The 12th International Congress of Human Genetics and the American Society of Human Genetics 61st Annual Meeting October 11-15, 2011 Montreal, Canada

POSTER ABSTRACTS

The letters **W**, **T**, or **F** of the program/abstract/board number indicate the day (i.e., Wednesday, Thursday or Friday) on which authors display their poster and present their work. The number indicates the board to use for displaying your poster (on the day of your presentation only).

	Abstract/ Poster Board #'s
Wednesday, Poster Session I, 2:00 pm – 4:00 pm	
Cardiovascular Genetics	325W-380W
Complex Traits: Theory and Methods	381W-433W
Evolutionary and Population Genetics	434W-495W
Psychiatric Genetics, Neurogenetics and Neurodegeneration	496W-610W

Genotype-phenotype correlation in hypertrophic cardiomyopathy: evaluation of a new slice mutation by minigene functional assay. *E. Maioli[1], M. Marini[2], M.I. Parodi[1], M.L. Galli[1], M. Castagnetta[1], D.A. Coviello[1], R. Ravazzolo[2], P. Spirito[3], L. Perroni[1].* 1) Laboratory of Human Genetics, E.O. Ospedali Galliera, Genova, GE, Italy; 2) Laboratory of Molecular Genetics, IRCCS, Istituto Giannina Gaslini, Genova, Italy; 3) Cardiology Unit, E.O. Ospedali Galliera, Genova, GE, Italy.

Hypertrophic cardiomyopathy (HCM) is the most common genetic cardiac disease affecting 1 in 500 people. The prevalence is greater in males than in females. HCM, defined as unexplained thickening of the left ventricle, represents the most common cause of premature sudden cardiac death (SCD) in the young. Morphologically, HCM can manifest with negligible to extreme hypertrophy, minimal to extensive fibrosis and myocyte disarray, associated or not with left ventricular outflow tract obstruction. The six most common genes involved in HCM are) -myosin heavy chain MYH7, cardiac myosin binding protein C (MYBPC3), cardiac troponin T (TNNT2) , cardiac troponin I (TNNI3), tropomyosins-1 (TPM1), (-actin 1 (ACTC1). Testing for these genes led to identify disease-causing mutations in 30-62% of unrelated HCM patients across the various cohorts tested around the world. One of the major features of HCM is its marked genetic and phenotypic heterogeneity. Carriers of HCM mutations may present clinical course that range from benign forms to malignant forms with a high risk of cardiac failure or sudden cardiac death. This variability in expression is also seen among family members sharing the same mutation. This variable expressivity, which confuses genotype/phenotype correlations, could be partially explained by both environmental influences and genetic modifiers. In case of novel mutations at splice sites or adjacent regions, analysis of mRNA is virtually unfeasible because of the lack of cardiac tissue, where sarcomeric genes are expressed. Here we report on a minigene assay used to overcome this problem in a case of an undescribed putative splicing mutation in the MYBPC3 gene. A HCM affected newborn, deceased at 15 days, was double heterozygous for two mutations of the MYBPC3 gene c.772G>A and c.2414-1G>A. The paternal mutation c.772G>A was reported as causative of HCM. The c.2414-1G>A mutation, involving a splice site was inherited from the unaffected mother and never reported in the scientific literature. It was absent in 500 control chromosomes. The position of the nucleotide substitution and the bioinformatic analysis (Alamut Splicing Predictions) suggested that it could be causative of a splicing abnormality with removal of the functional splice site. As MYBPC3 is selectively expressed in the heart and no cardiac tissue of the proband was available, expression studies could not be performed. To overcome this problem minigene splice assay was performed.

326W

BRAP, encoded by a gene associated with myocardial infarction, binds several key inflammatory molecules. *K. Ozaki[1], Y. Onouchi[1], Y. Nakamura[2], T. Tanaka[1].* 1) Cardiovascular Disease, Center for Genomic Medicine, RIKEN, Yokohama,; 2) Laboratory of Molecular Medicine, Human Genome Center, Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Myocardial infarction (MI) is a multifactorial disease and among the leading cause of death in the world. The pathogenesis includes chronic formation of plaque inside the vessel wall of the coronary artery and acute rupture of the artery, implicating a number of inflammatory molecules. We have identified a genetic association of a variant in *LGALS2*, encoding galectin-2 that binds an inflammatory cytokine lymphotoxin-alpha (LTA) protein encoded by a gene conferred risk of MI, with the disease. We also showed that a functional variation in *BRAP*, encoding a galectin-2 binding protein, associated with susceptibility to MI in Asian populations. We have found that the BRAP protein seemed to regulate the activity of NF kappa B, a central transcription factor of inflammation. To clarify detailed function of BRAP in the pathogenesis of MI, we searched for its binding partners by using an S-protein tag pull down method and identified several molecules related to cell proliferation and inflammation. TNF receptor-associated factor 5 (TRAF5) was one of them, which plays an important role in the TNF receptor mediated inflammatory systems. Interestingly, we also identified TNF receptor associated protein 1(TRAP1) as a binding partner of BRAP. Combined with previous results that galectin-2 protein binds with lymphotoxin-((LTA; also known as TNF-( ), known as one of the cytokines produced at earliest phase of vascular inflammatory processes, and regulates its extracellular secretion, we hypothesized BRAP-galectin-2 pathway plays a pivotal role in inflammatory signal cascade, specifically TNF receptor mediated inflammation and thereby influence the MI susceptibility.

327W

Hierarchical clustering of genetic variants according to their effect size on multiple lipid phenotypes. *J. Engert[1,2,3], S. Bailey[2], P. Lee[3], N. Rudzicz[3], I. Karp[4,5].* 1) Cardiology Division, Department of Medicine, McGill University Health Centre, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 4) University of Montreal Hospital Research Centre, University of Montreal, Montreal, PQ, Canada; 5) Department of Social and Preventive Medicine, University of Montreal, Montreal, PQ, Canada.

The results of many genome wide association (GWA) studies have recently been published. However, they frequently analyze only one disease state or phenotype at a time. We reasoned that an analysis of multiple related phenotypes could lead to important insights into their shared genetic etiology. The Global Lipids Genetics Consortium (GLGC) meta-analysis recently made available the p-values for 2.2 million SNPs in their association tests of four lipid traits in >100,000 individuals. Using publicly available allele frequencies, we converted the p-values to effect sizes and then applied hierarchical clustering to the SNPs based on their estimated shared effect sizes across the four lipid traits: total cholesterol, LDL-cholesterol, HDL-cholesterol and triglycerides. Clustering was performed using Cluster, a package initially developed for clustering of microarray data developed by Michael Eisen. By this naïve adaptation of the original application, SNPs are treated analogously to genes. An eigenvector is calculated from the effect size profile across the traits for each SNP. Resulting eigenvectors are then compared using various similarity metrics. In this analysis we compare correlation and Euclidean metrics with no data normalization or transformation. We hypothesize that clustering of effect sizes may provide a more intuitive interface for the identification of genes that share a similar pathway in the control of lipid metabolism. By incorporating our knowledge of known lipid genes and their cluster assignment, we are able to assign novel genes to known functional pathways. This is important given the multiple tissue types that play a role in plasma lipid traits.

328W

Unraveling the genetics behind lymphedema with whole exome sequencing and near-infrared fluorescence imaging. *M.L. Gonzalez-Garay[1], C.T. Caskey[1], E.M. Sevick[1], O. Hall[1], C.E. Fife[2], E.A. Maus[2].* 1) Institute of Molecular Medicine, University of Texas, 1825 Pressler, Houston, TX; 2) UT Medical School and MHH Wound Care and Lymphedema Clinic, 6410 Fannin, Suite 600, Houston, TX 77030.

Lymphedema is a condition of irreversible tissue swelling caused by a compromised lymphatic system. The disease affects both males and females, sometimes with onset at puberty. Primary lymphedema (PL) has been attributed to genetic causes since the late nineteenth century. There are five known genetic causes of PL (FLT4, FOXC2, SOX18, CCBE1, and CJC2); however the majority of patients with lymphedema do not possess mutations in these genes. When individuals present with lymphedema after trauma or infection, the disease is termed secondary lymphedema (SL). Yet to date, there have been no human genetic studies that utilize next generation sequencing (NGS) for discovery of gene variants across the entire genome or exome that may be causative for either primary or secondary lymphedema. We studied families with multiple affected individuals recruited from the MHH-WCLC. The lymphatic phenotype of family members was non-invasively imaged used NIR fluorescence to directly visualize lymph pumping in the arms and legs and to detect lymphatic vascular anomalies i. Whole exome capture and deep sequencing was used to identify disease gene candidates for individual families. After NGS data analysis, common variants were eliminated by filtering against our control set consisting of samples from 80 non-related lymphedema-free individuals. The remaining variants were annotated using our annotation pipeline and non-synonymous coding variants (ns-cvs) were isolated. We performed co-segregation analysis followed by a triage process in which we evaluated the possible role of the mutated gene on the lymphatic system and the damage of the variant on the protein. Variants were validated using an orthogonal system to detect any false positives. In addition, copy-number variant (CNV) analysis in ongoing to eliminate the possibility that a large insertion or deletion responsible for the observed phenotype. We have identified two rare alleles each in a pair of interactive proteins that participate in the HGF/c-MET and PI3K pathways as the most likely candidates for lymphedema. Two probands, from a single family, inherited the two alleles (one from maternal and the other from paternal origin). Since the mother of the probands developed secondary lymphedema we are hypothesizing that the paternal allele may act as a modifier. Future work in our lab will be directed to experimentally demonstrate the biological significance of this finding.

Genome-Wide Association Study of Transcripts for Genes Implicated in GWAS Studies for Coronary Artery Disease and Blood Phenotypes. *C.J. O'Donnell[1], A.D. Johnson[1], A. Hendricks[1], S. Hwang[1], J.E. Freedman[2], X. Zhang[1].* 1) Division of Intramural Research, National Heart, Lung and Blood Institute; the NHLBI's Framingham Heart Study; 2) Department of Medicine, University of Massachusetts Medical School.

Introduction: Genome-wide association studies (GWAS) have uncovered many loci associated with heart diseases. However, data remain sparse regarding causal/functional genetic variants within implicated loci. We sought to identify regulatory variants (cis-eQTLs) affecting gene expression levels of 96 transcripts selected by their proximity to SNPs discovered in prior GWAS. **Methods**: 1846 participants of the Framingham Heart Study Offspring cohort were included. Total RNA was isolated from leukocytes. High-throughput qRT-PCR TaqMan assays were used to measure gene expression. A total of 96 genes were chosen from top loci in published GWAS studies associated with coronary artery disease (CAD) and blood risk factor traits including haemostatic factors, lipid levels, and RBC count. A GWAS analysis for each of the 96 transcripts was conducted using an additive regression model applied to 2.5 million imputed SNPs adjusting for age, sex and expression level of 3 housekeeping genes. SNPs associated < 100kb of each gene were defined as cis-eQTLs. **Results**: On average, ~150 SNPs are located within 100kb of each gene. Over 1/3 of these genes (N= 35) harbor at least one *cis*-eSNP with P < 0.0005, suggesting trait-associated loci often harbor eQTLs. Notably, the expression level of 10 genes was strongly associated with >1 *cis*-eSNPs (P<5e-08). Among them, most genome-wide significant eSNPs included those for ABO (P<1e-91), FADS2 (P<6e-73), LPL (P<1e-52), APOC2 (P<2e-36), FNTB (P<2e-22), CDKN2B (P<2e-13), FAM117B (P<3e-11), C6orf184 (P<7e-11), ANRIL (P<5e-10), and SCARA5 (P<4e-08). When we examined the NHGRI GWAS catalog, we found these *cis*-eSNPs were significantly associated with CAD risk factors. For example, eSNPs associated with ABO gene expression in our study are also associated with multiple traits including hematological and biochemical traits, plasma E-selectin levels, pancreatic cancer and CAD. Further, significant ABO eSNPs are also reported by other genome-wide cis-eQTL studies in monocyte and CD4+ cells. In *trans*-eQTL analyses we found many SNPs located on different chromosome strongly associated with the expression level of several target genes (P<5e-08). **Conclusion**: Many strong *cis*-acting regulatory variants are localized within loci implicated by GWAS of heart disease/risk factors. Our data also suggest the existence of important *trans*-acting variants. Genetic analysis of gene expression may help identify alleles implicated in disease risk.

GENETIC DETERMINANTS OF MULTIPLE CIRCULATING INFLAMMATORY BIOMARKERS AND THEIR RELATIONSHIP TO INCIDENT HEART FAILURE. *V.K. Topkara[1,2], J. Chu[2], C.C. Gu[2,3].* 1) Department of Medicine, Washington University School of Medicine, Saint Louis, MO; 2) Division of Biostatistics, Washington University School of Medicine, Saint Louis, MO; 3) Department of Genetics, Washington University School of Medicine, Saint Louis, MO.

Background: Activation of inflammatory signaling pathways including TNF-alpha, IL-6, and IL-18 have been implicated in the pathogenesis of heart failure. However, therapies targeting these molecules have not yet proven to be a clinically effective strategy. We sought to profile genetic determinants of six inflammatory biomarkers commonly used in clinical medicine, via genome-wide association (GWAS) analysis of biomarker levels and systematical review of biomarker-associated SNPs for their associations with heart failure incidence and/or mortality. Material and Methods: 2201 patients with complete serum biomarker level data on TNF, TNFR2, IL-6, IL-18, adrenomedullin, and CD40 ligand inflammatory biomarkers from the Framingham Heart Study Offspring Cohort were included in the analysis. Genotyping was performed using Affymetrix 500K Array as detailed in the Framingham SNP Health Association Resource. GWAS was performed using MERLIN to identify variants significantly associated with log-transformed serum biomarker levels. Candidate loci (p-value $<10^{-5}$) were ranked based on number of hits on the 6 biomarkers as endophenotypes. Highly ranked significant genes (score greater than 3) were further investigated for established associations with heart failure through online search. Results: A total of 361 SNPs (only 1 common) were significantly associated with serum inflammatory biomarkers traits at a p-value of $<10^{-5}$. Candidate regions associated with highest rank scores were FIGN-CRB14 for TNF trait, DTWD2-SEMA6A for TNFR2 trait, CDCA7-SP3 for IL-6 trait, SPAST5 for IL-18 trait, C4orf67 for adrenomedullin trait, and AUTS2 for CD40 ligand trait. We identified 4 variants in upstream of LRIG3 gene which was significantly associated with serum IL-6 levels and previously shown to be associated with incident heart failure in African-American population. None of the other candidate gene variants were previously shown to be related to heart failure incidence or mortality. Interestingly, 11 out of 56 candidate genes were shown to be associated with neuropsychological disorders. Conclusion: Serum inflammatory biomarker traits appear to have distinct genetic determinants. Vast majority of the genetic markers associated with serum inflammatory biomarkers have not been associated with heart failure pathogenesis or outcome, however such relationship seems to exist for neuropsychological disorders.

331W

Assessment of a possible relation between osteoporosis and hypertension in spontaneously hypertensive rats and recombinant inbred strains. *R. El Bikai[1], P. Dumas[1], J. Peng[1], S. Koltsova[1], V. Křen[2], M. Pravenec[3], O. Seda[1], J. Tremblay[1], P. Hamet[1].* 1) CHUM Research Center (CRCHUM), Montréal, Québec, Canada; 2) 1st Medical Faculty, Charles University, Prague, Czech Republic; 3) Institute of Physiology, Academy of Sciences of the Czech Republic,.

Aim: Osteoporosis and hypertension are two age related diseases that could be associated with accelerated ageing. Our project focuses on studying the common genetic determinants related with the progression of hypertension and the changes in bone structural parameters associated to osteoporosis. Methods: The spontaneously hypertensive rats (SHR) exhibit a gradual increase in blood pressure during puberty and young adulthood that resembles what is seen in human essential hypertension. In addition to high blood pressure, SHR display many defects related to calcium handling and abnormal bone mineralization. Therefore, the SHR strain and the SHR-derived recombinant inbred strains (RIS), the HXB / BXH set, will serve as our genetic model to study these two phenotypes. RIS are a unique opportunity to study genetically identical animals at different ages. They are considered as a very valuable tool for genetic studies. More then 20,000 single nucleotide polymorphisms are mapped across the HXB/BXH genome and are publicly available. The individual RIS carry fixed different combinations of the parental genotypes which allow the dissection and mapping of the polygenic phenotypes segregating in the RIS. Systolic, diastolic, temperature as well as heart rate were assessed by telemetry measurements at 3, 6, 9 and 12 months of age of 3 RIS and the SHR. The structural parameters of the proximal tibia bone were obtained from in vivo micro-CT scans in the same animals to assess the microarchitectural changes. Results: The results showed that the SHR and the HxB 17 strains displayed the highest significant blood pressure (P<0.0001)compared to the other strains as shown in our telemetry results. The scanning of the proximal tibia bone showed that the HxB 17 and HxB 13 develop an osteoporotic phenotype while ageing since they display a gradual decrease in the bone trabecular volume and in trabecular number (P<0.0001). Conclusion: Our data indicate the existence of strain differences in bone parameters as well as in blood pressure. This phenotypic study allows the assessment of strain distribution pattern of the traits which will then serve to map the genetic loci responsible for the observed differences.

332W

Associations between fibrinolysis pathway genes and ischemic stroke in young adults. *Y. Cheng[1], Y.J. Kim[1], J.W. Cole[2,3], S.J. Kittner[2,3], B.D. Mitchell[1].* 1) Department of Medicine, University of Maryland School of Medicine, Baltimore, MD; 2) Department of Neurology, Veterans Affairs Medical Center, Baltimore, MD; 3) Department of Neurology, University of Maryland School of Medicine, Baltimore, MD.

In healthy individuals, there is a dynamic balance in the processes of clot formation (coagulation) and clot dissolution (fibrinolysis). Ischemic stroke (IS), which can occur when a cerebral vessel is blocked by a fibrin-containing clot, accounts for 87% of all stroke. Therefore, fibrinolysis is an important candidate pathway for IS and its subtypes. We tested 431 SNPs from 12 genes (*PLAT*, *FGG*, *FGA*, *FGB*, *F13A1*, *SERPINE1*, *F2*, *SERPINB2*, *CPB2*, *PLG*, *PLAU*, *F2R*) in the fibrinolysis pathway for association with IS and its subtypes. SNPs were genotyped by Illumina Omni1-Quad array or imputed in 448 cases and 498 controls of European ancestry (EA) and 381 cases and 352 controls of African ancestry (AA), aged between 15-49 years old. SNPs with call rates<95%, HWE P-value<1.0E-7 and minor allele frequency<1% were excluded from analysis. Single SNP association testing was performed using logistic regressions adjusting for age, recruitment stages and population structure in EA and AA, separately. To obtain a gene-set or pathway-set p-value, we used the set-based test implemented in PLINK v1.07 to obtain the set-specific statistic (i.e. the mean of those single SNP statistics that had P<0.05 within the gene or fibrinolysis pathway), and the empirical p-value for the set-specific statistic was calculated by permutation (N=1,000) to maintain the correlation structure among SNPs. SNP-level analyses did not reveal any consistent associations with individual SNPs that replicated across ethnic groups. In gene-based analysis, *PLAU*, a serine protease involved in degradation of extracellular matrix, cell migration, and proliferation and which may affect affinity for fibrin-binding, was significantly associated with overall IS in both EA (P=0.03) and AA (P=0.01), although neither *PLAU* nor any other gene showed consistent associations across ethnic groups in subtype analyses. A test of association with the entire fibrinolysis pathway revealed this pathway to be significantly associated with cardioembolic (CE) stroke in EA (P=0.017) but not with any other stroke subtype or with overall IS. Our data supports a pivotal role for fibrinolysis in the etiology of CE strokes. The fibrinolysis-CE stroke association is particularly interesting in light of the fact that CE stroke is caused by arterial occlusions presumably due to an embolus arising in the heart, and an individual's ability to break down the fibrin clot could impact one's susceptibility to this form of stroke.

333W

FBN1 and _TGFBR2_ mutations in patients with bicuspid aortic valve. *N.R. Abdulkareem, G. Arno, J.A. Aragon-Martin, A.H. Child, M. Jahangiri.* Cardiac and Vascular Sciences, St. George's University of London, London, UK.

Fibrillin-1 expression has been shown to correlate with the differentiation of cushion mesenchymal cells into mature valve cells; therefore its deficiency may account for the development of bicuspid aortic valve (BAV) and the associated more fragile aortic wall which is prone to aneurysmal dilatation. The intrinsic aortic wall properties of decreased fibrillin-1 content have been suggested to be the culprit in aortic aneurysm dilatation associated with BAV. Loss of transforming growth factor-beta receptor 2 (TGFBR2) function can lead to a wide spectrum of connective tissue disorders, and mutations in TGFBR2 have been identified in patients affected by clinically overlapping Marfan-related disorders e.g. thoracic aortic aneurysm and dissection (TAAD2). Fibrillin interacts with TGF-) , collagen and elastin to maintain the mechanical strength and architecture of the aortic wall and so mutations in *FBN1* or *TGFBR2* lead to dysregulated TGF-) signalling causing an increased extracellular matrix degradation and apoptosis resulting in aortic aneurysm. As a result it is important to determine if mutations in *FBN1* or *TGFBR2* are causative in BAV development and related aortic aneurysm formation. A consecutive series of 35 well characterised UK Caucasian BAV patients were included in our study (age, 59.26±12.65 years). BAV was confirmed at surgery. Twenty one patients had concomitant aortic root aneurysm. Patients with Marfan syndrome or other diagnosed connective tissue diseases were excluded. Genomic DNA was extracted from venous blood, and polymerase chain reaction was performed to amplify all 65 *FBN1* and 7 *TGFBR2* exons including the intron/exon boundaries. Targeted gene sequencing was carried out and results were analysed to check for gene mutations and single nucleotide polymorphisms. No pathogenic mutations in either *FBN1* or *TGFBR2* were identified in our series. Other possible candidate genes important in outflow tract development e.g. *GATA5* are currently being studied.

Association study of Fms-related tyrosine kinase 1 (FLT-1) gene polymorphisms with the occurrence of coronary artery disease in Koreans. *p. ahram[1], S. Dong-Jik[1,2], P. Boram[1,3], S. Nak-Hoon[1,3], L. Jin-Woo[1], K. Jisun[1], P. Sungha[1,4], L. Sang-Hak[1,4], J. Yangsoo[1,4].* 1) Cardiovascular Genome Center, Yonsei University College of MedicineYonsei Cardiovascular Genome Center, seoul, Korea; 2) Yonsei University Research Institute of Science for Aging; 3) Department of Biostaistics, Yonsei University College of Medicine; 4) Cardiology Division, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Republic of Korea.

Fms-related tyrosine kinase 1(FLT1) gene encodes a member of the vascular endothelial growth factor receptor(VEGFR) family. The FLT1 protein binds to placental growth factor(PGF) and plays an important role in angiogenesis and vasculogenesis. The role of these factors by angiogenesis in condition of atherogenesis has been an object of active research. Several studies have reported that the levels of FLT1 and VEGF are elevated in patients with cardiovascular risk factors such as hypertension, hyperlipidemia, and atherosclerosis. As far, FLT1 molecule is known to be positively or negatively associated with various cardiovascular diseases, therefore, results of association studies of FLT1 with CAD have been controversial. Thus, we carried out a case-control study to evaluate the presently controversial question of whether FLT1 gene polymorphisms are associated with CAD in the Korean population. This case-control study included 451 CAD patients and 600 controls. Participants were drawn from the patient database of Cardiovascular Genome Center at Yonsei University Health System, Seoul, Republic of Korea. We identified 10 tagging-SNPs in the FLT1 gene by whole gene sequencing, and genotyped using the TaqMan®Assay and single base primer extension assay using SNaPShot Multiplex kit (Applied Biosystems). The allele and genotype frequencies of FLT1 rs664393 polymorphism were significantly differences between case and control groups for multiple testing; Pgenotype=0.008; Pdominant=0.002, OR=0.674(95% confidence interval(CI):0.526-0.864); Pallele=0.004, OR=0.746(CI:0.611-0.912). The SNP rs2296188 was association between the history of MI and without an MI history in dominant(OR=0.674,CI:0.461-0.985;P=0.041) and allele(OR=0.741, CI:0.556-0.988; P=0.041) models, respectively. In addition, the subgroup with a history of MI had significantly difference rs2296188 dominant(OR=0.677,CI:0.486-0.945;P=0.021) and allele(OR=0.738,CI:0.575-0.946;P=0.041) models when compared with controls. Therefore, the major allele (G) of rs664393 was associated with a protective effect for CAD. The differences in rs2296188 genotype distribution between the patient groups according to MI and non-MI status may also reflect the overall atherosclerotic development stage. These findings suggest that FLT1 gene polymorphisms are associated with the occurrence of CAD in Koreans. Further investigations should be performed to evaluate the functional role of these genes as a genetic contributor.

335W

The genetics of dilated cardiomyopathy: a prioritized candidate gene study. *K. Desbiens[1], N. Giannetti[2], I. Ruel[1], J. Genest[1,2], J. Engert[1,2,3].* 1) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Cardiology Division, Department of Medicine, McGill University Health Centre, Montreal, Quebec, Canada; 3) Department of Human Genetics, McGill University, Montreal, Quebec, Canada.

Dilated cardiomyopathy (DCM) is characterized by left ventricular enlargement and systolic dysfunction resulting in impaired heart function that can lead to heart failure. DCM can broadly be divided into cases for which there is a clear predisposing condition (e.g. hypothyroidism, chemotherapeutic agents, alcoholism, etc.) and those for which the cause is unknown. This condition clusters in certain families (called familial dilated cardiomyopathy or FDC) thus revealing that at least some DCM is determined by genetic predisposition. For these inherited cases, a large number of genes have been implicated and many involve “private” mutations not shared between unrelated families. It has been previously demonstrated that a large number of cases that do not present as familial clusters also have a genetic predisposition and again, a large number of genes have been implicated. The goal of this study was to identify mutations in genes known to be associated with DCM, in a Quebec study sample including both familial and non-familial DCM cases. We sequenced four previously identified genes (Lamin A/C, cardiac troponin T, titin-cap and phospholamban) in DCM patients. These genes were selected based on a previously developed prioritization strategy. In one patient, we discovered a mutation that leads to a stop codon in the Lamin A/C gene. Some of the other coding mutations that we discovered were predicted to be “probably damaging” using PolyPhen. We are currently genotyping those discovered mutations in additional patients, family members and controls as they are recruited. We will also investigate the possible long-term prognosis and response to therapeutic regimes of individuals who have specific mutations.

336W

Knockouts of the murine ortholog of the atypical Williams-Beuren tyrosine-protein kinase gene Baz1b present cardiac and circadian rhythm impairments. *G. Didelot[1], C. Berthonneche[2], A. Sarre[2], Y. Emmenegger[1], P. Franken[1], T. Pedrazzini[2], A. Reymond[1].* 1) Center Integrative Genomics, University of Lausanne, Lausanne, Lausanne, Switzerland; 2) Cardiovascular Assessment Facility, Cardiomet, Centre Hospitalier Universitaire Vaudois, CH-1005 Lausanne, Switzerland.

The Williams-Beuren syndrome (WBS) is a multisystem disorder caused by the hemizygosity of 25 genes, five of which encode transcription factors or chromatin remodeler. Modest perturbations in the dosage of the latter might substantially alter the expression of multiple target genes. Hence these genes are prime candidates to play a role in the phenotype of the patients. To address the physiological and molecular role of one of these genes, the Bromodomain Adjacent to Zinc finger 1b gene (BAZ1B), in vivo, we ablated by transposable element insertion the expression of its ortholog in mice. Almost all Baz1b-/- embryos (97%) die a few hours after birth. The rare survivors do not present any of the craniofacial abnormalities previously identified in knockouts of the murine orthologs of other genes of the WBS interval. They are, however, smaller in size than their control littermates and present a smaller heart with larger ventricular walls. Noticeably, this abnormal heart appears to be associated with an increased cardiac function as measured by the percentage of blood ejected with each contraction. This translates in a significant increase in nighttime activity and sleep perturbation. We are currently characterizing histologically the heart of Baz1b-/- embryos. Potential candidates genes for these multiple phenotypes have been identified by chromatin immunoprecipitation with antibodies raised against the BAZ1B unusual tyrosine-kinase.

Association of PLA2G4A with Myocardial Infarction is Modulated by Dietary Polyunsaturated Fatty Acids. *J. Hartiala[1,2], S. Vikman[1,2], E. Gilliam[1,2], H. Campos[3], H. Allayee[1,2].* 1) Dept Prev Med, USC Keck School of Medicine, Los Angeles, CA 90033; 2) Institute for Genetic Medicine, USC Keck School of Medicine, Los Angeles, CA 90033; 3) Department of Nutrition, Harvard University School of Public Health, Boston, MA 02115.

