.28, p=0.0007). Analyses (correcting for familial correlations) of 46032 SNPs under the linkage peak for TG, revealed multiple SNPs with suggestive associations ($P < 10^{-5}$) within a 600kb region. This genomic region includes the genes *TFCP2L1, RNU4ATAC, CLASP1, MKI67IP*, and *TSN*. We next performed WGA and detected associations for (1) TBG and SNPs within the intronic region of *ANKS1B* gene on 12q23 ($P<10^{-7}$) and (2) TSH and SNPs in the 5'-UTR of the *DDX18* gene on 2q14 ($P<10^{-7}$). None of these genes are known to be associated with thryroid function. These findings illustrate that linkage and association, two complementary approaches for detecting QTLs, can enhance our understanding of genetic control of thyroid hormone variation by revealing genomic locations that harbor previously unrecognized genetic features that influence thyroid-related hormone metabolism and function, thereby facilitating their identification.

663T

Population Stratification in Burden Tests for Rare Variant Associations. *M. Zawistowski[1,2], D. Wegmann[3], M.G. Ehm[4], M.R. Nelson[4], J. Novembre[3], S. Zöllner[1,2,5].* 1) Department of Biostatistics, The University of Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, The University of Michigan, Ann Arbor, MI; 3) Department of Ecology and Evolutionary Biology / Interdepartmental Program in Bioinformatics, University of California, Los Angeles, CA, USA; 4) GlaxoSmithKline, Department of Genetics, RTP, NC; 5) Department of Psychiatry, The University of Michigan, Ann Arbor, MI.

Next generation sequencing datasets will dramatically improve our ability to identify rare variants contributing to disease risk. Such datasets are typically assumed to be drawn from a homogeneous population but, in practice, are often unintentionally heterogeneous with respect to population of origin. Correlation between population of origin and both phenotypes and genotypes can result in population stratification, a known cause of spurious genetic associations. Genomic control and principal components work well to correct for population stratification in single marker tests. However, tests for excess accumulation of rare variants within a genomic region in cases or controls, so-called burden tests, are more powerful than single marker tests of rare variants. In this analysis, we use real sequence data and population genetic models to determine the effects of population stratification on burden tests and identify factors likely to cause stratification. We used real sequence data from the exons of 202 drug target genes in >14,000 subjects to simulate case-control datasets containing no direct genotype-phenotype association. However, we induce an indirect association via population stratification by differentially sampling cases and controls with respect to population of origin. The diverse European and non-European populations included in this study make it ideal for considering realistic levels of rare variation across a wide range of stratification scenarios. We show that analyses of these datasets using a variety of existing burden tests have severely inflated false positive rates even when closely related populations are considered. Moreover, existing correction methods, such as those used in the genotype-phenotype analyses of the drug target genes, often fail to control for the stratification. We also perform a simulation analysis using population genetic models to determine the cumulative effects of forces such as growth, migration and selection that can each affect population-specific levels of rare variation and drive stratification in burden tests. Our results are used to predict genes and study designs likely to suffer from stratification, highlighting conditions under which existing correction methods fail. We suggest novel methods to control for rare variant stratification and, ultimately, interpret the genotype-phenotype analyses of the 202 drug target genes in this and future rare variant studies.

A genome scan for vesicoureteric reflux reveals a new recessive locus on chromosome 10 with an HLOD score of >6. *J.M. Darlow[1, 2], M.G. Dobson[1, 2], M. Hunziker[2, 3], C.M. Molony[4], P. Puri[2, 3], D.E. Barton[1].* 1) Natl Ctre Med Gen, Our Lady's Children's Hosp, Dublin, Ireland; 2) National Children's Research Centre, Our Lady's Children's Hosp, Dublin, Ireland; 3) National Children's Hospital, Tallaght, Dublin 24, Ireland; 4) Merck & Co., Inc., 1 Merck Drive, Whitehouse Station, New Jersey, USA 08889.

Vesicoureteric reflux (VUR), the retrograde flow of urine from the bladder towards the kidneys, results from a developmental anomaly of the vesicoureteric valve mechanism, and is often associated with other urinary tract anomalies. It is the most common urological problem in children, with an estimated incidence at birth of 1-2%. Though it may be symptomless and often resolves with age, about 8% of affected individuals develop renal failure, in childhood or adult life, accounting for ~25% of all renal failure. Several genome scans have been performed, with conflicting results, including one by us with 4,700 SNP markers on 129 VUR families. We have now performed a new scan on 246 families (530 cases (514 children 15 parents and 1 grandparent) and 435 other family members, 119 with a history or family history of urinary tract problems) with 900,000 markers on the Affymetrix SNP Array 6.0. Numerous analyses have been carried out - singlepoint and multipoint, parametric and non-parametric, counting and not counting probable carriers as affected, and at the time of abstract deadline we are not yet ready to give exact details, but we are confident that our previous non-parametric linkage peaks on 2q, 6q and 10q are confirmed (though with slightly altered position) and are all dominant, the highest being on 10q with an HLOD of ~5, and our previous peak on 7q is confirmed with HLOD >3 on a common recessive model but also some linkage on a very rare dominant model. However, the most exciting finding is a very narrow recessive peak in a different position on 10q with an HLOD >6 that was previously missed because the markers were too far apart. There is also a dominant peak on 22q in one analysis. Numerous other smaller peaks remain to be examined. Our new results did not replicate the peaks on chromosomes 5, 13, and 18 found by Briggs et al.(2009)(even though we had previously found some linkage on 13q) nor the recessive peak of Weng et al. (2009) on 12p11-q13, nor linkage to ROBO2 or anywhere in the region identified on Chromosome 3 by Conte et al. (2007). The novel linkage peak of HLOD >6 on chromosome 10 is of particular interest and will focus attention on novel positional candidate genes for VUR. Analysis of the data for association and copy-number variation is ongoing.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Efficient and Accurate Genome-wide Genotyping of 100,000 Subjects using the Affymetrix Axiom Genotyping System. *S. Hesselson[1], M. Kvale[1], Y. Cao[1], J. Eshragh[1], R. Lao[1], G. Mathauda[1], T. Shenoy[1], E. Wan[1], S. Wong[1], M. Patil[2], D. Chan[2], M. Mittmann[2], M. Purdy[2], J. Gollub[2], T. Webster[2], S. Miles[3], S. Rowell[3], L. Walter[3], W. McGuire[3], S. Connell[3], C. Zau[3], D. Ranatunga[3], L. Shen[3], D. Smethurst[3], A. Finn[2], C. Schaefer[3], N. Risch[1], P.-Y. Kwok[1].* 1) Institute for Human Genetics, UCSF, San Francisco, CA; 2) Affymetrix Inc., Santa Clara, CA; 3) Kaiser Permanente Northern California Division of Research, Oakland, CA.

As part of the Kaiser Permanente/UCSF Genetic Epidemiology Research Resource on Adult Health and Aging, we needed to genotype 100,000 saliva-based DNA samples successfully (i.e. passing strict QC and call-rate thresholds) in a 14 month period using the Affymetrix Axiom genotyping system. This required a processing rate of nearly 24 plates (2,304 samples) per week. This high, consistent throughput was achieved with 6 laboratory staff, 4 Affymetrix Gene Titans, and 3 Beckman FX robots. Critical to the continuous throughput was rapid return of genotyping results in order to detect and diagnose problems as they arose. Array plates were hybridized continuously. Three Gene Titans were used full time; the availability of a fourth was critical to the throughput due to periodic machine breakdown that would otherwise compromise the ability to wash hybridized plates in a timely manner. Two plates were washed on each of 3 Gene Titans per day. The data were then transferred to a computer cluster and genotyped automatically. Plate-by-plate reports were evaluated in real time, to allow for a rapid respond to any apparent problems. In the short term, problems were detected by identifying plates with higher than average failure rates. One of the most informative indicators of a problem on a plate is the distribution of dQC and call rate values. Problems were also detected by examining individual images on every plate. The most common causes of increased failure rates (in order of temporal occurrence) were pellets that wouldn't resuspend at the end of DNA preparation, array lot performance variation, leaking of fluidics reservoirs, and scanner malfunctions. We deviated from Affymetrix's standard protocol at times, the most notable being an increase in the hybridization time from 24 hours to 48 hours per plate. This modification was implemented due to global decrease of the number of passing samples on all Gene Titans over many plates. Increased hybridization time raised the mean dQC from .896 to .910, and led to a nearly 50% decrease in the number of failing samples (dQC<.82) per plate. To allow for the inclusion of more minority subjects, we also tested assay robustness to decrease in DNA concentration. We found that reducing concentrations from 30 to 15 ng/μl had little impact on genotyping success rates. We achieved an overall success rate of 94% on this saliva-based cohort.

Efficient capture of allele frequency spectra in sequencing studies by selection of independent chromosomes. *T. Edwards[1], C. Li[2].* 1) Center for Human Genetics Research, Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, TN; 2) Center for Human Genetics Research, Department of Biostatistics, Vanderbilt University, Nashville, TN.

Sequencing studies using whole-genome or exome scans are still more expensive than GWAS on a per-subject basis for accurately calling genotypes. As a result, a subset of subjects from a larger study is often selected for sequencing studies. The choice of study subjects should capture as many ancestral lineages as possible to avoid redundant information from regions that were inherited identical by descent (IBD) from a common ancestor, estimable through genotype data or pedigree structure. We present SampleSeq2, which can select a subset of optimally unrelated subjects with minimal IBD sharing and estimate the number of independently inherited chromosomes in a sample, GT, or alternately select the minimum number of subjects for a target GT. We evaluated SampleSeq2 compared to a random draw by simulation and using the Amish Study of Successful Aging. We simulated a random mating island population growing 10.5% per generation from 500 founders for 30 generations to N=10,000. The simulated genome was 3,000cM, with 30 recombinations expected per meiosis. Comparing the known value of GT to the value estimated for GT, the estimate was close to the true value of GT, and SampleSeq2 provided an increase in GT relative to a random draw across a range of sample sizes. In the Amish study, there were 4,995 subjects in the pedigree, with 827 in the Aging study. The average IBD among the 827 subjects was 2.4%. Among the 341551 subject pairs, 83.1% pairs had >1% genome expected to be shared IBD, 5.3% pairs had >5% genome shared IBD, 1.1% pairs had >10% genome shared IBD, and 810 pairs of subjects shared⁄ 50% of the genome. We compared our approach with the alternative of random selection for K subjects (K=50, 100). For K=50, the average GT was 41.5 using SampleSeq2 and 29.7 for random selection. On average, our algorithm resulted in 11.8 additional independent genomes, a 39% increase. While random selection resulted in subsets with 2.4% average IBD sharing, our method resulted in 0.8% average pairwise IBD, a 67% reduction. For K=100, the average GT was 60.6 using SampleSeq2 and 39.9 for random selection. On average, our algorithm resulted in 20.7 extra independent genomes, a 52% increase. The average pairwise IBD sharing was 2.40% for random selection and 1.11% for our method, a 54% reduction. This increase in chromosomes will improve power of association tests, mitigate effects of relatedness on parameter estimates, and increase the yield of alleles from sequencing.

667T

Whole-genome sequencing of six canine disease models. *F.H.G. Farias[1], G.S. Johnson[1], T. Mhlanga-Mutangadura[1], R. Zeng[1], J.F. Taylor[2], D.P. O'Brien[3], R.D. Schnabel[2].* 1) Veterinary Pathobiology, University of Missouri, Columbia, MO., USA; 2) Division of Animal Sciences, University of Missouri, Columbia, USA; 3) Department of Veterinary Medicine and Surgery, University of Missouri, Columbia, USA.

Whole-genome sequencing is a comprehensive approach to the detection of genetic variants. Improvement of next generation sequencing technology coupled with drastic reductions in cost has opened an opportunity for a fast and effective way of identifying causal mutations for Mendelian diseases. We have begun the search for these disease-causing mutations by sequencing the whole genomes of six dogs from different breeds that are individually affected with different inherited diseases including: Polymicrogyria, Multisystem degeneration, Cerebellar ataxias (two distinct types), Fanconi syndrome and Paroxismal dyskinesia. Four of the six disease loci have previously been mapped by genome-wide association studies either using microsatellites or SNP assays. Each of the six dogs has been sequenced to 12-23X genomic coverage on either an Illumina GAIIx or Hi-Seq 2000. We have used NextGENe® software to align the sequences to build 2.1 of the NCBI canine reference genome sequence and identify sequence variants (SV). Aggregated across dogs, approximately 6-8 million unique SV were produced from these data. Since each disease is believed to be the result of a founder event or de novo mutation within a breed, we expect the causal variant to be present in the case animal while the remaining animals serve as controls and must lack the causal variant. As such, we have developed algorithms to identify the SV present in the case dog that fit the disease mode of inheritance and which are not present in the remaining five control dogs. For the disease loci which have previously been mapped to a genomic region we have reduced the candidate SV from millions genome-wide to approximately 2000 total in the mapped region. Further filtering SV to include only those present in coding regions reduces the causal candidate set to less than 20 variants. For the two diseases that have not previously been mapped we are able to reduce the candidate causal mutations to approximately 1500 variants within the coding regions genome-wide. We are currently evaluating mutations for each disease by testing for associations between genotype and disease phenotype in pertinent canine populations.

668T

Detecting sample contamination using array-based genotype data. *M. Flickinger[1], G. Jun[1], K.F. Doheny[2], J. Romm[2], K.N. Hetrick[2], G.R. Abecasis[1], M. Boehnke[1], H.M. Kang[1].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109-2029; 2) Center for Inherited Disease Research (CIDR), Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

While advances in array-based genotyping and next generation sequencing have resulted in lower costs per genotype and reduced error rates, DNA sample contamination remains a threat to data quality. Here we describe methods to detect whether a sample contains DNA from two or more individuals. Early detection of sample contamination is both a useful quality control step for genotype data, and an effective way to pre-screen samples prior to re-sequencing so resources are not wasted on lower-quality samples. High levels of contamination are often easily discovered by low SNP call rates or unexpectedly high heterozygosity rates in GWAS, but low-levels of contamination (say <10%) may have been previously undetected. Our goal is to detect low-levels of contamination using data available from existing array-based genotyping methods. We propose two methods to detect contamination. The first uses a regression-based analysis to detect systematic shifts in the Illumina reported B-allele frequencies (BAF) associated with changes in the minor allele frequency (MAF) in the population across all assayed SNPs. In contaminated samples, as the population MAF increases, it becomes increasingly likely that the contaminated samples will have different alleles at a particular SNP, shifting the BAF of homozygous SNPs from the expected value of 0 or 1 towards the expected heterozygote value of 0.5. Our second method models the Illumina reported normalized intensity data using a Gaussian mixture model and compares the likelihoods across different mixture proportions to estimate the true contamination fraction. To validate these methods, we analyzed mixtures of DNA samples from HapMap individuals created to have specific, known levels of contamination ranging from 0.5%-10%. We genotyped these samples using the Metabochip genotype array (a custom Illumina iSelect SNP array with ~200,000 markers in regions previously shown to be associated with metabolic traits). Our results show that the regression-based method is more sensitive to lower levels of contamination while the mixture model is better at quantifying contamination fraction at higher levels of contamination. We find that these methods are valuable for pre-screening samples prior to re-sequencing and as a quality control check for genotype data.

669T

Design of DNA pooling to allow incorporation of covariates in rare variants analysis. *W. Guan[1], C. Li[2].* 1) Division of Biostatistics, Univ of Minnesota, Minneapolis, MN; 2) Department of Biostatistics, Vanderbilit University.

Rapid advances in next-generation sequencing technologies facilitate genetic association studies of an increasingly wide array of rare variants. To capture the rare or less common variants, a large number of individuals will be needed. However, the cost of a large scale study using whole genome or exome sequencing is still high. DNA pooling can serve as a cost-effective approach, but with a potential limitation that the identity of individual genomes would be lost and therefore individual characteristics and environmental factors could not be adjusted in association tests, which may result in power loss and a biased estimate of genetic effect, especially at presence of gene-environment interactions. For case-control studies, we propose a design strategy for pool creation and an analysis strategy that allows covariate adjustment. In our approach, we first calculate a propensity score for each individual, which is the estimated odds of disease given a set of potential confounders [Rosenbaum and Rubin, 1983]. We then group cases and controls based on their propensity scores, and divide them into case/control pools with desired size. After sequencing is done for pooled DNA, we impute genotypes and values of covariates for each individual, and perform association tests between phenotype and genotype while adjusting for the covariates, using multiple imputation technique. Simulations show that our approach can obtain consistent estimate for genotypic effect with only slight loss of power compared to the more expensive approach of sequencing individual genomes. For example, given a causal variant with minor allele frequency 0.01 and odds ratio (OR) of 3.0 and an environmental factor with OR of 1.5, at a significance level of 5%, a study of 600 cases and 600 controls has 76% power to detect the causal variant using individual sequencing, and 73% power using our approach at a fraction of the cost (with pool size 12 and an average depth of 200). Our design and analysis strategies enable more powerful and cost-effective sequencing studies of complex diseases, while allowing incorporation of covariate adjustment.

670T

Genotype calling from next-generation sequencing data in pedigrees. *S.C. Heath, E. Raineri.* CNAG, Barcelona, Spain.

We present a Hidden Markov Model (HMM) based approach for simultaneously calling genetic variants from genome wide sequence data in related individuals. The method combines information across individuals and between nearby genomic regions to increase the precision of genotype calling compared with individual genotype calling algorithms. Alternatively, it allows the accuracy of genotype prediction to be maintained while reducing the amount of sequence data required. The cost of genome wide sequencing in families can therefore be reduced, expanding the range of projects for which sequencing is feasible. Our approach follows that of linkage analysis programs using HMMs to model inheritance patterns along the chromosome. At a given locus let $\boldsymbol{S}$ be the inheritance pattern at a locus, $\boldsymbol{Y}$ the sequence data and $\boldsymbol{G}$ the (true) genotypes. The HMM has one node per observed locus along the chromosome, with the possible states at each node corresponding to the possible states of $\boldsymbol{S}$. The transmission probabilities for the HMM are the same as for regular linkage calculations, but the emission probabilities are calculated conditional on the sequence rather than on the genotype data. The emission probabilities can be written as $p(\boldsymbol{Y}|\boldsymbol{S})$. To calculate this we note that conditional on the true genotypes, $p(\boldsymbol{G}|\boldsymbol{S})$ is simple to calculate (and forms the basis of the use of HMMs for linkage). Also, $p(\boldsymbol{Y}|\boldsymbol{G})$ is the probability of the observed sequence data given the genotypes, and any parametric model used for calling genotypes from sequence data can be used here. $p(\boldsymbol{Y}|\boldsymbol{S})$ can therefore be calculated by the summation $\Sigma_G p(\boldsymbol{Y}|\boldsymbol{G})p(\boldsymbol{G}|\boldsymbol{S})p(\boldsymbol{G})$ over all possible values of $\boldsymbol{G}$ (where $p(\boldsymbol{G})$ is the prior of $\boldsymbol{G}$). The structure of the pedigree can be utilized to perform this summation in an efficient manner, even for general pedigrees with possible complex structures. Direct inference is made of the joint distribution of the inheritance relationships between pedigree members along the chromosome, and genotypes for pedigree members at each location can be estimated conditional on the most likely inheritance pattern and the sequence data. The method has been implemented and tested on a human nuclear family with 3 siblings, where exome sequencing had been carried out on all family members. The estimation procedure was performed both with and without the sequence data on the parents showing the the effect of the missing data on the precision of the estimates of genotypes and inheritance patterns.

671T

Single nucleotide polymorphisms in the promoter of tumor necrosis factor—(gene in korean retired workers exposed to inorganic dusts. *J. Hwang, K. Lee, J. Shin, J. Lee, B. Choi.* Research Dept, Occupational Lung Diseases Institute, Ansan-si, Gyeonggi-do, Korea.

Pneumoconiosis is a restrictive lung disease caused by the inhalation of inorganic dusts, often in mines that leads to inflammation and fibrosis. Tumor necrosis factor-((TNF-( ) plays an important pro-inflammatory cytokine in pneumoconiosis. Single nucleotide polymorphisms (SNPs) in the promoter region of TNF-(gene have been associated with regulating its production and effect. The aim of this study was to investigate the SNPs at position -308 and -238 in the promoter of TNF-(gene in 163 korean retired workers exposed to inorganic dusts. 96 of participants (58.9%) were pneumoconiosis and 67 (41.1%) non-pneumoconiosis patients by the pneumoconiosis review committee of Korea Worker's Compensation & Welfare Service. These alleles were in linkage disequilibrium ($p<0.001$), and so were not independent. But, there were no significant differences between pneumoconiosis and non-pneumoconiosis group at position -308 (16.7% vs 13.4%, Fisher's exact p value=0.662)and -238 (9.3% vs 13.4%, Fisher's exact p value= 0.453) in the promoter of TNF-(gene. The association between SNPs at position -308 and -238 in the promoter of TNF-(gene and pneumoconiosis need to be clarified by the involvement of a large number of subject as well as follow-up study.

Finding genes in Mendelian disorders using sequence data: methods and applications. *I. Ionita-Laza[1], V. Makarov[2], J.D. Buxbaum[2], D.L. Nicolae[3], X. Lin[4].* 1) Columbia University, New York, NY; 2) Mount Sinai School of Medicine, New York, NY; 3) University of Chicago, Chicago, IL; 4) Harvard University, Boston, MA.

Many sequencing studies are now underway to identify the genetic causes for both Mendelian and complex traits. Using exome-sequencing, genes for several Mendelian traits including Miller Syndrome, Freeman-Sheldon Syndrome and Kabuki Syndrome have already been identified. The underlying methodology in these studies is a multi-step algorithm based on filtering variants identified in a small number of affected individuals depending on whether they are novel (not yet seen in public resources such as dbSNP, and 1000 Genomes Project), shared among affected (possibly related) individuals, and other external functional information available on the variants. While intuitive, these filtering-based methods are non-optimal and do not allow for uncertainty to be quantified in the form of P-values. We describe here a formal statistical framework that has several distinct advantages: (1) provides analytical, fast computation of approximate P-values, (2) accommodates designs based on both affected relative pairs and unrelated affected individuals, (3) adjusts for the background variation in each gene so that large genes do not rise to the top based on their sheer size alone, and (4) allows for natural incorporation of functional or linkage-based information. We show via simulations that the proposed approach achieves a substantially better ranking of a disease gene when compared with currently used filter-based approaches, especially in the presence of disease locus heterogeneity. We revisit recent studies on three Mendelian diseases that used filter-based approaches to identify the corresponding disease genes and show how the proposed approach can be applied in such cases, resulting in the disease gene being ranked first in all three studies, and approximate P-values of E-12 for the gene for the Miller Syndrome, 3E-4 for the gene for the Freeman-Sheldon Syndrome, and 1.4E-4 for the gene for the Kabuki Syndrome.

673T

A Powerful and Efficient Two-Stage Design for Next Generation Sequencing Data Analysis Using Extreme Phenotype Sequencing. *G. Kang, D. Lin, M. Li, J. Chen.* Department of Epidemiology and Biostatistics, University of Pennsylvania, Philadelphia, PA 19104.

Rare variants have been conjectured to contribute to a large proportion of genetic variation in complex traits that is not yet explained by associated genes identified from genome-wide association studies. The next-generation sequencing technology provides an unprecedented opportunity to discover rare variants. Currently, it is not financially feasible to perform whole-genome sequencing on a large number of subjects, and a two-stage design has been advocated to be a practical option. In stage I, variants are discovered by whole-genome sequencing on a small set of carefully selected individuals. In stage II, the discovered variants are genotyped on a large set of individuals for screening associations. Extreme phenotype sequencing is one of the primary designs for selecting stage I individuals. Using simulated data for unrelated individuals, we explore two important aspects of this design: the efficiency of discovering both common and rare SNPs in stage I, and the impact of incomplete SNP discovery in stage I on the power for testing associations in stage II. We apply a sum test and a sum of squared score test to perform gene-based association tests for evaluating the power of the two-stage design. Simulations and application to GAW17 data set show that, given the sample size, using individuals at both a cutoff ranging from 0.3% to 1.9% tails of the quantitative trait, 1) less than half of the total SNPs were discovered, including all common SNPs, nearly all of the less common SNPs, and less than half of the rare SNPs, which included nearly half of causal SNPs; 2) more than half of the total cost could be saved; 3) the two-stage method could achieve the same as or even higher power than the one-stage method if the rare variants contribute to the trait with large effect sizes.

674T

The Empirical Power of Rare Variant Association Methods: Results from Sanger Sequencing in 1,998 Individuals. *M. Ladouceur[1,2], Z. Dastani[2,3], Y.S. Aulchenko[4,5], M.T. Greenwood[2,3,7], J.B. Richards[1,2,6,8].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, Quebec, Canada; 3) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Quebec, Canada; 4) Department of Epidemiology, Erasmus MC, Rotterdam, the Netherlands; 5) Institute of Cytology and Genetics SD RAS, Novosibirsk, Russia; 6) Department of Medicine, Jewish General Hospital, McGill University, Montreal, Quebec, Canada,; 7) Department of Oncology, McGill University, Montreal, Quebec, Canada; 8) Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

The role of rare genetic variation in the etiology of complex disease remains unclear. However, the development of next-generation sequencing technologies offers the experimental opportunity to address this question. Several novel statistical methodologies have been recently proposed to assess the contribution of rare variation to complex disease etiology. Nevertheless, no empirical estimates comparing their relative power are available. We therefore assessed the parameters that influence their statistical power in 1,998 individuals Sanger-sequenced at seven genes by modeling different distribution of effect, proportions of causal variants, and direction of the associations (deleterious, protective or both) in simulated phenotypes. Our results demonstrate that the power of recently proposed statistical methods depend strongly on underlying assumptions about each of these three factors. No method demonstrates consistently acceptable power despite this large sample size, and the performance of each method depends upon the underlying assumption of the relationship between rare variants and complex traits. Sensitivity analyses are therefore recommended to compare the stability of the results arising from different methods, and promising results should be replicated using the same method in an independent sample. These findings provide guidance in the analysis and interpretation of the role of rare base-pair variation in the etiology of complex disease.

675T

Quality assurance of variant calling (SNV and Indels) using next-generation sequencing (NGS) data. *H. Ling, H. Kurt, E. Pugh, J. Romm, B. Craig, B. Marosy, K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

CIDR provides high quality NGS, genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. The constantly evolving NGS technology and bioinformatics tools have greatly improved the accuracy of SNP and genotype calling using deep sequencing data (>=30x). However, the nature of sequencing technology and data processing pipelines have made variant calling platform specific and involve lab-to-lab, batch-to-batch and even sample-to-sample variations. This brings new challenges for variant calling in terms of quality assurance and filtering as even low level genotype errors can lead to a strong decrease in power for association mapping of complex traits for which the strategies focus on collapsing rare/low frequency variants into a compound variant based on gene, region or pathway. Therefore, high quality variant calling is essential for meaningful association mapping involving NGS data, and even more critical for family studies that look for variants shared among affected but not unaffected family members to narrow down candidate variants. After raw variants are called by the CIDRSeqSuite pipeline, a set of filters are applied to remove uncertain calls with quality metrics below a pre-determined threshold. These variants are then filtered by different BED files to define NearBait, OnBait and OnTarget calls for either WES or custom-targeted resequencing(CTS). Less than 2% raw variants from a WES are removed due to biases in strand, BaseQ, MapQ or tail distance. In the remaining 91K variants, 39%(35K) and 21%(19K) fall on Bait and Exon respectively. To investigate whether the filtered out set contains the majority of false positive calls, we compare a number of QC metrics between the filtered and the remaining sets at varying level of the filtering thresholds which include TiTv ratio, %dbSNP, SNP and genotype calling reproducibility for blind and HapMap duplicates, along with metrics obtained by comparing NGS against GWAS such as concordance and heterozygote sensitivity. In most cases, we found a fixed cutoff is effective in eliminating false positives. But under some circumstances, such as CTS with a much higher depth, the optimal cutoff for many filters can vary by sequencing depth. By choosing the optimal threshold for filtering parameters and examining data from blind duplicates and HapMap controls, we are able to release high quality variant lists and perform rapid troubleshooting for NGS data.

676T

Smoothed Functional Principal Component Analysis for Next-Generation Association Studies. *L. Luo[1], Y. Zhu[2], H. Kang[1], C. Stidley[1], E. Boerwinkle[2], M. Xiong[2].* 1) Division of Epidemiology and Biostatistics, University of New Mexico, Albuquerque, NM; 2) Human Genetics Center, University of Texas School of Public Health, Houston TX.