Background: Leukotrienes are pro-inflammatory molecules derived from dietary polyunsaturated fatty acids (PUFAs) and have been associated with cardiovascular disease (CVD). We previously reported that an A>G variant (rs12746200) of the cytosolic phospholipase A2 group IVA gene (PLA2G4A), which encodes the enzyme that liberates PUFAs from cellular membranes for LT synthesis, decreases the risk of CVD. Objective: We sought to replicate these initial observations with a more clinically relevant phenotype such as myocardial infarction (MI) and determine whether dietary PUFAs mediate this association. Methods: Rs12746200 was genotyped in a Costa Rican case-control dataset (n=3971) and tested for association with MI. Functional experiments were carried out to determine whether rs12746200 led to differences in mRNA expression. Results: Risk of MI was significantly lower in AG/GG subjects compared to AA homozygotes (OR = 0.86, 95% CI 0.75-0.99; p=0.038). This protective effect was observed primarily in AG/GG subjects who were in the upper median for dietary omega-6 PUFAs (OR = 0.73, 95% CI 0.60-0.89; p-interaction=0.04). A similar analysis with dietary omega-3 PUFAs also revealed a trend towards a nutrigenetic association although these results did not achieve statistical significance (p-interaction= 0.12). Functional analysis in human aortic endothelial cells showed that the carriers of the G allele had significantly lower PLA2G4A gene expression (p=0.014), consistent with the athero-protective effect of this variant. Conclusions: These results replicate the association of rs12746200 with CVD phenotypes and provide evidence that the protective effect of this functional PLA2G4A variant is mediated by dietary PUFAs.

Variation at the INSIG2 gene is associated with myocardial infarction in multiple ethnicities of the INTERHEART study. *S. Hooda[1], R. Do[2], G. Pare[3,6], A. Montpetit[3], N. Rudzicz[1], T. Hudson[4], S. Yusuf[5,6], S. Anand[5,6], J. Engert[1,2,7].* 1) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Ontario Institute of Cancer Research, Toronto, Ontario, Canada; 5) Department of Medicine, McMaster University, Hamilton, Ontario, Canada; 6) Population Health Research Institute, McMaster University, Hamilton, Ontario, Canada; 7) Cardiology Division, Department of Medicine, McGill University Health Centre, Montreal, Quebec, Canada.

Previous studies identified a variant of the INSIG2 gene associated with obesity. In addition, the locus harbors variants contributing to allele specific expression. More recently, we have shown that an upstream SNP is associated with ApoB and LDL-C in multiple study samples, a finding that was replicated in the Global Lipids Genetics Consortium and that is consistent with the role of INSIG2 in the regulation of cholesterol levels. Thus, INSIG2 variants may also be associated with myocardial infarction (MI). To address this question, we examined INSIG2 SNPs in 8487 individuals from five ethnicities of the INTERHEART study (Arabs, Europeans, Iranians, Nepalese and South-Asians). A weighted meta-analysis was performed using METAL based on association results of each ethnicity. Two SNPs, rs2113485 and rs889904 were associated with MI (p= 0.008 and 0.05, respectively and MAFs>0.14 in all ethnicities). The most significant SNP, rs2113485, was also significant in the two largest ethnic groups, Europeans and South Asians, when these were analyzed separately (p< 0.03 for both). Consistent with other common genetic susceptibility alleles for MI, we observed greater ORs in individuals <50 years old (OR=1.28, CI=1.11-1.48) in both men (OR=1.24, CI=1.07-1.45) and women (OR=1.89, CI=1.068-3.36). In summary, our results provide evidence that genetic variation at the INSIG2 locus contributes to MI as well as to plasma cholesterol levels in multiple ethnicities.

339W

Vitamin D Association of Sequence Variants in the *SVEP1* Gene and the Prediction of Mortality and Myocardial Infarction. *B.D. Horne[1,2], J.B. Muhlestein[1,3], J.F. Carlquist[1,3], D.J. Rader[4,5], H.T. May[1], M.P. Reilly[4,5], J.L. Anderson[1,3].* 1) Cardiovasc Dept, Intermountain Med Ctr, SLC, UT; 2) Genet Epidemiol, Univ Utah, SLC, UT; 3) Cardiol Div, Univ Utah, SLC, UT; 4) Inst Translational Med & Ther, Univ Penn, Philadelphia, PA; 5) Cardiovasc Inst, Univ Penn, Philadelphia, PA.

Background: In a genome-wide association study for early-onset acute coronary syndromes (unstable angina, myocardial infarction [MI]), two single nucleotide polymorphisms (SNPs) in the Sushi, von Willebrand factor type A, EGF and pentraxin domain containing 1 (*SVEP1*) gene on 9q31.3 had some of the lowest p-values. While those associations did not replicate in validation studies, *SVEP1* is known to interact with calcitriol. Low levels of vitamin D are associated with higher mortality and MI. This study evaluated whether SNPs in *SVEP1* are associated with 25(OH) vitamin D levels and clinical events. Methods: Among patients undergoing coronary angiography (N=1,127), 25(OH) vitamin D level was measured along with rs7035733 (minor allele frequency: 0.08) and rs7863519 (minor allele frequency: 0.20). Patients with 25(OH)D >100 ng/mL were excluded from the study due to potentially toxic levels. Results: Linkage disequilibrium between the two SNPs was low (r2=0.29). In analysis of variance, mean 25(OH)D was 23.0±6.4, 23.1±5.6, and 27.4±4.7 ng/mL (p-trend=0.07) for rs7035733 genotypes GG (n=952), GA (n=168), and AA (n=7), respectively, and was 23.2±6.4, 23.2±6.0, 20.6±7.3 ng/mL (p-trend=0.010) for rs7863519 genotypes TT (n=720), TG (n=363), and GG (n=44), respectively. Together the two SNPs accounted for 0.3% of the variance in 25(OH)D. Patients were followed for clinical events over a mean of 10.5±2.5 years (range 3.8-17.2 years). In bivariable Cox regression, rs7035733 (hazard ratio [HR]=1.39 per allele, 95% CI=1.03, 1.87; p-trend=0.032) and rs7863519 (HR=0.79 per allele, 95% CI=0.63, 0.98; p-trend=0.035) predicted mortality/MI, which remained with adjustment for age, sex, and 25(OH)D: p=0.029 for rs7035733 and p=0.035 for rs7863519 (adjustment for 15 additional clinical variables: HR=1.35, p=0.055 for rs7035733 and, for rs7863519: HR=0.79, p=0.044). Conclusion: Two SNPs in the *SVEP1* gene were associated with vitamin D and with subsequent mortality/MI. *SVEP1* is 215 kilobases in length and produces a 3,571 amino acid product, thus many other potential variants may affect this locus, vitamin D, and outcomes. This gene deserves comprehensive evaluation as a vitamin D-associated locus.

Prediction of Vitamin D Levels Using Three Significant SNPs from a Genome-wide Association Study. *S. Knight, J.L. Anderson, B.D. Horne, H.T. May, J. Huntinghouse, J.F. Carlquist, J.B. Muhlestein.* Intermountain Healthcare, Cardiovascular Department 5121 S Cottonwood Street Murray, Utah 84157.

Background: A recent GWAS found three SNPS, rs2282679, rs12785878, and rs10741657, in or near the genes GC, DHCR7, and CYP2R1, respectively, are associated with vitamin D levels. Here we further evaluate these three SNPs simultaneously in a cardiovascular population. Methods: We studied patients undergoing coronary angiography enrolled in the Intermountain Heart Collaborative Study (n=2213). Genotyping was performed by Taqman real-time PCR for the three variants and additive models were assumed. Vitamin D testing used the enzyme-linked immunoassay (ELISA) by Immunodiagnostics. Univariate and multivariate linear regression analyses using the natural log transformed vitamin D values were done. Results: In univariate analyses, only rs12785878 was significantly associated with vitamin D (p=0.0029) (See table). This SNP, rs12785878, remained the only significant SNP when all three SNPs were considered simultaneously (p= 0.0066) and when other variables (age, sex, BMI and season) were added to the model (p=0.0142). Interactions between rs12785878 and the other two SNPs were not significant. Conclusions: We replicated the association found between the SNP rs12785878 near gene DHCR7, and 25-hydroxyvitamin D concentrations (25-OH vitamin D). DHCR7 codes the enzyme that converts 7-dehydrocholesterol to cholesterol and in de novo synthesis was associated with 25-OH vitamin D concentrations; therefore, these findings have a persuasive biological foundation.

Linear Regression P-Values

	univariate	SNPs only	SNPs+var.
rs2282679	0.4133	0.1194	0.1297
rs12785878	0.0029	0.0066	0.0142

Rare Recurrent DNA Copy Number Variants Associated with Syndromic Cardiovascular Malformations. *S.R. Lalani[1], C. Shaw[1], X. Wang[1], A. Patel[1], L.W. Patterson[2], K.E. Kolodziejska[1], P. Szafranski[1], Z. Ou[1], Q. Tian[1], S.L. Kang[1], A. Jinnah[1], A.M. Baycroft[2], S. Ali[3], A. Malik[4], P. Hixson[1], L. Potocki[1], J.R. Lupski[1], P. Stankiewicz[1], C.A. Bacino[1], B. Dawson[1], A.L. Beaudet[1], F.M. Boricha[5], R. Whittaker[6], C. Li[7], S.M. Ware[8], S.W. Cheung[1], J.L. Jefferies[9], J.W. Belmont[1].* 1) Dept of Genetics, Baylor College of Medicine, Houston, TX; 2) Section of Pediatric Cardiology, Texas Children's Hospital, Houston, Texas; 3) The University of Texas at Austin, Texas; 4) The Aga Khan University Hospital, Karachi, Pakistan; 5) Department of Pediatrics, University of Texas, Houston, Texas; 6) St John Medical Center, Inc, Tulsa, Oklahoma; 7) Department of Pediatrics, McMaster University, Canada; 8) Division of Molecular Cardiovascular Biology, Cincinnati Children's Hospital and University of Cincinnati College of Medicine, Cincinnati, Ohio; 9) Division of Pediatric Cardiology, Cincinnati Children's Hospital and University of Cincinnati College of Medicine, Cincinnati, Ohio.

Rationale: Clinically significant cardiovascular malformations (CVM) occur in 5-8/1000 live births. Extracardiac malformations are seen in approximately 30% of individuals with CVM, characterized as syndromic CVM. Recurrent copy number variations (CNVs) are an important cause of syndromic CVM, however these account for only a small fraction of described cases. Hypothesis: We hypothesized that many additional rare, highly penetrant CNVs confer susceptibility to CVM and are significantly overrepresented in pediatric populations with syndromic CVM. Methods and Results: Through a genome-wide survey of 203 subjects with syndromic CVM, we identified 55 CNVs greater than 50 kb, that were enriched in the syndromic CVM cohort, and were not present in children with normal cardiovascular studies (n= 872). The enrichment of sixteen of these variants was replicated in an independent CVM cohort (n = 511). In all, 20 variants were overrepresented in the combined 714 cases, and were not present in 2883 unaffected controls (P <0.05); fourteen of these variants were *de novo* in origin (70%). The enriched CNVs included 16q24.3 loss encompassing *ANKRD11* (4/714, P = .001), 5p13.2 gain involving *C50rf42*, *NUP155*, and *WDR70* (3/714, P = .007) and 2q31.3q q32. 1 loss including *PDE1A* (2/714, P = .039). The study also narrowed critical intervals associated with CVM in three well-recognized genomic disorder, such as the Cat-eye syndrome region on 22q11.1 (4/714, P = .001), 8p23.1 loss encompassing *GATA4* and *SOX7* (3/714, P = .007), and 17p13.3-p13.2 loss involving *CAMTA2* (2/714, P = .039). The genes within the enriched CNVs encode proteins that directly interact with proteins such as Nkx2-5, EP300, SMAD5, and TGFBR3. The CNVs disrupt genes involved in filamentous actin/cytoskeleton organization, embryonic development and regulation of Ras protein signal transduction. Conclusions: Our findings implicate novel cardiac specific loci such as 16q24.3 loss, 5p13.2 gain, and 2q31.3-q32.1 loss and delineate highly penetrant regions within established structural variations that are associated with syndromic CVM. The protein interaction network demonstrates that the rare inherited and *de novo* recurrent CNVs within syndromic CVM cohort are enriched for protein encoding genes that directly interact with human cardiac developmental proteins.

342W

Excess of deleterious mutations in genes associated with VEGF-A in Down syndrome-related heart defects. *C.L. Maslen[1], D. Babcock[1], B. Reshey[1], J. Thusberg[2], S. Mooney[2], E. Feingold[3], R.H. Reeves[4], S.L. Sherman[5].* 1) Cardiovascular Med, Oregon Hlth & Sci Univ, Portland, OR; 2) Buck Institute for Research on Aging, Novato, CA; 3) Human Genetics, Univ. Pittsburgh, Pittsburgh, PA; 4) Physiology and Genetic Medicine, Johns Hopkins Univ Schl of Medicine, Baltimore, MD; 5) Human Genetics, Emory Univ. Schl. of Medicine, Atlanta, GA.

Atrioventricular septal defect (AVSD) is a severe congenital heart malformation and a significant health concern because even when the defect is surgically repaired there is increased morbidity and mortality. Our long-term goal is to identify the compilation of modifiers that confer risk for AVSD. We conducted a case-control, candidate gene resequencing study to identify rare variants associated with AVSD using a Down syndrome (DS) cohort that is highly sensitized to developing heart defects. All cases (DS+AVSD) and controls (DS without heart defect) were non-Hispanic white. To date we have resequenced all exons and intron-exon boundaries of 26 genes; 18 were resequenced in 141 cases and 141 controls, and 8 were resequenced in at least 100 of each. More than 3,000 variants were identified. In coding regions the majority of variants detected were single nucleotide variants. Missense variants were analyzed by predictive software (Polyphen, SIFT and MutPred) for the likelihood that the amino acid change would be deleterious. Ten of the 26 genes showed a significant increase of high probability damaging variants in cases compared to controls. Those 10 genes contained 40 case-specific putatively deleterious mutations seen in 57 different cases (>40% of cases examined); 11 case-specific mutations were found in more than one individual. In contrast, only 11 potentially damaging variants were specific to controls (seen in ~9% of controls). This significant skewing toward cases suggests a causal relationship with AVSD for at least some of the mutations. Although the original 26-gene list was not biased in terms of function, the genes showing the excess of case-specific mutations are all related in some way to VEGF-A, suggesting a pathway and rationale for identifying additional genetic modifiers of AVSD. VEGF-A involvement is not surprising given that it is a known regulator of AV canal morphogenesis. However, our study did not find variants in genes from a number of other pathways thought to be equally important in the development of the atrioventricular valves and septa. Overall, these data support our hypothesis that individuals with DS and AVSD carry a significantly higher burden of protein-altering mutations in heart development genes found throughout the genome than individuals with DS but no heart defect, and that genes in the VEGF-A pathway may play a predominant role in the etiology of AVSD.

Defining a new syndrome of arterial calcification with segmental sclerosis: A systems approach to diagnosis. *K. Menghrajani[1], D. Yang[2], C. Shuen[1], T. Markello[1], R. Rupps[3], M. Boehm[2], W.A. Gahl[1], C.F. Boerkoel[1].* 1) NIH Undiagnosed Diseases Program, Office of Rare Disease Research and Medical Genetics Branch, National Human Genome Research Institute and NIH Clinical Center; 2) Laboratory of Cardiovascular Regenerative Medicine, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, USA; 3) Department of Medical Genetics, University of British Columbia, Vancouver, BC Canada.

Fibromuscular dysplasia (FMD) and similar disorders of segmental arteriosclerosis are estimated to affect 4-5% of the population. FMD, which generally develops between 14 and 50 years of age, is considered an autosomal dominant disorder. However, despite this prevalence and knowledge, the molecular bases of FMD and related disorders remain largely uncharacterized. To address this, we define the molecular pathogenesis of an undescribed syndrome of severe arteriosclerosis through the study of a 17-year-old man with arotation of the intestine, anal atresia and progressive segmental arteriosclerosis of his medium-sized arteries. The arteriosclerosis has caused occlusion of his internal carotid, posterior cerebral, celiac, and superior mesenteric arteries and partial occlusion of his renal arteries. We have used whole-exome sequencing, gene expression analysis, metabolomics, histopathology, cell biology and zebrafish modeling to identify the molecular pathogenesis of his disease. This approach has identified mutations in nine candidate genes, distinctive fragmentation and calcification of the arterial internal elastic lamina, significant changes in the IL6 and WNT signaling pathways, and increased production of TGF-) . We synthesize these observations to characterize this syndrome and to define its potential disease mechanism. In summary, this constitutes one of the first systems approaches to characterization of segmental arteriosclerosis.

344W

Investigation of the role of *PLXNA2* in genetic susceptibility to congenital heart disease. *O. Migita[1], A.C. Lionel[1,2], C.R. Marshall[1,2], S.W. Scherer[1,2], C.K. Silversides[2,3,4], A.S. Bassett[2,3,5].* 1) The Centre for Applied Genomics, Genetics & Genome Biology, The Hospital for Sick Children, Ontario, Canada; 2) University of Toronto, Toronto, Ontario, Canada; 3) Toronto Congenital Cardiac Centre for Adults, University Health Network, Toronto, Ontario, Canada; 4) Obstetric Medicine Program, Mount Sinai Hospital, Toronto, Ontario, Canada; 5) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

Tetralogy of Fallot (TOF) is a congenital conotruncal defect that is the most common form of cyanotic congenital heart disease (CHD), affecting 2.5 to 3.5 per 10,000 live births. Family studies show high heritability with sibling recurrence risk of 2-4% for cardiac defects. Although, TOF can be associated with known genetic abnormalities including 22q11.2 microdeletions, trisomy 21 as well as single gene mutations (e.g. *GATA6, JAG1, TBX1*), in the majority of cases the genetic cause of TOF is unknown. In a high resolution genome wide scan for copy number variants (CNVs) in samples from 407 adult TOF patients we detected deletions at the *PLXNA2* gene locus in two unrelated patients. CNVs at this locus were absent in 8,427 population based controls genotyped and analyzed using the same methodology (Fisher's exact test p value= 0.00212). *PLXNA2*, which codes for a plexin protein, plays a role in cardiac neural crest migration during embryonic development. Mice with *Plxna2* mutations exhibit cardiac defects including TOF. Despite the strong functional evidence in support of involvement of *PLXNA2* in TOF, there have been no reports of TOF patients with mutations in this gene. To determine if other mutations in *PLXNA2* are associated with TOF, we re-sequenced the gene in 96 TOF patients of European ancestry that were part of the microarray screen.

In addition to the structural mutations detected, identifying pathogenic sequence variants in *PLXNA2* in TOF cases would support the importance of this gene in cardiac development and enhance our understanding of the genetic causes of major cardiac malformations.

Association of Genomic Loci from a Cardiovascular Gene SNP array with Plasma B-type Natriuretic Peptide Concentration in African Americans: the Jackson Heart Study. *S.K. Musani[1], V.S. Ramachandran[2], A. Bidulescu[3], H. Nagarajarao[1], P. Singh[4], T.E. Samdarshi[1], M.W. Steffes[5], H.A. Taylor[1], E.R. Fox[1].* 1) Department of Medicine, University of Mississippi Medical Center, JACKSON, MS; 2) Boston University School of Medicine, Boston; 3) Morehouse School of Medicine, Atlanta, GA; 4) Texas Tech University Health Science Center, Lubbock TX; 5) University of Minnesota, Minneapolis MN.

B-type Natriuretic Peptide (BNP) maintains salt and water homeostasis as well as regulate vascular function. Abnormalities in the natriuretic peptide system have been implicated in salt-sensitive and obesity-related hypertension across multiple ethnic groups. The genetic determinants of plasma BNP concentration in African Americans however have been poorly characterized despite the higher incidence of hypertension in this population. We hypothesized that variation in plasma BNP among African Americans is due to common and low frequency genetic variants. Methods: Our study population consisted of 2485 Jackson Heart Study participants (54 ± 13 years, 62% women). The median plasma BNP concentration was 7.2 pg/mL. Plasma BNP was measured on a Siemens Advia Centaur machine using a chemiluminescent immunoassay. Genotyping was done using IBC genotyping array, which captures 49320 SNPs across 2,100 candidate genes known to be related to cardiovascular, inflammatory, homeostasis/coagulation and metabolic phenotypes. Pooled residuals of log transformed BNP were generated after adjusting for age, sex and BMI. Participants with MI, CHF, and creatinine levels >2 were excluded. Phenotype-genotype association analyses were performed using PLINK software assuming an additive genetic model. Population stratification was accounted for by incorporating 10 principal components as covariates. To account for multiple testing, we considered only SNPs in approximate linkage equilibrium by pruning based on variance inflation factor. A total of 22811 SNPs were retained, and to maintain an overall type I error of 5%, a statistical threshold of $2.2x10^{-6}$ was employed to declare array-wide significance. Results: We identified 2 common array-wide significant loci in the coagulation factor XII gene F12 ($P=2.8x10^{-9}$) and the natriuretic peptide B gene NPPB ($P=3.14x10^{-7}$). The effective allele frequencies (and genetic effects) were 44% () = 0.20±0.03) and 40% () = -0.17±0.03), and they explained 1.5% and 1.2% of the variance in plasma BNP concentration. The polymorphism in F12 gene was associated with higher plasma BNP concentration, while NPPB was associated with lower levels. Conclusion: Common sequence variants of coagulation factor XII and natriuretic B-type peptide genes are associated with BNP in this community-based cohort of middle aged African Americans. Further studies are necessary to determine potential physiological changes that result from variations in these genes.

Screening for microdeletions and sequencing candidate genes associated with conotruncal heart defects. *K. Osoegawa[1,2], D.M. Iovannisci[1], M.B. Ladner[1], K. Schultz[1], C. Parodi[1], F. Cohen[1], D. Noonan[1], A. Borg[3], G.M. Shaw[4], E. Trachtenberg[1,2], E.J. Lammer[1].* 1) Research Inst, Childrens Hosp Oakland, Oakland, CA; 2) Center for Applied Genomics, Children's Hospital and Research Center Oakland, Oakland, CA; 3) Department of Oncology, Lund University, Sweden; 4) Dept. of Pediatrics, Stanford University School of Medicine, Palo Alto, CA.

Congenital heart defects are the most common anatomical grouping of human birth defects, yet little is known about their etiologies. Conotruncal defects are an important pathogenetic subset of congenital heart defects, comprising nearly 20 percent of the total. DNA samples from a population-based sample of 389 California infants born during 1999-2004 with conotruncal defects were screened for chromosomal microdeletions/duplications as an approach to identify candidate genes for conotruncal defects using array comparative genomic hybridization (array-CGH). Of all cases analyzed, we identified one subject with a novel 3.9 Mb duplication at 8p23.1 and four subjects who had 47,XYY or mosaic 47,XYY karyotypes. We also identified deletion cases at 1q44, 10q23.1, 22q11.21 and 22q11.22. The majority of these chromosomal anomalies were identified from cases with Tetralogy of Fallot. In addition to the genome wide screening with array-CGH, we have developed an efficient strategy for sequencing 10 candidate genes. FGF8, FOXH1, NKX2-5, GATA4, GATA5, GATA6, ISL1, ZFPM2, MEF2C and CRKL are either expressed in secondary heart field cells, for which mutations have been reported in a few infants with conotruncal defects, or identified via array-CGH experiments. Ninety-six DNA fragments or “amplicons” containing exons from these genes were amplified using Fluidigm's Access Array System. The system enabled us to amplify up to 48 samples, each with a unique multiplex identifier, x 48 amplicons (2304 independent PCRs) in a single chip. The amplicons were pooled, and sequenced using the Roche 454 GS FLX system. As of June 1 2011, we have sequenced ~90 DNA samples using this strategy. We developed DNA sequence analysis programs using Perl and Java programming languages for quality control and quality assessment of all DNA sequence data. Initial analyses indicated that we obtained sufficient DNA sequence redundancy (>50 sequence reads per amplicon) from >90% amplicons. The resulting DNA sequences were aligned against reference human DNA sequences, and potential novel mutations or single nucleotide polymorphisms (SNPs) have been identified within protein coding sequences using SeqNext (JSI Medical Systems).

Exome Sequencing and Linkage Filters Identify Novel Candidate Mutations in a Family with Left-Ventricular Non-Compaction. *S. Pan[1], R. Chen[2], M. Perez[1], K. Sallam[1], A. Pavlovic[1], F. Haddad[1], M. Snyder[2], E. Ashley[1].* 1) Division of Cardiovascular Medicine, Stanford Hospital & Clinics, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

Background: Left ventricular non-compaction (LVNC) is a rare form of cardiomyopathy that presents as hyper-trabeculation of the myocardium that can lead to heart failure, with a heterogeneous genetic etiology. While previous work has identified several genes that are associated with LVNC, the genetic basis of LVNC in the majority of cases still remains unknown. **Aim:** We sought to use exome sequencing in conjunction with linkage information to identify candidate causative mutations in a family with LVNC. **Methods:** DNA was isolated from the blood mononuclear cells from 6 members of an extended family with LVNC (5 affected, 1 unaffected) as determined by echocardiography. Whole exome capture was performed and libraries were sequenced at a coverage of ~96% of targeted bases and average read depth of ~90x per exome. Coding and splice site variants were called against the hg19 human reference and common SNPs from dbSNP131 were removed from the candidate list. Linkage analysis was also performed using the genotypes called at the positions of common SNPs from the exome data and candidates were further filtered by positions with LOD > 0, using an autosomal dominant model. **Results:** Filtering out common SNPs and using cosegregation, we were initially able to narrow down the list of candidates to 11 missense mutations and 19 indels. Using linkage as a further filter reduced the number of candidate mutations by half, with the majority of excluded variants found to be due to erroneous calls as confirmed by Sanger sequencing. By genotyping 5 further individuals in the family (1 affected, 3 unaffected, and 1 of unclear phenotype), we were able to narrow the current list of candidates to two missense mutations, one in *amphiphysin* which encodes a bridging integrator protein implicated in clathrin-mediated endocytosis and actin polymerization, and another in *versican* which encodes a proteoglycan that has a vital role in early myocardial development. **Conclusion:** We used linkage analysis on exome sequencing data as an effective filter for candidate mutations and to control for sequencing error. These filters along with cosegregation data identified mutations in *amphiphysin* and *versican* as possible causative mutations in LVNC. Further analysis of the biological role of these mutations, as well as an analysis of structural variants, are currently underway.

Novel associations of SNPs and transcripts with paraoxonase activity in Mexican-American families. *E.E. Quillen, D.L. Rainwater, T.D. Dyer, M.A. Carless, J.E. Curran, M.P. Johnson, H.H.H. Goring, J.W. MacCluer, E.K. Moses, J. Blangero, L. Almasy, M.C. Mahaney.* Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX.

Low serum activity of the paraoxonase 1 (PON1) protein is associated with decreased antioxidant and anti-inflammatory activity by high-density lipoprotein (HDL) cholesterol leading to atherosclerosis and heart disease. Mutations in the gene *PON1* have been associated with the majority of the observed variation in serum paraoxonase activity; however, there remains substantial unexplained variation. To identify additional genes contributing to PON1 activity, 990 Mexican-American participants in the San Antonio Family Heart Study were genotyped for approximately one million SNPs on a series of Illumina microarrays. PON1 activity was assessed on four substrates: paraoxon (+/- high levels of salt), phenyl acetate (+/- high levels of salt), dihydrocoumarin, and diazoxon. Genome-wide association analysis was performed conditioning on variation in the *PON1* region on chromosome 7 and adjusting for stratification in the sample using principal components. The phenotypic variation explained by age, sex, *PON1* alleles, and newly identified loci differs among the substrates. On average, age explains 2.9% of phenotypic variance, sex explains 0.5%, and allelic variation in and around *PON1* explains 42% with a range of 22% for phenyl acetate - salt to 66% for paraoxon + salt. Three SNPs (rs1158731, chr 1; rs6985222, chr 8; and rs7245370, chr 18) are significantly associated ($p < 5e-8$) with one of the measurements of paraoxonase activity. rs6985222 is adjacent to *CYP7B1*, one of a family of cytochromes involved in cholesterol catabolism. An additional seven SNPs are suggestively associated ($p < 5e-7$) with one of the measurements. Using the Illumina Sentrix Human Whole Genome (WG-6) Series I BeadChips, gene expression levels for 47,289 transcripts were characterized in the sample. The ten SNPs significantly or suggestively associated with PON1 activity were found to be significantly associated ($p < 1e-5$) with variation in the expression of 38 transcripts. Among these are lipin-1 (*LPIN1*), a candidate for adipose development and triglyceride metabolism; sterol 27-hydroxylase (*CYP27A1*), which is involved in the degradation of cholesterol and the production of 27-hydrocholesterol, a protein elevated in individuals with hypercholesterolemia and found in atherosclerotic lesions; and macrophage scavenger receptor 1 (*MSR1/CD204*), a macrophage-expressed receptor previously implicated in atherosclerosis.