There is a consensus that common diseases are caused by an entire allele frequency spectrum of genetic variations including common and rare variants, such as SNPs, CNVs and other structural variations. To systematically investigate the genetic architecture of common diseases requires complete knowledge of the human DNA sequence variation across the entire spectrum of allele frequencies and types of DNA alterations. The current single marker association analysis platform is being shifted to joint multiple marker association analysis where a combination of common and rare variants from multiple genomic regions is taken as the unit for association analysis. Functional principal component analysis (FPCA) was recently developed as a tool to test the association of either common or rare SNPs or CNVs within a genomic region with disease. However, we often observe substantial variability of the principal component curves. These will be sensitive to sampling and dramatically reduce the power of FPCA. To overcome this limitation, we develop a statistical method which incorporates smoothing into FPCA. With the majority of smoothed FPCA methods focusing on the estimation procedures of FPCs, the statistics using smoothed FPC scores for inference has yet to receive much attention and have not been well developed for next-generation association studies. The goal of this research is to develop a novel smoothed FPCA-based statistic for inference and to apply it to testing the association of genetic variants generated by next-generation sequencing. This new statistic can jointly test for the association of risk increasing variants and protective variants within a genomic region without compromising power. We also develop a modified smoothed FPCA which takes population stratification into consideration. Extensive simulations using software based on coalescent theory are conducted to evaluate type 1 error rates and power. The simulation results show that the newly developed statistic has type I error rates not appreciably different from the expected nominal level, and has much higher power than the FPCA-based statistic and other existing methods for various disease models under a wide range of disease risk, allele frequencies and linkage disequilibrium patterns. The newly developed statistic is also applied to the Dallas Heart Study and the Framingham Heart Study. Our method identifies more significant genomic regions and yields much smaller p-values than existing methods.

677T

Genome-wide DNA Methylation Analysis for Osteoporosis Risk. *C. Qiu[1,2], H. Shen[1,2], J. Li[1,2], H.W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) School of Medicine, University of Missouri-Kansas City, Kansas City, MO 64108, USA.

Osteoporosis is a common disease mainly characterized by low bone mineral density (BMD) and increased risk of fractures. Peripheral blood monocytes (PBM) may act as precursors of osteoclasts, the bone resorption cells, and also produce cytokines important for osteoclast activity, and thus represent major systemic target cells for bone metabolism. Alterations in DNA methylation has been implicated as a key regulatory mechanism in the etiology of human complex diseases. However, the DNA methylation profiles in humans underlying osteoporosis risk are largely unknown. In this study, we performed a comparative genome-wide DNA methylation analysis of PBMs from 18 unrelated Caucasian postmenopausal females with extremely high (n =9) or low (n =9) BMD. By coupling methylated DNA immunoprecipitation with next-generation sequencing (MeDIP-seq), we generated over 282 million uniquely mapped reads for all the 18 samples. Genome-wide DNA methylation signals of each sample were normalized and quantified using MEDIPS analysis package. Differentially methylated regions (DMRs) were identified by comparing the genome-wide methylation profiles between the high and the low BMD subjects. The PBM methylome profile shows similar patterns as that in other somatic cells. For instance, most of the promoters are unmethylated or partially methylated, especially for promoters with high CpG density. In addition, while only 9% of promoter CGIs are methylated, over 30% of intragenic and intergenic CGIs are methylated. A total of 122 regions showed significant difference ($p \leq$ 1E-5, fold change$\geq$ 2) in methylation levels between the high and the low BMD groups, such as the promoter of SNTB1 gene (p<1E-6, fold change=3.6) and the promoter of BLVRA gene (p<1E-6, fold change=4.5). Interestingly, a number of known bone-related genes also showed differential methylation between the high and the low BMD subjects, such as the BMP7 gene (p=7.4E-5, fold change=10.4) and the RUNX2 gene (p=3.0E-5, fold change=2.3). Hierarchical clustering analysis using the top 100 genome-wide DMRs clearly separates the 18 samples into two distinct groups that are consistent with their BMD status. In summary, we conducted the first genome-wide DNA methylation analysis for PBMs and identified a number of novel epigenetic-regulated candidate genes for osteoporosis risk.

Study design considerations to improve power in association tests for rare variants. *I. Ruczinski, R. Mathias.* Johns Hopkins Univ, Baltimore, MD.

The assumption that common complex diseases are attributable in part to allelic variants that are reasonably common in a population is often termed the “common disease, common variant” hypothesis, and is the underlying rationale for genome-wide association studies (GWAs). While GWAs have been successful identifying hundreds of such genetic variants associated with many complex diseases, the individual variants typically only represent a small increment in risk for any particular disease, and together, can usually explain only a small proportion of the familial clustering (heritability) observed. Thus, the paradigm has shifted somewhat towards whole exome and whole genome sequencing approaches to assess the effects of rare variants (with possibly larger effect sizes), which are poorly tagged by standard genotyping arrays. In this presentation, we focus on family and population based study design considerations, and show how family records can be leveraged to improve power even in population based studies.

Detection of identity by descent using next-generation sequencing data. *S. Su, E. Jorgenson.* Ernest Gallo Clinic and Research Center, UCSF, Emeryville, CA.

Identity by descent (IBD) has played a fundamental role in the discovery of human disease genes. Both pedigree-based and population-based linkage analyses rely on estimating recent IBD, and evidence of ancient IBD can be used to detect population structure in genetic association studies. Various methods for detecting IBD, such as those implemented in the software programs fastIBD and GERMLINE, have been proposed for use with population genotype data from microarray platforms. Now, next-generation DNA sequencing data is becoming increasingly available, enabling the comprehensive analysis of genomes, including identifying rare variants. These sequencing data may provide an opportunity to detect IBD with higher resolution than previously possible, potentially enabling the detection of disease causing loci that were previously undetectable with sparser genetic data. Here, we conduct a comprehensive evaluation and comparison of these methods for detecting IBD using sequencing data. We investigate the resolution of detectable IBD for data with different levels of variant coverage. This includes micorarray genotype data from the WTCCC study, denser genotype data from the HapMap Project, low coverage sequencing data from the 1000 Genomes Project, and deep coverage complete genome data from our own projects. With high power, we can detect segments of length 0.4 cM or larger using fastIBD and GERMLINE in sequencing data. This compares to similar power to detect segments of length 2.0 cM or higher with microarray genotype data. We find that GERMLINE has slightly higher power than fastIBD for detecting IBD segments using sequencing data, but also has a much higher false positive rate. We further quantify the effect of variant density, conditional on genetic map length, on the power to resolve IBD segments. The results of our analysis may help guide the design of future next generation sequencing studies that utilize IBD.

Genome-wide association study of African Americans implicates multiple lung and inflammatory disease-associated loci in sarcoidosis susceptibility. *I. Adrianto[1], C.P. Lin[1], J.J. Hale[1], A.M. Levin[2], I. Datta[2], R. Parker[1], A. Adler[1], J.A. Kelly[1], K.M. Kaufman[1,3,4], C.J. Lessard[1], K.L. Moser[1,3], M.C. Iannuzzi[5], B.A. Rybicki[2], C.G. Montgomery[1].* 1) Arthritis and Clinical Immunology Research 1Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104, USA; 2) 2Department of Biostatistics and Research Epidemiology, Henry Ford Health System, Detroit, MI 48202, USA; 3) Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, USA; 4) Oklahoma City VA Medical Center, Oklahoma City, OK 73104, USA; 5) Department of Medicine, SUNY Upstate Medical University, Syracuse, NY 13210, USA.

Sarcoidosis is a systemic granulomatous disease characterized by the formation of granulomas mainly in the lungs, but also in multiple organ systems. While the etiology of this disease remains elusive, the causal chain likely involves a dysregulated immune response to an environmental agent in a genetically susceptible host. This study sought to identify loci associated with sarcoidosis in African Americans using a large cohort of both families and independent cases and controls. We genotyped 1487 cases and 1504 controls using the Illumina HumanOmni1-Quad platform for 1.1 million SNPs across the genome. After applying sample and SNP quality control, the final set comprised 2918 samples (1273 cases and 1645 controls) including 180 HapMap YRI and ASW controls from the Illumina iControlDB and 887,296 SNPs. We assessed single SNP association to sarcoidosis using the Efficient Mixed-Model Association eXpedited (EMMAX) software that simultaneously controls for both pairwise genetic relatedness between individuals and population stratification under an additive model. Regions associated at a suggestive level of $p < 1 \times 10^{-4}$ were imputed using IMPUTE2 program and the 1000 Genomes Project reference panels. We identified 5 regions associated at the genome-wide significance level of $p < 5 \times 10^{-8}$ including the previously identified HLA-DRA and HLA-DRB1, and novel effects at NOTCH4 ($p = 4.30 \times 10^{-9}$), HLA-DQA1 ($p = 1.04 \times 10^{-11}$), and HLA-DQB1 ($p = 3.12 \times 10^{-10}$). Ninety-eight regions were associated at a suggestive level and 12 were associated with other inflammatory or lung diseases including FRMD3 ($p = 1.39 \times 10^{-6}$), PRDM1 ($p = 1.07 \times 10^{-5}$), and DMBT1 ($p = 8.70 \times 10^{-5}$). These genes have been associated with lung cancer (FRMD3) and inflammatory bowel disease (PRDM1 and DMBT1). We also found association within sarcoidosis susceptibility loci: BTNL2 ($p = 1.24 \times 10^{-5}$) and near RAB23 ($p = 9.47 \times 10^{-5}$). Pathway analysis of these data highlighted the calcium-dependent phospholipid binding pathway, which contained two genes (DOC2A and MCTP2) with $p < 1 \times 10^{-4}$ and seven of the Annexin (ANX) genes, one of which, ANXA11, has been associated with sarcoidosis. In this study, we expanded the number of putative candidate sarcoidosis susceptibility loci and replicated sarcoidosis associations in multiple gene regions. Future replication and sequencing studies are required to further elucidate the functional variants that may underlie these novel associations.

Fine-scale association mapping of the xMHC-region in celiac disease cases and controls. *R.S. Ahn[1], A. Adamson[2], X. Deng[2], H. Gao[2], C. Garner[1], S. Neuhausen[2].* 1) Epidemiology Department, Sprague Hall, Room 318, University of California, Irvine, Irvine, CA 92697-3905; 2) Beckman Research Institute of City of Hope, 1500 E. Duarte, Duarte, CA 91010.

Celiac disease (gluten-sensitive enteropathy) is a chronic inflammatory disease of the small intestine caused by an autoimmune response to ingestion of dietary gluten peptides. It is a common disease with a prevalence of approximately 1% in populations of European descent. Classic symptoms include diarrhea, abdominal distension, as well as developmental delays in affected children. The majority of celiac cases present with minimal classic symptoms. Complications include anemia and osteoporosis, as well as other autoimmune disorders. The only known treatment is to remove all gluten from the diet. Multiple studies have shown a strong association with human leukocyte antigen (HLA) as well as associations with 39 non-HLA risk loci. More than 90% of celiac disease cases express the HLA-DQ2 heterodimer and 5% express HLA-DQ8. The alleles that encode for HLA-DQ2 are HLA-DQA1*05 and HLA-DQB1*02 and HLA-DQ8 is encoded for by HLA-DQA1*03 and HLA-DQB1*0302. We have carried out a fine-scale association analysis of the 7.6 Mb extended major histocompatibility region (xMHC) on chromosome 6p using a set of 1,898 single nucleotide polymorphisms (SNPs) genotyped in 1,695 celiac disease cases and 520 controls from the U.S. The purpose of the analysis was to search for evidence of novel genetic determinants of celiac disease within the xMHC that are independent of the known high-risk HLA-DQ genotypes. Association analysis of all 1,898 SNPs was followed by SNP selection based on linkage disequilibrium and the rank-order of p-values in order to generate a minimal set of SNPs that appear to have independent effects on celiac disease risk. We present the genetic and statistical evidence for novel celiac disease susceptibility loci within the xMHC. Furthermore, the study highlights the analytical challenges and pitfalls of fine-scale association mapping within the xMHC, where known strong disease risk genotypes, complex linkage disequilibrium patterns and extensive genetic variation predominate.

Common Variants Identified by Meta-Analysis of 110,238 Individuals Associate with Serum Urate Concentrations. *E. Albrecht[1], A. Köttgen[2,3], A. Teumer[4], G. Pistis[5], V. Vitart[6], C. Hundertmark[2], D. Ruggiero[7], T. Tanaka[8], Q. Yang[9], T. Haller[10], J.C. Chambers[11], A. Tin[3], W.H. Kao[3], C.S. Fox[12], C. Gieger[1], CARe Consortium, Global Urate Genetics Consortium.* 1) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 2) Renal Division, Freiburg University Hospital, Freiburg, Germany; 3) Dept. of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, USA; 4) Interfaculty Institute for Genetics and Functional Genomics, University of Greifswald, Germany; 5) San Raffaele Scientific Institute, Division of Genetics and Cell Biology, Milan, Italy; 6) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, Edinburgh, UK; 7) Istitute of Genetics and Biophisics “Adriano-Buzzati Traverso”, CNR, Napoli, Italy; 8) Clinical Research Branch, National Institute on Aging, Baltimore, USA; 9) Department of Biostatistics, Boston University, Boston MA, USA; 10) Estonian Genome Center, University of Tartu, Estonia; 11) Dept Epidemiology and Biostatistics, School of Public Health, Imperial College London, UK; 12) National Heart, Lung, and Blood Institute, Framingham, USA.