Hunting for Novel Dilated Cardiomyopathy Genes using Haplotype Sharing and Exome Sequencing. *R.J. Sinke[1], A. Pósafalvi[1], K.Y. van Spaendonck-Zwarts[1], J.P. van Tintelen[1], P.A. van der Zwaag[1], L.G. Boven[1], J.J. Bergsma[1], W.B. Koetsier[1], D.J. van Veldhuisen[2], M.P. van den Berg[2], R.M.W. Hofstra[1], J.D.H. Jongbloed[1].* 1) Dept Genetics, UMC Groningen, Groningen, Netherlands; 2) Dept Cardiology, UMC Groningen, Groningen, Netherlands.

Background: Idiopathic dilated cardiomyopathy (DCM) is a clinically highly heterogeneous disorder, characterized by dilation and impaired contraction of the left ventricle. Monogenic inheritance is observed in one-third of the idiopathic cases and mutations in the >40 known genes explain only ~25% of familial cases. In order to identify novel DCM disease genes, we investigated two DCM families by Haplotype Sharing Test (HST) combined with exome sequencing. Methods: To localise novel DCM genes, 250K SNP genotyping was performed to identify regions shared between patients from a single pedigree. The HST was applied to (I) a family with 4 DCM and 2 peripartum cardiomyopathy patients and (II) a family with 3 DCM patients and 1 patient with reduced left ventricular function. To subsequently identify the corresponding disease genes, DNA of the index-patient and an affected relative from each family were analysed by exome sequencing. Results: The HST revealed largest shared haplotypes of 71 cM on chromosome 15 containing ~600 genes (family I) and 46 cM on chromosome 9 containing ~475 genes (family II). Exome sequencing revealed potentially pathogenic variants shared by the two affected family members in both families. Confirmation by Sanger sequencing and carriership analysis in affected family members and healthy controls is in progress. Conclusions: We identified potentially pathogenic variants in the largest shared haplotypes in two DCM families. Our results show that a combination of the HST and exome sequencing is a promising approach to identify novel genes underlying familial cardiomyopathies.

Massively parallel sequencing of the mitochondrial genome in patients with pediatric cardiomyopathies. *M. Tariq[1], V.W. Zhang[2], F. Scaglia[2], L.J. Wong[2], S.M. Ware[1,3].* 1) Division of Molecular Cardiovascular Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Mitochondrial diseases are clinically and genetically heterogeneous disorders caused by alterations in either nuclear or mitochondrial genomes. They are associated with a variety of clinical symptoms including cardiomyopathy, in which they have classically been characterized by infantile onset, rapid progression, and fatal outcome. The underlying gene defects have been identified in only a minority of cases. We hypothesized that mitochondrial disorders are an under-recognized cause of pediatric cardiomyopathy and occur in patients with isolated cardiomyopathy without additional systemic symptoms. To investigate this hypothesis, we used massively parallel sequencing to analyze the mitochondrial genome (mtDNA) and 9 nuclear genes known to cause mitochondrial disease in 84 pediatric cardiomyopathy patients, including 11 patients (13% of cohort) who met modified Walker criteria for mitochondrial disease based on their biochemical and clinical evaluations. We identified 15/84 patients (18%) homoplasmic for previously described mtDNA mutations. Variants previously associated with myopathy and cardiomyopathy, m.5567T>C in $tRNA^{Trp}$ gene, m.5783G>A in $tRNA^{Cys}$ gene, and m.8348A>G in $tRNA^{Lys}$ gene, were identified in five patients. Ten patients had variants in genes known as LHON secondary mutations, including eight patients with haplogroup T and m.4917A>G (p.N150D in *ND2* gene), one patient with m.3394T>C (p.Y30H in *ND1* gene) and one patient with m.15257G>A (p.D171N in *cytochrome b* gene). Altogether, these mutations were found in 22% patients (5/23) with left ventricular noncompaction, 17% (3/18) with hypertrophic, 21% (4/19) with restrictive, and 16% (3/19) with dilated cardiomyopathy. On average, each patient has 3 novel changes which were not reported in mitomap and mtDB, suggesting that additional candidates exist within the cohort. No homozygous or compound heterozygous mutations were identified in 9 nuclear genes screened (*SCO2, SOD2, TSFM, TK2, COX17, SURF1, DGUOK, NDUFA11, and NDUFS8*). Overall, 18% of patients (2/11) meeting modified Walker criteria had mtDNA mutations (m.5567T>C in $tRNA^{Trp}$ and m.15257G>A; p.D171N in *cytochrome b* gene). The remaining mutations were identified in patients that were not previously suspected to have a mitochondrial etiology for their cardiomyopathy (13/73 patients). This study shows the importance of mtDNA genomic analysis and demonstrates that mtDNA variants may play a role in pediatric cardiomyopathy.

351W

Mutation in MYOF: a new cardiomyopathy gene? *M. Wallace[1], M. Burch[2].* 1) Prof, Molec Gen & Microbiol, Univ Florida, Gainesville, FL; 2) Molec Gen & Microbol, Univ Florida, Gainesville, FL.

Increasingly it is being found that idiopathic cardiomyopathy, especially in children, is caused by autosomal dominant mutations in genes such as those involved in sarcomere function. Mutations in such patients/families have now been found in dozens of genes. A family with dilated cardiomyopathy (DCM) was investigated for mutations in 8 candidate genes using single-strand conformational analysis (SSCP) analysis of exons containing functional domains or exons previously reported with mutations. A gene that had not previously been reported mutated in cardiomyopathy (or any other condition), but was a logical candidate, myoferlin (MYOF), was included in the analysis. Myoferlin is a very large type II membrane protein, associating with both the plasma and nuclear membranes, related to dysferlin (a muscular dystrophy gene). It binds both calcium and phospholipids, and is highly expressed in the heart and skeletal muscle. The gene spans 175kb on chromosome 10q24, with 53 exons encoding 2061 amino acids. __ MYOF exons were analyzed, and an abnormal gel pattern was seen in the proband of this family (UF574) in exon 13. DNA sequencing of the PCR product identified a single-base deletion in the open reading frame, c.1216delG, on one allele. This deletion causes a frameshift at codon 405 (normally Gly), resulting in a premature stop 7 codons into the aberrant frame. This exon is in the region containing a C2 domain and region necessary for interaction with EDH2. This mutation was found in the proband's mother, who is asymptomatic for signs of cardiomyopathy. However, the mutation was found in an affected brother but not an unaffected sib. While NCBI shows several isoforms of MYOF, including some as short as 437 amino acids, this specific DNA change has not previously been reported. Its identification in a family with DCM implicates it in the etiology of this condition, although the mother would be considered currently non-penetrant based on symptoms. This is the first report of a MYOF mutation in cardiomyopathy. Further analysis is needed to validate the involvement of this gene/mutation in the pathogenesis of DCM.

Replication study of prior GWAS candidate genes/loci for coronary artery diseases in the genetic isolated Newfoundland and Labrador population. *Y. Xie[1,2,4], J. Cui[1], E. Randell[1], J. Renouf[2], S. Li[1], A. Pope[3], S. Sun[4], W. Gullive[4], F. Han[1].* 1) Dept Lab Med, Faculty of Medicine, Memorial University, St John's, NF, Canada; 2) Laboratory Medicine Program, Eastern Health, St. John's, NL, Canada; 3) Dept. of Molecular Genetics, Newfound Genomics, St. John's, NL, Canada; 4) Disciplines of Medicine, Faculty of Medicine, Memorial University, St. John's, NL, Canada.

Genome-wide association studies (GWAS), have provided some promising achievements for a number of multifactor diseases including coronary artery disease (CAD). However, many of these GWAS candidate genes failed to been replicated in studies using different ethnic populations which indicates the variety of genetic modifiers among different ethnic populations. Additionally, the genetic heterogeneity in the studied population can reduce the sensitivity in detection of weak genetic effects and leads to false negative results in replication studies. The population of Newfoundland and Labrador (NL) is a well known genetic isolated population, and this population has a high prevalence of CAD in Canada. As a part of our ongoing study, 15 genetic variants from 12 selected prior GWAS candidate genes/loci have been genotyped in 500 patients with myocardial infarction (MI) and 500 age and sex matched controls from the NL population to determine the disease risk impact in the studied population. Genotyping was carried out by using the Sequenom's MassARRAY system. Among the 12 studied genes/loci, only the 9p21 locus (rs 133049, rs 10757274, rs238306 and rs238307) was successfully associated to the patients (P<0.000 in all SNPs). This association was further confirmed in another study with enlarged sample size (1,000 MI patients and 1,000 controls) from the same population (P<0.000 in all SNPs). We, therefore, conclude that the 9p21 locus is a genetic susceptibility for CAD in the NL population. The failure of replicating other11 GWAS candidate genes for CAD in NL patients strongly suggests the diversity of genetic modifiers for CAD in NL population.

SNP-based genome-wide analysis identifies a novel EFEMP2 mutation in four unrelated families with dilatation of the ascending aorta. *Z. Al-Hassnan[1,6], S. Tulbah[2], A. Hakami[1], S. Mohammed[3], A. Al-Omrani[4], A. Almesned[5], M. Al-Fayyadh[4,7].* 1) Dept. of Medical Genetics; 2) Dept. of Genetics; 3) Dept. of Pathology & Laboratory Medicine; 4) King Faisal Heart Institute, King Faisal Specialist Hospital & Resaerch Center, Riyadh; 5) Prince Sultan Cardiac Center, Qassim, Saudi Arabia; 6) Alfaisal University, Riyadh; 7) King Saud University, Chair of Sudden Death Research, Riyadh, Saudi Arabia.

Dilatation of the ascending aorta (AA) is rarely inherited in an autosomal recessive pattern that results from mutated EFEMP2 gene in patients with cutis laxa (type 1A). Here we describe the identification of a novel EFEMP2 mutation in 9 patients, from 4 unrelated Saudi families, with dilatation of the AA in the absence of the skin and joint manifestations of cutis laxa. The clinical presentation ranged from episodes of cyanosis in a 5-month-old infant to incidental finding in an asymptomatic adult. Echocardiogram measurements revealed a wide-spectrum of severity of the dilatation of AA, varying from a Z-score of 33.9 in an asymptomatic 8-year-old child to a Z-score of 5 in a 20-year-old lady. Intrafamilial variability was also evident; 2 unrelated individuals were detected at the age of 17 and 20 years through family screening after the diagnosis in their severely affected siblings. Eight patients underwent replacement of the AA. Pathological examination showed myxoid and cystic medial degeneration. In one non-consanguineous family, SNP-based analysis using Affymetrix® Axiom™ Genome-Wide Array detected a homozygous block, shared by 2 affected siblings, on chromosome 11q13 where EFEMP2 gene is located. Sequencing EFEMP2 identified a novel homozygous mutation c.481G>A (p.E161K) in the two affected children as well as in all the other 7 patients. The parents in all the four families were heterozygous carriers and the unaffected children were either homozygous normal or heterozygous carriers. To our knowledge, this is the largest cohort of patients reported with mutated EFEMP2. Our work describes the wide phenotypic expression and the inrafamilial variability of the AA dilatation as a result of a novel EFEMP2 mutation that is probably a founder allele in the Saudi population. In addition, we also illustrate that in highly inbred populations, genome-wide homozygosity analysis can be powerful in identifying haplotypes carrying founder homozygous mutations for rare recessive disorders even in non- consanguineous families.

A study of the adiponectin Q as a susceptibility gene for atherosclerosis. *M. Al-Najai, M. Vigilla, E. Andres, S. Elhawari, D. Gueco, P. Muiya, N. Mazher, B.F. Meyer, M. Alshahid, N. Dzimiri.* King Fisal Specialist Hospital, Riyadh, Riyadh, Saudi Arabia.

Adiponectin (ADIPOQ) is a protein that plays an important role in the regulation of various processes that may lead to atherosclerosis. In a preliminary genome-wide linkage study using the Affymetrix Gene Chip 250 sty1 mapping array, we identified several loci, among others, in chromosome 3 region which harbours the ADIPOQ gene linked to early onset coronary artery disease (CAD) in a Saudi family of 11 individuals with predominant heterozygous familial hypercholesterolemia. We then sequenced the gene in 200 individuals to identify variants of interest, followed by a population-based association study for 8 SNPs with myocardial infarction (MI)/CAD in 4638 Saudi individuals (2301 CAD cases versus 2338 angiographed controls) using the Applied Biosystems real-time PCR procedure. Two of the studied variants, the rs2082940C>T[Odds ratio(95% Confidence Interval = 1.13(1.02-1.25); p=0.022) and the rs1063537C>T [1.16(1.04-1.30; p=0.008) conferred risk for MI. These associations followed a recessive mode of inheritance. Interestingly, the rs1063539 (p=0.079) was only weakly associated with CAD [1.29(0.99-1.68); p=0.058) and hypertension [0.74(0.55-1.03); p=0.073]. Our results demonstrate that the ADIPOQ gene harbours susceptibility variants for MI in the Saudi population.

355W

Thrombospondin 4 gene harbours a common susceptibility locus for atherosclerosis and its risk traits. *M.M. Alrasheed[1], M.G. Vigilla[1], D. Gueco[1], P. Muiya[1], S. Elhawari[1], M. Al-Najai[1], E. Andres[1], B.F. Meyer[1], M. Alshahid[2], N. Dzimiri[1].* 1) Genetics, King Faisal Specialist Hospital and Research Centr, Riyadh, Saudi Arabia; 2) King Faisal Heart Institute, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Thrombospondin 4 (THBS4) is a member of adhesive glycoprotein family that mediates cell-to-cell and cell-to-matrix interactions, and may be involved in localized signaling in the developing and adult nervous system. By virtue of its function, genetic changes in THBS4 gene are likely to constitute cardiovascular risk. In present study, we first identified a linkage of early onset of coronary artery disease (CAD) to chromosome 5, which encompasses the THBS4 gene locus, and sequenced the gene to identify variants of interest. We then pursued a population-based association study for CAD and its risk factors involving 4 SNPs (rs17885704G>A, rs438042A>T, rs17882513A>G, rs1866389C>G) in 4650 Saudi individuals (2307 CAD cases versus 2343 controls) using the Applied Biosystems real-time PCR procedure. The rs17885704 conferred risk for CAD [Odds ratio(95% Confidence Interval = 1.53(1.34-1.76); p<0.00001], myocardial infarction [1.40(1.22-1.61; p<0.00001], hyperlipidaemia [1.89(1.61-2.21; p<0.00001], hypertension [1.6740(1.4422-1.9261; p<0.00001] and exhibited borderline association with type 2 diabetes mellitus [1.14(0.99-1.30; p<0.060]. The associations followed a dominant mode of inheritance for all four variables. Another SNP, the rs1866389, was also weakly associated with CAD. These results clearly demonstrate that the rs1788704G variant of the THBS4 gene constitutes a locus for independently acquiring atherosclerosis and its important risk traits.

Identification of Additional Genetic Factors Contributing to LQTS in the First Nations Population in Northern BC. *L. Arbour[1,2], S. Asuri[1,2], S. McIntosh[1], L. Fields[1].* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Division of Medical Sciences, University of Victoria,Victoria, BC, Canada.

Introduction: Congenital Long QT syndrome (LQTS) is a potentially fatal condition predisposing to ventricular tachyarrythmias characterized by a prolonged QT interval on electrocardiogram (QTc >460). Although usually rare, LQTS is common in First Nations people of Northern British Columbia. Inheritance for LQTS is considered of single gene origin (twelve known genes accounting for 80% of cases) but frequently involves additional genes and interactions with exogenous triggers characteristic of a complex disease. We have previously identified a novel missense mutation (V205M) in KCNQ1in this FN population and to date 328 participants have enrolled, 58 carry the mutation. Mechanistic studies and epidemiological evidence for a prolonged QT interval amongst carriers support pathogenesis. However, some individuals with the V205M mutation are more severely affected than others, and some with a prolonged QT interval without the V205M mutation have been identified, indicating the possibility of other genetic factors altering the phenotype or accounting for LQTS in this community. Such a founder population allows the opportunity to carry out studies which might provide insight. Family based linkage analysis was undertaken to identify additional contributing loci. **Methods:** Of the 328 community participants, those with QT interval >470 ms were included as potential “cases” (n=61), 27 of those with the V205M mutation (OR 5.07 95% CI 2.64-9.7). Medical records were reviewed for co-existing morbidities that might increase the QT interval and those cases were excluded for this analysis. Ultimately after genotyping remaining cases with one array of the Affymetrix mapping 500K 2 array sets, 22 cases were considered informative. An “affecteds” only, multipoint linkage analysis was carried out using Merlin software. Linkage disequilibrium was controlled for to prevent inflation of LOD scores and parametric and nonparametric modeling was utilized. **Results:** Maximum LOD scores of >3.0 were seen at an 8 cM region on chromosome 10q and a narrow region on chromosome 2p. LOD scores above 2.5 were seen at tighter regions on chromosomes 4, 15 and 21. Several potential candidate genes contributing to the LQTS phenotype in this population were identified in these regions, including those previously implicated in the regulation of the cardiomyocyte cytoskeleton, ion channels and other cardiac conditions. Further exploration is underway.

Genome-Wide Association Study of Hypertension in a Diverse Population. *G. Beecham[1], A. Patel[2], N. Sikka[1], M. Nakamura[2], P. Goldschmidt-Clermont[2], M. Pericak-Vance[1], D. Seo[2].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) University of Miami, Miami, FL.

BACKGROUND Coronary heart disease is the leading cause of death in the United States, with hypertension being one of the major underlying etiologies. Patients with hypertension are more likely to suffer a myocardial infarction or sudden cardiac death. Though the role of genetics on hypertension has been studied in European ancestry populations, its role in Hispanic populations is less clear. To further determine the genetic etiology of hypertension, we have performed a genome-wide association study of hypertension using a diverse set of cardiac catheterization patients. METHODS This study utilizes the Miami Cardiovascular Registry of the University of Miami Miller School of Medicine. A diverse set of patients were ascertained through cardiac catheterization labs; the dataset consists of over 65% Hispanic and 15% African American. All 2,000 patients were phenotyped for both systolic and diastolic blood pressure. Genotype data were generated using the Affymetrix SNP array 6.0 platform for 900,000 SNPs. Extensive QC tests were performed to ensure the integrity of the data, including sample filters (gender consistencies, efficiency thresholds, etc), SNP filters (HWE, genotyping efficiency, MAF, etc), and EIGENSTRAT methods to correct for population substructure. We tested for association using linear regression using the PLINK software package, and included smoking, cholesterol, age, sex, and three vectors describing the population substructure of the sample. RESULTS For the systolic phenotype we detected strong association ($p < 0.00001$) at 12 SNPs on 7 different chromosomes, in 6 different genes. Included in these is one SNP with p-value < 1x10-6 (rs2240491, p-value= 9.04x10-7) near the OTOG gene. For the diastolic phenotype we detected strong association ($p < 0.00001$) at 8 SNPs on 6 different chromosomes, in 3 different genes. Included in these are variants in the DAB1 gene, a gene previously associated with schizophrenia and one SNP with p-value < 1x10-6 (rs1105266, p-value=2.45x10-7). This SNP is in the PRMT10 gene, a putative protein arginine methyltransferase. CONCLUSION These signals and genes are being further investigated in our full dataset. And additional analyses are underway. Additional analyses include a gene-based pathway analysis and a gene-gene interaction analysis. These data provide promising results that may lead to further insights into the genetics of anatomic coronary artery disease.

358W

A genome wide association study of carotid intima-medial thickness: a surrogate marker for cardiovascular disease. *S.H. Blanton[1], A.H. Beecham[1], L. Wang[1], C. Dong[1], D. Della-Morte[1], D. Cabral[1], M. Elkind[2], R. Sacco[1], T. Rundek[1].* 1) Human Genetics, Univ Miami, Miami, FL; 2) Columbia Univ, New York, NY.

Carotid intima-medial thickness (CIMT) is a recognized risk factor for cardiovascular disease. The genetic underpinnings of CIMT are not known. The aim of this study was to identify risk loci for CIMT by performing a genome-wide association study. CIMT of 991 individuals from the population-based Northern Manhattan Study was measured by high-resolution B-mode ultrasound and expressed as the total IMT defined as mean of the maximum (IMTm). Other carotid segment-specific IMT phenotypes (including bifurcation-BIF, common-CCA and internal carotid artery-CCA) were also examined. Genotyping was done using the Affymetrix SNP array 6.0. Linear regression was used to look for association between the SNPs and our phenotypes while controlling for age, sex, date of ultrasound, pack years of smoking, hypertension, diabetes, dyslipidemia, BMI, and WHR. Additionally, two vectors from Eigenstrat were used to control for substructure. While no SNPs met genome-wide significance, we observed strong associations ($p < 1.0\times10\text{-}5$) with IMTm on 5 chromosomes (1, 5, 9, 11, 20) and 4 genes including in Astroactin 1 (ASTN1), Astroactin 2 (ASTN2), and Rho GTPase activating protein 26 (ARHGAP26). Most notable were associations in ASTN1 and ASTN2 on chromosomes 1 and 9, respectively, because of the association of ASTN1 with other carotid segments. Nine ASTN1 SNPs were associated with BIF ($p < 1.0\times10\text{-}6$) and to a lesser degree with ICA (p from $9.0\times10\text{-}3$ to $1.2\times10\text{-}1$) and CCA (p from $6.9\times10\text{-}5$ to $1.2\times10\text{-}2$). Other strong associations ($p < 1.0\times10\text{-}5$) were seen for BIF in WDR66 and ARHGAP26; for CCA in SBF2, ASTN2, and USP6NL; and for ICA in SETX, TLL1, PRND, and NOS1AP. The genes identified in our study do not play an obvious role in atherosclerosis. Fine mapping and pathway analysis are being undertaken to further investigate these genes/regions in CIMT.

359W

Renin gene polymorphism modulates extent of hypertrophy in hypertrophic cardiomyopathy, independent of blood pressure. *N. Carstens[1], L. Van der Merwe[2], M. Revera[3], M. Heradien[4], A. Goosen[4], P.A. Brink[4], J.C. Moolman-Smook[1].* 1) US/MRC Centre for Molecular and Cellular Biology, Stellenbosch University, Tygerberg, Western Cape, South Africa; 2) Biostatistics Unit, Medical Research Council of South Africa, Tygerberg, South Africa; 3) Department of Cardiology, IRCCS San Matteo Hospital, Pavia, Italy; 4) Department of Medicine, University of Stellenbosch Health Sciences Faculty, Tygerberg, South Africa.

Hypertrophic cardiomyopathy (HCM), an inherited primary cardiac disorder mostly caused by defective sarcomeric proteins, serves as a model to investigate left ventricular hypertrophy (LVH). The disease manifests extreme variability in the degree and pattern of LVH, even in HCM patients with the same causal mutation. Previous studies identified renin-angiotensin-aldosterone system (RAAS) components as hypertrophy modifiers in HCM; however, investigations of the renin section of the RAAS pathway in HCM have not previously been reported. We investigated six single nucleotide polymorphisms (SNPs) within the renin (REN) gene for association with heritable cardiac hypertrophy traits in a cohort of families that each harbour one of three HCM founder mutations. After adjustment for known hypertrophy confounders and the primary HCM causal mutation, we report a significant association between rs1464816 and left ventricular mass (LVM) ($p = 0.021$) as well as a composite hypertrophy score that best described the variability in hypertrophy in the present cohort ($p = 0.013$). We demonstrate that variation in REN plays a role in modulating hypertrophy in HCM, independent of blood pressure. Given the efficacy of the direct renin inhibitor in promoting LVH regression in hypertensive patients, this study informs on potential anti-hypertrophic therapy targets for HCM.

Blood pressure and retinal arterial narrowing: assessing causality through Mendelian randomization. *C.Y. Cheng[1,2,3], X. Sim[4], M.K. Ikram[2,3,5], B. Cornes[3], J.J. Wang[6,7], P. Mitchell[6], Y.Y. Teo[2,4,8,9], S.M. Saw[2,3], T. Aung[1,3,10], E.S. Tai[2,5], T.Y. Wong[1,3,7,10].* 1) Department of Ophthalmology, National University of Singapore, Singapore; 2) Department of Epidemiology and Public Health, National University of Singapore; 3) Singapore Eye Research Institute, Singapore; 4) Centre for Molecular Epidemiology, National University of Singapore, Singapore; 5) Department of Medicine, National University of Singapore; 6) Centre for Vision Research, Department of Ophthalmology, University of Sydney, New South Wales, Australia; 7) Center for Eye Research Australia, University of Melbourne, Melbourne, Australia; 8) Department of Statistics and Applied Probability, National University of Singapore, Singapore; 9) Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore; 10) Singapore National Eye Centre, Singapore.

Purpose: Retinal arteriolar narrowing is strongly associated with higher blood pressure (BP) and independently predicts clinical hypertension. However, previous cross-sectional observational studies prevent direct inference of causality between BP and development of retinal arteriolar narrowing. We aimed to generate estimates of the association between BP and retinal arteriolar caliber that were free from confounding and reverse causation. **Methods:** We examined the association between BP and retinal arteriolar caliber using conventional linear regression among 1976 participants from the Singapore Malay Eye Study. We compared these estimates with those derived from a Mendelian randomization framework with variants in four recently-discovered loci for BP in East Asians. We used a genetic risk score as the instrument variable, by combining four SNPs (rs17030613 [*ST7L-CAPZA1*], rs6825911 [*ENPEP*], rs35444 [*TBX3*], and rs17249754 [*ATP2B1*]) and weighting each SNP by its strength of association with systolic (SBP) and mean arterial BP (MABP). **Results:** The genetic risk score was significantly associated with both SBP (F = 13.5, P <0.001) and MABP (F = 19.0, P <0.001), but not associated with potential confounders (body mass index, lipid, blood glucose, diabetes, smoking, alcohol drinking, and C-reactive protein). On controlling for age, gender, genetic ancestry and potential confounders, each 10 mmHg increase in SBP and MABP was associated with a 1.4 μm (95% confidence interval [CI]: 1.1, 1.7) and 2.8 μm (95% CI: 2.3, 3.2) narrowing of retinal arterioles (both P <0.001), respectively. In the Mendelian randomization analysis using the genetic risk score as an instrument, the estimated causal effect was a decrease in arteriolar caliber of 1.3 μm (95% CI: -2.2, 4.8) and 1.7 μm (95% CI: -3.2, 6.6) for each 10 mmHg increase in SBP and MABP, respectively. The difference between the linear regression and instrumental variables estimates was not significant for both SBP and MABP (both P >0.05, by the Durbin-Wu-Hausman tests). **Conclusion:** The point estimates from the instrumental variable analysis did not substantially differ from those obtained from conventional regression analysis, but were not significant. Based on this Mendelian randomization study, we could not precisely estimate the causal association between BP and retinal arteriolar caliber. A larger sample size is needed to determine the causal effects.

A Genome-wide Gene Expression Association Study of Young-Onset Hypertension in Han Chinese Population of Taiwan. *K.M. Chiang[1,4], H.C. Yang[2], J.W. Chen[3], W.H. Pan[1].* 1) Institute of Biomedical sciences, Academia Sinica, Taipei, Taiwan; 2) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan; 3) National Yang-Ming University School of Medical and Taipei Veterans General Hospital, Taipei, Taiwan; 4) Institute of Life Science, National Defense Medical Center, Taipei, Taiwan.