Elevated urate levels are associated with gout and are considered a risk factor for cardiovascular diseases, metabolic syndrome and type II diabetes. To investigate the polygenic basis of serum urate levels, we conducted a meta-analysis of genome-wide association studies of approximately 2.5 million genotyped or imputed SNPs, combining data from 48 studies, totalling 110,238 participants of European descent. The detected loci were subsequently investigated among study participants of different ancestries from independent studies. We identified 26 independent loci reaching genome-wide significance at a level of 5×10^{-8} in the discovery analysis, including all previously reported loci, as well as 16 novel loci. The effects of the discovered risk alleles on urate concentrations ranged between 0.04 ($p=7.3 \times 10^{-9}$, *ORC4L*) and 0.38 ($p=1.2 \times 10^{-786}$, *SLC2A9*) mg/dl. In addition to the known sex-specific effects of variants in *SLC2A9* and *ABCG2*, no additional gender associations were identified. The strongest signals, in or near *SLC2A9*, *ABCG2*, *SLC17A1*, *GCKR* and *SLC22A11* also showed robust and direction-consistent associations in 9,867 participants of Indian ancestry () =0.10-0.39, $p=5.0 \times 10^{-8}$-4.3×10^{-21}). In a lookup among 7,129 African American participants from the CARe consortium, only variants at *SLC2A9* () =0.30, $p=8.62 \times 10^{-29}$) and *SLC22A11* () =0.15, $p=2.16 \times 10^{-4}$) showed significant associations. However, the effects of the risk alleles among European ancestry participants were consistent in their direction for 21/24 loci among Indian ancestry and 21/25 loci in African American participants. Taken together, these newly identified associations highlight additional genetic regions that are associated with serum urate levels across groups of different ancestries.

Performance of different balancing score methods in case-control genetic association studies. *A. Barhdadi[1], MP. Dubé[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada, PHD; 2) Faculté de Médecine, Université de Montréal.

Background Confounding can be a major source of bias in non-experimental research. The propensity score is a popular method to control for confounding in prospective observational studies. Its counterpart for the case-control design is the stratification score which is a retrospective balancing score. Our study examines the performance of different balancing score methods in case-control genetic association studies. Methods and Results Three different methods for the stratification score have been described in the literature: stratification on the balancing score (SB), matching on the balancing score (MB) and covariate adjustment using the balancing score (CAB). We compared the performance of SB, MB and CAB to simple covariate adjustment with 1000 simulated datasets of 4000 subjects. We randomly generated replicates of 3 continuous covariates and 3 binary covariates that were imbalanced between cases and controls. For each of the 4000 subjects, we simulated genotypes at 9 single nucleotide polymorphisms (SNPs) of varying the minor allele frequency (MAF) and odds ratios (OR). We calculated the stratification score using 5 strata. Each of the 3 methods were evaluated for their ability to identify the simulated genetic effect based on the mean relative bias (distance of the method OR estimator to the true value of OR divided by OR). We find that the power to detect the causal SNP was 100% for all methods with a MAF of 0.30. Type I error rate was (0.053, 0.049 and 0.053) for CAB, SB and MB respectively. The relative bias mean was (0.08±0.07, 0.08±0.06, 0.12 ±0.09). With MAF of 0.05, the power to detect the associated SNP was 49.9%, 52.8%, and 16.4% for CAB, SB and MB respectively. Type I error rate was 0.014, 0.024 and 0.010and the relative bias mean was 0.58 ±0.83, 0.58+0.80, 0.62 ±0.69 for CAB, SB and MB respectively. Conclusion CAB, SB and MB methods outperformed simple covariate adjustment to identify a simulated genetic factor at varying levels of MAF and OR. The SB method had more power, lower false positive error rate and lower relative bias when used to adjust for covariates in the context of a case-control genetic association study. Keywords Association, Propensity score, Balancing score, Case-control, SNP.

At least 95 loci have been associated with plasma lipid traits in European populations. Importantly, the common variants identified using large-scale GWA studies explain a substantial amount of the total variance of these traits (10-12% of the total variance, which represents approximately 25-30% of the genetic variance). These efforts have led to the discovery on new regulatory pathways in lipid metabolism, opening new potential targets for therapeutic intervention, and demonstrated the relevance of the GWA approach from the clinical point of view. We report here the results of the first meta-analysis of GWA studies for lipid traits (LDL-C, HDL-C, Total-C and Triglycerides) in populations of Mexican ancestry. We identified several previously identified loci with genome-wide significant associations, as well as other regions showing suggestive associations (p-value< 10-5). Top associations include genome-wide significant signals predicting LDL-C within the 3-prime untranslated region of the CELSR2 gene (rs964184, p= 1.2x10-9). In the analysis of Total-C, we approach genome-wide significance in the same region (rs7528419, p=5.9x10-8). We identify genome-wide significant signals for triglycerides at SNPs in a known region: 116.0-116.3 Mb; the lowest p-value falls between ZNF259 and BUD13 (rs964184, p= 2.3x10-19. Suggestive associations replicate regions APOB, DOCK6, and TRIB1. We also identify suggestive evidence in several novel regions including TNS1, SPOCK3, EPHA7, MNT, KCNJ15, and RUNX1, as well as several intergenic regions. To explore the functional relevance of our top findings, we conducted simulations to test for an enrichment of eQTLs (p-value < 1×10-4) among the top signals (p-value < 1×10-3) associated with lipid levels by generating 1000 random SNP sets, each of the same size as the original list of LD-pruned top signals (r2>0.30), containing variants matched on MAF distribution, sampled without replacement. We observe tissue specific enrichment of eQTLs for each lipid phenotype.

685T

Genome wide association study identifies several regions associated with malignant mesothelioma susceptibility. *G. Cadby[1,2], S. Mukherjee[3], A. Reid[4], M. Garlepp[4,5], B.W.S. Robinson[4], N. de Klerk[4,5], A.W. Musk[3,4], L.J. Palmer[1,2].* 1) Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) Samuel Lunenfeld Research Institute, Toronto, Ontario, Canada; 3) Sir Charles Gairdner Hospital, Perth, Western Australia; 4) University of Western Australia, Perth, Western Australia; 5) Telethon Institute for Child Health Research, Perth, Western Australia.

Malignant mesothelioma (MM) is a malignant tumour which arises from the single layer of mesothelial cells which line the pleural and peritoneal cavities. The main environmental risk factor for MM is exposure to asbestos, however only 5-10% of individuals exposed to high levels of asbestos develop MM, indicating the role of genetic variation in MM predisposition. Despite the evidence of genes in MM predisposition, there has been little consistency in the published findings from genetic studies of MM. The aim of this study is to perform a genome wide association study (GWAS) of MM cases and population-based controls to identify genetic variants associated with MM susceptibility.

Clinical data and DNA samples were obtained from individuals diagnosed with MM who attended a hospital clinic in Perth, Western Australia (WA) between 1995 and 2010. Case status was confirmed via the WA Mesothelioma Registry and expert review of clinical notes. Control DNA samples were obtained from a general population cohort of residents from the town of Busselton, Western Australia, who were part of the 1994/1995 Busselton Health Study. Genotyped and imputed single nucleotide polymorphisms (n~2.5 million) were compared between MM cases and controls using mach-2dat. All models were adjusted for age and sex. Adjustment for population stratification was made by including significant eigenvectors as covariates in the regression.

The GWAS has been performed on 428 individuals with MM (89% male) and 1,269 general population controls (42.6% male). Mean age of cases was 67 years (±10 years SD) compared to 54 years (±17 years SD) for controls. All cases and controls were confirmed as Caucasian-European. Preliminary analyses have identified several genes which appear to be associated with MM susceptibility, including SDK1 and RASGRF2.

This is the first GWAS for MM. Despite the limited sample size, several regions have been identified which may increase the risk of developing MM. Further analyses are planned, including using asbestos exposed controls, analysing gene-environment interactions in cases, and replicating results in other MM samples. These results will improve our understanding of the complex relationships between genes and asbestos, and their role in MM susceptibility, progression and response to therapy.

Integrated analysis of variants and pathways for genome-wide association studies. *P. Carbonetto, M. Stephens.* Depts of Statistics and Human Genetics, University of Chicago.

Motivated be the shortcomings of conventional, “hypothesis-free” approaches to the analysis of genome-wide association studies, researchers have developed “pathway analysis” methods, grounded on the theory that complex diseases arise from the accumulation of genetic effects acting in common biological pathways. The aim of pathway analysis is to identify pathways that are “enriched” for disease. This can give us greater ability to identify relevant genetic factors, and can enhance interpretation of an association study. But pathway analysis does not give us feedback about associated variants within pathways; findings at the level of variants (``what are the variants associated with disease risk?'') are often more useful than results at the level of pathways (``what are the enriched pathways?''). We address this limitation by jointly analyzing variants and pathways in a genome-wide association study. We take a Bayesian approach to joint analysis because it offers a coherent way to resolve the interdependency of associations and enrichments. We demonstrate joint analysis of variants and pathways for genome-wide association studies of two chronic autoimmune disorders, Crohn's disease and type 1 diabetes.

Identification of Genetic Variants Related to Hepatitis B Virus Infection in Hepatocellular Carcinoma Families and Chronic Liver Diseases in Han Chinese. *S. Chang[1], C. Hsu[1], A. Hsieh[1], C. Fann[1], D. Tai[2].* 1) IBMS, Academia Sinica, Taipei, Taiwan; 2) Liver Research Unit, Chang Gung Memorial Hospital, Chung Gung University College of Medicine, Taipei, Taiwan.

Hepatitis B is a major health problem worldwide and a potentially life-endangering liver infection. Previous studies have shown that male gender was a significant host factor related to hepatitis severity. However, a large part about the biomedical mechanism of persistence and protection for HBV infection is still unknown. In this study, we conducted a multi-stage genome-wide association analysis on 625 male Taiwanese. The first-stage sample comprised 321 HBsAg positive cases and 304 HBsAg negative controls with genotype data from Illumina HumanHap550K and 610K beadchips. A total of 456,262 SNPs were used in the GWAS analysis after quality control filters with an average call rate of 99.95%. We performed single-locus association tests and identified 61 SNPs that were potentially associated with persistent HBV infection (P < 10-5). Among those, 38 out of the 61 markers were clustering in the HLA Class II region on chromosome 6. One SNP at HLA-DQB2 locus was replicated in the two independent cohorts (with 410 cases/282 controls and 709 cases/419 controls, respectively). The underlying function remains uncertain and requires further investigation.

688T

Population analysis of asthma genome-wide association data using GenAMap. *R.E. Curtis[1,2], S. Wenzel[4], D.A. Myers[5], E. Bleecker[5], E.P. Xing[3].* 1) Joint Carnegie Mellon - University of Pittsburgh PhD Program in Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 2) Lane Center for Computational Biology, Carnegie Mellon University, Pittsburgh, PA; 3) Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA; 4) University of Pittsburgh Medical Center Montefiore, Pittsburgh, PA; 5) Center for Human Genomics, Wake Forest University School of Medicine, Winston-Salem, NC.

Structured association mapping has the potential to discover weaker associations by leveraging structures inherent in GWAS and eQTL data. Population stratification is one such structure that must be considered in any genome-wide association study. Although geneticists frequently analyze association strengths between different populations in GWAS data, this is often done one population at a time as geneticists are limited by the lack of tools and strategies available to compare results between populations. In order to facilitate population analyses, we added new analysis and visualization tools into GenAMap, a visual analytics software platform for structured association mapping. We integrated association mapping methods including the Multi-population Group Lasso (MPGL), Wald test (plink), likelihood ratio test, and t-test. New interactive charts, tables, and plots provide both an overview and details of the associations in a population analysis, which allow geneticists to analyze and compare association strengths between different populations and tests. We used GenAMap to perform a structured association analysis using data collected through the Severe Asthma Research Program (SARP) and Cooperative Study for the Genetics of Asthma (CGSA). Both datasets include individuals from African American and non-Hispanic white populations. As has been previously appreciated, population analysis using GenAMap also revealed that the two populations have different patterns of association. Among the top 50 SNPs associated with asthma in each population, none of the SNPs were associated with asthma in the other population. These results suggest that different SNPs are affecting the acquisition of asthma in the two populations. Despite a large number of SNPs associated with asthma at the 1e-4 significance level, we used GenAMap to look at each population separately. By comparing the results from four tests, we identified twelve SNPs associated with asthma. Finally, we used GenAMap to run MPGL to find associations while accounting for population structure. We found support for an association between the SNP rs7661051 and the clinical lung function trait “Forced Vital Capacity (FVC), % predicted” in the non-Hispanic white population. Cases have a lower level of FVC (p-value=4.1e-17), thus rs7661051 could potentially impact asthma in non-Hispanic whites with effects to alter FVC. rs7661051 is located on chromosome 4 in a non-coding region near the genes CXCL13 and CCNG2.

A novel variant in the MCF2L gene is associated with osteoarthritis. *A.G. Day-Williams on behalf of the arcOGEN Consortium and the replication data sets.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Osteoarthritis (OA) is the most common form of arthritis, with the sibling recurrence risk (λ_s) estimated to be approximately 5 in the UK. We recently completed stage 1 of a large UK-based genome-wide association (GWAS) scan of knee and/or hip OA (the arcOGEN study) and detected no novel replicating signals. Here, we used 1000 Genomes Project (1KGP) pilot 1 data of 60 CEU individuals as a reference set and imputed 1KGP-identified variants into the stage 1 arcOGEN GWAS of 3,177 cases and 4,894 UK controls. After removing rare variants (with minor allele frequency [MAF] < 0.01) and SNPs with low imputation quality, 7,258,070 variants were tested for association with OA. We selected eight SNPs with $p < 1x10^{-5}$ from six loci for validation in the original arcOGEN data, and for de novo replication in independent sample sets. We first genotyped an independent set of 5,165 arcOGEN-collected cases and 6,155 population-based controls from the UK. Seven out of the eight SNPs were successfully genotyped in the replication samples and one SNP, rs11842874 on chromosome 13q34, replicated with $p=2.60x10^{-3}$ (OR 1.17 [1.06-1.30]) and consistent effect direction as the original scan. We subsequently sought replication of this signal in 6 further sample sets: the UK-based GOAL study (1,686 total joint replacement cases, 743 non-OA controls); newly-collected UK-based arcOGEN data (2,409 cases, 2,319 population-based controls); two from the Netherlands (RSI: 1,950 cases and 3,243 controls; RSII: 485 cases and 1,460 controls); one from Estonia (EGCUT: 2,617 cases and 2,619 controls); and one from Iceland (deCODE: 1,552 cases and 3,071 controls). In all seven replication sets combined, rs1184874 associated with OA with $p=3.0x10^{-5}$ (OR 1.13 [1.07 - 1.20]). Combined with the discovery sample set, the overall fixed effects meta-analysis (19,041 cases and 24,504 controls) established association at this variant with $p=2.07x10^{-8}$ (OR 1.17 [1.11-1.23]). rs11842874 is one of several highly-correlated SNPs at 13q34 constituting the association signal and they reside in intron 4 of the guanine nucleotide exchange factor-encoding gene MCF2L. Mcf2l studies in rat models of OA have shown expression in articular chondrocytes. In human cells MCF2L regulates neurotrophin-3 induced cell migration in Schwann cells. Neurotrophin-3 is a member of the nerve growth factor (NGF) family, and inhibition of NGF has shown reduction of pain in knee OA.

690T

Genetic loci implicated in erythroid differentiation and cell cycle regulation are associated with red blood cell traits. *K. Ding[1], K. Shameer[1], H. Jouni[1], D.R. Masys[2], G.P. Jarvik[3], A.N. Kho[4], M.D. Ritchie[5], C.A. McCarty[6], I.J. Kullo[1].* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Departments of Medicine and Biomedical Informatics, Vanderbilt University, Nashville, TN; 3) Departments of Medicine (Medical Genetics) and Genome Sciences, University of Washington, Seattle, WA; 4) Department of Medicine, Northwestern University, Chicago, IL; 5) Center for Human Genetics, Department of Molecular Physiology & Biophysics, Vanderbilt University, Nashville, TN; 6) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI.

Disorders involving red blood cells (RBC), such as anemia, are common and associated with adverse health outcomes. We performed a genome-wide association study for six RBC traits, including hemoglobin (HGB), hematocrit (HCT), RBC count, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC), in 12,486 patients of European ancestry in the electronic Medical Records and Genomic (eMERGE) network (www.gwas.net). We developed an electronic medical record-based algorithm which included individuals who had RBC measurements obtained for clinical care, and excluded RBC trait values measured in the setting of hematopoietic disorders, comorbid conditions or medications known to affect red cell production, or a history of blood loss. We identified six novel genetic loci associated with at least one RBC trait at $P<5\times10^{-8}$ in individuals of European ancestry and replicated nine previously reported loci. Notably, four of the six newly identified loci (*KLF1*, *THRB*, *PTPLAD1*, *CDT1*) and four of the nine replicated loci (*CCND3*, *SPTA1*, *FBXO7*, *TFR2/EPO*) are implicated in erythroid differentiation and regulation of cell cycle in hematopoietic stem cells. These findings provide insights into the molecular basis underlying variation in RBC traits, in particular highlighting that genes in the erythroid differentiation and cell cycle regulation pathways influence such variation.

Strategy for genotype imputation in Hispanic-Americans in the Women's Health Initiative SNP Health Association Resource (WHI-SHARe). *J. Divers[1], W.M. Brown[1], L. Yang[1], A.P. Reiner[2,3], T.A. Thornton[4], Y. Li[5], H. Tang[6], M.Z. Vitolins[7], B.M. Snively[1].* 1) Dept Biostatistical Sci, Wake Forest Univ, Winston-Salem, NC; 2) Department of Epidemiology,University of Washington, Seattle, WA; 3) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Department of Genetics, University of North Carolina Chapel Hill, Chapel Hill, NC; 6) Department of Genetics, Stanford University, Stanford, CA; 7) Dept Epidemiology, Wake Forest Univ, Winston-Salem, NC.

Questions remain about the number and combination of reference panels to use for genotype imputation in admixed populations. Imputation in Hispanic-Americans is particularly challenging because of the ancestral diversity that typically underlies this group. We compared the performance of various imputation strategies using different combinations of the CEU, YRI, MEX and JPT+CHB panels in HapMap3. Comparisons were made using chromosome 22 markers, where 9,584 SNPs were genotyped as part of WHI-SHARe; we also randomly masked 25%; of the genotyped markers. SNPs were imputed using each panel separately and all 6 two-panel combinations. Finally, we considered the union of the best performing combinations, which led to a three-panel reference and evaluated its benefits over the two-panel combinations. We used two metrics for judging the performance of each combination: percentage of SNPs that had $R^2 \geq 0.5$, and concordance rate between directly genotyped and imputed SNPs among those with $R^2 \geq 0.5$. We ran MACH on 3,586 self-reported Hispanic participants, and on more homogenous subsets of individuals, which were created from estimated ancestry proportions. We defined 11 subsets whose composition ranged from having individuals with at least 85%; ancestry from one ancestral group, to subsets of individuals with substantial ancestry from all 4 groups. When a single HapMap panel was considered, the percentage of SNPs with $R^2 \geq 0.5$ and the concordance between genotyped and imputed SNPs with $R^2 \geq 0.5$ were (88%, 99.2%), (88.8, 98.1), (90.8, 99.3) and (81, 98.3) using respectively the CEU, YRI, MEX and JPT+CHB panel. All two-panel combinations led to at least 90%; of the SNPs with $R^2 \geq 0.5$ and concordance of at least 99.5% The (YRI, CEU) and (YRI, MEX) had the best performance with (99, 99.7) and (99.3, 99.6), respectively. The (YRI, MEX, CEU) panel led to 99.7%SNPs with $R^2 \geq 0.5$ and concordance of 99.8% for a small improvement in performance. As expected, these metrics decreased somewhat in the masked set, with (92.2, 96.7) for (YRI, MEX, CEU). The three-panel combinations required 3 times the RAM space and took 3 times longer to run than any of the two-panel combinations. Performing the imputation on the more homogenous subsets did not affect the concordance in most sets, which suggests that the (YRI, MEX) and the three-panel combination would lead to reliable genotype imputation in many Hispanic-American populations. These results need validation in other study populations.

Improving the power of genomewide association scans through two-step approaches using external summary data. *F. Dudbridge[1], J.M. Wason[2].* 1) London School of Hygiene and Tropical Medicine, London, United Kingdom; 2) Medical Research Council Biostatistics Unit, Cambridge, United Kingdom.

Two step approaches have been proposed to increase the power of genomewide association scans in some specific settings. In the first step a liberal significance threshold is applied to a test statistic that may not be robust to model assumptions. SNPs that pass this threshold are then analysed using an unbiased test in the second step, which is independent of the first step and has a reduced multiple testing burden. This approach has been developed for specific applications, in particular for family-based association and gene-environment interaction. We give a general formulation of this strategy in terms of pairs of estimators of an underlying parameter, which allows the idea to be extended to a very wide range of analyses. We show how the power of case/control studies can be improved by using external estimates of allele frequencies in the first step. This approach is robust to population differences between the external data and the study at hand, though we find that fairly small differences lead to lower power relative to a standard analysis. An illustration using the WTCCC1 data shows several regions, subsequently validated, which reach genomewide significance in the two-step approach but do not in a standard analysis. With the advent of biobanks and repositories for sharing large scale summary data, two-step analysis will become an important option for all types of exploratory study.

Bayesian Hierarchical Modelling of SNPs and Pathways for Identifying Associated Pathways. *M. Evangelou[1], F. Dudbridge[2], L. Wernisch[1].* 1) MRC-Biostatistics Unit, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; 2) Department of Non-communicable Disease Epidemiology, London School of Hygiene and Tropical Medicine, University of London, London, United Kingdom.

Pathway analysis incorporates the available biological knowledge of SNPs and genes for revealing the underlying genetic structure of the studied phenotype. Several methods have been proposed for identifying pathways associated with a phenotype. Some of these methods combine the pathway SNP p-values into a single pathway p-value, for example Fisher's Method (FM) and Tail Strength Measure (TSM). Other pathway analysis methods look for enrichment of pathways within the list of top ranking SNPs, e.g. Fisher's Exact Test (FET).

We propose a Bayesian Hierarchical framework that includes the pathway membership of SNPs for modelling both pathway level effects and SNP effects within pathways. The phenotype of each individual is assumed to depend both on its genotype data and on the sum of its alleles within each pathway. The goal of our framework is to identify pathways associated with the phenotype; SNP parameters are considered as nuisance parameters and integrated out of the analysis. A sparse normal distribution and a standard normal distribution are considered and tested for the pathway parameters.

We carried out a simulation study for testing the performance of the proposed Bayesian Hierarchical framework and comparing it with other methods like FM, TSM and FET. The results of the study show that our proposed framework with a sparse normal distribution for the pathway parameters outperforms the standard normal distribution as well as the other tested methods.Our proposed framework does not rely on the results of single-SNP analysis, unlike the other methods, and uses the advantage of hierarchical modelling to decrease the signal-to-noise ratio.

Genome-wide association scans for ocular axial length of East Asian populations in Singapore. *Q. Fan[1], X. Zhou[1], CY. Cheng[1,2,3], LK. Goh[1,4,5], VA. Barathi[2], CC. Khor[2,6,7,8], MK. Ikram[1,2,4,9], WT. Tay[2], XL. Sim[7], KS. Sim[7], RT. Ong[1,10], KS. Chia[1,7,10], JJ. Liu[6], E. Vithana[2,3], ES. Tai[1,11], T. Aung[2,3], TY. Wong[1,2,3,12], YY. Teo[1,6,10,13], SM. Saw[1,2,3,10].* 1) Department of Epidemiology and Public Health, National University of Singapore, Singapore; 2) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 3) Department of Ophthalmology, National University of Singapore, Singapore; 4) Duke-National University of Singapore Graduate Medical School, Singapore; 5) Department of Medical Oncology, National Cancer Centre Singapore, Singapore; 6) Genome Institute of Singapore, Agency for Science, Technology and Research, Singapore; 7) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 8) Department of Pediatrics, National University of Singapore; 9) Department of Ophthalmology, Erasmus Medical Center, Rotterdam, the Netherlands; 10) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 11) Department of Medicine, National University of Singapore, Singapore; 12) Centre for Eye Research Australia, University of Melbourne, Australia; 13) Department of Statistics and Applied Probability, National University of Singapore, Singapore.

Ocular axial length (AL) is an endophenotype and major contributor of myopia, which causes vision loss and poses a significant public health concern. AL is highly heritable but the genetic etiology remains unknown. So far, two linkage scans found AL is linked to chromosome 2p24 and 5q; whereas no genome-wide association study (GWAS) has been reported. We conducted a meta-analysis of three GWAS for AL quantitative trait on 3,540 Singaporean individuals including 2,155 Malay adults, 928 Chinese children and 457 Chinese family trios (n=1,163). 460,528 autosomes SNPs genotyped by Illumina 550-Duo or 600-Quad BeadArray were present for the three cohorts after stringent quality control. We identified a significant association of common variants on chromosome 2p13 ($P_{meta} = 3.27 \times 10^{-8}$). The association between the identified SNPs and refractive error remained significant through candidate gene approaches ($P_{meta} = 2.14 \times 10^{-4}$). Further functional analysis revealed that the associated genetic locus encompassing top SNPs significantly up-regulated the myopia progression in the induced mouse model ($P = 7.1 \times 10^{-12}$, fold change of gene expression = 2.16). Our data suggest common genetic variants on chromosome 2p13 might influence susceptibility for ocular axial length and myopia.

An Empirical Approach for Inferring Polygenic Contributions in Genome-wide Case-Control studies. *S. Feng[1], A. Mulas[2], R. Nagaraja[3], C. Sidore[2], M. Uda[2], S. Sanna[2], F. Cucca[4], D. Schlessinger[3], G.R. Abecasis[1], H.M. Kang[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) Istituto di Neurogenetica e Neurofarmacologia del CNR, Cagliari, Italy; 3) Laboratory of Genetics, National Institute on Aging, Baltimore, MD, USA; 4) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy.

Variance component models have been successfully applied to family-based quantitative trait analysis such as linkage studies and heritability estimation for many decades. The availability of high-density genotype data allows us to more precisely estimate the subtle genetic relatedness between reportedly unrelated individuals, and these information has been successfully used in inferring polygenic contributions from genome-wide studies of complex quantitative traits such as human heights or lipid levels via variance component models. Estimation of polygenic contributions from dichotomous traits, however, has been more challenging, because of the heavy computational burden required to make inferences under generalized linear mixed model (GLMM) for large data sets. Lee et al (2011) suggested an approach to estimating polygenic contributions using linear mixed model (LMM) and analytically adjusting it to be unbiased under probit-normal GLMM. We propose a flexible simulation-based approach to estimate polygenic contributions to dichotomous traits under GLMM. Our method can handle a wide range of generative models including logit-nomal and probit-normal GLMMs with an arbitrary ascertainment procedure. Our method empirically adjusts estimates from LMM into GLMM via computationally efficient simulations. Although inference under LMM is still in general computationally demanding, our method leverages the fact that given the spectral decomposition of variance components, parameter estimation under LMM can be reduced into linear time complexity, expediting the inference in orders of magnitude than a naïve approach. We evaluated our approach using extended families of >6,000 Sardinians genotyped with the Metabochip at 196,725 SNPs. Simulations under various distributions of causative loci and their effect sizes, across both logit-normal and probit-normal models, demonstrate that our method is accurate and computationally efficient in estimating polygenic contributions of complex dichotomous traits via a variance component model.

696T

Assessing the causes of heterogeneity in GWAS by combining various eQTL analyzes. *T. Flutre[1,2], X. Wen[1,3], M. Stephens[1,3].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Plant Breeding, Institut National de la Recherche Agronomique, France; 3) Statistics, University of Chicago, Chicago, IL.

By using intermediate phenotypes, e.g. gene expression, current research in quantitative genetics aim at bridging the gap between genotypes and phenotypes at the organismal level, e.g. disease status. Thanks to high-throughput technologies, such analyzes can be performed genomewide, assessing the association of millions of genetic variants with thousands, or more, phenotypic features. Given the high dimension of such datasets and the low fraction of genetic variants expected to be truly associated, several statistical methods have been proposed, notably Bayesian, emphasizing their advantages over frequentist approaches. As a result, numerous quantitative trait loci have been detected, and insights have been gained on the regulation of gene expression.

However, these results were obtained from various populations and cell types, using data measured on different platforms. As it is desirable to combine different studies to improve power, a Bayesian method for single-SNP analysis has been previously developed in our lab to deal with meta-analysis and gene-by-environment interactions. In this work, we apply this method on several existing datasets, each involving several subgroups, e.g. different populations (Stranger et al, 2007) or different cell types (Dimas et al, 2009). Genotype data from each study are imputed with IMPUTE2, using the same, deep and dense, set of genetic variants combining HapMap3 and the pilot project of the 1000 Genomes. Bayes factors and effect size estimates for each subgroup will be made available, e.g. as a custom track for the UCSC genome browser.