Hypertension is a common and complex disorder. Although many large-scale genome-wide association studies have been performed, only a few studies have successfully identified the loci that are related to the hypertension, not to mention the scanty Asian studies. Young-onset hypertension (YOH) may be a more feasible target disorder to investigate than the late-onset one due to its stronger genetic component. We performed a two stage genome-wide gene expression association study to map YOH susceptibility genes. In the first stage, we analyzed 126 YOH cases and 149 normotensive controls with age, sex and BMI adjusted in all the analyses. In the second stage, an independent set of 127 YOH cases and 150 normotensive controls were used to validate the findings from the first stage. Phalanx Human OneArray v5.1 (30,275 transcripts) was used to measure the whole genome gene expression profiles. Several researches have been shown that CNVs may cause the gene dosage effect. According to this issue, we also check the CNVs status in the genes that we found. About 4,300 CNV SNP probes on the Illumina HumanHap 550K Genotyping BeadChip were used for CNV calling. Two softwares, PennCNV and QuantiSNP which implements a hidden Markov model (HMM) that integrates multiple sources of information to infer CNV calls for individual genotyped samples were used to identify the CNV regions. In addition to the single gene tests, we also perform the gene set analyses based on 4277 Gene Ontology categories, 299 BioCarta pathways and 128 KEGG pathways. Several gene sets have been identified in our study (p-value < 10^{-5}). We will also use WTCCC data to verify those gene sets by the SNP-based Gene set analysis.

Cardiomyopathy and sudden cardiac death in Newfoundland. *F. Curtis[1], S. Connors[2], A. Williams[2], J. Houston[3], T. Young[3], K. Hodgkinson[4].* 1) Provincial Medical Genetics, Eastern Health, St. John's, Newfoundland, Canada; 2) Cardiology, Memorial University, St. John's Newfoundland, Canada; 3) Molecular Genetics, Memorial University, St. John's, Newfoundland, Canada; 4) Clinical Epidemiology and Genetics, Memorial University, St. John's, Newfoundland, Canada.

Introduction: Newfoundland is a genetic isolate, known for its founder population. Research into cardiomyopathies (CM) and sudden cardiac death (SCD) began in 1996 with a team of academics and clinicians. Aim: To ascertain all families with SCD and cardiomyopathy in Newfoundland, and determine their genetic etiology. Method: All families consnting to the research were originally referred for clinical work-up, firstly to the Provincial Medical Genetics Program, then to a Genetics/Cardiac clinic formed in 2004. Results: Since 1996, 369 families (the largest family comprising 1200 subjects over 10 generations) were ascertained. There were 17 different referral diagnoses, 50% of which were cardiomyopathies (dilated CM (DCM), hypertrophic CM (HCM) and CM not specified), 28% with a family history of SCD, 8% for arrhythmogenic right ventricular CM (ARVC), and 2% for Long QT syndrome (LQTS). The remaining 12% comprised 11 other referral diagnoses. To date 15 genes associated with inherited heart conditions with varying mutations have been found in74 families (from 135 families with DNA available (57%)). Of these 74, 30% (22 families) have the *TMEM43* mutation discovered by our team in 2008 and 32% (23 families) have either a *MYBH3* or *MYH7* mutation. Twelve families have mutations in other ARVC genes, and 4 families have *LMNA* mutations. At least three families have more than one mutation segregating, and ongoing genotype phenotype studies are taking place. Since the start of the clinic, referral numbers continue to increase with 47% of the referrals falling into the last three years. Discussion. We have determined the genetic etiology of over 50% of families with available DNA to date. Families with large histories and negative for known mutations will be clinically ascertained and genetic research will continue. Our combined team of clinicians, epidemiologists, geneticists, bioethicists, genetic counsellors, nurses and molecular geneticists have an unparalleled opportunity to determine the genetic and clinical epidemiology of all Newfoundlanders.

Marfan Syndrome - A comparison of the Ghent nosologies. *J. Dean[1], J. Crow[2], W. Lam[2].* 1) North of Scotland Regional Genetics Service, Ashgrove House, Aberdeen, United Kingdom; 2) South East Scotland Regional Genetics Service, Western General Hospital, Edinburgh, United Kingdom.

Marfan syndrome is a variable, autosomal dominant connective tissue disorder whose cardinal features include ascending thoracic aortic aneurysm, lens subluxation, and skeletal abnormalities. Some of the milder features may be seen in unaffected people, which complicates the clinical diagnosis. The Ghent 1996 nosology was devised to assist diagnostic consistency, but is complex requiring evaluation of 30 clinical features. It is unreliable in children because of age-dependent penetrance of some features. The revised Ghent 2010 nosology is intended to address some of these issues. We reviewed findings in Marfan index patients from the East of Scotland using both nosologies to compare effectiveness and ease of use of each. 71 patients fulfilled Ghent 1996. Using Ghent 2010, 58 of these were diagnosed as Marfan syndrome, 13 were diagnosed unaffected. A fibrillin 1 mutation was detected in 79% of cases diagnosed using Ghent 1996, and 87% of cases diagnosed using Ghent 2010. 3 cases diagnosed Marfan by Ghent 1996 were scored unaffected by Ghent 2010, yet had fibrillin 1 mutations. Ghent 2010 is more specific but less sensitive for diagnosing fibrillin 1 mutation Marfan syndrome than Ghent 1996. Current cardiac findings have more weight, other findings less. Some Marfan patients, who may develop aortic aneurysm in the future, will be missed by Ghent 2010. Patients who fulfil Ghent 1996 should have fibrillin 1 testing and appropriate aortic follow-up.

The Complex Genetics of ARVC/D in Maritime Canada. *S. Dyack[1 2 3], J. Hathaway[2], A. Crowley[2], C. Gray[3 4], M. Gardner[3 4].* 1) Department of Paediatrics, Dalhousie University, Halifax, NS, Canada; 2) Maritime Medical Genetics Service, IWK Health Centre, Halifax, NS, Canada; 3) Department of Medicine, Dalhousie University, Halifax, NS, Canada; 4) Division of Cardiology, QEII Health Sciences Centre, Halifax, NS, Canada.

Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) is an inherited condition that can lead to fatal arrhythmias and shows great clinical variability and genetic heterogeneity. Here we describe difficult genetic and cardiac management issues faced as a result of complex genetic test results and the expression of clinical phenotypes in these families. A retrospective chart review was undertaken of probands and their assessed family members referred to Genetics for a personal or family history of ARVC/D. Our Genetic/Cardiology team sees all ARVC families in our region. A total of thirty-three probands were assessed between 2008-2011. Twelve (36.4%) were found to carry a mutation(s) felt to be definite or likely pathogenic. Six (18%) probands were found to carry a VUS. Twelve probands (34.4%) were found to carry neither a mutation nor a VUS. In 4 probands (12.1%), testing could not be completed. We have had difficult counseling and management issues in this population including: Sex specific penetrance for a presumed pathogenetic change in a large family with a DSP mutation, apparent autosomal recessive inheritance for severe ARVC with minimal expression in “carriers”, overlap of features of long QT syndrome and ARVC in several families, and cases where there is a clear pathogenic mutation, but gene negative individuals experience life threatening events. These cases illustrate that the clinical evaluation of family members by expert Cardiologists in concert with a Medical Genetics assessment and genetic testing is optimal to ensure that families receive accurate risk management. Especially in smaller families, it can be difficult to provide accurate counselling and management based on genetic test results alone.

Clinical, Cytogenetic and Molecular studies in Egyptian Children with Congenital Heart Disease (CHD). *M.O. EL RUBY[1], S. El-Seaady[2], N. Helmy[1], H. Hussein[1], A. El-Gerzawy[1], A. Fayez[1], G. Noreldin[1], A. Abdel-Rahman[1], N. Ismaeil[1], M. Kobeisy[1], R. Lotfy[1], A. El Darsh[1], I. Hussein[1].* 1) National Research Centre, , El Bohooth st., Cairo ,Egypt; 2) Faculty of Medicine -Cairo University - Cairo - Egypt.

The cardiovascular anomalies responsible for congenital heart disease (CHD) are common birth defects and are a leading cause of infant mortality, morbidity. CHD is a primary feature of many genetic syndromes, but genetic causes of non-syndromic CHD are increasingly being recognized. CHD affects at least one in 100 live births. It ranges widely in severity, from tiny holes between heart chambers that close naturally, to life-threatening abnormal structures such as hypoplastic left-heart syndrome. Recently identified disease genes for syndromes associated with CHD are also increasing. To date, very few studies were performed in Egypt for studying the genetic basis of CHD. This study included 500 cases with CHD out of total 8000 cases referred as genetic disorder to the Clinical Genetic Department of the NRC during a period of 6 years (2004-2010). It aims to identify at risk families and types of syndromes with CHD, identify types of chromosomal anomalies causing these diseases & study the spectrum of mutations in known candidate genes. Chromosomal analysis was performed on 200 cases. Molecular studies were carried out for 189 cases. Mutation detection was done using PCR/ SSCP and DNA sequencing. Associated malformations as known syndromes included Russell Silver, Jacobsen, Noonan, Costello, Apert, Kamptomelic dysplasia, McKusik Kaufman, Rubinstien-Taybi, William, Holt-Oram & Roberts. Chromosomal anomalies reported are trisomy 21, trisomy 13, trisomy 18, 46, XY, t (14;18), 46, XYt (8;9), 47, XX, + mar ; 46, XX del 11q ,46, XX, dup13q, 47, XXX, 45, X, 47XXY, 46, XX, inv(18). DNA sequencing of NKX2.5 gene revealed two different mutations in two unrelated patients. Sequencing of GATA4 gene in patients with TOF has shown polymorphism in exon 6 at nucleotide 53423 (A-G) in 5 patients. The genetic investigation results of Nkx2.5 gene concluded the presence of missense mutation in one case with TOF, two missense mutation in two cases of ASD and one silent mutation in one ASD case. Results of GATA4 gene concluded the presence of two silent mutations in two TOF cases ,and 3 SNPs in 9 TOF cases .Results of 22q11.2 critical DiGeorge region concluded the presence of microdeletion in 6 DiGeorge/ VCF syndrome cases .Results of PTPN11 gene concluded the presence of Polymorphism -21 (C ◇ T) in one case with Noonan syndrome.

Motivation to pursue genetic testing in individuals with a personal or family history of cardiac events or sudden death. *K.E. Erskine[1], L. Cohen[2], M. Stolerman[3], E. Paljevic[4], C.A. Walsh[5], T.V. McDonald[6], R.W. Marion[7], S.M. Dolan[1].* 1) Department of Obstetrics & Gynecology and Women's Health, Montefiore Medical Center, Bronx, NY; 2) Montefiore Medical Center, Bronx, NY; 3) Ferkauf Graduate School of Psychology, Yeshiva University, Bronx, NY; 4) Pediatric Heart Center, Children's Hospital at Montefiore, Bronx, NY; 5) Pediatric Dysrhythmia Center, Children's Hospital at Montefiore, Bronx, NY; 6) Departments of Molecular Pharmacology and Medicine/Cardiology, Albert Einstein College of Medicine, Bronx, NY; 7) Divisions of Developmental Medicine & Genetics, Children's Hospital at Montefiore, Bronx, NY.

In the era of personalized medicine, genetic testing is becoming increasingly more available for diagnostic and predictive testing for a variety of genetic conditions. Previous studies have assessed the motivations of individuals pursuing this genetic testing, particularly in the area of hereditary cancer syndromes and have found that individuals cite a variety of motivations for pursuing testing. In the area of sudden cardiac death, genetic testing exists to detect mutations responsible for cardiac channelopathies, such as Long QT syndrome and Brugada syndrome, and results of this testing can be used to shape medical management and lifestyle changes for the proband as well as to screen at-risk family members. An interdisciplinary team at the Montefiore-Einstein Center for Cardiogenetics (MECC) has interviewed a total of 49 individuals, who were recruited from the MECC, Sudden Unexplained Death in Childhood Program (SUDC), and Sudden Arrhythmic Death Syndromes Foundation (SADS). The participants were engaged in open-ended interviews or focus groups, and these sessions were recorded and transcribed verbatim. Of the 49 individuals interviewed, 36 described their motivation to pursue genetic testing. Key motivations identified include: personal medical management, concern about children or future generations, wanting to relieve uncertainty or to obtain peace of mind, and in response to the recommendation of a physician. Through data from previous studies as well as the responses of these participants, it is clear that individuals have varying motivations for pursuing genetic testing that must be recognized in order to provide effective genetic counseling and obtain informed consent.

Identification of EGFR polymorphisms that interact with body weight and systolic blood pressure in young Finnish adults and the prevalence of hypertension in elderly Canadians. *M. Fan[1], T. Lehtimaki[2], O. Raitakari[2], M. Kähönen[2], R.W. Davies[1], L. Chen[1], G.A. Wells[1], R. McPherson[1], R. Roberts[1], A.F.R. Stewart[1].* 1) University of Ottawa Heart Institute, Ottawa, Ontario, Canada; 2) Department of Clinical Chemistry, University of Tampere, Tampere, Finland.

Background: Hypertension is more frequent in obese subjects and substances released from adipocytes may link obesity to increased blood pressure. Methods and Results: We performed a genome-wide interaction analysis for single nucleotide polymorphisms that associate with hypertension through interaction with body weight. A discovery population consisted of the control group from the Ottawa Heart Genomics Study, elderly European-ancestry Canadian men aged >65 and women aged >70 years without symptoms of coronary artery disease (N=2392). A threshold for association was set at $p<0.01$ and polymorphisms were selected by biological plausibility. We identified a polymorphism, rs7795743 (MAF=0.37) in the epidermal growth factor receptor (EGFR) gene where body weight showed an interaction with hypertension ($P=2\times10^{-4}$). The interaction was tested in the Cardiovascular Risk in Young Finns cohort comprised of 2103 young adults aged 24-39 years. In the Young Finns cohort, the interaction of rs7795743 with body weight was also related to systolic blood pressure (P=0.009), but not to diastolic blood pressure. rs7795743 directly influenced the body mass index (BMI) either among young Finnish adults (P=0.009) or elderly Canadians (P=0.019). No influence was found on blood pressure. In a stratified analysis according to body weight, the prevalence of hypertension was significantly increased among carriers of the minor allele in the over-weight group (BMI>27.8, p=0.006). Conclusion: Polymorphisms in EGFR gene influence the risk of hypertension differently among obese and non-obese individuals. Given the complexity of hypertension, our study reveals the need to refine hypertensive phenotypes to identify genetic loci that confer risk through phenotypic interaction.

368W

Prioritized-GWAS based on linkage information identifies novel putative loci influencing coagulation. *F. Gagnon[1], A. Dimitromanolakis[1], G. Antoni[1,2], A. Martinez[3], N. Greliche[2], A. de Buil[3], J.M. Soria[3], P.E. Morange[4], P.S. Wells[5], D.A. Tregouet[2], L. Sun[1,6].* 1) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 2) INSERM, UMR_S 937, Paris, France; 3) Unitat de Genomica de Malalties Complexes, Institut de Recerca Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 4) INSERM, UMR_S 626; Université de la Méditerranée, Marseille, France; 5) Ottawa Health Research Institute, Ottawa, Canada; 6) Department of Statistics, University of Toronto, Toronto, Canada.

Better understanding of the modulation of coagulation Factor XII (FXII) will provide critical insight into thrombi formation and repair, and inflammatory processes. The identification of new molecular pathways underlying some complex traits has been possible with genome-wide association studies (GWAS). However, most often, GWAS do not provide overwhelming evidence for association and results are difficult to replicate due the inherent challenges associated with multiple hypothesis testing. An alternative strategy is to use oligogenic genome-wide linkage studies (GWLS), which can be powerful to identify loci, but these regions are imprecise. We hypothesized that coupling the information brought by both strategies can increase the efficiency for identifying loci. We applied such combined approach to study coagulation FXII levels using 5 multigenerational French-Canadian families (n=253) ascertained through single probands with venous thrombosis and carrier of Factor V Leiden variant. We conducted a combined analysis involving: 1) GWLS using 6522 informative and independent GWAS SNPs (MAF>0.2; r^2<0.8); 2) family-based GWAS using 528438 autosomal SNPs after QC; 3) combined analysis of GWLS and GWAS results using the novel stratified false discovery rate (SFDR) approach (Yoo et al. 2010), allowing for SNPs with some evidence of linkage to have higher weight in the prioritized-GWAS. In addition to the known structural gene encoding FXII protein, regions on chr 1 and 11 showed promising evidence for both linkage (LOD>1.5) and association ($p=10^{-5}$). When SFDR was applied to these results, several SNPs in chr 1 and 11 loci reached genome-wide significance. The strongest evidence for association was observed at the SLC35F3 locus (q-value=0.0003). Interestingly, interaction between the SLC35F3 locus and the structural gene encoding FXII protein was detected (p=0.005) in the French-Canadian families. This SLC35F3 locus was then validated in the GAIT study for the) 2-glycoprotein 1 trait and in a case-control study of venous thrombosis, suggesting a pleiotropic effect of the SLC35F3 locus. The biological plausibility of such pleiotropic effect is supported by) 2-glycoprotein 1 being known to inhibit coagulation factor FXI activation by FXIIa. Our prioritized-GWAS incorporating linkage information allowed the identification of novel loci implicated in coagulation, despite the initial absence of genome-wide significance based on association or linkage alone.

369W

Association of e2, e4 alleles of polymorphism Apo E in Mexican pre-eclampsia patients. *M. Gallegos Jr[1], A. Acevedo[1], LE. Figuera[3], AM. Puebla[2], GM. Zuñga[4].* 1) Dept Med Molec, Guadalajara, CIBO, IMSS, Jalisco, Mexico; 2) Laboratorio de Inmunifarmacologia, CUCEI, UdeG; 3) Division de Genetica, CIBO, IMSS; 4) Laboratorio de Mutagenesis, CIBO, IMSS.

The etiology of preeclampsia is unknown, but different studies have been observed that the endothelial cell injury and altered endothelial cell function play a role in this syndrome and also observed the increased values of triglycerides and cholesterol in patients with preeclampsia. The allele e4 is a genetic marker for dyslipidaemia, the e2 allele has been suggested they might increase the risk of developing preeclampsia and the e3 allele is most common in the population. In the present study we describe to frequency of e3, e2 and e4 alleles of polymorphism Apo E in 51 patients and 49 woman health controls from Mexico. The frequency observed of 18.8% (19/102) and 5% (5/98) of e2 allele; 64.7% (66/102) and 90.8% (89/98) for allele e3; 16.7% (17/102) and 4.1% (4/98) for allele 4 in cases and controls respectively. Statistically different (p<0.05) were observed when to compared each one alleles in the studied groups. These results suggest that e2 and e4 allele is risk allele for Mexican preeclampsia patients.

370W

Does genetics add value? Our experience of cardiac genetics referrals at Loma Linda University Medical Center Center (LLUMC) in the USA, highlighting the need for a protocol for cardiac genetic work-ups. *J. Gold[1], S. Ramanathan[1], J. Bartley[1], L. Bailey[2], R. Clark[1].* 1) Pediatrics,Department Genetics and Metabolism Loma Linda University Medical Center, Loma Linda, CA; 2) Department Cardiothoracic Surgery, Loma Linda University Medical Center, Loma Linda, CA.

LLUMC is internationally recognized in infant transplants, pioneering the baboon to infant heart xenotransplant in 1984 and an allotransplant program since 1985. The study is from a review of 102 patients seen during the year April 2010-May 2011 with cardiac disease by geneticists at LLUMC. A total of 532 patients were seen in the genetics department over the same period. Individuals were seen as consults on the PICU, NICU or genetics clinic. The patients were referred to the genetics clinic pre or post cardiac transplant or when cardiac anomalies were isolated or part of a syndrome e.g. Williams. This has initiated the need for a genetics protocol prior to cardiac transplant. Methods: Review of all cardiac cases that were evaluated. Patients were seen due to isolated cardiac disease or as part of a work-up for multiple congenital anomalies. The data is from the department data base. A total of 19.2% (n102) of all cases referred to the genetics department had a cardiac component. I will present the data and individual cases, for example: 6 year old female, known to have a restrictive cardiomyopathy phenotype. Post cardiac-transplant, on histological examination hypertrophic cardiomyopathy was seen on the explanted heart. Genetic testing demonstrated a pathogenic mutation in TNN 13 and a variant of unknown significance in MYH7. We still await the test results for the parents and younger sibling. All, except the subject, had negative ECG and echocardiograms. Results: Total number of individuals with a cardiac anomaly is 102. 18.6 % (n19) have a syndrome diagnosis. 16.6% (n17) have a micro-deletion or duplication. Of these the commonest is the micro deletion syndrome 22q11 29.4% (n5).The total with chromosomal anomalies including aneuploidy and micro- deletion / duplications is 25.5% (n26). The commonest aneuploidy was trisomy 21 (n6). Conclusion From this review of data presented the value of genetics input is clear. It is difficult to evaluate value. It was recently defined as outcome achieved relative to cost incurred. But what cost can be attributed to a diagnosis? Because of the wide variation in cases it is important to have a protocol in place to be uniform in the treatment of all individuals with cardiac anomalies. I will present a protocol for pre-transplant patients. It is difficult to evaluate value. It was recently defined as outcome achieved relative to cost incurred.

Genome-Wide Association Study for Resting Heart Rate: Variants Detection and Replication. *B. Gombojav[1], D.H. Lee[1], Y.S. Ju[2], J.I. Kim[2,3], J.S. Seo[2,3], M. Lee[1], Y.M. Song[4], K. Lee[5], J. Sung[1].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Health, Seoul National University; 2) Genomic Medicine Institute Medical Research Center Seoul National University; 3) Department of Biochemistry and Molecular Biology Seoul National University College of Medicine; 4) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, SungKyunKwan University School of Medicine, Seoul, Korea; 5) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Korea.

Background: Previous studies have identified increased resting heart rate as an independent risk factor for cardiovascular morbidity and mortality. Although heritable factors play a substantial role in regulating heart rate, evidence about specific genetic determinants is limited. A recent genome-wide association study that enrolled individuals of Asian population has revealed a locus (6q22.31) associated with pulse rate. Objective: To identify common genetic variants associated with heart rate. Methods: A genome - wide association analyses was performed among 3,029 individuals from 661 families of the Healthy Twin Study Korea, and 1026 individuals from 73 extended families of the GENDISCAN study Mongolia. The association between heart rate (adjusted for age and sex) and genetic markers analyzed by Affymetrix GeneChip v6 and Illumina 610K was estimated. A total of 516,452 markers for Korean and 586,875 markers for Mongolian samples remained after cleaning for conventional quality control. Heart rate was measured by electrocardiogram in resting state. Individuals were excluded if they had atrial fibrillation (n = 4), atrioventricular block (n = 13), right bundle branch block (n=6), left anterior fascicular block (n=8) and myocardial infarction (n = 12) as well as ischemia (n = 7). Results: The estimated heritability of heart rate was 0.44 (P <.0001) for Korean, and 0.32 (P <.0001) for Mongolian samples. We have identified six novel loci, which associated with heart rate: 6q22.31 near AL713649 (P = 1.02 x 10-6); 22q13.1 near CACNA1I (P < .00001); 7q33 near CHRM2 (P < .00002); 3p21.31 near LTF (P < .00001); 1p31.1 near KIAA0786 (P < .00002); and 4q22.3 near LIM (P = 5.94 x 10-7). Among the six candidate loci, 6q22.31 has been reported to associate with heart rate and CACNA1I controls the rapid entry of Ca 2 + into a cell. The genotypic effect of AL713649, individuals with the GG genotype had a significantly higher heart rate than those who had TG and TT, the mean heart rate was 67.4 bpm, 65.9 bpm and 65.4 bpm, respectively (P < .0013). Individuals with the CC genotype of CACNA1I had a significantly higher heart rate than those who had TC and TT, the mean heart rate was 66.6 bpm, 64.8 bpm, and 60.3 bpm, respectively (P < .0164). Conclusion: We have identified six candidate genetic loci harboring common genetic variants that were associated with resting heart rate. Further studies are required to replicate these findings and biological validation.

372W

Salt-sensitivity of blood pressure is strongly associated with polymorphisms in the sodium-bicarbonate symporter. *L. Gordon[1], R. Carey[2], C. Schoeffel[2], J. Gildea[2], J. Jones[3], H. McGrath[2], M. Park[1], S. Williams[1], P. Jose[3], R. Felder[2].* 1) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN; 2) Departments of Medicine and Pathology, University of Virginia School of Medicine, Charlottesville, VA; 3) Center for Molecular Physiology Research, Children's National Medical Center, Department of Pediatrics and Medicine, George Washington University School of Medicine and Health Sciences, Washington, DC.

The $NaHCO_3$ cotransporter gene (SLC4A5) on chromosome 2 encodes a protein that transports Na^+ and HCO_3^- electrogenically across the basolateral membrane of many cell types, including renal tubule cells, to the interstitial fluid and ultimately into the circulation. Single nucleotide polymorphisms (SNPs) of SLC4A5 have previously been associated with baseline and 10-year follow-up blood pressure (BP). We tested the hypothesis that SNPs in SLC4A5 and other candidate genes are associated with salt-sensitivity of BP (SS) in Caucasians. Tests for genetic association for BP traits were performed in 185 subjects of European ancestry ages 18-70 y with body mass index (BMI) 18-30, consuming an isocaloric constant diet containing 1g protein/kg body weight /d and 60 meq/d K^+ with a randomized order of 7 days low Na^+; (10 mEq/d) and 7 days high Na^+ (300 mEq/d) intake. SS was defined as a⁄ 7mm Hg increase in mean arterial pressure (MAP) with the subject on high as compared to low Na^+ intake. A total of 41 polymorphisms in 17 candidate genes were assayed. Association with hypertension at baseline revealed only one marginally significant association, rs3830634 in caveolin 1 (CAV1) (P= 0.027). Association analyses with SS revealed several variants that marginally associated with SS in SLC4A5, the dopamine D2 receptor (DRD2), and G protein-related kinase-4 (GRK4) (P < 0.05). However, two SNPs in SLC4A5 (rs10177833 and rs7571842) demonstrated significant results using logistic regression. These two SNPs had P values of $3.5X10^{-4}$ and $8.0X10^{-4}$ and odds ratios of 3.7 and 2.9 in unadjusted regression models, respectively. After adjusting for BMI and age, the associations became stronger (P values $8.9X10^{-5}$ and $2.6X10^{-4}$ and ORs 4.7 and 3.5, respectively). These two SLC4A5 SNPs were in linkage disequilibrium (LD) in both our SS and salt resistant (SR) subjects, but the strength of the LD was greater in SR subjects, (r^2= 0.87 and 0.98, respectively), further supporting the conclusion of an association of SLC4A5 with SS. Lastly, we assessed whether there were any associations with a negative response to salt loading (i.e., a decrease of MAP with high sodium intake). One SNP in DRD2 (rs6276) revealed a highly significant association (P=$8.9X10^{-4}$, OR= 2.5 in an unadjusted model and P= $7.5X10^{-4}$, OR= 2.6 in a model adjusting for BMI and age). Therefore, SLC4A5 variants are strongly associated with SS and DRD2 is negatively associated with SS in Caucasians.

ENPP1 polymorphisms influence the risk of developing calcific aortic valve stenosis. *S. Guauque-Olarte[1], V. Ducharme[1], N. Gaudreault[1], P. Pibarot[1], P. Mathieu[1], Y. Bossé[1,2].* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

Calcific aortic valve stenosis (AS) affects 2% of people older than 65 years. AS is a life threatening disease that is increasing in prevalence with the aging population and for which there is currently no medical treatment. Calcification of the aortic valve is a defining pathological feature of AS. Loss-of-function mutations in the ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) gene are known to cause bone diseases and arterial calcification. ENPP1 is also known to generate inorganic pyrophosphates, which are inhibitors of calcification. ENPP1 is thus a biological candidate gene for AS. The goal of the present study was to perform a genetic association study testing ENPP1 polymorphisms in a case-control series of patients with AS. The study involved 457 patients who underwent surgical aortic valve replacement for severe AS. Tagging SNPs were selected using Haploview and the European-derived (CEU) HapMap genotyping dataset. SNPs in ENPP1 previously associated with risk factors for the progression of AS were forced into the SNP set. A total of 30 SNPs were genotyped using the Illumina® BeadXpress platform. The controls were 3,294 white individuals from the Illumina® iControlDB, genotyped on the HumanHap550 genotyping BeadChip. The MACH program was used to infer the genotypes of 5 SNPs not genotyped in controls using the phased haplotypes of 60 unrelated individuals from the HapMap CEU as a reference set. The association tests were performed on 20 SNPs that passed genotyping quality control filters. Six SNPs were significantly associated with AS (p < 0.05). Following correction for multiple testing, three SNPs were significantly associated with AS including rs1800949 located in the promoter (p = 2.4E-03), rs9402349 in intron 9 (p = 1.2E-03) and rs7754586 in the 3'UTR region (p = 6.0E-04). The pairwise linkage disequilibrium for these three SNPs measured by r^2 range from 0 to 0.14. The results of this study suggest that a number of independent SNPs in the ENPP1 gene modulate the risk of AS. Further analyses are needed to understand how these associated SNPs lead to abnormal function of the ENPP1 gene that in turn promotes the development of AS.