From a biological point of view, the aim of this work is to study the amount and extent of heterogeneity among the effect sizes of genetic variants. Indeed, several questions still remain unanswered, such as which genetic variants are functional in which cell types, and how (dis)similar functional variants are among populations. From a statistical point of view, the aim is to assess the reliability of effect size estimates when combining heterogeneous datasets, and to improve prior specification, e.g. via empirical Bayes approaches capitalizing on available data from the ENCODE project.

eHF-algorithm: a fast and scalable method for hidden factor analysis in eQTL studies. *C. Gao[1], J.G. Mezey[1,2].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Genetic Medicine, Weill Cornell Medical College, NY, NY.

We present an expression Hidden Factor (eHF-)algorithm for estimating and accounting for unmeasured environmental factors in an eQTL analysis when simultaneously analyzing thousands of expression probes. Our approach is to include factors without a pre-defined loading matrix within a multivariate factor analysis model, where both the hidden factors and the genotypic effects are treated as random effects with the same underlying distribution. We use a likelihood treatment of this model and implement an Expectation-Maximization (EM) algorithm for the simultaneous analysis of genetic associations and factors, where we provide an exact likelihood ratio test for assessing the pleiotropic effects of eQTL. Using simulated data, we demonstrate that our method can correctly account for an unknown number of hidden confounding factors and, compared to a two-step procedure, a simultaneous analysis of genetic markers and hidden factors is essential for reducing the identification of false positives. With our simulation analysis, we also demonstrate that our method has better scaling and performance than a proposed variational Bayes and a mixed model method designed for hidden factor analysis. We also analyzed existing datasets used for eQTL analysis, including the immortalized cell lines harvested from the HapMap individuals and gene expression measurements in human tissues affected by disease, and demonstrate the ability of our method to identify hidden factors and boost performance in the detection of eQTL.

Genotype imputation accuracy for Mexican Americans using the HapMap Phase 3 reference panels. *X. Gao[1], P. Marjoram[2], R. Mckean-Cowdin[2], M. Torres[1], W.J. Gauderman[2], R. Varma[1].* 1) Department of Ophthalmology and Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA 90033; 2) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA 90033.

Genotype imputation is a vital tool in genome-wide association studies (GWAS) and meta-analyses of multiple GWAS results. Imputation enables researchers to increase genomic coverage and to pool data generated using different genotyping platforms. Based on a reference panel of genetically similar population samples genotyped at a dense set of single nucleotide polymorphisms (SNPs), imputation methods infer genotypes at markers that were not directly typed in a study sample that was genotyped at only a subset of these SNPs. HapMap samples are often employed as the reference panel. Multiple GWAS are targeting Mexican Americans (MA), the most populous and fastest growing minority group in the US. Some consortia are also planning to meta-analyze the MA GWAS results. However, genotype imputation resources for MA are rather limited compared to European Americans at present, largely because of the lack of good reference data. One choice of reference panels for MA is one derived from the population of MA in Los Angeles contained in the HapMap Phase 3 project (MXL). However, a detailed evaluation of the quality of the imputed genotypes derived from the MXL reference panels has not yet been reported. Using the Los Angles Latino Eye Study (LALES) pilot GWAS samples genotyped using the Illumina OmniExpress BeadChips (~733K markers), and simulation studies, we evaluated the accuracy of genotype imputation in MA samples based on the MXL reference panel. Our results will provide insight for genotype imputation in MA using the MXL reference panel.

Genome-Wide Association Study Identifies Four Loci Associated with Eruption of Permanent Teeth. *F. Geller[1], B. Feenstra[1], H. Zhang[1], J.R. Shaffer[2], T. Hansen[3], H.A. Boyd[1], E.A. Nohr[4], N.J. Timpson[5,6], D.M. Evans[5,6], R.J. Weyant[7], S.M. Levy[8], M. Lathrop[9,10], G. Davey Smith[5,6], J.C. Murray[11], T. Werge[3], M.L. Marazita[2,12], T.I.A. Sorensen[13], M. Melbye[1].* 1) Dept. of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Dept. of Human Genetics, Univ. of Pittsburgh, PA, USA; 3) Research Institute of Biological Psychiatry Sct Hans, Roskilde, Denmark; 4) Institute of Public Health, Aarhus Univ., Denmark; 5) MRC CAiTE centre, Univ. of Bristol, UK; 6) School of Social and Community Medicine, Univ. of Bristol, UK; 7) Dept. of Dental Public Health, Univ. of Pittsburgh, PA, USA; 8) Dept. of Preventive and Community Dentistry, Univ. of Iowa, IA, USA; 9) Centre National de Genotypage, Evry, France; 10) Foundation Jean Dausset, Paris, France; 11) Dept. of Pediatrics, Univ. of Iowa, IA, USA; 12) Center for Cranofacial & Dental Genetics, Univ. of Pittsburgh, PA, USA; 13) Institute of Preventive Medicine, Copenhagen, Denmark.

The sequence and timing of permanent tooth eruption is thought to be highly heritable, and can have important implications for the risk of malocclusion, crowding, and periodontal disease. We conducted a genome-wide association study of number of permanent teeth erupted between age 6 and 14 years, analyzed as age-adjusted standard deviation score averaged over multiple time points, based on childhood records for 5,104 women from the Danish National Birth Cohort. Four loci showed association at $P<5 \cdot 10^{-8}$, and were replicated in four independent study groups from the United States and Denmark with a total of 3,762 individuals, all combined p-values were below 10^{-11}. Two loci agreed with previous findings in primary tooth eruption and were also known to influence height and breast cancer, respectively. The two other loci point to genomic regions without any previous significant GWAS results. However, the intronic SNP in *ADK* could be linked to gene expression in monocytes. The combined effect of the four genetic variants was most pronounced between age 10 and 12 years, where children with 6 to 8 delayed tooth eruption alleles had on average 3.5 (95%CI: 2.9-4.1) fewer permanent teeth than children with 0 or 1 of these alleles. During the age period of permanent tooth eruption many important developmental processes take place. Thus, we suggest following up the four reported SNPs in other growth related traits to further elucidate the genetic background of maturation.

700T

Genome-IBDLD: Estimating Pairwise Relatedness and Individual Inbreeding Coefficients and Discovery of Identity by Descent. *L. Han, M. Abney.* Human genetics, University of Chicago, Chicago, IL.

SNP data collected from natural populations allows information on genetic relationships to be established without referencing an exact pedigree. Many methods have been developed to use marker data for this purpose. These methods however are appropriate only when the analyzed pair is very distantly related or when there is no linkage disequilibrium (LD) between markers. We present a method, Genome-IBDLD, of estimating pairwise relatedness and individual inbreeding coefficients for any kind of pair given dense SNP genotypes. We use a new method based on ridge regression of unphased genotypes to account for LD in the identity by descent (IBD) estimation, that does not require phased data. Monte Carlo simulations show that Genome-IBDLD obtains as good an estimate as the IBDLD method based on pedigree information for sibling, avuncular, 1th cousin, 2nd cousin and more distantly related pairs and obtains more accurate genetic relationship matrix than GCTA and PLINK. The method is appropriate also for finding IBD tracts for any kind of pair. Simulations show that it is not only similarly efficient for finding short tracts of IBD as fastIBD/Beagle for distantly related pairs, but also has high power, a low FDR, large sensitivity for finding IBD tracts for closely related pairs and is highly robust to genotype errors. We use Genome-IBDLD to generate highly accurate estimates of genome-wide IBD sharing and discover IBD tracts in the HapMap data. Genome-IBDLD can be applied to thousands of samples with genome-wide SNP data. This is useful for estimation and adjustment for relatedness in association studies. Genome-IBDLD will be incorporated in the freely available IBDLD software package.

Accurate phenotyping is key to the success of genome-wide association studies (GWAS). As part of the electronic Medical Records and Genomics (eMERGE) network, we identified type 2 diabetes (T2D) cases and controls for GWAS, using data captured through routine clinical care across five institutions with different electronic Medical Record (EMR) systems. We developed an algorithm using a combination of ICD9 codes, oral T2D medications, and abnormal glucose or glycated hemoglobin (HbA1c) lab tests. We excluded patients diagnosed with type 1 diabetes and those who were currently being treated with insulin only, had never been on a T2D medication, and did not have abnormal glucose or HbA1c. Controls were required to have ⁄2 clinical visits, no diabetes-related billing codes, no oral T2D medications or insulin, ⁄1 normal glucose values, and no family history of T2D. Our stringent criteria for source and specificity of the data achieved a minimum of 98 and 100% positive predictive values for identification of T2D cases and controls, respectively, compared against clinician review when the T2D algorithm was validated across three eMERGE sites. By collaboratively developing, standardizing and implementing the algorithm across sites, we reliably identified a total of 3,266 cases and 3,286 controls of African-ancestry (AA) and European-ancestry (EA) (AA: 810 cases and 873 controls genotyped on Illumina 1M BeadChips; EA: 2413 cases and 2392 controls genotyped on Illumina 660W BeadChips). Genotype data were collaboratively quality-controlled across all five sites. Logistic regression analyses were performed for T2D case-control status under an additive model, adjusting for age, sex, BMI, study site, and the first two principal components of ancestry in the AA and EA cohorts separately. These results were then combined using standard meta-analytic methods. Our most significant association in the joint meta-analysis, as well as in both the separate AA and EA cohorts, was the previously reported T2D associated SNP rs7903146 in *TCF7L2* (EA $p = 3.0 \times 10^{-10}$, AA $p = 5.3 \times 10^{-7}$, combined meta-analysis $p = 2.1 \times 10^{-15}$). T2D odds ratios for the minor allele were nearly identical to recently published meta-analyses (1.41, 1.64, and 1.46 in the EA, AA, and combined cohorts respectively). This study demonstrates that data derived from EMRs can accurately and reliably identify T2D cases and controls for genetic studies across multiple institutions.

702T

FaST Linear Mixed Models for Genome-Wide Association Studies. *D. Heckerman[1], C. Lippert[1], Y. Liu[1], C. Kadie[2], R. Davidson[2], J. Listgarten[1].* 1) Microsoft Res, Los Angeles, CA; 2) Microsoft Res, Redmond, WA.

Linear mixed models (LMMs) are among the richest class of models used today for genome-wide association studies as they are capable of correcting for population structure, family structure, and cryptic relatedness. Although their popularity is rapidly increasing for this reason, their use on contemporary data sets is limited because the required computations are prohibitive when many individuals are analyzed, with runtime increasing as the cube of the number of individuals and memory footprint increasing as the square of the number of individuals. We introduce a mathematical reformulation of LMMs called FaST-LMM to overcome this barrier, wherein results remain exact, but both runtime and memory footprint become linear in the number of individuals. On data from the Wellcome Trust with 15,000 individuals, our approach is an order of magnitude faster than the state-of-the art LMM implementation. On a data set containing 120,000 individuals, the state-of-the-art implementation is unable to run, whereas FaST-LMM completes in just a few hours.

703T

Genetics of Obesity in Mexican-Americans in Starr County, Texas. *H.M. Highland[1], J.E. Below[2], E.R. Gamazon[2], G.I. Bell[2], N.J. Cox[2], C.L. Hanis[1].* 1) Human Genetics Center, University of Texas, Health Science Center at Houston, Houston, Texas 77030, USA; 2) Department of Medicine, Section of Genetic Medicine, University of Chicago, Chicago, Illinois, 60637, USA.

The prevalence of obesity is increasing at an alarming rate across the United States and most developed countries. Current estimates indicate that 66% of Americans are either overweight or obese. Obesity increases risk for many diseases including type 2 diabetes, cardiovascular disease, stroke, sleep apnea and some cancers. Currently, 32 loci have been reproducibly associated with obesity in genome wide association studies. Only one genome-wide association study has previously been conducted in Hispanic-Americans, a population at particularly high risk of being obese. This makes the present study more important for understanding obesity genetics across populations. The current study utilizes a sample of 813 Starr-County Mexican-Americans with previously undiagnosed diabetes or without diabetes to identify genetic variants associated with obesity related traits. Samples were genotyped on the Affymetrix Genome-Wide Human SNP Array 6.0 and imputed to the HapMap resource using MACH (Li et al. 2006) to a total of 1.97 million SNPs. MaCH2qtl (Li et al. 2006) was used to analyze BMI and identify 22 SNPs with p-values less than $1x10^{-5}$. Top signals are rs10793047 and rs7731488 ($p=8.61x10^{-7}$ and $p=1.24x10^{-6}$, respectively), which map to hypothetical proteins on chromosomes 11 and 5 respectively. Other top SNPs are located in SUMF1 (rs12629402, rs17036134, and rs17036162, $p=1.26x10^{-6}$, $6.90x10^{-6}$ and $9.76x10^{-6}$, respectively) and KCNH5 (rs17100176 and rs1119595, $p= 1.85x10^{-6}$ and $2.89x10^{-6}$, respectively). Further LCL eQTL enrichment was observed for the BMI SNPs with $p<0.001$ ($p=0.0375$). Similar analyses have been conducted for a composite measure of obesity that includes BMI, waist circumference, hip circumference and percent body fat calculated from bioimpedance measures. Through this analysis an additional 17 SNPs with p-values less than $1x10^{-5}$ were identified.

The PhenX Toolkit: Facilitating Cross-study Analysis in Genomic Studies. *W. Huggins[1], H. Pan[1], K.A. Tryka[2], M.J. Phillips[1], N. Whitehead[1], V. Bakalov[1], J. Levy[1], Y. Qin[1], M. Zmuda[1], D. Jackman[1], D. Nettles[1], J. Pratt[1], J.A. Hammond[1], T. Hendershot[1], D. Maiese[1], W.R. Harlan[3], J. Haines[4], H. Junkins[5], E. Ramos[5], L.C. Strader[1], C.M. Hamilton[1].* 1) RTI International, Research Triangle Park, NC; 2) National Center for Biotechnology Information, National Library of Medicine, Bethesda, MD; 3) National Library of Medicine, Chevy Chase, MD; 4) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 5) National Human Genome Research Institute, Bethesda, MD.