374W

ABCA1 gene promoter DNA methylation is associated with a deterioration of HDL-cholesterol metabolism in familial hypercholesterolemia. *S. Guay[1,2], D. Brisson[2,3], J. Munger[1,2], D. Gaudet[2,3], L. Bouchard[1,2].* 1) Deparment of biochemistry, Université de Sherbrooke, Sherbrooke, Québec, Canada; 2) ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Saguenay, Québec, Canada; 3) Department of medicine, Université de Montréal, Montréal, Québec, Canada.

Background: The cholesterol contained in high-density lipoproteins (HDL-C) is known as a negative clinical biomarker of cardiovascular disease (CVD), especially coronary artery disease (CAD). Significant interindividual variations in circulating HDL-C levels is common, even in subjects at high risk of CVD such as those with familial hypercholesterolemia (FH). Although heritability estimates for circulating HDL-C levels are high (up to 60%), the related genes and molecular mechanisms remain to be identified. The ATP-binding cassette A1 (ABCA1) is a membrane protein involved in cholesterol and phospholipid transfer from peripheral cells to nascent HDL particles in circulation, a key step of reverse cholesterol transport. ABCA1 deficiency is associated with decreased HDL-C levels and an increased CVD risk. Recently, DNA methylation profile perturbations at the *ABCA1* gene promoter have been observed in adults exposed in utero to famine. Our hypothesis is that DNA methylation variation at the *ABCA1* gene promoter explains interindividual differences in circulating HDL-C levels among FH patients. **Methods/Results:** DNA from 51 FH patients (74.5% men), all heterozygous for the same mutation in the *LDLR* gene (p.W66G), was purified from whole blood samples. Twenty-five of these patients were under hypolipidemic treatment before the beginning of the study (mean therapeutic wash-out of six days), whereas the remaining 26 were naïve of treatment. *ABCA1* DNA methylation levels were measured using bisulfite-converted DNA pyrosequencing. Cholesterol and phospholipids levels were measured enzymatically in HDL particles isolated by ultracentrifugation. The *ABCA1* gene promoter DNA methylation was negatively correlated with circulating HDL-C (r=-0.39; p=0.007) and HDL2-phospholipid levels (r=-0.43; p=0.044) when controlled for age, gender, waist circumference and fasting triglyceridemia. Although not significant, FH patients with CAD (n=11) had higher *ABCA1* DNA methylation levels compared to those without CAD (41.3% vs. 35.9%; p=0.076). This trend was confirmed in an independent sample of 223 heterozygous p.W66G FH patients (36.7% vs. 34.7%; p=0.077), especially in women (n=133; 39.3% vs. 34.7%; p=0.022). **Conclusion:** According to these results, epigenetic modification of the *ABCA1* gene promoter could explain a significant proportion of the interindividual circulating HDL-C level variation and is associated with CAD expression among FH women.

LQTS in Northern BC:A more severe cardiac phenotype but minimal impact on auditory function with homozygosity for KCNQ1 V205M rules out Jervell and Lange Nielson syndrome. *H. Jackson[1], S. Lauson[1], R. Rupps[2], S. McIntosh[1], B. Casey[2], A. Tang[1], L. Arbour[1].* 1) University of British Columbia, Victoria, British Columbia , Canada; 2) University of British Columbia, Vancouver, British Columbia , Canada.

Background: Two First Nations communities in northern British Columbia are affected disproportionately with LQTS due to two different KCNQ1 mutations (V205M and R591H). The current known mutation rate within these two communities (1/125) is predicted to be one of the highest in the world at 20 times that which is expected for the general population. The question remains, however, as to whether carrying more than one of these mutations is associated with a more severe clinical phenotype and/or with deafness (Jervell and Lange Nielsen syndrome (JLNS)). Methods: All individuals identified have been tested for both mutations. Clinical information was recorded. QT intervals were determined in all leads by the tangent method and the longest QT interval in any available ECG recording was used in the determination of the `peak' QTc (± SD). QTc values were calculated using the Bazett correction method and an average RR interval for the ECG. Results: More than 70 individuals were identified to have at least one mutation. While no compound heterozygotes have been identified, four individuals were homozygous for the KCNQ1 V205M mutation. Homozygous V205M carriers had a significantly higher `peak' QTc (570.3 ± 91.12 ms) when compared to 41 heterozygous V205M carriers (472.9 ± 37.40 ms, p<0.0001) and the first to third degree relatives (n=58) without mutations (437.5 ± 27.82 ms). Two of four homozygous cases report mild childhood onset hearing loss. The other two reported no hearing loss, one confirmed with normal audiology. Three are treated with beta blockers, one with an implanted defibrillator. Conclusion:The lack of pre-lingual hearing loss categorizes the phenotype of our patients as RWS even though their genotypes confirm homozygosity of V205M. Furthermore, heterozygous carriers in this community also present with cardiac symptoms, supporting the autosomal dominant nature of LQTS caused by the KCNQ1 V205M mutation. The double-hit on normal cardiac repolarization and the greater reduction of IKs current experienced by homozygous mutation carriers is presumed to lead to a more severe clinical cardiac phenotype. Meanwhile, the resultant current must be sufficient to maintain homeostasis in the auditory pathway. However, because two of the cases have reported childhood onset hearing loss, milder, post-lingual hearing loss due to KCNQ1 mutations cannot entirely be ruled out and a further audiology study is planned for this population.

376W

Assumption-free heritability estimates of electrocardiographic measures in the TwinsUK study. *Y. Jamshidi[1], I.M. Nolte[2], H. Riese[2,3], P. van der Harst[4], F.W. Asselbergs[6], T.D. Spector[5], H. Snieder[2].* 1) Biomedical Sciences Division, St Georges University of London, London, United Kingdom; 2) Department of Epidemiology, Unit of Genetic Epidemiology, and Bioinformatics, University Medical Center Groningen (UMCG)/University of Groningen (RuG), Groningen, The Netherlands; 3) Interdisciplinary Centre for Psychiatric Epidemiology, UMCG/RuG, The Netherlands; 4) Department of Cardiology, UMCG/RuG, Groningen, The Netherlands; 5) Department of Twin Research and Genetic Epidemiology, King's College London, United Kingdom; 6) Department of Cardiology, Division of Heart and Lungs, University Medical Center Utrecht, Utrecht, The Netherlands.

The standard 12-lead electrocardiogram (ECG) measurements are effective markers both for predicting the outcomes of patients with heart disease as well as for predicting cardiovascular mortality in healthy subjects. A number of genome-wide association studies have recently investigated the genes associated with ECG traits. The gene variants discovered thus far explain <10% of the total variability in population ECG characteristics, when heritability (h^2) estimates suggest that up to 50% of this variability is genetic. Classical twin analysis allows estimation of the effects of genetic factors on the variance of a trait. The power to estimate these variance components is derived by assuming that MZ-twins have inherited identical genomes and DZ-twins share on average 50% of their genes. A higher MZ than DZ-twin correlation suggests that the trait under study is heritable. Some have argued that assumptions of the twin model may be invalid resulting in inflated h^2 estimates, thus explaining part of the missing h^2. In order to help characterize more reliably than previously possible the heritability for ECG traits, we obtained estimates from 3,313 twins from the TwinsUK cohort, using both the classical twin method and an assumption-free method which makes use of genome-wide coverage of genetic markers to directly estimate degree of resemblance between relatives in a model free from confounding with non-genetic factors. Univariate structural equation models were fitted for assessing the genetic and environmental contributions to the ECG traits. The AE model combining additive and unique environmental factors produced the best fit for all traits except the Cornell product, which could be predominantly explained by common and unique environmental factors. Modest to high heritability estimates (h^2>0.5) were obtained for all ECG traits (Heart rate, PR interval, QRS duration, RV5SV1, QT interval, Sokolow-Lyon product, Cornell product) using both methods. Our study is one of the largest to date looking at the heritability of ECG measures and one of the first to compare the two methods of estimating heritability in a comprehensively phenotyped twin cohort. The two different methods give comparable but also unique information. Reasons for these different findings will be discussed. Accurate h^2 estimates are crucial as they provide a yardstick against which the success of the h^2 explained by GWAS can be gauged.

Genes and viruses in idiopathic (dilated) cardiomyopathy; a pilot study. *I.PC. Krapels[1], Y.H.J.M. Arens[1], A.T.J.M. Helderman-van den Enden[1], C. Eurlings[2], R. Jongbloed[1], A. van den Wijngaard[1], S.R.B. Heymans[2].* 1) Clinical Genetics, Maastricht University Medical Center, Maastricht, Netherlands; 2) Cardiology, Maastricht University Medical Center, Maastricht, the Netherlands.

Background: dilated cardiomyopathy (DCM) is characterized by impaired contractility and dilatation of the ventricles. Mutations in the currently known DCM-genes only explain a small number of DCM patients. The clinical phenotype in families with a known DCM mutation varies considerably. Cardiotropic viruses are involved in DCM and could explain the differences in clinical phenotype among individuals. We assessed the interaction between viral en genetic components in a group of idiopathic DCM patients. Methods: genetic analysis was performed through CardioCHIP analysis, a CHIP-based high throughput resequencing platform, simultaneously analysing 34 genes involved in inherited cardiomyopathies. The presence of cardiotropic viruses was assessed on the cardiac biopsies. Results: cardiac biopsy data was available for 177 patient; 59 (33%) of them had viral presence on cardiac biopsy (Parvo virus, >250 copies per mcg isolated DNA). One patient had an active myocarditis. Cardiochip data was available for 55 patients; 34 of them (62%) had genetic variations (either polymorphism, unclassified variant of mutation). The combined data of the Cardiochip analysis and cardiac biopsy was available for 30 patients. Of these 30 patients, 22 patients had no virus presence on biopsy. 12 of these 22 had genetic variants (55%), compared to 50% (4/8) in the group of patients with virus presence. Conclusion: Although based on small numbers, these data demonstrate that the presence of a viral infection as a cause for dilated cardiomyopathy does not exclude a genetic component. Further studies will address whether environmental factors such as a viral infections explain the difference in phenotype between patients and families with a known DCM mutation.

Genetic Testing for Dilated Cardiomyopathy (DCM) in the United States: A Health Technology Assessment. *A. Lea, S. Levine, D. Allingham-Hawkins.* Hayes, Inc, Lansdale, PA.

Objectives: DCM may be caused by either genetic or nongenetic factors. The genetics of DCM are complex, with many genes associated with it, but each gene accounting for only a small proportion of cases. Approximately 90% of DCM is inherited in an autosomal dominant fashion, although recessive and X-linked inheritance patterns have also been observed. Identification of asymptomatic relatives of individuals with a genetic cause of familial DCM is likely to be clinically useful by allowing preventative interventions. This health technology assessment focused on reviewing the evidence that linked individual genes with DCM for the purpose of preventative screening. Methods: Laboratories that provided clinical genetic testing for DCM in the United States (US) were surveyed to identify genes for which screening is available. For each of these genes, a literature search was performed to identify data linking sequence variants in the gene with DCM. This evidence base was reviewed to characterize the strength of the association of genes with DCM through 4 characteristics: pathogenicity in 2 or more reports; severity of phenotype; penetrance; and inheritance pattern. Results: Seven laboratories were identified that provided genetic testing for DCM in the US. Included in the DCM testing panels were 41 genes. There was a low degree of consistency of genes tested by different laboratories; there were only 8 genes (ACTC1, LAMP2, LDB3, LMNA, MYBPC3, MYH7, TNNT2, and TPM1) in common for 6 of the 7 laboratories. Review of the evidence indicated that the relationship between sequence variants and phenotype was well defined for only 3 genes (LMNA, MYH7, and TNNT2). For 10 genes (EMD, LAMP2, MT-ND6, MT-TD, MT-TH, MT-TM, MT-TQ, MT-TS1, MT-TS2, and TTR), no evidence was identified that linked them with DCM. The relationship with DCM was incompletely defined for the remaining 28 genes. Conclusions: Clinical genetic testing for DCM is available for 41 genes in the US; however, a review of available evidence indicates that for only 3 of these genes is the genotype-phenotype relationship clearly defined. While research in the genetic underpinnings of DCM is finding more genes reported to be associated with DCM, the evidence base supporting the associations with DCM is variable. Additional research to define the genotype-phenotype relationship may be needed before clinical genetic testing for sequence variants in the majority of genes associated with DCM has clinical utility.

MYLK and INK4/ARF genes are the susceptibility genes of cerebral small vessel disease in Chinese population. *W. Li[1,2], G. Li[3], X. Zhao[2], B. Xin[1], J. Lin[2], Y. Shen[2], X. Liang[2], H. Gao[2], X. Liao[2], Z. Liang[4], Y. Wang[2].* 1) DDC Clinic for Special Needs Children, Middlefield, OH; 2) Department of Neurology, Beijing Tiantan Hospital, Beijing, China; 3) Department of Neuropathology, Beijing Neurosurgical Institute, Beijing, China; 4) Department of Neurobiology, Capital Medical University, Beijing, China.

Backgroud and purpose: Cerebral small vessel disease (CSVD) is a common insidious progressive cerebrovascular disease in middle-aged and elderly. Previous studies showed that CSVD might have a genetic background .The project aims to investigate susceptibility loci and candidate genes associated with CSVD. **Methods and materials:** All study subjects admitted Beijing Tiantan Hospital from June 2009 to September 2010. The total study population is 792 Han Chinese, including 197 cerebral small vessel disease patients(S), 198 large artery atherosclerosis (stenosis greater than 50%) patients (L), 200 hypertensive cerebral hemorrhage patients (H) and 197 stroke-free control individuals(C). Genomic DNA was extracted from venous blood sample. Genotyping of the 15 SNPs in 4 genes (MYLK, AQP4, NINJ2 and INK4/ARF) were done using Multiplex Snapshot assay. Binary logistic regression analysis was performed for each SNP based on five models, including codominant model, dominant model, recessive model, overdominant model and log-additive model. The significant SNP loci were selected for further analysis of allelic and genotypic frequency in C, S, H, and L. Allelic and genotypic frequencies of cerebral small vessel disease at significant SNP loci were analysis in gender, diabetes, hyperlipidemia, smoking and drinking. **Result:** Evidence of association with CSVD was observed for 2 tagSNPs using permutation multitest: rs2222823 SNP locus (MYLK gene) in overdominant model, P = 0.0019, adjust p value was 0.03, T/A genotype, OR was 0.52 (95% CI, 0.35-0.79); rs2811712 SNP locus (INK4/ARF gene) in codominant model, P = 0.0035, adjust p value was 0.05, C/C genotype, OR was 0.47 (95% CI, 0.20-1.15). Further, the evidence of significant difference was found at rs2222823 in overdominant model between hypertensive intracerebral hemorrhage (IH) and CSVD, P value was 0.035, T/A genotype, OR was 0.65 (95% CI, 0.43-0.97). The prevalence rate of risk factors in CSVD, IH and large artery atherosclerosis (LAA) were 29.5%, 19.4% and 41.0% respectively in diabetes; 54.6%,47.2% and 76.3% respectively in hyperlipidemia; 42.5%,48.2% and 59.1% respectively in smoking; 37.3%,41.7% and 44.2% respectively in drinking. **Conclusion:** Our study found the evidence of significant association with CSVD at tagSNP loci, rs2222823 (MYLK) and rs2811712 (INK4/ARF), suggesting MYLK and INK4/ARF gene are likely susceptibility genes of CSVD.

Novel *ACTA2* mutation in a large family with familial thoracic aortic aneurysms and dissections exhibiting reduced penetrance in a female carrier. *M.A. McGinniss[1], H. Wang[2], J.N. Young[3], R. Calhoun[3], S. Mayberg[3], J. Martinezmoles[4], A.W. Grix[4], B.A. Westerfield[2], L.S. Pena[2], D.J. Penny[2], Y. Fan[2], S.A. Boyadjiev[1].* 1) Section of Genetics, Department of Pediatrics, University of California, Davis Medical Center, Sacramento, CA; 2) The John Welsh Cardiovascular Diagnostic Laboratory, Section of Cardiology, Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) Division of Cardiothoracic Surgery, University of California, Davis Medical Center, Sacramento, CA; 4) The Permanente Medical Group, Department of Medical Genetics, Sacramento, CA.

Familial thoracic aortic aneurysm and/or aortic dissection (TAAD) is a genetically heterogeneous disorder that is inherited in an autosomal dominant fashion. Mutations in *ACTA2*, encoding smooth muscle-specific alpha-actin, account for approximately 14% of familial TAAD. Only 19 *ACTA2* mutations have been described to date. In addition to the risk for TAADs, mutations in the *ACTA2* gene have been associated with increased risk for coronary artery disease and premature stroke. We report a large Italian-American family with a history of acute ascending and descending aortic dissections segregating in an autosomal dominant manner. The age of the first acute cardiac event is between 30 and 53 years of age. The mother and a brother of the proband died prior to surgical intervention at 53 and 45 years of age, respectively. In addition, two of the proband's brothers presented with acute aortic dissections and survived emergency surgical repair of the ascending aorta. Direct sequencing of the *ACTA2* gene in the proband revealed a novel heterozygous missense mutation (c.193T>C; p.Met49Thr) that was not detected in 190 control chromosomes. Polyphen-2 analysis indicates that this mutation is probably deleterious. This mutation was present in a symptomatic brother and in one clinically unaffected sister who had normal size of the aortic root at age 37. No affected family members had a history of premature stroke, coronary artery disease, iris flocculi and/or livedo reticularis on clinical examination. Results from this family expand the spectrum of *ACTA2* mutations causing TAAD by identifying a novel mutation and provides further phenotypic characterization. It also provides further evidence of reduced penetrance of the mutant allele and/or variable expressivity in female carriers. Functional studies of the Met49Thr mutation are ongoing.

Single nucleotide polymorphisms analysis of INSL3 and RXFP2 genes in Mexican patients with idiopathic cryptorchidism. *M.D. Chávez-Saldaña[1], J.C. Gutiérrez[1], I. Zamora[1], O. Cuevas[2], J. Rojas[1], O. Gutiérrez[1], E. Yokoyama[3], R.M. Vigueras[1].* 1) Laboratorio de Biología de la Reprod., Instituto Nacional de Pediatría S.S, México, Distrito Federal, Coyoacan, Mexico; 2) Servicio de Urología;Instituto Nacional de Pediatría S.S México, D.F; 3) Departamento de genética Humana, Instituto Nacional de Pediatría S.S México, D.F.

Criptorchidism (CO) or not testicular descent is considered the most common congenital birth defect in male children and could present itself like an isolated manifestation (idiopatica) or associated with a congenital malformation syndrome. CO is an important factor for male infertility and testicular malignancy on adulthood, its etiology is, in most cases, remain unknown, itself might be considered a complex disease in which multiple genes are involved in the testicular descent like INSL3, RXFP2 and HOXA10. In this study we analyzed some single nucleotide polymorphisms (SNPs) in the INSL3 and RXFP2 genes, that could contribute as risk factors or susceptibility for the idiopatic CO in Mexican patients. 85 patients were included with idiopatic CO and one hundred kids on the control group, where 3 and 9 SNPs were analyzed from previously present genes respectly. The allelic discrimination analysis was realized through the TAQ-MAN method. The SNPs association with the CO type was analyzed with the SPSS® statistic program. In the case of the INSL3 gene, after the allelic discrimination assays, the patients that were out normal for the three analyzed polymorphisms were put through the automatic sequencing analysis from exon 2 of this gene. 100% from patients but also from the control group, were out normal homozygous for the p.R102C and p.R105H from the gene INSL3 variables, while the p.R102H variable was detected in only one patient in heterozygous state, with bilateral CO and without any family antecedents. With the search of unknown alterations in the INSL3 gene, two alterations were detected: p.R105R and the p.T86M, on both cases patients presented bilateral CO. On the other hand the frequency of the analyzed variables in the RXFP2 gene is very similar to other populations, although, comparing the frequency of these variables with the patients and the control group, the c.51869A-G variable showed significative differences, since the GG genotype or at risk, is more common on idiopatic CO patients, on the other hand realizing the genotype-fenotype correlation, it shows that the c. 30704C-T variable, the TT genotype or at risk is more common on bilateral CO patients than those with unilateral CO. In the future knowing the type and distribution from the allelic variables in our population, will allow the improvement of risk prevention methods and susceptibility for this malformation and in the future the infertility and testicular cancer preventive care.

Molecular Markers for Effective prognosis in Systemic Lupus Erythematosus Patients at risk of Renal and Cardiovascular Diseases. *R. Chandirasekar[1], K. Sasikala[1], D. Nedumaran[2], K. Suresh[1], R. Jayakumar[1], R. Venkatesan[1], B. Laksmankumar[4], G. Karthik[3], S. Arun[1].* 1) Zoology, Bharathiar University, Coimbatore, India; 2) Government Medical College and Hospital, Coimbatore, India; 3) Department of Bioinformatics, Bharathiar University, Coimbatore, India; 4) Kongunadu arts and science college Coimbatore, India.

Systemic Lupus Erythematosus (SLE) is a complex, prototypic autoimmune disease that predominantly affects women population. The hallmark of SLE is the generation of auto antibodies that react with self nuclear and cytoplasmic antigens, culminating in immunologic attacks to body organs. Recent evidences suggest that SLE is a complex genetic disease, contributes with environmental and genetic factors. Angiotensin-converting enzyme (ACE) plays an important role in the development of SLE, expressed in a wide range of tissues including lung, vascular endothelium, kidney, Cardiovascular and testis. ACE catalyses the conversion of Angiotensin I to Angiotensin II by its metalloproteinase enzymatic activity and plays a major role in the renin-angiotensin and kallikrein-kininogen systems. ACE gene I/D polymorphisms, particularly DD genotype has been associated with lupus susceptibility and with risk of Renal Disease and cardiovascular disease. angiotensin II, plays an integral role in the regulatory system responsible for endothelial control and vascular tone. The study was analysed and evaluated the ACE gene polymorphic variants among the recruited 48 SLE patients associated with the Cardiovascular and renal disease (SLE was confirmed by Anti Nuclear antibody (ANA) and dsDNA tests) and 48 controls, on the basis of biochemical parameters (total serum cholesterol (HDL, LDL, VLDL, TGL) and C-reactive protein (CRP)) and molecular investigation by Polymerase chain reaction (PCR) and Restriction fragment length polymorphism (RFLP). Results: the biochemical parameter of this study showed that SLE patients had higher levels of cholesterol (36%) and CRP levels higher than normal reference range (<5 mg/L) compared to the controls. The genotype frequency of ACE gene polymorphism determined in SLE patients DD 46%, ID 30% and II 24% compared to controls showed the variance of higher the risk in SLE patients with DD polymorphism P = 0.0034. Hence our findings confirmed the ACE gene polymorphic variant has a major part in leading to cardiovascular disease. At present we focused the research toward RAAS pathway and kallikrein-kininogen systems associated gene for identifying the cause of cardiovascular disease.

Dynamic modularity beyond “date” and “party” hubs in protein-protein interaction networks. *X. Chang, K. Wang.* Zilkha Neurogenetic Institute, University of Southern California, 1501 San Pablo Street, Los Angeles, CA, USA 90089.

The concept of ``date" and ``party" hubs has been widely accepted in the area of protein-protein interaction networks. Party hubs interact with most of their partners simultaneously, while date hubs bind different partners at different locations and times. In theory, date hubs preferentially connect functional modules to each other, whereas party hubs preferentially act inside functional modules. The two types of hubs also display profound differences regarding topological roles and evolutionary constraint. Despite the preponderance of the evidence in its favor, there is still debate about the concept of date and party hubs owing to the potential biases of statistical model or datasets. We divided the network into modules and assigned roles to hubs according to network topology rather than on the basis of expression data. We applied our approaches on two datasets of yeast from different studies, one of which supported the “date” and “party” hubs concept and the other did not. Both datasets were generated on high-throughput yeast two-hybrid system with different filter thresholds and criterions for curation. The first dataset contains 2,561 proteins and 5,992 interactions, the second dataset includes 4,011 proteins and 10,055 interactions. We identified 23 and 16 modules from the two datasets respectively. Most modules have corresponding modules in the other dataset which shares a statistically significant number of nodes after Fisher's exact test. Noticeably, most genes involved in “ribosome biogenesis and their assembly” are enriched in one single module that displays high co-expression with their neighbors. Hubs of this module also contributed largely to the formation of the bimodal distribution of hub co-expression, which motivated the date/party distinction. We also found that co-expression of the nodes in functional modules was highly related to specific conditions under which the expression data was obtained. Therefore, party hubs in these modules could be mistakenly regarded as date hubs due to low co-expression levels calculated from the integration of datasets from various conditions. Our results confirmed the widespread existence of party hubs related to functional modules. As for date hubs, they may exist theoretically; however, using merely the co-expression measurements, we cannot define the date/party distinction.

Testing for a mixture of effects on either disease or quantitative traits across a set of rare variants. *G. Clarke, A. Morris.* Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford, OX3 7BN, United Kingdom.

Multiple rare variants either within or across genes are believed to collectively influence phenotypic expression. The increasing availability of high throughput sequencing technologies offers the opportunity to study the effect of rare variants on complex traits but appropriate analytical methods are required. Methods must be able to account for a collection of rare variants displaying a combination of protective, deleterious and null effects. Recently Neale et al.1 proposed a C-alpha score test to test for the presence of a mixture of effects on a disease phenotype across a set of rare variants. Here we propose an alternative C-alpha score test for the analysis of sequence level data that can be applied to both disease and qualitative phenotypes and which can adjust for the presence of covariates. For qualitative traits and variants with an allele frequency greater than 0.5%, our method has comparable or slightly better power than tests based on collapsing sets of variants when all effects are in the same direction and much greater power when a mixture of protective and deleterious variants are studied. For binary traits and variants with an allele frequency greater than 0.5%, our method has comparable or slightly better power than the method proposed by Neale et al. Our test is a simple, fast and effective method, which can account for covariates and which can be applied directly to both quantitative and binary traits in the analysis of sequence level data 1. Neale BM, Rivas MA, etc. Testing for an unusual distribution of rare variants. PLoS Genet 2011;7(3).

Pathway association analysis using an overall test for the most promising SNPs. *M. Mattheisen, W. Yip, P. Lipman, C. Lange*. Department of Biostatistics, Harvard School of Public Health, Boston, MA.

Pathway-based and set-based approaches (PAA) have been developed to facilitate the analysis of GWA study data sets. While exploiting existing biological knowledge of gene function/pathways, these approaches are capable to identify genes with large genetic effects, but also new genes/ pathways in which each single SNP (or even gene) confers only a small degree of disease risk. The combined effects of these SNPs/genes can then be implicated in the development of disease. Several methods using a wide range of algorithms have been proposed in the context of pathway association analyses. These approaches typically examine whether a group of related genes in the same functional pathway (or functional sets) are jointly associated with a trait of interest. For these methods the power to detect true disease association depends on the underlying genetic model and the phenotype under study. Nevertheless, under simple, realistic disease models, PAA can strongly outperform the GWAS single-marker approach. Here we present a new powerful approach, which is based on a recently published method for the follow-up of GWAS results (Lipman et al. 2011). Similar to the aforementioned study we partition the P-values for the SNPs in the gene-sets or pathways into a predetermined number of bins (J+1). While one bin collects all P-values of the SNPs that will be of less interest (i.e., all SNPs below a predefined threshold theta) the other J bins partition the P-values falling between 0 and theta. We then count how many P-values fall into each bin. If the bins contain more P-values than expected under the null-distribution, there is evidence to reject the null hypothesis and conclude that the gene-set/ pathway is of interest for the disease under study. We discuss the properties of the test statistic and compare the results for our method and several available approaches (among others ALIGATOR and GenGen) using both, a simulation study and a large scale GWAS data set. Finally we evaluate the usage of Kolmogorov-Smirnov tests in the context of pathway association analyses. Lipman PJ, Cho MH, Bakke P, Gulsvik A, Kong X, Lomas D, Anderson W, Silverman E, Lange C. On the Follow-Up of Genome-wide Association Studies: An Overall Test for the Most Promising SNPs. Genet Epidemiol 2011 (in press).

Modeling of the Interaction between the Serotonin Regulation Pathway and the Stress Response, mediated by the Hypothalamic-Pituitary-Adrenal Axis, using a Boolean Approximation: a Novel Study for Depression. *O.A. Moreno-Ramos[1,2], M.C. Lattig[1], A.F. Gonzalez[2].* 1) Biological Sciences, Laboratorio de Genetica Humana, Bogota, Colombia; 2) Grupo de Diseño de Productos y Procesos, Departamento de Ingeniería Química, Universidad de los Andes, Bogota, Colombia.