Cross-study analyses of genome-wide association studies (GWAS) are needed to increase statistical power and replicate results. However, these analyses have been hindered by the lack of standard measures for risk factors, covariates, and outcomes that are shared by common, complex diseases. To address this need, the PhenX (consensus measures for Phenotypes and eXposures) Toolkit (https://www.phenxtoolkit.org/) offers high-quality well-established measures of phenotypes and exposures for use by the scientific community. The Toolkit contains 295 measures drawn from 21 research domains (fields of research). The measures were selected by Working Groups of domain experts using a consensus process that included input from the scientific community. Because measures relevant to complex diseases (e.g., Cardiovascular and Diabetes) can be found in multiple domains, measures are also organized into Collections, which are groups of measures related to a specific topic or target population (e.g., Diet and Nutrition and Body Size and Composition). For each PhenX Measure, the Toolkit provides a description of the measure, the rationale for including the measure in the Toolkit, protocol(s) for collecting the measure, and supporting documentation. Users can browse by measures, domains, or collections or search the Toolkit using the Smart Query Tool (SQT). Once users have selected some measures, they can download a customized Data Collection Worksheet (DCW) that specifies what information needs to be collected and a Data Dictionary (DD) that describes each variable included in their DCW. To help researchers share data, PhenX measures and variables are being mapped to multiple data standards, including the Unified Medical Language System (UMLS) and Cancer Data Standards Registry and Repository (caDSR). To help researchers find studies with comparable data, PhenX measures and variables are being mapped to studies in the database of Genotypes and Phenotypes (dbGaP). In collaboration with dbGaP staff at the National Center for Biotechnology Information (NCBI), 13 studies from the Gene Environment Association Studies (GENEVA) consortium and 3 studies from the electronic Medical Records and Genomics (eMERGE) network have been mapped to PhenX measures and variables. These mappings are displayed in dbGaP and highlight opportunities for cross-study analysis for researchers who adopt PhenX measures. *Supported by: NHGRI, Award No. U01 HG004597-01.*.

MethLAB - A GUI Analysis Package for Array-based DNA Methylation Data. *V. Kilaru[1], R.T. Barfield[2], J.W. Schroeder[3], A.K. Smith[1,3], K.N. Conneely[2,4].* 1) Psychiatry & Behavioral Sci, Emory University, Atlanta, GA; 2) Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 3) Genetics & Molecular Biology Program, Emory University, Atlanta, GA; 4) Human Genetics, Emory University, Atlanta, GA.

DNA methylation is a type of epigenetic modification that has been associated with numerous complex traits and diseases. The advent of array-based methods to interrogate DNA methylation has led to an explosion of epigenetic data in the literature. These methods include the popular Illumina GoldenGate and Infinium platforms that interrogate DNA methylation of an individual sample across the genome and output beta values that represent the proportion of DNA methylated at a given CpG site. These arrays generate enormous amounts of data, but there are currently no standardized methods available to analyze the data. This obstacle may reduce reproducibility among studies. We have developed a software package called MethLAB using R, an open source statistical language, which can be edited to suit the needs of the user. MethLAB features a front end graphical user interface (GUI) designed to accept and manipulate input data in a flexible format. The back end analyzes the association between beta values and a designated phenotype by fitting a separate linear fixed or mixed effects model for each CpG site. This package can incorporate both continuous and categorical covariates, as well as fixed or random batch or chip effects. It accounts for multiple tests by controlling FDR at a user-specified level. MethLAB outputs a flat text file containing the test statistics (t-statistics and p-values) for each CpG site and indicators for FDR-significant sites. The package produces quantile-quantile plots with confidence intervals to allow users to visually assess whether there is an excess of associated CpG sites. For FDR-significant CpG sites, MethLAB automates plotting of the beta values against the phenotype, with regression lines based on the model specified by the user. Considering the growing interest in DNA methylation studies and the increasing complexity in analyzing methylation data, there is a great need for user-friendly open source software to perform these analyses. With MethLAB, we present a timely and important resource that will allow users with no experience using statistical software to implement flexible and powerful analyses of DNA methylation data.

706T

No evidence for common genetic basis for clustering of metabolic syndrome traits. *K. Kristiansson[1,2], M. Perola[1,2,3], E. Tikkanen[1,2], J. Kettunen[1,2], I. Surakka[1,2], A.S. Havulinna[4], A. Dyslipidemia, hypertension, insulin resistance, and measurements of obesity are key components in definition of the metabolic syndrome (MetS). To date, genome-wide association (GWA) studies have identified several susceptibility genes for these MetS component traits, but there is little evidence on genes contributing to the syndrome as an entity rather than on individual component traits. We conducted a genome-wide association (GWA) study on metabolic syndrome and its component traits in four Finnish cohorts consisting of 2,637 MetS cases free of diabetes and 7,927controls, and followed the top loci in an independent sample with transcriptome and NMR-based metabolome data. Furthermore, we tested for loci associated with multiple MetS component traits using factor analysis and built a genetic risk score for MetS risk. A previously known lipid locus, *APOA1/C3/A4/A5* gene cluster region (SNP *rs964184*), was associated with MetS in all four study samples (P=7.23x10^{-9} in meta-analysis). The primary source of the association was the SNPs effect on triglyceride (TG) (P=2.59x10^{-31}) and high-density lipoprotein (HDL) levels (P=5.83x10^{-8}), which was further supported by a serum metabolite analysis, where *rs964184* associated with various VLDL, TG, and HDL metabolites (P=0.024-1.88x10^{-5}). 22 previously identified susceptibility loci for individual MetS component traits were replicated in our GWA and factor analysis but none of these loci significantly associated with two or more uncorrelated MetS components. A genetic risk score (GRS), calculating the number of alleles in loci associated with individual MetS traits, was strongly associated with MetS status. Our findings suggest that common genetic variation does not explain the clustering of metabolic syndrome traits. The genetic predisposition is likely to result from relatively small effects of multiple genes predisposing to dyslipidemia and abdominal obesity, possibly complemented by low frequency and rare variation, and/or epigenetic modifications.

707T

Genome-wide association studies using Bayesian classification with singular value decomposition identify that nine of the known Crohn's disease susceptibility loci are associated with disease prognosis and the need for surgery. *S. Kwon, D. McGovern, M. Dubinsky, T. Haritunians, S. Targan, K. Taylor, P. Fleshner, A. Ippoliti, J. Rotter, X. Guo.* Med Gen Inst, Cedars-Sinai Med Ctr, Los Angeles, CA.

Genome-wide association studies (GWAS) involve large numbers (p) of single nucleotide polymorphisms (SNPs) and a relatively small number of subjects (n) (p>>n). Conventionally, statistical methods analyze a single SNP at a time, resulting in problems related to multiple testing. Penalized logistic regression methods have been proposed for analyzing multiple SNPs, but the number of SNPs per analysis is limited. To analyze all SNPs simultaneously, we developed the Bayesian classification with singular value decomposition (BCSVD) method. The method achieves a massive dimension reduction by applying singular value decomposition to the design matrix. It utilizes a binary probit model and fits the model using Markov chain Monte Carlo with Gibbs sampler. The significance of SNPs/genes can be determined with the test statistic generated by permutation. Here, we applied the BCSVD method to Crohn's disease (CD) patients to identify genes associated with the need for surgery, specifically intestinal resection. Disease phenotype, and specifically type and indication for surgery, were ascertained by chart review according to agreed criteria. Both single SNP association analysis and the BCSVD method were performed on 521 CD patients (311 with surgery and 210 without surgery) recruited through the Cedars-Sinai IBD center. 412,309 SNPs passed genotype quality controls (HWE <10-5 and MAF<0.05). Among the top 10 SNPs associated with the need for intestinal resection identified by the BCSVD method, 9 SNPs had p-value<10-5 from single SNP association analysis (even though they didn't reach genome-wide significance level). 57 out of 71 CD susceptibility loci that have been reported in recent GWAS studies were either present in our genotype data or had proxies available. With the BCSVD method, we were able to identify that 9 (7 genotyped, 2 proxies) disease predisposing loci (IL12B, SLC22A4, ATG16L1, JAK2, SMAD3, C13or31, PTPN22, and 2 unknown positional candidate genes (14q35 and 5q31)) were also associated with a disease complication, the need for surgery. For each of the 7 genotyped SNPs, the same risk alleles were found associated with the need for surgery and CD susceptibility. This finding implies that disease risk alleles also predict natural history. Since the individual SNPs did not reach nominal significance, but the aggregation did by the BCSVD, this suggests that the BCSVD method is a powerful tool for identifying risk genes in modest size clinical samples.

Identification of gene networks for caries of pit and fissure vs. smooth tooth surfaces through GWAS and protein network integration. *M. Lee[1], K.T. Cuenco[1], Z. Zhen[2], J.R. Shaffer[2], X. Wang[1], M.M. Barmada[2], R.J. Weyant[3], R.J. Crout[4], D.W. McNeil[5], D.E. Weeks[2], E. Feingold[2], M.L. Marazita[1,2].* 1) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV.

The Center for Oral Health Research in Appalachia (COHRA) began evaluating risk factors for dental caries in a population with limited health care access and elevated oral disease. COHRA study families were included in the NIH Gene, Environment Association Studies Consortium (GENEVA), for a genome-wide association study (GWAS) of dental caries. Dental caries is heritable even after adjustments for shared environment. Tooth surfaces subject to caries are divided into pit and fissure (PFS, anatomic landmarks where the enamel folds inward) and smooth surfaces (SMS, any surfaces other than PFS), with heritability estimated as 19-53% and 17-42%, respectively. Multiple genes may control PFS and SMS. GWAS has been conducted on PFS and SMS measures in COHRA-GENEVA subjects, but single SNP results did not evaluate interactions between different genes. We attempted to detect the combined effects of multiple markers/genes included from GWAS. We identified corresponding gene networks by integrating GWAS of PFS and SMS from our study population with existing protein interaction databases.

Demographics and caries status on PFS and SMS in primary dentition (PFS: n=572 and SMS: n=596) were obtained from COHRA-GENEVA subjects. Subjects self-reported as Caucasian and 3-14 years old were included. Illumina 610-Quad platform genotypes were generated by the Center for Inherited Disease Research. Genotype quality control was conducted by the GENEVA Coordinating Center and U. Pittsburgh using standardized protocols. Single-SNP GWAS results were combined with the Protein Interaction Network Analysis (PINA) database using dmGWAS software. dmGWAS identified gene networks through an agglomerative search favoring networks containing low p-value genes from the GWAS.

SNP GWAS results suggest several chromosome regions may be associated with PFS and SMS. By applying network search algorithms that combine GWAS and protein pathway data, we have identified additional genes influencing PFS and SMS caries. Identified modules provide insight into additional gene relationships and help prioritize genes for further inquiry. Support: DE018903, DE014899, DE020127.

Estimating the magnitude and influence of genetic marker errors by comparing conventional WTCCC guideline and further quality control using family and twin relationship. *D.H. Lee[1], M.K. Lee[1], Y.M. Song[2], K. Lee[3], J. Sung[1].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health Seoul National University; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, SungKyunKwan University School of Medicine, Seoul, Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea.

An increasing number of genetic studies are incorporating dense genome-wide single nucleotide polymorphism (SNP) marker information to explore gene-disease associations. The Wellcome Trust Case Control Consortium (WTCCC) guideline is a widely used quality control method for genetic marker cleaning, but the accuracy and the influence of marker errors evading the WTCCC cleaning methods has not been adequately evaluated. WTCCC method mainly depends on the call rates, minor allele frequency and Hardy-Weinberg equilibrium (HWE) test. Any of the three criteria, however, are methods developed to detect genotype errors. In the Healthy Twin Study of Korea, with dense SNP markers (Affymetrix GeneChip v6) and family relationship, we were able to test the validity of each marker using Mendelian (single point) and Non-Mendelian (multipoint) compatibility checks. Additionally, the presence of both genotyped monozygotic twins (MZ) (15 twin pairs) provides index of accuracy among initial 905,017 SNPs (excluding 3,014 duplicated markers) applying WTCCC guideline excluded 124,520 markers (exclusion - HWE incompatibility and call rate <95%). When we further applied Mendelian and Non-Mendelian inconsistency check, 87,608 markers were deleted additionally. Genotyping accuracy was calculated by confidence score and by MZ concordance rate. Confidence score on the Affymetrix platform using birdseed ranged from 0 (most confident) to 1 (least confident). Confidence score (SD) and MZ concordance rate are 0.008 (0.004) and 99.63 for WTCCC guideline application whereas 0.060 (0.047) and 96.52 for no application. Likewise, Confidence score and MZ concordance rate are 0.010 (0.015) and 99.79 for Mendelian and Non-Mendelian inconsistency check application whereas 0.038 (0.040) and 96.87 for no application. Previous studies showed most of genotyping errors removed by WTCCC guideline, but it is not. Mendelian and Non-Mendelian errors still remains. Consequentially, Mendelian and Non-Mendelian compatibility checks of genotype data by using family and twin relationship in GWAS will continue to be an important aspect of human genetics research.

710T

An evaluation of the accuracy of 1000 Genomes-based imputation. *M. Lemire, J. Rangrej, V. Peltekova.* Ontario Institute for Cancer Research, Toronto, ON, Canada.

Genotype imputation is routinely applied in the analysis of genome-wide association studies (GWAS). Genotypes derived from low-coverage, whole-genome sequencing data is available for 629 individuals in release 20100804 of the 1000 Genomes project. Of these, 283 are of European descent (EUR) and includes the CEPH samples from Utah (CEU) that are also available in all releases of HapMap as well as samples from Tuscany, Great Britain, Finland, Puerto Rico and Mexico. Because this data is derived from low-coverage sequencing data, misclassification of the genotype calls may occur. Moreover it is unclear if imputation based on a large set of potentially heterogeneous samples outperform that based on a smaller set of homogeneous samples. We thus aimed to evaluate the accuracy of 1000 Genomes-based imputation. We used data derived from a large-scale sequencing study of colorectal cancer (CRC) cases and controls. Eleven susceptibility regions from published GWAS, totalling 2.2 Mbp, were sequenced in 120 samples. The large majority of the SNPs identified were then genotyped in ~1200 cases of CRC and ~1200 controls using a custom iSelect array from Illumina; 5511 polymorphic SNPs were available after quality control. To evaluate the accuracy of the imputation, we pretended we only had genotyped a typical commercial high-density genotyping array, and used these SNPs along with the 1000 Genomes reference set to impute our remaining SNPs. The accuracy was measured by comparing the actual genotypes to the most-likely imputed calls, using Cohen's Kappa measure of agreement (k). We compared the use of the CEU to the use of the EUR reference sets, and compared MACH and BEAGLE software. Using MACH and EUR, there was more than 90% agreement (k>0.9) between the real genotypes and the most likely imputed calls for 59% of the imputed SNPs (84% among the SNPs with “imputation quality” r2>0.5, following MACH's guidelines). Based on minor allele frequency (MAF), the proportions of SNPs with k>0.9 are 86%, 39% and 14% for common (MAF>5%), uncommon (1%<MAF<5%) and rare SNPs (MAF<1%), respectively. Using CEU as the reference set, these proportions are slightly smaller. We found that MACH generally outperformed BEAGLE. Our results show that imputation is generally accurate, but that the accuracy declines dramatically with allele frequency, and that the potential heterogeneity of the EUR samples does not have a negative impact on accuracy.