Depression shows a high prevalence in the overall population and is a major public health problem worldwide (WHO, 2004). According to different studies performed in twins, a heritability of approximately 40%; is observed and it increases if another member of the family suffers from other affective disorders. Thus, it has been hypothesized that depression has a strong genetic background, and genes in the serotonin metabolic pathway have been implicated in the occurrence of the disease. Environmental factors such as stressor events are also strongly associated with depression. The principal aim of this work was to model the interaction between the serotoninergic pathway and the stress response pathway mediated by the hypothalamic-pituitary-adrenal axis using a Boolean approximation. We also determined which genes, when knocked out in-silico, cause the highest impact on the model stability. Furthermore, in this model we simulate the impact antidepressants have on the biological pathway. The results obtained indicate that the network is stable with or without stress, but that stability is reached faster when the pathway is run without stress. Also, we observed that the biological model generated predicts steady states (attractors) for each of the different runs performed. Those attractors change in shape, especially when antidepressants were also included in the simulation. We also found that when the model involves both the serotoninergic pathway and stress, antidepressants, like the SSRIs, do not have the expected effect. This work also predicted that the genes that cause the highest impact on this model stability were CREB, BDNF (which in different association studies, has been associated to major depression disorder) and TR2) ; followed by the genes and metabolites that are related to the serotonin synthesis.

Large-scale transcriptome study in the Sardinian founder population. *M. Pala[1,5], M. Marongiu[1], A. Mulas[1], R. Cusano[1], F. Crobu[1], F. Reinier[2], R. Berutti[2,5], M.G. Piras[1], C. Jones[2], D. Schlessinger[4], G. Abecasis[3], A. Angius[1], S. Sanna[1], F. Cucca[1,5].* 1) Istituto di Ricerca Genetica e Biomedica (IRGB), CNR, Monserrato, 09042, Italy; 2) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 3) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 4) Laboratory of Genetics, National Institute on Aging, Baltimore, Maryland, USA; 5) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy.

With the advent of next-generation sequencing technologies, high throughput dissection of complex traits and diseases can be extended to underlying biological mechanisms by assessing changes in the transcriptome or methylome. Studies conducted so far were limited by the small sample size, were restricted to the correlation of only one clinical condition (or none), or relied on polyA enrichment protocols that detect only a small fraction of total RNA species. We are sequencing the RNA of 1,000 individuals from the Sardinian founder population enrolled in the SardiNIA project and hence characterized for >200 quantitative traits, with measurements repeated in follow-up visits. To survey both coding and non-coding RNA species, we used an rRNA-depletion protocol and focused on peripheral blood mononuclear cells (PBMC) to catalogue transcription variation in a critical tissue implicated in the wide range of immune-affected phenotypes. The augmented scale facilitates the discovery of novel splicing isoforms and novel species from regulatory regions that extend to “inter-genic” regions as well as within known genes, which can be directly tested for correlations with clinical conditions. In addition, because this RNA sequencing effort is coupled with DNA sequencing of the same samples, eQTLs and RNA-editing sites can be assessed as well. Preliminary analysis of a pilot run of 12 samples, with an average of 50 million reads (51+51 nucleotides at paired ends) sequenced using the Illumina HiSeq2000, shows the relative enrichment of different RNA subclasses. Reads were aligned to the reference genome with TopHat, and an average of 91% were properly mapped. Of those, less than half (45%) fall, on average, within known exons; the others define inferred novel transcripts. Among all the aligned reads, those in unequivocally known transcript classes include protein coding (14%), mitochondrial rRNA (8%), pseudogene (1%), miscRNA (0.6%), lincRNA (0.5%), snoRNA (0.3%), snRNA (0.2%) and miRNA (0.05%) species. The remaining reads map within transcripts annotated in multiple categories; with low abundance in rRNAs (as expected by the chosen protocol); outside annotated transcripts or to multiple genomic sites. This relatively unbiased representation of the transcriptome provides the basics for the ongoing integration with corresponding DNA sequencing and phenotypic trait values.

Development and use of a pipeline to generate strand and position information for common genotyping chips. *N.W. Rayner[1,2], M.I. McCarthy[1,2,3].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Churchill Hospital, Oxford, United Kingdom; 3) Oxford National Institute for Health Research Biomedical Research Centre, Churchill Hospital, Oxford, UK.

With the increasing use of ever larger meta-analyses the number of data sets being combined has increased dramatically. This can lead to a number of problems, not least in ensuring all data sets are aligned to the same genomic build and strand. Traditionally data sets in meta-analyses were likely to have been imputed, thereby aligning the SNPs to the reference panel, using their alleles and Minor Allele Frequency (MAF). Imputation can still encounter problems, for example with A/T and G/C SNPs having a MAF close to 50% or those SNPs that do not appear in the reference panel. When utilising directly genotyped data, an ever increasing occurrence with the new large genotyping arrays, the problem becomes even more acute. Options do already exist to update the genome build such as the lift-over tool at UCSC however this does not provide the orientation to the reference strand which can change. The situation is further complicated by a profusion of genotype calling algorithms, leading to the final calls being reported to a number of different orientations, something we have observed in ~20% of cohorts studied to date. To address these issues we have created a pipeline to map SNPs on the genotyping platforms to the genome using flanking or probe sequences from the annotation files. The core of the pipeline is a local installation of a BLAT server, to map the sequences to the genome. This is wrapped in a set of Perl programs which automate the running of the server and the processing of the input and output files. The final output is a set of files that give, the position and orientation of each SNP to the genome build used, the SNPs that do not map to the genome and those SNPs that show mappings to more than one position. The strand and position files have been generated for a number of ongoing meta-analyses such as the DIAGRAM replication effort where 26 cohorts comprising ~85,000 samples, all utilising the same Illumina iSelect Metabochip genotyping platform, have successfully combined directly genotyped data on 196,725 SNPs to follow up top signals from the earlier DIAGRAM meta-analyses. We have expanded the number of files available by running the most common Illumina and Affymetrix chips for genome builds >35, the resulting files have all been uploaded to a web site where they are freely available. This page is constantly updated to keep pace with new chips, the differing orientations of the genotype calling algorithms and changes in the genome build.

Association of Endothelial nitric oxide synthase gene haplotypes with systemic lupus erythematosus in Kuwaiti Arabs. *M. Haider[1], S. Alfadhli[2], B. Altamimy[2], K. Alsaeid[1].* 1) Dept Pediatrics, Fac Med, Kuwait Univ, Safat, Kuwait; 2) Dept Medical Lab Sci, Fac Allied Health, Kuwait Univ, Safat, Kuwait.

Endothelial nitric oxide synthase (eNOS) catalyses the production of nitric oxide, which has been shown to participate in the pathogenesis of systemic lupus erythematosus (SLE). eNOS gene polymorphism may have an effect on eNOS gene expression, eNOS protein synthesis and enzymatic activity. We investigated the influence of eNOS gene polymorphisms on susceptibility to SLE. eNOS T-786C, G894T and intron 4 27-base pair tandem repeat (VNTR4) polymorphisms were investigated in 152 Kuwaiti SLE patients and 184 controls using RFLP-PCR, direct sequencing and fragment analysis. Allele, genotype and haplotype frequency comparisons, Hardy-Weinberg equilibrium and linkage disequilibrium (LD) analysis were performed. No significant association was detected between SLE and single-nucleotide polymorphisms (SNPs) T-786C and G894T. VNTR4 allele 4b was associated with susceptibility to SLE (OR 1.89, p = 0.023), as was the genotype 4bb (OR 2.41, p = 0.007). However, allele 4a was protective (OR 0.53, p = 0.023), as was genotype 4ab (OR 0.41, p = 0.007). T-786C and VNTR4 were in high LD (r (2)= 0.34). Haplotypes T4bC and C4aG of the three tested polymorphisms had a susceptibility effect on SLE (OR 1.89 and 4.23 at p = 0.005 and 0.001, respectively), while haplotypes T4aG and C4bG had a protective effect (OR 0.06 and 0.11 at p = 0.000001 and 0.0005, respectively). The novel finding in our study is that individual eNOS polymorphisms most likely do not exert a major influence on susceptibility to SLE, but they have significant effects when combined within a specific haplotype.

***FRIZZLED* mutations in patients with Neural Tube Defects.** *V. Capra[1], P. De Marco[1], E. Merello[1], G. Piatelli[1], A. Cama[1], Z. Kibar[2].* 1) Lab U.O. Neurochirurgia, Istituto Scientifico G Gaslini, Genova, Italy; 2) Department of Obstetrics and Gynecology, CHU Sainte Justine Research Center and University of Montreal, Montreal, Québec, H3T 1C5, Canada.

Neural Tube Defects (NTDs) are severe congenital malformations caused by failure of the neural tube to close during neurulation. Their etiology is complex involving both environmental and genetic factors. During embryogenesis of CNS, the major driving force essential to the shaping of the neural plate is a process which is referred to as convergent extension (CE): a process by which cells elongate medio-laterally and intercalate with other neighboring cells forming a longer, narrower array. This changes lead to the conversion of an initially wide and short neural plate into a narrow and elongated one. A crucial role in CE has been assigned to the Planar Cell Polarity (PCP) pathway, a highly conserved, non-canonical Wnt-Frizzled-Dishevelled signaling cascade, that involves a number of additional core genes including *Stbm/Vangl*, *Flamingo (Fmi)*, *Prickle (Pk)*, and *Diego (Dgo)*. The identification of mutations of PCP genes in NTD mouse models, such as the *Loop-tail* mouse carrying mutations in the *Ltap (Vangl2)* gene, suggests that such genes may be good candidates also for human NTDs. Recently, we identified mutations in two human PCP genes, *VANGL1* and *VANGL2*, providing evidence for a pathogenic role of PCP signaling in human NTDs. Other PCP genes have a potential role in convergent extension movements and neural tube closure, and hence need to be studied in large human NTDs cohorts. Frizzled are seven-pass transmembrane receptors that transduce PCP signalling. It is widely accepted that binding of the phosphoprotein Dishevelled (Dvl/Dsh) and its membrane recruitment by Frizzled is the critical event for PCP signaling. Double mutants *Fzd3* $^{-/-}$/ *Fzd6* $^{-/-}$ embryos exhibit craniorachischisis and curled-tail with a fully penetrance, a partially penetrant failure of eyelid closure, and misorientated auditory and vestibular sensory hair cells, providing the most direct evidence for a functional connection between PCP components and mammalian tissues fusion processes. Expression studies in humans have shown that *FZD3* and *FZD6* are widely expressed in both embryonic and adult tissues, including brain and central nervous system. Based on the highly penetrant occurrence of NTDs in double *Fzd3* $^{-/-}$/*Fzd6* $^{-/-}$ mutant mice, we have investigating the role of the human orthologues, *FZD3* and *FZD6*, by resequencing a cohort of 473 unrelated NTDs patients and 639 ethnically-matched controls.

Replication of a FOXP2 association with motor sequencing during an oral task in families with familial speech sound disorder. *B. Peter[1], M. Matsushita[2], K. Oda[2], W. Raskind[2].* 1) Speech & Hearing Sci, Univ of Washington, Seattle, WA; 2) Dpt of Medicine, Univ Washington, Seattle, WA.

PURPOSE: This study was conducted with the approval of the University of Washington Human Subjects Division. Its purpose was to replicate a FOXP2 association with measures of motor sequencing ability in a dyslexia family sample (Peter et al., 2010) in a new sample of families with familial speech sound disorder (SSD). SSD is a disorder affecting the acquisition of intelligible speech in the absence of known causes. There is evidence that SSD has a genetic etiology, but causal genes have not yet been identified. FOXP2 is causal in a rare syndromic form of disordered speech and language. It was not implicated in a sample of individuals with a motor-based form of SSD but its role in component phenotypes of common, nonsyndromic SSD is unknown. METHOD: Five multigenerational families with evidence of familial SSD (N = 39) participated in a variety of behavioral tasks including diadochokinetic testing. Standard scores were computed for the speed of producing monosyllabic strings of /pa/ (“papapa ...”) and disyllabic strings of /pata/ (“patapatapata ...”). Higher standard scores in the monosyllabic task, compared to the disyllabic task, were interpreted as a relative deficit in motor sequencing. This standard score difference proved to be largely robust against age effects across the lifespan. As in our 2010 study, we typed six FOXP2 markers tagging relevant genomic elements and tested linear association models using the qfam algorithm in PLINK. RESULTS: A significant association between a SNP in the promoter and CpG island region, rs923875, and the motor sequencing measure was found (empirical p = .0067). No other SNP markers reached nominal or adjusted statistical significance. CONCLUSIONS: Results from this SSD family study replicate our 2010 finding that SNP markers in the promoter region and transcription start site of FOXP2 were associated with measures of motor sequencing in oral and finger tasks in dyslexia families. This outcome is consistent with the hypothesis that a locus in the FOXP2 promoter and start site region influences motor sequencing in both dyslexia and SSD and that this trait may be an endophenotype in these disorders.

Relative Impact of Genetic and Epigenetic Factors on Gene Expression in Tumor Tissue Samples. *H. Dong[1], L. Jin[1], M. Xiong[2,1].* 1) Sch Life Sci, Fudan Univ, Shanghai, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030, USA.

Gene expression is influenced by genetic factors such as mutation, SNPs, CNVs and epigenetic factors such as methylation, histone modifications and miRNA. An essential issue in understanding how genetic and epigenetic variation regulates the gene expression is to estimate the proportion of gene expression variation explained by SNPs, CNVs, methylation and miRNA variation. Traditional single marker analysis will miss many variants which individually have small genetic effects, but collectively make a large contribution to the phenotypic variation and miss potential linear and nonlinear interaction among genomic and epigenomic variants. To overcome this limitation, we propose to change quantitative trait analysis platform from single-variant regression (SVR) to joint genomic and epigenomic analysis. The dimension of all available genomic and epigenomic variation is extremely high. Ultrahigh dimensional genomic and epigenomic data analysis poses great challenges. To meet the challenge, we propose to use a recently developed sparse locally linear embedding (LLE), a parse manifold learning algorithm as a powerful high dimensional data reduction tool to project high dimensional genomic and epigenomic data into a low dimensional space. Then, we use lasso regression on the reduced data in low dimensional space to estimate the impact of genomic and epigenomic variants on gene expression. The combined sparse LLE and lasso regression were applied to the two cancer tumor tissue datasets: TCGA Glioblastoma Multiform (198 tumor tissue samples) and Ovarian Cancer (512 tumor tissue samples). We have made several remarkable findings. First, we showed that on average, expression variance was explained mainly by miRNA, methylation, CNVs, rather than SNPs. Especially, the contribution of miRNA and methylation on gene expression variation is larger and more direct than CNVs and SNPs. Second, the contribution of SNPs to miRNA and methylation variation is small. The contribution of CNVs to miRNA is small, but their contribution to methylation cannot be ignored. The above observations could be replicated in GBM and ovarian cancer studies. Our study demonstrates the feasibility and power of sparse manifold learning and lasso regression for evaluating the contribution of genetic and epigenetic variation to gene expression valuation.

***eNOS* (27bp deletion/insertion in intron 4) and *Mn-SOD* (p.Val16Ala) polymorphisms analysis in type 2 diabetic retinopathy (DR) patients from north India.** *P. Badhan, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

Purpose: Present study aimed to elucidate role of 27bp deletion/insertion polymorphism in intron 4 of *eNOS* and p.Val16Ala in *Mn-SOD* with DR in north Indian patients. Material and Methods: In this cross-sectional case-control association study 256 patients were enrolled (150 with DR and 106 with type 2 diabetes (T2D) without any sign of retinopathy as controls). All these patients were recruited from Dr. Daljit Singh Eye Hospital, Amritsar. *eNOS* (27bp deletion/insertion in intron 4) polymorphism was analyzed by PCR and agarose gel electrophoresis and *Mn-SOD* (p.Val16Ala) polymorphism by PCR-RFLP. Chi-square test was performed to analyze the genotype distribution and allele frequencies using statistical calculator (StatPac) V.3.0. Using SPSS V.16.0, one way ANOVA test was performed to find significant association of various clinical parameters (age of patients, age of onset of diabetes, duration of diabetes, BMI, systolic and diastolic blood pressure) with diabetic retinopathy. Results: Among the two polymorphisms screened, *eNOS* (27bp deletion/insertion in intron 4) showed no statistically significant association in allele frequency (p=0.4288) and genotype distribution (p=0.3379) with DR. However, *Mn-SOD* (p.Val16Ala) polymorphism showed statistically significant association in genotype distribution (p= 0.028), and not in allele frequency (p=0.2233). Calculated odds ratios (OR) for the genotypes of *Mn-SOD* (p.Val16Ala) polymorphism were 1.05 (95% CI: 0.5976-1.8374, p=0.8705), 0.4265 (95% CI: 0.2650-0.6865, p=0.0004) and 1.78 (95% CI: 0.9807-3.2384, p=0.058) for CC (mutant allele)-, TC- and TT- (wild type) genotypes respectively and in present study CC-genotype is found to be associated with diabetic retinopathy. Also association was found in age of onset of diabetes (p=0.021), duration of diabetes (p=0.001), BMI (p= 0.032) and systolic blood pressure (p=0.00). Conclusion: In present study, no association has been observed in *eNOS* (27bp deletion/insertion in intron 4) polymorphism with type 2 diabetic retinopathy in patients from north India. Thus this polymorphism in *eNOS* does not seem to be a good biomarker for DR. However, a statistical significance has been observed in *Mn-SOD* (p.Val16Ala) polymorphism with type 2 diabetic retinopathy indicating that it might be a risk factor for the development of diabetic retinopathy. Therefore, p.Val16Ala polymorphism in *Mn-SOD* appears to be a good biomarker in determining genetic susceptibility to DR.

NTF4 mutations in primary open-angle glaucoma. *L. Chen[1], T. Ng[1], P. Tam[1], A. Fan[1], M. Zhang[2], C. Tham[1], N. Wang[3], D. Lam[1], C. Pang[1].* 1) Ophthalmology & Visual Sci, Chinese Univ Hong, Hong Kong, China; 2) Joint Shantou International Eye Center of Shantou University and the Chinese University of Hong Kong, Shantou, China; 3) Beijing Tongren Eye Center, Beijing Tongren Hospital, Capital Medical University, Beijing, China.

Purpose: The neurotrophin-4 (NTF4; GLC1O) gene has recently been implicated in primary open-angle glaucoma (POAG). This study was to determine the contribution of NTF4 mutations in POAG in the Chinese populations. Methods: 950 unrelated Chinese Han subjects, consisting of a Hong Kong cohort of 390 POAG patients and 230 controls, a Shantou case-only cohort of 130 patients and a Beijing case-only cohort of 200 patients, were screened for mutations in the coding region and exon-intron boundaries of NTF4 by using direct DNA sequencing. Constructs carrying the missense variants detected were generated using site-directed mutagenesis and transfected into HeLa cells for subsequent solubility and migration analyses. Results: Three variants, p.Pro151Pro, p.Gly157Ala and p.Ala182-Val, were identified. p.Pro151Pro was detected in 3 POAG and 1 control subject. The missense variants p.Gly157Ala and p.Ala182Val were detected in one patient each, but not in the control subjects. The p.Gly157Ala variant protein was less soluble in Triton X-100. HeLa cells transfected with either mutant construct showed less migration as compared to those transfected with the wildtype construct. Conclusions: The two missense NTF4 variants detected in our study are likely to be functional mutations. NTF4 mutations may thus contribute to a small proportion (~0.3%) of Chinese POAG.

Integrating gene expression data with genome-wide association studies to identify novel asthma susceptibility candidate genes. *D.A. Cusanovich, C. Billstrand, C. Chavarria, K. Michelini, A.A. Pai, C. Ober, Y. Gilad.* Human Genetics, University of Chicago, Chicago, IL.

Despite recent success identifying novel genotype-phenotype associations in human populations, a large proportion of inter-individual variation in susceptibility to many complex diseases remains unexplained. Results from genome-wide association studies (GWAS), a common approach for mapping disease-associated loci, rarely account for a major proportion of the heritability of complex traits, a phenomenon that has been termed “the missing heritability problem.” Several models have been proposed to account for missing heritability in GWAS, including the suggestion that the heritability of complex traits can be explained by a large number of common alleles with small effects. Typical GWAS, however, lack the power to distinguish true genetic associations with small-effect alleles from the large number of false positives. To address this gap, we combined gene expression data with a GWAS for lymphocyte count, an intermediate phenotype associated with susceptibility to asthma. Specifically, we integrated results from a GWAS for lymphocyte count in 462 Hutterites and genome-wide gene expression profiles from lymphoblastoid cell lines derived from 96 Hutterites. Using this approach, we found that eQTLs for genes whose expression levels are correlated with lymphocyte counts in the 96 individuals also have significantly stronger association signals with lymphocyte counts in the 462 individuals. Importantly, a subset of eQTLs that were associated with lymphocyte count also exhibits significantly stronger association signals with asthma in an independent meta-analysis of GWAS in European populations (the GABRIEL study). In addition, we found that those genes with expression patterns correlated with lymphocyte counts are 2.5 times more likely to be associated with asthma than genes with uncorrelated expression patterns in the HuGE Navigator. Moreover, these genes are enriched for “NK cell mediated cytotoxicity,” “hematopoietic cell lineage,” and “T cell receptor signaling” KEGG pathway annotations. All of this substantiates these genes as promising asthma susceptibility candidates. More generally, our observations suggest that a multitude of small-effect loci may contribute to inter-individual variation in lymphocyte count, and to variation in susceptibility to asthma.

Genome-wide Linkage and Association Analyses in Uterine Leiomyomata Reveal *FASN* as predisposition gene. *S.L. Eggert[1], R. Kavalla[2], K.L. Huyck[4], P. Somasundaram[2], E.A. Stewart[5], A.T. Lu[6], J.N. Painter[7], G.W. Montgomery[7], S.E. Medland[7], S.A. Treloar[7], L. Rose[8], P.M. Ridker[8,9], D.I. Chasman[8,9], N.G. Martin[7], R.M. Cantor[6], C.C. Morton[2,3,9].* 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Departments of Obstetrics, Gynecology and Reproductive Biology and; 3) of Pathology, Brigham and Women's Hospital, Boston, MA; 4) Department of Medicine, Dartmouth-Hitchcock Medical Center, Lebanon, NH; 5) Mayo Clinic, Rochester, MN; 6) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 7) Queensland Institute of Medical Research, Brisbane, Australia; 8) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA; 9) Harvard Medical School, Boston, MA.

Uterine leiomyomata (UL) are the most common pelvic tumors in women. UL pose a major public health problem given their prevalence (>70%) and rate of symptoms (~25%) in women of reproductive age and their indication for >200,000 hysterectomies in the U.S. annually. A genetic basis for tumor development is supported by recurrent chromosomal aberrations and a genetic component to UL predisposition is supported by analyses of ethnic predisposition, twin studies, and familial aggregation. A genome-wide SNP linkage panel was applied to 261 white UL sister pair families from the Finding Genes for Fibroids study. Two significant linkage regions were detected in 10p11 (LOD=4.15) and 3p21 (LOD=3.73) while five additional linkage regions were identified with LOD scores >2.00 in 2q37, 5p13, 11p15, 12q14, and 17q25. Fine mapping was performed with an independent sample of white women from the Women's Genome Health Study (WGHS) and 39,115 SNPs positioned under the linkage regions. Cases were defined as women who reported being diagnosed with fibroids under age 40 years, and/or had a hysterectomy, and have a mother or sister also diagnosed with fibroids. A standard case/control analysis was performed with 746 cases and 4487 controls; 44 SNPs were identified with suggestive p-values $<10^{-3}$. Replication was performed with the 44 suggestive SNPs in a third independent sample of white women from an Australian twin cohort in which cases are defined as women who have been diagnosed with fibroids. A standard case/control analysis was performed with 484 cases and 610 controls; seven SNPs were identified with p-values <0.05. Of the seven candidate SNPs, six are in a block of linkage disequilibrium in 17q25.3 which spans the genes fatty acid synthase (*FASN*) and coiled-coil domain containing 57 (*CCDC57*). The p-values of the six candidate SNPs reach genome-wide significance after meta-analysis of the WGHS and Australian samples. By tissue microarray immunohistochemistry, we found FAS protein expression elevated (3-fold) in UL when compared to matched myometrial tissue. Preliminary qPCR results show the same trend for mRNA expression of *FASN*. FAS transcripts and protein levels are up-regulated in many cancers (e.g. colon, prostate, breast, ovary, endometrium) and seem to play a role in tumor cell survival. *FASN* represents the first UL predisposition allele identified in white women by a genome-wide, unbiased approach and opens a new field of UL research concerning cell metabolism.

Association of Gene Variants and Biochemical Markers with Chronic Obstructive Pulmonary Disease. *A. Jyothy[1], B. Ashrafunnisa[1], A. Venkateshwari[1], A. Munshi[1], S.V. Prasad[2].* 1) Institute of Genetics & Hospital for Genetic Diseases, Hyderabad-16, A.P. India; 2) Govt.Chest Hospital ,Hyderabad ,Andhra Pradesh, India.

Chronic Obstructive Pulmonary Disease (COPD), a chronic inflammatory disorder of lungs, is characterized by an inability to normally move air in and out of lungs . Airflow limitation in patients with COPD is not fully reversible. The pathophysiology of COPD encompasses multiple injurious processes including inflammation, cellular apoptosis, altered cellular and molecular alveolar maintenance, abnormal cell repair, extracellular matrix destruction and oxidative stress. Twin studies, family studies and case-control association studies have suggested that genetic factors are important in COPD risk. A number of genes like (1- Antitrypsin, Matrix Metalloproteinase-1&3 (MMP-1&3), Tissue Inhibitory Metalloproteinase-2(TIMP-2), Hemoxygenase-1 (HMOX-1), Microsomal Epoxide Hydrolase (EPHX1), Tumor necrosis factor-((TNF- ( ) and Surfactant Protein B (SFTPB) have been implicated in the pathogenesis of COPD. The genes related to nitric oxide synthesis on lung airway are also been studied because of their important role in airway remodeling. The gene variants of endothelial nitric oxide synthase (eNOS) , matrix mtallopoteinase-3(MMP-3) , cytochrome 450A1 (CYPA1) and tumor necrosis factor alpha (TNF-( ) and biochemical markers associated with COPD in a South Indian Population from Andhra Pradesh are being evaluated. The results of the study will be presented. Research into genetics of COPD, may be helpful in developing new treatment strategies for better management.

A family-based association study between vitiligo and positional candidate genes EDNRA, PTPN12, PTK2B and ADAM9. *L. Nascimento[1], C. Silva de Castro[1,2], R. Werneck[1], M. Mira[1].* 1) PPGCS-CCBS, PUCPR, Curitiba, Parana, Brazil; 2) Department of Dermatology, Santa Casa de Misericordia Hospital, PUCPR, Curitiba, Parana, Brazil.

Vitiligo is an acquired systemic, chronic, multifactorial, polygenic disease characterized by macules devoid of melanic pigment and identifiable melanocytes. A previous study detected evidence for linkage between vitiligo and loci on chromosomes 7q21 an 8p21 in a collection of multigerational families presenting generalized vitiligo associated with other autoimmune diseases. Moreover, a genome-wide linkage scan conducted in Chinese families affected with generalized vitiligo localized a new susceptibility locus on chromosomal region 4q13-q21. To date, no strong candidate gene has emerged from these linkage susceptibility loci to date. We selected four biological candidate genes located at these three chromosomal regions for a comprehensive association analysis involving 35 tag SNPs completely capturing the information of genes endothelin receptor type A - EDNRA (Cr 4), protein tyrosine phosphatase, non-receptor type 12 - PTPN12 (Cr7), protein tyrosine kinase 2 beta - PTK2B (Cr8) and disintegrin and metalloproteinase domain 9 - ADAM9 (Cr8). All SNPs were genotyped in 596 individuals distributed in 212 trios composed by an affected child and both parents. Markers were genotyped using the mass spectrometry-based SEQUENOM MassARRAY platform. Family-based association analysis was performed as implemented in the FBAT software. Logistic multivariate analysis was performed as implemented in the SAS software. No evidence of allelic or genotypic association ($p<0.05$) was detected between the gene variants and vitiligo, even when co-variables age-of-onset and presence/absence of additional autoimmune diseases were included in the analysis. The exact nature of the linkage observed between vitiligo and chromosomal regions 7q21, 8p21 and 4q13-q21 remains elusive.

CNV screening identifies chromosomal regions of interest and candidate genes in patients with orofacial clefts. *M. Simioni, T.K. Araujo, C.V. Maurer-Morelli, I. Lopes-Cendes, V.L. Gil-da-Silva-Lopes.* Medical Genetics, FCM/UNICAMP, Campinas, Brazil.

Cleft lip and palate (CL/P) is one of the most common craniofacial defects with birth prevalence ranging from 1:500 to 1:2500. Different etiological factors are involved on the genesis of clefts, including gene-gene interactions and environmental influences. To date, a number of genes have been suggested as playing a role in CL/P, but they account for only a small proportion of patients. The screening for copy number variation (CNV) in the human genome has proven to be a very powerful strategy to narrow down candidate disease gene and/or regions involved in various disorders, as well as in clefts. The purpose of this study was to analyze the role of CNVs and the genes included within this variations in a group of patients with CL/P. We studied a total of 23 trios (proband-parents) and 20 control individuals without orofacial clefts in at least 3 generations. All probands were clinically classified according to the International Clearinghouse for Birth Defects and Surveillance and Ressearch (ICBDSR 2007). CNV screening was performed using the Genome-Wide Human SNP Array 6.0 (Affymetrix) and analyzed by the Affymetrix Genotyping Console software. We identified six candidate genes, possibly associated with CL/P, among the CNVs detected: two duplications on 5q13.2 and 9p24.3regions (GTF2H2 and FOXD4 genes - transcription factors); a deletion on 19p13.3 region (FGF22 gene - fibrobrast grow factor); a 3.8Mb duplication on 8p23.1 region (SOX7 and GATA4 genes - transcription factor and binding protein, respectively); and a deletion on 1p36.11 region involving TCEB3 gene. This gene encodes a type of elongin protein that makes part of a complex with the SPRY protein family in which SPRY1 gene is a member, SPRY1 has been previously associated with CL/P. All of these CNVs are de novo (not identified in the parents) and, except for 8p23.1 duplication, they were not present in the control group genotyped. To validate the CNVs found in these patients, an independent method is underway. Financial support: FAPESP, CNPq.

Analysis of *VEGF* (-634 C/G and 936 C/T) polymorphisms in T2D retinopathy patients from North India. *H. Singh, V. Vanita.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

Purpose: The aim of present study was to analyze the -634 C/G polymorphism of the 5' untranslated region (5'UTR) and 936 C/T polymorphism of the 3' untranslated region (3'UTR) of *VEGF* with diabetic retinopathy (DR) in T2D patients from north India. Material and methods: In this case-control association study, 820 unrelated patients with T2D were collected from Dr. Daljit Singh Eye Hospital, Amritsar. Out of these, 471 T2D patients had different types of retinopathies. Of these 275 patients were diagnosed with Proliferative Diabetic Retinopathy (PDR), 84 with Pre-proliferative Diabetic Retinopathy (PPDR), 112 with Back-ground/Non proliferative Diabetic Retinopathy (BDR/NPDR) and 349 patients having T2D but no any sign of retinopathy were analyzed as controls. Both *VEGF* -634 C/G (5'UTR) and 936C/T (3'UTR) polymorphism analyses were undertaken by PCR-RFLP. One way analysis (ANOVA) test was undertaken with the help of SPSS V 16.0 on all the clinical parameters of DR patients and controls. Genotypes and allele frequencies were compared for Chi-square test with the help of statistical calculator (StatPac) V.3.0. Results: The present study revealed statistically significant difference between age, age of onset, and duration of diabetes when different DR groups (PDR, PPDR, BDR) were compared with controls. However, the genotypes (p=0.7988) and allele frequencies (p=0.7959) with *VEGF*-634 C/G (5'UTR) polymorphism in DR patients showed no statistically significant difference as compared to controls. In case of *VEGF* 936 C/T (3'UTR) polymorphism, we observed statistically significant difference between age of onset, and duration of diabetes when different DR groups were compared with controls. The genotypes (p=0.967) and allele frequencies (p=0.910) with VEGF 936 C/T polymorphism in DR patients however, showed no statistically significance as compared to controls. Further according to present findings, when PDR, PPDR, and BDR groups were compared individually with controls for *VEGF*-634 C/G and 936 C/T polymorphism, no statistically significant differences were observed. Conclusion: We observed no any association of *VEGF* -634 C/G and 936 C/T polymorphisms with DR in the analyzed north Indian patients. Therefore, we conclude that these polymorphisms are not useful markers for the diabetic retinopathy.

401W

Angiotensin converting enzyme (ACE) gene I/D polymorphism analysis in type 2 diabetic retinopathy patients from North India. *V. Vanita[1], H. Singh[1], I.R. Singh[2], J.R. Singh[3].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Dr. Daljit Singh Eye Hospital, Sheranwala Gate, Amritsar, India; 3) Central University of Punjab, Bathinda, India.

Purpose: The aim of present study was to analyze the ACE I/D (insertion of 287bp DNA fragment in intron 16) polymorphism with diabetic retinopathy (DR) in type 2 diabetic (T2D) patients from north India. Materials and methods: In this case-control association study, 857 unrelated patients with T2D were collected from Dr. Daljit Singh Eye Hospital, Amritsar. Out of these, 507 diabetic patients had different types of retinopathies. Of these 290 patients were diagnosed with Proliferative Diabetic Retinopathy (PDR), 94 with Pre-proliferative Diabetic Retinopathy (PPDR), 121 with Back-ground/Non proliferative Diabetic Retinopathy (BDR/NPDR) and 350 patients having T2D but no signs of retinopathy were also analyzed as controls. ACE I/D polymorphism analysis was undertaken by polymerase chain reaction (PCR) followed by agarose gel electrophoresis. Chi-square test was performed to analyze the genotypes distribution and allele frequencies using statistical calculator (StatPac) V.3.0. Using SPSS V.16.0, one way ANOVA test was performed to find significant association of various clinical parameters (age of patients, age of onset of diabetes, duration of diabetes, BMI, systolic and diastolic blood pressure) with diabetic retinopathy. Also the ACE I/D genotype distribution of DR (PDR, PPDR, BDR) patients was analyzed with controls for any modifications on severity of the retinopathy. Results: The present study revealed statistically significant difference between age, age of onset, and duration of diabetes when DR patients were compared with controls. The genotypes (p=0.1790) and allele frequencies (p=0.6115) with ACE I/D polymorphism however showed no statistically significance with DR as compared to controls. However, patients having PPDR showed higher frequency of ID genotype (p=0.0327), when compared with controls. Conclusion: Present study reveals no association of ACE I/D polymorphism with diabetic retinopathy in the analyzed north Indian patients. Hence, we conclude that this polymorphism does not seem to be a useful marker for the diabetic retinopathy. However, the association of ID genotype with PPDR when compared with controls indicates that it may have a role in proliferation.

Genetically determined metabotypes in the context of complex diseases. *C. Gieger[1], S-Y. Shin[2], A-K. Petersen[1], G. Zhai[3,4], T.D. Spector[3], N. Soranzo[2], K. Suhre[5,6,7].* 1) Institute of Genetic Epidemiology, Helmholtz Zentrum Munich, German Research Center for Environmental Health, Neuherberg, German; 2) The Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton UK; 3) Department of Twin Research & Genetic Epidemiology, King's College London, UK; 4) Discipline of Genetics, Faculty of Medicine, Memorial University of Newfoundland, Canada; 5) Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum Munich, German Research Center for Environmental Health, Neuherberg, Germany; 6) Faculty of Biology, Ludwig-Maximilians-Universität, Planegg-Martinsried, Germany; 7) Department of Physiology and Biophysics, Weill Cornell Medical College in Qatar, Education City - Qatar Foundation, Doha, Qatar.

The better understanding of mechanisms controlling human health and disease, in particular the role of genetic predispositions and their interaction with environmental factors, is a prerequisite for the development of safe and efficient therapies for complex disorders, such as type 2 diabetes and cardiovascular disease. Genome wide association studies (GWAS) have identified many risk loci for complex diseases, but effect sizes are generally small and information on the underlying biological processes is often lacking. Associations with metabolic traits as functional intermediates can overcome many of these problems and potentially inform individualized therapy. Advances in analytical biochemistry have made it possible to obtain global snapshots of metabolism allowing for GWAS with broad panels of metabolite concentrations in different body fluids, like blood serum, plasma or urine. In a series of GWAS we have identified more than 40 genetic loci, typically explaining a large fraction of the variation of the associated metabolic trait. In the majority of cases a protein biochemically related to the associated metabolic traits is encoded at these loci which we call genetically determined metabotypes. We present results from our recent study in the German KORA study and the British TwinsUK study (N = 2,800), that provided us a wide spectrum of disease related and pharmaceutically relevant genetic associations. For instance, the *AHR* locus associates with coffee consumption habits in a meta-analysis of over 35,000 individuals - we find an association of the same locus with serum caffeine concentration in our study of 2,800 individuals (P-value = 4.8×10^{-15}). Furthermore, a locus at 19q13, including *RASIP1* and *FUT2*, showed an association with retinal vascular caliber in 15,000 Europeans. The original paper proposes *RASIP1* as the causative gene due to its involvement in endothelial cell motility, angiogenesis and vessel formation. However, our data show at the same locus ($r^2 = 0.61$) an association with metabolites related to blood coagulation, indicating that these properties and rather the functional related *FUT2* gene are at the basis of the association with this microvascular disorder. These examples show the high power and the ability of genetically determined metabotypes to better characterize risk factors. To make this resource available for the scientific community, we have implemented a freely available database to query newly discovered risk loci.

Objective: Impaired insulin sensitivity (IS) represents a risk factor for cardiovascular disease and type 2 diabetes. Genome-wide association studies (GWAS) of type 2 diabetes and IS surrogates have primarily identified genes related to) cell action rather than IS. We conducted a GWAS for IS as defined by quantitative measures of insulin sensitivity in the GENESIS consortium to identify genetic factors that modulate IS.

Research Design and Methods: The GENESIS consortium is comprised of three studies of Caucasian subjects, namely, RISC (n = 1,042), Stanford (n = 381), and EUGENE2 (n=595), and one of East Asian subjects (SAPPHIRE, n = 455). Standard single marker association analyses within each study were performed along with a meta-analysis of all Caucasian subjects (n = 2018). We augmented these analyses with the integrative SNP set enrichment test (SSET) that leverages GWAS association, genetics of gene expression, and knowledge-driven pathways or data-driven gene networks.

Results: Single-marker association testing did not identify SNPs with genome-wide significant associations, likely due to the moderate sample size. However, in the integrative analyses, pathways or gene sets relevant to obesity, fat cell differentiation, calcium homeostasis, mitochondrial dysfunction, lipid metabolism, and cell cycle were significantly enriched for IS polymorphisms at Bonferroni-corrected p <0.05 using SSET.

Conclusions: Multiple gene sets were found to be associated with IS, suggesting a complex genetic architecture. The systems biology approach we applied may be especially useful where study size is limited.

Genome-wide association study on the variation of quantitative trait may help identify important genetic variants for complex diseases, an example of CHD risk in T2D patients. *Z. Liu[1], Q. Qi[2], F. Hu[2], L. Qi[2], L. Liang[1].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Nutrition, Harvard School of Public Health, Boston, MA.

Extreme levels of quantitative metabolic traits may be important to complex diseases, for example low HDL is associated with higher risk of Type-2 diabetes (T2D) and coronary heart disease (CHD). Genome-wide association studies for quantitative traits have been focusing on the comparison of the mean levels of the traits among individual with different genotypes. While this approach successfully identified many genetic variants associated with extreme level of quantitative traits, it might miss the genetic variants related to the increased perturbation or variation of the trait, which is another source leading to extreme level of the quantitative trait. In this study, we show that novel genetic variants may be identified by testing association with the different levels of the variation of quantitative traits instead of the mean values. In particular, we carried out a genome-wide association scan for the variation of HDL using the 700,000 SNPs on Affymetrix 6.0 array typed on 1461 (NHS: 660; HPFS: 801) T2D cases (505 with CHD and 745 without CHD, 66 stroke and 145 unknown) from a T2D study in the Nurses Health Study (NHS) and the Health Professionals Follow up Study (HPFS). After adjusting for age, BMI and eigenvectors obtained from genotype, we found a locus, SLC2A9, on chr4p16.1 significantly associated with the variation of HDL in both NHS and the HPFS samples (meta-analysis pvalue=4.2x10-9). The SLC2A9 locus we identified has been shown to be associated with uric acid level which is a risk factor for T2D and CHD and might imply important gene-environment interaction or other mechanism underlying the genetics of HDL. We further tested the association with CHD risk in T2D and found that the SNP rs1996335 (in perfect LD with rs1401441, r2=1) was associated with CHD risk in diabetic men (OR [95%CI]: 0.52 [0.29-0.94], P=0.029) but not in diabetic women (1.24 [0.74-2.08], P=0.40). In summary, we show that genome-wide association study on the variation of quantitative trait provides a promising approach to identify new loci and improve the understanding of the genetic bases of complex diseases.

405W

Sub-phenotyping via Metropolis-coupled MCMC to improve the power in association studies. *Z. Geng[1], S. Z&oumlllner[1,2].* 1) Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Psychiatry, Univ Michigan, Ann Arbor, MI.

Genetic heterogeneity in complex traits is a major challenge for identifying risk genes. Such heterogeneity may be the result of broad, descriptive definitions of a disease and many common diseases may have unidentified genetically more homogeneous subtypes. Under this hypothesis, genetic heterogeneity is reflected in clinical heterogeneity of a disease and clinical traits or sub-phenotypes (covariates) may be correlated with specific risk variants. However, single covariates may not provide enough information to identify such subtypes. Thus, we propose a method to identify a cluster of covariates that are co-inherited with affection status compatible with a single underlying risk variant. Focusing on related individuals, we identify clusters of covariates that are heritable, rather than just correlated due to reasons unrelated to genetics. We consider a dataset of related affected individuals with a large number of measured covariates but no genotype data. We fit the covariate data to a model where a subset of covariates is affected by an unobserved risk variant, while the remaining covariates are independent of the genotype. Using a Metropolis-coupled MCMC, we identify the subset of informative covariates and the posterior probabilities of all model parameters. Based on these parameters, we obtain a logistic model of carrying a specific risk variant conditional on the covariates. Using this model, we can then calculate a posterior probability of carrying the risk variant to each individual in a population sample. Using simulated data of affected sibpairs, we illustrate the ability of our algorithm to correctly estimate model parameters. Even when assuming only weak effects of the underlying risk variants on each individual covariate, we are able to correctly identify the underlying model and identify carriers of the underlying risk variant. Moreover, we show the gain of power obtained in a case control study from up-weighting cases that have a higher probability of carrying the risk variant. We emphasize a model of rare risk alleles with intermediate effect sizes and show that our method can be used to select a subset of individuals for sequencing. In summary, we have developed a novel approach to mine rich phenotypic data for disentangling underlying genetic heterogeneity. This algorithm can be used to improve the power of single marker tests in GWAS and to prioritize individuals in resequencing studies.

Balanced Translocations and Inversions in the Genome of Finns. *T. Varilo[1], T. Luukkonen[2,3], M. Pöyhönen[4], L. Peltonen[2,3,7,10], A. Palotie[2,7], K. Aittomäki[4], J. Ignatius[9], K.O.J. Simola[5], J.D. Terwilliger[2,8], R. Salonen-Cajander[6].* 1) Dept of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Inst for Molecular Medicine Finland; 3) Nat Inst for Health and Welfare, Finland; 4) Dept of Clinical Genetics, Helsinki University Central Hospital; 5) Dept of Pediatrics, Tampere University Hospital; 6) Dept of Medical Genetics, Väestöliitto, Helsinki; 7) Welcome Trust Sanger Inst, Hinxton, Cambridge, UK; 8) Dept of Genetics and Development, Columbia University, NYC, NY, USA; 9) Dept of Clinical Genetics, Turku University Central Hospital; 10) Deceased.

Finland is acknowledged of its high standard of clinical medicine and in the disease gene hunt of its founder populations. What is perhaps not so well recognized in the field of genetics is that Finland has probably the most comprehensive health registers and records: hospitalizations, surgeries, chronic diseases, cancers and prescriptions etc. have been filed for decades. Relying on this infrastructure we have gathered clinical information from all distinct hospitals and laboratories on all reciprocal balanced translocations and inversions identified in Finland, and are constructing a national database (www.fintransloc.org). By analyses of the medical records and by searches of additional national registers, we are obtaining novel information of not only monogenic traits with unidentified mutations, but also of multifactorial traits associated with any given chromosomal abnormality. Moreover, we believe that such a database will greatly assist genetic counseling efforts and scientific collaborations. To date, we have surveyed all the 2575 hospital or laboratory contacts involving translocations or inversions consisting of 572 families plus singletons. The largest family consists of some 40 carriers who have common ancestors in the 1600s. We are breakpoint mapping two interesting pilot families (phenotypes: aortic aneurysm and height)--with significant linkage signal exactly at the breakpoint--to provide shortcut in the identification of their predisposing disease genes. A nationwide systematic sample collection of DNA, RNA and cells with so far over 80% coverage of participants was launched in Aug 2010.

A chromosome 21 association study suggests DSCAM as a susceptibility locus for the Hirschsprung disease endophenotype in Down syndrome. *A.S. Jannot[1,2,3,4], A. Pelet[2,4], A. Henrion-Caude[2,4], M. Masse-Morel[2,4], S. Arnold[5], I. Ceccherini[6], S. Borrego[7,8], R.M.W. Hofstra[9], A. Munnich[2,4], A. Chakravarti[5], J. Amiel[2,4], F. Clerget-Darpoux[1,3], S. Lyonnet[2,4].* 1) Unite 669, INSERM, Villejuif, France; 2) INSERM U-781, AP-HP Hôpital Necker-Enfants Malades, Paris 78743, France; 3) Université Paris Sud, Faculté de médecine, Le Kremlin-Bicêtre 94275, France; 4) Département de Génétique, Université Paris Descartes, Faculté de Médecine, Paris 75006, France; 5) Center for Complex Disease Genomics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 6) Laboratorio di Genetica Molecolare, Istituto Gaslini, Genova 16147, Italy; 7) Unidad de Gestión Clínica de Genética, Reproducción y Medicina Fetal. Instituto de Biomedicina de Sevilla (IBIS), Hospital Universitario Virgen del Rocío/CSIC/Universidad de Sevilla, Sevilla, 41013 Spain; 8) CIBER de Enfermedades Raras (CIBERER), ISCIII, Sevilla, 41013, Spain; 9) Department of Genetics, University Medical Center Groningen, Groningen 9700, The Netherlands.

Hirschsprung disease (HSCR), or aganglionic megacolon, is a congenital disorder characterized by the absence of enteric ganglia along a variable length of the distal intestine. The RET gene is a well-established susceptibility locus in all isolated forms cases of HSCR, and some syndromic variants. Predisposition to HSCR in Down syndrome patients strongly suggests that additional factor(s) contributing to HSCR map to chromosome 21. To identify these additional factors, we carried out a GWAS focused on chromosome 21 in a series of 28 cases with the association of Down syndrome and HSCR, and their parents. We successfully genotyped 7,691 SNPs on chromosome 21. After correction for multiple testing, the only significant result was obtained for 2 SNPs in complete linkage disequilibrium (rs2837770 and rs8134673) located in intron 3 of the DSCAM gene (nominal p-value p= 2.2x10-5, and p-value after correction for multiple testing=0.018). Importantly, DSCAM is expressed in the developing enteric nervous system. Association with these SNPs was replicated (p=0.01) using an independent sample of 220 non-syndromic HSCR patients and their parents. Our association findings are supported by two previous independent studies mapping an HSCR susceptibility factor in a region including the DSCAM gene locus. Furthermore, the methodology proposed in order to perform chromosome 21 association analyses in Down syndrome patients could also help to deconstruct the genetic bases of other endophenotypes of trisomy 21 syndrome.

Prediction of complex multifactorial disease: comparing family history and genetics. *C.B. Do[1], J.M. Macpherson[1], D.A. Hinds[1], B. Naughton[1], U. Francke[1,2], N. Eriksson[1].* 1) 23andMe, Inc, Mountain View, CA; 2) Stanford University School of Medicine, Stanford, CA.

In clinical practice, family history is generally considered an important risk factor for a wide variety of complex diseases. Over the last several years, however, commercial SNP-based tests for low penetrance common variants associated with complex diseases have become increasingly available. Although the use of family history and genetic risk prediction is well understood for simple Mendelian disorders, to date, little is known regarding the relative performance of these methods for diseases with complex multifactorial inheritance.

Using quantitative genetic theory, we analyze the influence of disease architecture on the predictive capacity of family history and genetic models with the goal of understanding the range of scenarios in which one of the approaches may be advantageous compared to the other. We find that for extremely common multifactorial disorders (>10% prevalence, e.g., type 2 diabetes in the United States), an idealized family history-based algorithm can achieve predictive accuracies on par with SNP-based models that account for 20-30% of the heritability of the disease, meeting or exceeding what SNP-based models have achieved thus far. However, many diseases of important public health consequence are neither extremely common nor extremely rare, occurring in one out of every 100 to 1,000 individuals (e.g., Crohn's disease). For these diseases of moderate frequency, the point of equivalency occurs at only 1-4% of the variance explained, well within the detection limits of GWAS today. These findings suggest that for less common diseases, currently known genetic factors may in fact already be better discriminators of risk than their family history-based counterparts, despite the large fraction of missing heritability that remains to be explained.

Our results provide insight into the influence of disease architecture on risk prediction performance and its implications for clinical practice. In particular, our findings highlight the potential pitfalls of drawing conclusions regarding the relative merits of family history and genetics without considering the broad spectrum of human disorders, and illustrate the importance of considering both family history and genetics in combination when evaluating an individual's predisposition to disease.

Assessment of Psoriatic Quality of Life and Qunatity of Disease by using PDI and PASI. *R.K. Golee, R. Singla, R. Kaur.* Human Biology, Punjabi University, Patiala, Patiala, Punjab, India.

Psoriasis is an ancient and universal inflammatory longest known disease of human beings. It is an autoimmune disease which is more prone to peripheral portion and joints. The main objectives of the present study was to access the quality of life, affected body surface area, inheritance pattern and epidemiological study in punjabi population of India. These parmeters were analysed by using the Psoriasis area and sevrity index (PASI) developed by Fredrikkson and Patterson in 1978 and Psoriasis disability index (PDI) developed by Finlay in 1999 (revised form), family tree and statistical calculations. Epidemiological study was done in the Mansa district from the Civil Hospital from the last five years skin OPD's record and it was observed that a total of 82500 skin patients were registered for routine check up and only 300 patients were clinically diagnosed as suffering from psoriatic disease ranging from chronic to mild form. Percentage analysis shows that 0.3636% population of this area suffered from psoriasis. Family tree analysis shows that more males(20.82%) suffered from the disease as compared to females(7.39%). Male female ratio comes out to be 5:1 with mean age of patient 42.33 years. Mean chronicity age of the psoriatic patients comes out to be 1.95 years. The total PASI score ranges between 4% to 19.9% in males where as in females it lie between 10.6% to 13.5%. The average value of Head and Neck score was 3.3%, Upper Limb 8.64%, Trunk 12.6%, Lower Limb 10.2%. When the PDI administered for understanding the effect of psoriasis on the daily life of patients, the result shows trmendous high score as highest PDI score is 29 out of total 30. The average value of PDI for females was 25.2 while the males stand out at 19.65. The higher range of PDI showed that the disease effects greatly to the quality of daily life and hinders their routine activities. So, it concluded that psoriasis causes major discomfort in their daily life which is difficult to handle as the pain and itching some times lead to suicidal tendencies, psychosocial stress, unbearable behaviour and addiction to drugs, smoking and alcoholism.

Assessing Pleiotropic Influences on Comorbid Disease Phenotypes. *R.C. McEachin, A. Karnovsky, J.D. Cavalcoli, M.A. Sartor.* CCMB, Univ Michigan, Ann Arbor, MI.

Complex diseases are predisposed, in part, by genetic variation, and are often overrepresented for comorbid phenotypes (e.g. diabetes and hypertension are frequently comorbid). This comorbidity is consistent with the existence of pleiotropic genetic variation influencing both disease phenotypes. A Genome Wide Association Study (GWAS) assesses evidence of association between individual SNPs and a single disease phenotype, and GWAS datasets for related phenotypes are being generated. We consider how GWA data from studies of multiple comorbid disease phenotypes may be effectively merged to reveal pleiotropic influences. Fisher meta-analysis is an approach for combining summary statistics (i.e., p-values), which can be used to merge GWA data derived from multiple studies, each testing for association between SNPs and a single disease phenotype. If all necessary assumptions are met, the distribution of the Fisher statistic is known and significance of association can be assessed simply. We recently showed that a nonparametric adaptation of Fisher meta-analysis, where we assess significance by permutation, can be useful in identifying pleiotropic variation underlying comorbidity, based on GWAS summary data from related phenotypes (McEachin, et al., ISCB GLBIO 2011). Other groups have developed approaches to this problem, based on assumed distributions of statistics derived from combining primary data from GWA studies for related phenotypes. While the various approaches appear to have utility, in this work we compare methods based on standardized input. Notably, with observed data, the true genetic effect is not known, so both positive and negative controls are generally unavailable. To overcome this obstacle, we compare methods using simulated genotype data, where pertinent details of the population, SNP minor allele frequency, and the strength of the genetic influence are controlled, yielding true positive and negative controls. We show that the overall results of testing for pleiotropic effects may vary, depending on the approach used. However, for pleiotropic variation that strongly influences the comorbidity, differences between the methods may be modest and we may be well on our way to identifying these effects.

Using protein-protein interactions to long QT syndrome proteins reveals networks underlying genetic association to QT interval variation. *E.J. Rossin[1,2,3], A. Lundby[4], A.B. Steffensen[4], S. Pulit[1,3], P. DeBakker[1,3], A. Pfeufer[6], C. Newton-Cheh[1,2,3], K. Lage[5], J. Olsen[4].* 1) The Broad Institute, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) University of Copenhagen, NNF Center for Protein Research, Copenhagen, Denmark; 5) Center for Biological Sequence Analysis, Department of Systems Biology, Technical University of Denmark, Lyngby, Denmark; 6) Institute of Human Genetics, Helmholtz Center Munich, Germany.

Variation of the QT interval duration in the heart's electric cycle is a risk factor for sudden cardiac death and drug-induced arrhythmia. Genome-wide association studies (GWAS) have identified 11 genomic loci associated with QT interval variation. We have previously shown that the leveraging protein-protein interaction (PPI) data to identify physical connections between proteins encoded in associated loci can help propose underlying mechanisms, pinpoint critical genes and predict new associations (Rossin et al. 2011). We hypothesized that looking for physical interactions between proteins in QT-interval variation associated loci and 12 proteins known to be important in cardiac ion channel function and disrupted in Mendelian long-QT syndromes (LQTS) may be similarly fruitful. To test this, we first applied a published *in silico* network analysis tool (called DAPPLE) to the 11 loci and 12 LQTS genes. We found more connections between these input proteins than chance expectation (p=1e-4), suggesting a function common to interacting proteins. To see if this network could predict new genetic associations, we tested the 497 yet-unassociated proteins in the network in a new QT-interval duration meta-analysis consisting of 100,000 individuals. Using a composite test for association, we found that the genes encoding these proteins were enriched for association (p=2e-4) and that 5 of the genes were in newly genome-wide significant regions, more than chance expectation. To expand our search experimentally and in the relevant tissue, we immuno-precipitated proteins encoded by 5 LQTS genes (*CACNA1C*, *CAV3*, *KCNH2*, *KCNQ1* and *SNTA1*) in mouse cardiac tissue and resolved their associated complexes by mass-spectrometry. Similar to what we observed *in silico*, we found that proteins that bind to the 5 Mendelian baits were encoded for by genes enriched for association (p=1.1e-6) and contained proteins encoded in 8 genome-wide significant loci, suggesting the likely candidate in those regions. One particular interaction had not be previously described in the literature, so we followed up with electrophysiological measurements and confirmed a functional effect on ion channel current mediation of one of the LQTS channels by a QT-interval associated protein. We therefore show that common genetic variation associated to the QT-interval is spread across a network of proteins that interact with each other and known LQTS proteins.

optiCall: A robust genotype calling algorithm for rare, low-frequency and common variants. *T. Shah, C.A. Anderson.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

Burgeoning whole-genome and whole-exome sequencing projects are likely to require large-scale microarray based follow-up studies. Already, custom arrays such as Metabochip and Immunochip utilize SNPs identified through population-based sequencing efforts such as 1000 genomes to better survey loci known to underpin variation across related phenotypes. Typically, the allelic probes on these custom arrays have undergone less stringent quality control compared to those that make it onto mass-produced GWAS arrays. This drop in probe quality, in addition to a greater focus on low-frequency and rare variants, presents many problems for existing genotype-calling algorithms. To tackle this problem we have developed a novel genotype calling algorithm, optiCall, which can accurately call SNP genotypes across the entire minor allele frequency spectrum (including SNPs with atypical cluster positions) for both small and large sample sizes. Existing methods typically either call genotypes on a SNP-wise or sample-wise basis, whereas optiCall uses both sources of information to make accurate genotype calls. First, a random subset of the intensity data, both within and across samples, is clustered to create a data-derived prior for genotype-class probabilities across the X and Y intensity range. Second, a mixture model is fitted on a SNP-wise basis, guided by the data-derived prior. The result is that rare variants are accurately called because they fall in regions of high probability defined by the prior, and common variants are well called by the SNP-wise guided mixture model in the second step. optiCall internally estimates clustering quality using Hardy-Weinberg equilibrium (HWE), with any SNPs showing significant deviation from HWE subjected to a series of rescue steps designed to accurately call SNPs with atypical cluster positions. Using Immunochip data we compare genotype calls from optiCall to those from alternative algorithms, and to a set of manually-derived calls. We show that existing algorithms have unfavoured areas of the minor allele frequency spectrum or were unable to accurately call SNPs with atypical cluster positions. optiCall performs well across the minor allele frequency range and deals well with atypical SNPs that existing algorithms consistently call incorrectly. optiCall is available for download at https://bitbucket.org/tss101/opticall/.