711T

Rapid optimization of genotype imputation using parallelization. *J.L. Levy[1], D.B. Hancock[1], G.P. Page[2], E.O. Johnson[1].* 1) RTI International, Durham, NC; 2) RTI International, Atlanta, GA.

Genotype imputation of untyped markers is a computationally-intensive operation that improves power of genome-wide association studies and allows results to be combined across studies. We sought to evaluate imputation using 15 different Hapmap phase III reference panel combinations with optimization criteria of minor allele frequency (MAF), MACH imputation quality (r2), and concordance rate of imputed vs. actual genotype for 10 sets of randomly-masked SNPs. Because of the large number of imputations (15 reference panel combinations x 10 repetitions = 150) we devised a 3-step parallelized imputation procedure using our 172-core computing cluster to both speed performance and generate the optimization metrics. In Step 1 we used MACH to estimate crossover and error rates, which is parallelizable by chromosome. In Step 2 we split the individuals and imputed each one separately on its own compute core, using a version of MACH that we modified for calculating MAF and r2, which were originally not available from MACH when parallelized. In Step 3 we merged output from step 2, and calculated MAF, r2, and concordance. Another modified MACH algorithm, MINIMAC, speeds computing time and produces MAF and r2 values but it does not give the output needed to calculate concordance. We compared total run time of our 3-step strategy on our cluster ("split") vs. a 2-step MACH strategy on a single core ("unsplit") using two different sets of input genotypes (from 595 and 1,071 individuals) and 6 different sets of reference haplotypes (from 116, 124, 134, 250, 366 and 638 individuals), giving a total of 12 split and 12 unsplit times. On chromosome 22, the split runs showed up to a 4-fold reduction in computing time over the unsplit runs, with time savings increasing with larger reference panels or number of input genotypes. The greatest reduction in computing time came from step 2 (up to almost 114-fold), where we split individuals onto separate compute cores. The difference in computing time was even greater for larger chromosomes. In summary we have devised a parallelization strategy for generating metrics for optimizing imputation reference panel selection that shows a substantial improvement over imputation on a single machine. This strategy will also reduce computing time for genome-wide genotype imputation by parallelizing across chromosomes and individuals.

712T

Meta-analysis of genome-wide association studies identifies additional susceptibility loci for psoriasis. *Y. Li[1], S.L. Spain[4], J. Knight[4], P.E. Stuart[2], E. Ellinghaus[3], H.M. Kang[1], W. Chen[1], T. Tejasvi[2], J. Barker[4], G.R. Abecasis[1], J.T. Elder[2,5], R.P. Nair[2], A. Franke[3], R. Trembath[4].* 1) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, Michigan 48109, USA; 2) Department of Dermatology, University of Michigan, Ann Arbor, Michigan 48109, USA; 3) Institute of Clinical Molecular Biology, Christian-Albrechts-University, Kiel, 24105, Germany; 4) Department of Medical and Molecular Genetics, Division of Genetics and Molecular Medicine, King's College London School of Medicine, London SE1 9RT UK; 5) Ann Arbor Veterans Affairs Hospital, Ann Arbor, Michigan 48105, USA.

Psoriasis is a chronic and debilitating disorder of the skin, nails, and joints, affecting about 2% of people of European descent. Its clinical characteristics include epidermal hyperplasia and inflammation. To evaluate the contribution of common genetic variants to psoriasis disease susceptibility, we carried out a meta-analysis of 3 independent recent genome-wide association studies (meta-GWAS): the Collaborative Association Study of Psoriasis (**CASP**, Nair, R.P. *et al., 2009*), a German study conducted in Kiel, (**KIEL**, Ellinghaus E, *et al., 2010*) and a third from the Wellcome Trust Case Control Consortium 2 (**WTCCC2**, Strange *et al., 2010*). Together, these studies constitute a European-origin discovery sample of 4011 psoriasis cases and 7721 controls. Genotypes in each study were imputed using the most recently released (Nov 2010) 1000 Genomes Project CEU haplotypes as a reference. Association analysis was performed on the 8 million imputed SNPs separately within each cohort, followed by adjustment for population stratification (genomic control parameters **CASP** 1.06, **KIEL** 1.09, **WTCCC2** 1.04), and meta-analysis. The discovery results confirmed 15 previously reported psoriasis associated loci: *HLA-C* (p<10-300), *IL12B* (p<10-25), *TRAF3IP2* (p<10-20), *TNIP1* (p<10-16), *LCE3D* (p<10-14), *TNFAIP3* (p<10-13), *IL23R* (p<10-13), *IL23A* (p<10-11), *REL* (p<10-10), *TYK2* (p<10-9), *RPS26* (p<10-9), *NFKBIA* (p<10-8), *RNF114* (p<10-8), *IFIH1* (p<10-8), and *ERAP1* (p<5x10-8), and showed strong support for another 3 known loci: *NOS2* (p~6x10-8), *FBXL19* (p~8x10-7), and *IL13* (p~8x10-6). We also identified a novel locus passing the genome-wide significance threshold and several other novel loci approaching it. Current replication efforts are being prioritized based on p-values, involvement in IBD (Inflammatory Bowel Disease), and functional relationships with known psoriasis loci as determined by GRAIL (Gene Relationships Across Implicated Loci). Our study validates and extends the catalog of psoriasis susceptibility loci and will eventually provide a better understanding of the pathogenesis of psoriasis.

713T

Identification of 6 Novel Susceptibility Loci for Androgenetic Alopecia and Their Association with Common Disease: A Genome-Wide Association Study. *R. Li[1], F. Brockschmidt[2,3], A. Kiefer[4], H. Stefansson[5], D.R. Nyholt[6], K. Song[7], S.H. Vermeulen[8,9], S. Kanoni[10], D. Glass[11], D. Waterworth[7], F. Geller[12], S. Hanneken[13], S. Moebus[14], C. Herold[15], G.W. Montgomery[6], P. Male pattern baldness, also known as androgenetic alopecia (AGA), is a highly heritable condition, and has been associated with coronary heart disease and prostate cancer. Previous susceptibility loci have been described on chromosomes 20 and the X chromosome, but these loci explain a minority of its heritable variance. We therefore conducted a large-scale meta-analysis of seven genome-wide association studies for male pattern baldness in 12,806 individuals of European ancestry. Genotype scores were created by combining the risk alleles of novel and established susceptibility loci. We identified six novel susceptibility loci in or near 17q21.31, *HDAC4*, *HDAC9*, *AUTS2*, *TARDBP* and *SETBP1* that reached genome-wide significance ($P = 2.62 \times 10^{-9}$ - 1.01×10^{-12}) and confirmed known loci. Unexpectedly, the 17q21.31 locus harbored genome-wide significant alleles in the *MAPT* gene, which have also recently been described to be associated with Parkinson's disease at a genome-wide significant level. Further other genome-wide significant alleles at 17q21.31 have been demonstrated to be under negative selection pressure and are associated with decreased fertility in women. *HDAC4* and *HDAC9* act as transcriptional co-repressors and play an important role in prostate cancer progression. Individuals in the highest risk quartile of the genotype risk score had a five-fold increased risk of male pattern baldness (OR = 5.61, $P = 2.7 \times 10^{-20}$) compared to the individuals in the lowest quartile. In conclusion, our results highlight unexpected associations between AGA, Parkinson's disease and fertility, as well as expand our understanding of the role of the androgen pathway in susceptibility to male pattern baldness.

The impact of genomic coverage on the power to detect additional variants with genome-wide association studies. *K.J. Lindquist[1], E. Jorgenson[2], T.J. Hoffmann[1], J.S. Witte[1].* 1) Department of Epidemiology and Biostatistics, Institute for Human Genetics, University of California, San Francisco, CA; 2) Ernest Gallo Clinic and Research Center, Department of Neurology, University of California, San Francisco, CA.

Genome-wide association studies (GWAS) have identified many variants that are associated with complex human diseases and traits. Most of these associations have been discovered by genotyping common single nucleotide polymorphisms (SNPs) using one of the early generation of GWAS microarray SNP chips. The latest generation of GWAS chips promises to offer better coverage of the genome by genotyping more SNPs that are in linkage disequilibrium (LD) with a larger proportion of the variants across the entire genome. This improvement is made possible by the availability of the 1000 Genomes Project data, which has identified many novel, less common SNPs in diverse populations. The new GWAS chips should enable the discovery of some additional associations that may have been missed by previous studies, but it is not clear how many more. In this study, we estimate how many additional SNPs might be found to be associated with several complex diseases that have been studied and recorded in the Catalog of Published Genome-Wide Association Studies (www.genome.gov/gwastudies). The studies all used a popular GWAS chip measuring close to a million SNPs, and the genomic coverage of this chip was calculated using the 1000 Genomes pilot data as a reference (1000 Genomes Project Consortium, Nature 467(7319), 2010). The power to detect the effect size of each SNP associated at p<1x10^-5 with each disease was calculated using a method that takes the coverage of the chip into account (Jorgenson and Witte, Am J Hum Genet 78(5), 2006). The power to detect the same effect size for each SNP was calculated using one of the newer commercially available chips with approximately 2.5 times as many SNPs and better coverage of the genome. The number of false negatives was compared under the two scenarios to determine how many additional SNPs might be associated using the larger chip. For eight diseases (breast cancer, chronic lymphocytic leukemia, coronary heart disease, hypertension, major depression, schizophrenia, age-related macular degeneration, and type 2 diabetes) and 31 SNPs included in this study, we estimated that an additional 7 SNPs could be found to be associated using the larger chip for these diseases combined. Future work will explore the impact of genomic coverage on the power to detect associations using additional diseases and chips with different SNP densities.

Obesity and its resulting complications comprise a major health care burden. To find additional genetic contributors to obesity, the Genetic Investigation of ANthropometric Traits (GIANT) Consortium is conducting a meta-analysis of association data with BMI in 198,846 adults of European ancestry. This effort uses data from 45 existing genome-wide association studies (GWAS) and 29 studies genotyped for the Metabochip, a custom-designed SNP genotyping array of ~200,000 markers focused on metabolic and cardiovascular traits. Metabochip includes approximately 5,000 of the most strongly associated SNPs from the previous meta-analysis for BMI (Speliotes et al., 2010) that did not reach genome-wide significance. In a meta-analysis of only Metabochip data (n=79,285), we confirmed at genome-wide significance ($p<5*10^{-8}$) ten loci previously associated with BMI and three novel regions (*GPR61*, *AGBL4*, and *CADM1*). 73% of independent SNPs ($r^{2<0.1} < 0.1$) on the Metabochip selected as potentially associated with BMI showed consistent effect direction with the recent GIANT BMI GWAS meta-analysis (1,730 of 2360 compared to 1180 expected; $p<1*10^{-100}$). In a combined meta-analysis of all 198,846 individuals on the 100,077 SNPs available in both GWAS and Metabochip meta-analyses, we identified 39 apparently independent loci reaching genome-wide significance ($p<5*10^{-8}$). These include 28 of 32 (88%) previously established BMI-related loci and eleven regions not previously reported as associated with obesity-related or metabolic traits. New association signals include *AGBL4*, *HIP1*, *OLFM4*, and *NLRC3*, genes associated with inflammatory diseases, and near *FHIT*, *AMPD2*, and *AK5* associated with purine metabolism. We also identified new associations near genes for cell adhesion (*CADM1*), cell-cell interactions (*INADL*), and tyrosine metabolism (*C9orf4*). An association with BMI at the diabetes-associated *TCF7L2* variant indicates a link between obesity and glucose and insulin homeostasis. Collectively, these new loci suggest additional pathways and mechanisms underlying the biology of obesity, potentially opening new avenues for research and therapeutic intervention. In summary, our extensive follow-up effort using the Metabochip has been effective in identifying novel BMI-associated loci, and suggests that many of the loci not reaching conventional levels of genome-wide significance likely contain additional true associations.

Identification of novel associations using genome-wide penalized regression for height, white blood cell count, and platelet count in African-Americans within the Women's Health Initiative. *B.A. Logsdon, C.L. Carty, A.P. Reiner, J.Y. Dai, C. Kooperberg.* Public Health Sciences Div., Fred Hutchinson Cancer Research Center, Seattle, WA.

Genome-wide association studies (GWAS) to date have identified over 1000 common variants associated with human traits. For many complex traits, including height and platelet count, the majority of these variants have a small effect, leaving a significant proportion of the heritable variation unexplained. To increase statistical evidence for additional associations beyond those that reach a stringent genome-wide significance threshold of marginal association, we use a penalized regression methodology. Our methodology incorporates all approximately 900,000 genotyped single nucleotide polymorphisms (SNPs) within the study in a single multiple regression model, where the identified solutions are constrained to be highly sparse based on our specific choice of penalty. Using data from the Women's Health Initiative SNP Health Association Resource (SHARe) GWAS of African-Americans, we demonstrate that our penalized regression method has power to detect novel associations beyond those that reach a stringent Bonferroni cutoff of marginal association. We run multiple empirical null simulations to choose a significance cutoff for the output of our algorithm to control the Type-1 error rate. Our methodology, which we call “variational Bayes model selector” (VBMS), is designed specifically to identify sparse, multiple locus models, as well as the degree of sparsity of the models, such that there are few false positives included within a model for a given ultra-high dimensional GWAS data-set. This is achieved through a stringent “spike-and-slab” prior and a fast and highly scalable variational Bayes approximate inference algorithm. Combined with empirical null simulations to control the Type-1 error rates, we demonstrate that the VBMS algorithm is a powerful tool in the analysis of GWAS for elucidating additional loci contributing to heritable variation for body height, platelet count, and white blood cell count within a minority cohort.