Assessment of methylation in combination with computational assessments of allelic imbalance in human fibroblasts. *J.R. Wagner[1], B. Ge[2], S. Busche[2], T. Pastinen[2,3], M. Blanchette[1].* 1) School of Computer Science McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 3) Department of Human and Medical Genetics, McGill University Health Centre, McGill University, Montreal, Quebec, Canada.

Allelic expression (AE) occurs when the two alleles of a given genomic locus are transcribed at different levels in a given cell, either because of epigenetic inactivation of one of the two alleles, or because of genetic variation in regulatory regions. We have developed a computational approach to analyze high throughput data measuring levels of AE and identify human genomic regions with AE in an unbiased and robust statistical manner. In brief, this approach consists of applying a Hidden Markov Model (HMM) with the added property of having specific transition probabilities for each locus in the array. We have combined AE measurements at ~750k single nucleotide polymorphisms (SNPs) dispersed across genic and intergenic regions throughout human autosomes, and measured in fibroblast cell lines from 58 individuals, with a high-throughput methylation experiment measuring methylation levels at ~450k probes measured in fibroblasts from the same individuals. We found that SNPs whose phased haplotype values correlate with methylation levels at nearby probes (mSNPs) are also frequently associated with genomic regions exhibiting AE levels, as determined from our HMM approach. Interestingly, of the correlations between mSNPS and AE found, a substantial percentage were in regions not previously annotated as genes. The majority of highly correlated pairings occur when the mSNP is 5-10kb from the AE region. We find overall that methylation is an important contributor to allelic expression and also to regulation in particular categories of genomic regions.

Evidence of genetic interaction between SNPs in candidate genes that may confer increased risk for oral clefts. *M.A. Mansilla[1], M.E. Cooper[2], K. Christensen[3], R.G. Munger[4], T.H. Beaty[5], M.L. Marazita[2,6], J.C. Murray[1].* 1) Dept Pediatrics, Univ of Iowa, Iowa City, IA; 2) School of Dental Medicine, Univ of Pittsburgh, Pittsburgh, PA; 3) Univ of Southern Denmark, Odense, Denmark; 4) Utah State Univ, Logan, UT; 5) Johns Hopkins Univ, School of Public Health, Baltimore, MD; 6) Department of Psychiatry, Univ of Pittsburgh, PA.

Cleft lip with or without cleft palate (CL/P) is a common congenital anomaly of complex etiology that affects about 1/700 births worldwide and imposes substantial medical, social and economic burden on families. Advances in genetic counseling and prevention for CL/P rely on identification of genes controlling risk. In the past two years five genes have been identified as influencing occurrence of CL/P thhrough linkage and/or association, including *IRF6, FOXE1, MAFB, ABCA4-ARGHAP29* and the gene desert region, on chr. 8q24. In an effort to determine the impact of apparent risk alleles when they are present together, we calculated population attributable risks (PAR) and odds ratios (OR) for the most significant SNPs in the above mentioned candidate genes and pairwise combinations across genes in case-control cohorts from Denmark (290 cases and 223 controls) and Utah, USA (233 cases and 493 controls). The two most significant PARs were found for rs13041247 in *MAFB*, PAR 26 % with an accompanying OR=1.8 and for rs987525 in 8q24, PAR 16 % with an estimated OR=3.1, among individuals who are homozygous for these risk alleles in the Denmark study (rs13041427 risk allele T, rs987525 risk allele A). Moreover, a combined effect for these two SNPs showed an increased risk for those homozygous individuals at both variants with a PAR 32 % and a estimated OR increase from 1.8 (*MAFB* - rs13041427 - TT) and 3.1 (8q - rs987525 - AA) to 10.7 (*MAFB* - rs13041427 - TT X 8q - rs987525 - AA). For the Utah study, when considered individually the markers rs987525 (in 8q24) gave an estimated PAR 16 % (with an OR=1.7), rs642961 (in *IRF6*) gave a PAR 15 % (with an OR=1.6) and rs 3758249 (in *FOXE1*) gave a PAR 13 % (with an OR= 1.7) presented an increase in attributable risk when one risk allele was present at each of the three markers, PAR 27 % (with an OR =2.2) (rs987525 risk allele A, rs642961 risk allele A, rs3758249 risk allele G). These findings should improve our understanding gene by gene interactions and could be applied to genetic counseling and possible prevention programs. (Support: DE016148 and DE008559).

Genome-wide copy number analysis uncovers a new HSCR gene: *NRG3*. *M. GARCIA-BARCELO[1], C.S.M. TANG[1,2], M.T. SO[1], C.R. MARSHALL[3], S. SCHERER[4], S. CHERNY[2], P. SHAM[2], P. TAM[1].* 1) Department of Surgery, Li Ka Shing Faculty of Medicine, The University of Hong Kong; Hong Kong, China; 2) Department of Psychiatry, Li Ka Shing Faculty of Medicine, The University of Hong Kong; Hong Kong, China; 3) Program in Genetics and Genome Biology and The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) The McLaughlin Centre and the Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Hirschsprung disease (HSCR) is a congenital disorder characterized by aganglionosis of the distal intestine. To assess the contribution of Copy Number Variants (CNVs) to HSCR, we analysed the data generated from our previous genome-wide association study on HSCR patients whereby we identified NRG1 as a new HSCR susceptibility locus. Analysis of 129 Chinese patients and 331 ethnically matched controls showed that HSCR patients have a greater burden of rare CNVs (p=1.50x10-5), particularly for those encompassing genes (p=5.00x10-6). We identified 246 rare-genic CNVs exclusive to patients. Among those, we detected a *NRG3* deletion (p=1.64x10-3). Subsequent NRG3 follow-up (96 additional patients and 105 controls) revealed 9 deletions and 2 de novo duplications among patients and two deletions among controls (p=1.67x10-6). Importantly, *NRG3* is a paralog of *NRG1*. Stratification of patients by presence/absence of HSCR-associated syndromes showed that while syndromic-HSCR patients carried significantly longer CNVs than the non-syndromic or controls (p=1.50x10-5), non-syndromic patients were enriched in CNV number when compared to controls (p=4.00x10-6) or the syndromic counterpart. Our results suggest a role for *NRG3* in HSCR etiology and provide insights into the relative contribution of structural variants in both syndromic and non-syndromic HSCR. This would be the first genome-wide catalog of copy number variants identified in HSCR.

Finding structural variants in individual human genomes with Random Forests. *J.J. Michaelson[1,2], J. Sebat[1,2,3].* 1) Beyster Center for Molecular Genomics of Neuropsychiatric Diseases,University of California, San Diego, La Jolla, CA; 2) Department of Psychiatry, University of California, San Diego, La Jolla, CA; 3) Department of Cellular and Molecular Medicine, University of California, San Diego, La Jolla, CA.

The detection of structural variants (SVs) from high-throughput short read sequencing data is a complex and unsolved problem. Most SV detection methods available today utilize information derived from a small number of metrics such as depth of coverage, read pair signals, or a combination of the two. These approaches have proven useful for identifying some SVs, but problems of sensitivity and specificity remain.

To address these issues, we have derived additional discriminating metrics from aligned sequencing data, and have brought the discovery problem into a supervised learning paradigm. We trained a Random Forest classifier to discriminate known SVs from invariant regions and false positives called as SVs by other methods. When presented with new data, the classifier was able to identify SVs at high sensitivity and specificity.

The development of this method has led to several contributions. First, the classifier can be viewed as a single method that embodies the strengths of the various calling methods that provided training calls; users need not expend the effort of merging callsets from disparate methods to obtain reliable results. Second, the method is adaptive. As calls are experimentally validated or invalidated, they may be added to the training data, leading to a new classifier that has learned from its previous successes and failures. In addition, as new discriminating features are proposed (e.g. as a means to identify a new class of SV), they may be incorporated into the classifier without a fundamental redevelopment of the method.

Identification of a novel clefting locus through genome-wide CNV analysis. *A.L. Petrin[1], J.M. Dierdorff[2], B.A. Lentz[1], X. Hong[2], G. de la Garza[3,4], R.A. Cornell[4], J.C. Murray[1], J.R. Manak[1,2].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Department of Biology, University of Iowa, Iowa City, IA; 3) Department of Otolaryngology-Head and Neck Surgery, University of Iowa, Iowa City, IA; 4) Department of Anatomy & Cell Biology - University of Iowa, Iowa City, IA.

Orofacial clefts are one of the most common birth defects affecting 1-2 per 1000 births and have a complex etiology involving both genetic and environmental factors. The recent use of high resolution array-based comparative genomic hybridization (aCGH) has increased the ability to detect sub-microscopic deletions and amplifications that can be causative for complex diseases such as cleft lip and palate (CLP). We report progress on an ongoing study to search for causal or contributory copy number variants (CNVs) using whole-genome tiling arrays that offer comprehensive high resolution analysis of copy number changes across the genome. Analysis of 120 samples with cleft lip and palate (CLP) and 43 samples with cleft palate only (CPO) identified several rare CNVs ranging in size from 1 to 110kb. In one family with CPO we found a deletion of *MSX2*, a homeobox gene that is a good candidate gene for clefting as prior studies have identified point mutations in cases with isolated cleft and craniosynostosis. Additionally, we identified deletions of *ISM1* in 2 independent families with CLP. *ISM1* is a strong candidate for clefting as it is in the same synexpression group as *FGF8*, mutations in which cause Kallman syndrome which has clefting as a feature. Morpholino knockdown of ism1 in zebrafish resulted in severely malformed or absent jaw and pharyngeal cartilage consistent with *ism1* playing a role in craniofacial development. Our study demonstrates a successful high throughput pipeline from CNV identification to gene knockdown in a vertebrate model system and reveals *ISM1* as a new clefting locus in humans. NIH R01 DE021071.

Multi-allelic and complex copy number variations (CNVs) of contiguous genes for Fc. receptors *FCGR2* and *FCGR3* and heat-shock protein *HSP70* in healthy subjects and systemic lupus erythematosus (SLE). *Y.L. Wu[1,2], B. Zhou[1], D.J. Birmingham[2], G.C. Higgins[1,2], L.A. Hebert[2], B.H. Rovin[2], C.Y. Yu[1,2].* 1) Center for Molecular and Human Genetics, the Research Institute at Nationwide Children's Hospital, Columbus Ohio 43205; 2) College of Medicine and Public Health, The Ohio State University, Columbus, Ohio.

Receptors for immunoglobulin Fc., Fc. RIIA and IIB, Fc. RIIIA and IIIB are important effectors of immune response. CNV of *FCGR3B* has been suggested to be a risk factor for human SLE but the published data are controversial because of a lack of definitive methodologies to accurately determine the multi-allelic CNVs of *FCGR3A* and *3B*, their neighboring genes *FCGR2A*, *2B* and *2C*, and heat-shock protein *HSP70* genes *HSPA6* and *A7*. The objectives of this study are to create specific techniques to elucidate the patterns of *FCGR2-HSP70-FCGR3* segmental duplications on chromosome 1q23, and to determine the CNVs of *FCGR3A* and *FCGR3B* in healthy subjects and SLE patients. The study population included 281 SLE patients and 485 unrelated healthy controls of European ancestry. Pulsed-field gel electrophoresis (PFGE) using genomic DNA samples digested with *Pme*I enzyme was applied to determine segmental duplications. *Taq*I restriction fragment length polymorphisms (RFLPs) were used to elucidate copy numbers of *FCGR2A*, *2B* and *2C*; *FCGR3A* and *3B*; and *HSP70* genes *HSPA7* and *HSPA6*. *Pme*I-PFGE and *Taq*I-RFLPs revealed discrete 85-kb segmental duplications for contiguous genes *FCGR2, HSP70* and *FCGR3*, which are termed an FRH module. One to five FRH modules on a haplotype were detectable by PFGE. Monomodular FRH usually had the structure *FCGR2A-HSPA6-FCGR3A-FCGR2B*. Each additional FRH module was inserted between *FCGR3A* and *FCGR2B*, and mostly included *FCGR2C-HSPA7-FCGR3B*. However, *HSPA6* instead of *HSPA7*, and *FCGR3A* instead of *FCGR3B*, could be present in a duplicated module because of gene conversion-like events. A deficiency of *FCGR3B* was caused either by the presence of a monomodular structure with one copy of *FCGR3A*, or a bimodular structure with two copies of *FCGR3A* but no *FCGR3B*. Homozygous and heterozygous deficiencies of *FCGR3B* had a frequency of 12.5% in SLE and 6.2% in controls (odds ratio: 2.16, 95% CI: 1.29-3.60; p=0.0044). By contrast, high copy numbers of *FCGR3B* had a frequency of 8.2% in SLE and 12.0% in controls. Similar CNV phenomena were observable for *FCGR2C* and *HSPA7*. In conclusion, we have defined 85-kb segmental duplications of FRH that contribute to the multi-allelic and complex CNVs of *FCGR3B* and *FCGR3A*, and showed that homozygous and heterozygous deficiency of *FCGR3B* is a common risk factor with medium effect size for human SLE. Notably, the frequency of *FCGR3B* deficiency in SLE is three to four times lower than those reported in the literature.

419W

Eight novel susceptibility genes associated with type 2 diabetes and glycaemic traits in a gene rich linkage region on chromosome 3q for T2D and metabolic traits - what can be learnt? *T. Andrew[1], W. Lau[2], K. Direk[1], H. Elding[2], N. Maniatis[2].* 1) Department of Twin Research & Genetic Epidemiology, Kings College London, London, United Kingdom; 2) Genetics, Evolution & Environment, University College London, Gower Street, UCL, London WC1E 6BT.

The chromosome 3q quantitative trait locus (QTL) that influences metabolic traits (including insulin resistance) is one of the most replicated human quantitative trait linkages. There is also meta-analytic evidence for linkage to this region for type 2 diabetes (T2D). Given that T2D is defined in relation to elevated fasting glucose serum levels (>7mmol/l), it is to be expected that any evidence of association with T2D disease should also be observed for glycaemic traits, but genome-wide association studies to date have failed to show such a relationship. Using prior evidence of linkage to chromosome 3q, we set out to test this hypothesis as part of a candidate 3q locus study. Using the WTCCC1 type 2 diabetes data (Affymetrix 500K, n=4864) and two TwinsUK population-based samples measured for insulin and glucose fasting serum levels (Illumina 610k, n=1611 and 317k, n=801), we confirm association to *IGF2BP2* and the *SLC2A2* gene region at 3q and identify and replicate four novel disease susceptibility loci - *MFSD1*, *PLD1*, *NAA-LADL2* and *MCCC1*. In addition, upon meta-analysis, we identify a further 4 novel genes *VEPH1*, *BCHE*, *KCNMB2* and *ABCC5* of interest ((=< 1E-05). For the ten genes showing evidence of association, eight are associated with both T2D and glycaemic traits and two show association with T2D only (*IGF2BP2*, *ABCC5*). This is the first time that association results for glucose homeostasis have been consistently shown for both disease and healthy populations relating to the same underlying trait, which suggests that previous inability to detect association for both phenotypes to the same genes is likely to reflect a lack of study power rather than any distinct aetiology that separates T2D and normal fasting glucose levels. This talk will focus upon the importance of high-resolution genetic maps for fine mapping (e.g. based upon international projects such as the HapMap consortium) and why it may be premature to abandon the CDCV hypothesis.

Prior studies have provided compelling evidence linking skeletal and glucose metabolism. Despite normal to high bone mineral density (BMD), people with type 2 diabetes (T2D) have a higher risk of fracture, and laboratory mouse models have linked glucose regulation to bone-derived hormones. We leveraged data from genome-wide association studies (GWAS) to detect genetic pleiotropy linking BMD and glycemic traits to further explain the epidemiological and experimental observations connecting bone disease and T2D. We examined SNPs previously associated with BMD or glycemia-related traits at levels of genome-wide significance (P<5 x 10-8), the contribution of common variation in their annotated genes, and the correlation with nearby variants induced by linkage disequilibrium for association with the alternate phenotype in two existing GWAS meta-analysis datasets: 1) up to 46,186 participants in the Meta-Analyses of Glucose and Insulin-Related Traits Consortium (MAGIC) and 2) up to 19,195 participants in the Genetic Factors for Osteoporosis (GEFOS) consortium. BMD SNPs found to be associated with glycemic phenotypes and glycemic SNPs associated with bone phenotypes at test-wide levels of significance were followed-up in either ~19,000 participants with in silico genotype and glycemia data and a large case-control T2D meta-analysis or eQTL analysis in human osteoblasts, respectively. A BMD-associated locus, ITGA1, was associated with fasting glucose in the MAGIC discovery cohort, with one SNP (rs6867040) nominally significant in an in silico replication. A glycemia-related SNP (rs287716) in locus, ADCY5, was associated with femoral neck BMD in GEFOS. Another glycemia- and height-related locus, JAZF1, was suggestively associated with BMD. Selected SNPs at these loci appear to underlie BMD and glycemic traits irrespective of body mass index (BMI), as they were not shown to be highly associated with BMI in about 123,000 genotyped participants from the GIANT consortium. We highlighted the genes ITGA1, ADCY5, and JAZF1 as potential new candidates influencing both BMD and glycemia-related traits. New insights into genetic pleiotropy of both conditions may further underscore the link between skeletal and glycemic phenotypes, improve our understanding of their pathogenesis, and reveal potential targets for bone disease and T2D therapies.

Genome-wide association (GWA) analysis has proved a powerful tool for the discovery of common variants influencing type 2 diabetes (T2D) risk. To date more than 40 susceptibility loci have been identified. However, the known variants account for no more than 10% of the inherited risk. It is likely that a substantial proportion of the remaining risk is contributed by low frequency or rare variants, including structural variants (SVs), which are not covered by GWA SNP arrays. A 23Mb region on chromosome 1q21-25 has shown evidence of linkage to T2D in 8 ethnically diverse populations. Association studies have failed to identify any common variant associations underlying this signal. We are performing two studies to identify rare and low frequency variants causal for the linkage signal, one focusing on SVs, the other and one on rare SNPs in coding regions. SVs were investigated using a Nimblegen tiling array spanning the complete 1q region. The SV assay was carried out on 360 case and control samples from the various populations in which a linkage signal had been found. The samples were all compared to a single control and signal ratios were used to determine the dose variation for each probe. Results were filtered for variants which appeared enriched in cases or controls, and these SVs are being validated using multiplex amplicon quantification (MAQ). The second resequencing study involves 1872 case and control samples from 8 populations in a pooled format. These samples are being run on Nimblegen and Agilent pulldown assays targeted at the exons of all 1q genes. In a pilot analysis of the SV experiment, we identified 21 variants of which 8 were novel. Of the novel SVs, two were validated by MAQ. The two novel SVs identified in the interim analysis are a deletion in intron 1 of GABRB3 and a duplication in an intergenic region between SPRR2G and LELP1. The SV in GABRB3 was identified in 5% of the samples and the SV in SPRR2G-LELP1 in 20%. Analysis of the full data set identified 68 putative SVs (of which 43 are novel) which are undergoing validation. To date, the resequencing assay has identified 19,478 putative novel variants, of which 11,869 have a MAF of <0.01, and APOA2 (P = 0.003) and THEM4 (P = 6X10-6) have shown an enrichment of rare variants in cases in multiple populations. Validation of these novel, rare variants is a key step in explaining the molecular basis of the linkage signal in the 1q region and in unravelling the aetiology of T2D.

422W

Examination of rare variants in HNF4(in European Americans with Type 2 Diabetes. *J.N. Hellwege[1, 4, 5], P.J. Hicks[2], N.D. Palmer[2, 4, 5], B.I. Freedman[3], D.W. Bowden[2, 4, 5].* 1) Program in Molecular Genetics & Genomics, Wake Forest School of Medicine, Winston Salem, NC; 2) Department of Biochemistry, Wake Forest School of Medicine, Winston Salem, NC; 3) Department of Internal Medicine-Nephrology, Wake Forest School of Medicine, Winston Salem, NC; 4) Center for Diabetes Research, Wake Forest School of Medicine, Winston Salem, NC; 5) Center for Genomics and Personalized Medicine, Wake Forest School of Medicine, Winston Salem, NC.

The hepatocyte nuclear factor 4-((HNF4( ) gene codes for a transcription factor which is responsible for regulating gene transcription in pancreatic beta cells, in addition to its primary role in regulation of hepatic genes. Mutations in this gene can lead to maturity-onset diabetes of the young (MODY), an uncommon, autosomal dominant, non-insulin dependent form of diabetes. Mutations in HNF4(have only been found in a handful of individuals, and only occasionally have they segregated completely with MODY. In addition, due to a similarity of phenotypes, it is unclear what proportion of type 2 diabetes (T2D) in the general population is due to MODY. In this study, 27 rare (MAF <0.05) and common variants were chosen for genotyping in a European American population of 1270 T2D cases and 1017 controls from review of databases and literature implicating HNF4(variants in MODY and T2D. Of the 27 variants there were 16 missense mutations four nonsense mutations, three splice site mutations, two small deletions and one 6-bp deletion in the P2 promoter region. Seventeen variants were found to be monomorphic in this population. Two cases and one control subject had one copy of the 6-bp P2 promoter deletion. The common intron 1 variant (rs6103716; MAF = 0.31) was not significantly associated with disease status (p>0.8). The missense variant Thr130Ile (rs1800961; MAF = 0.027) was also not significantly different between cases and controls (p>0.2). Of the six variants that were found to be rare and polymorphic, Val393Ile (n=1), IVS-4-4G<A (n=1), and IVS-5+1G>A (n=2), were found as heterozygotes in cases only; Glu276Gln (n=1), was found as a heterozygote in controls only and Arg244Gln (n=2 cases, 2 controls) and Ile454Val (n=2 cases, 1 control) were found as heterozygotes in both cases and controls. Due to the small numbers, a pooled chi-squared analysis of rare mutations was used to assess the overall burden of variants between T2D cases (92 rare alleles) and controls (59 rare alleles). This analysis revealed no significant difference (p=0.18).We conclude there is no evidence to suggest that HNF4(variants contribute significantly to risk of T2D. In addition, the observation of some mutations in controls suggests they are not highly penetrant MODY-causing variants.

423W

Using time-to-event analysis for genome-wide association study in a long-term cohort of diabetic retinopathy. *S.M. Hosseini[1,2], K. Howard[3], A.P. Boright[4], L. Sun[5,6], A.D. Canty[7], S.B. Bull[5,8], B.E. Klein[3], R. Klein[3], A.D. Paterson[1,2,5].* 1) Genetics & Genome Biology Program, The Hospital for Sick Children, Toronto, Canada; 2) Institute of Medical Science, Univ Toronto, Toronto, Canada; 3) Dept of Ophthalmology & Visual Sciences, Univ Wisconsin, Madison, WI, USA; 4) Dept of Medicine & University Health Network, Univ Toronto, Toronto, Canada; 5) Dalla Lana School of Public Health, Univ Toronto, Toronto, Canada; 6) Dept of Statistics, Univ Toronto, Toronto, Canada; 7) Dept of Mathematics & Statistics, McMaster Univ, Hamilton, Canada; 8) Prosserman Centre for Health Research, Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Toronto, Canada.

Diabetic retinopathy (DR) affects up to 82% of the patients with type 1 diabetes (T1D) and is largely determined by diabetes duration and poor glycemic control. However, consistent with a genetic contribution, the severity of DR clusters in families. So far, few genetic variants have been identified with convincing and consistent association with DR.

White T1D participants (n=627) in the Wisconsin Epidemiologic Study of Diabetic Retinopathy (WESDR) were genotyped by Illumina HumanOmni1-Quad assay. A logistic regression association analysis of DR [level 35/<35 or worse (step⁄ 4) on ETDRS scale] at the first visit [293 cases vs 334 controls (ETDRS step<4)] does not make full use of the cohort nature of the study. We used repeated retinal photographs taken at 5 study examinations over 25 years to define a time-to-DR outcome which was analyzed as a survival trait using parametric models to address both left and interval censoring. We built models to adjust for the effect of glycemia and other relevant covariates in the analyses.

The results from the two GWAS analyses are largely consistent (rank correlation of 0.73 for SNP-specific test statistics, p<0.001). Survival analysis, however, seems to improve the power compared to the logistic regression (14 vs 2 SNPs with p<1E-5; genomic control 3 1.01 vs 0.99). No SNP in either analysis met the genome-wide significance threshold. The strongest association was observed for a group of SNPs on 7q36.1 near *AGAP3*. The results will be replicated in independent cohorts.

The use of time-to-event analysis and explanatory covariates improves our ability to identify loci for DR. These findings have implications for future genetic studies of DR.

424W

Fine-mapping haplotype analysis of established type 2 diabetes loci using the "Metabochip". *A. Kumar[1,6], A.P. Morris[1], R. Magi[1], P. Deloukas[2], P. Donnelly[1], T. Frayling[3], A. Hattersley[3], C.N.A. Palmer[4], A.D. Morris[4], M.I. McCarthy[1,5].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 3) Institute of Biomedical and Clinical Science, Peninsula Medical School, Exeter, United Kingdom; 4) Biomedical Research Institute, University of Dundee, Ninewells Hospital & Medical School, Dundee, United Kingdom; 5) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 6) Swiss Tropical and Public Health Institute, University of Basel, Switzerland.

The number of established loci influencing susceptibility to type 2 diabetes (T2D) is now in excess of 40. Most of these have been identified by single-SNP analysis of genome-wide association studies, but together they explain less than 10% of the disease heritability. We have thus undertaken haplotype-based analysis within established T2D loci to identify multi-SNP signals of association that might better explain the genetic architecture underlying the disease. We have considered UK subjects with 5,938 T2D cases and 9,356 controls. The samples were genotyped using the "Metabochip" (a custom iSELECT array with ~195,000 SNPs), designed to support large-scale follow-up of putative novel associations for T2D and other cardiometabolic traits, as well as fine-scale mapping of established loci. We followed two parallel haplotype (phasing by Plink's E-M algorithm) analysis strategies: (i)forward selection, adding SNPs in turn to a haplotype in order to maximise the association signal; and (ii) a complete evaluation of all possible 2- and 3-SNP haplotype combinations, in four T2D fine-mapping loci (CDKN2A/B, KCNQ1, FTO, TCF7L2). Meta-analysis of "omnibus" haplotype association p-values across the two cohorts was performed via Fisher's method. Our analyses revealed stronger signals of association of T2D with haplotypes than single SNPs in two loci: KCNQ1 and CDKN2A/B. In KCNQ1, an omnibus haplotype test of rs163184, rs2237896 and rs10400376 (all r2<0.04) yielded the strongest signal of association with p=2.0x10-14. The specific GGG haplotype was the most strongly associated, with p=5.65x10-13, OR=1.20 [95%CI 1.14-1.26], while the strongest single SNP association was for rs163184 (p=1.1x10-9). In CDKN2A/B, the strongest association signal was observed for a 3 SNP omnibus haplotype test of rs10757283, rs10811660 and rs73652848 (p=6.7x10-16). The best individual association was with haplotype CGT with p=5.63x10-14, OR=1.26 [95%CI 1.16-1.29]. The 3-SNP omnibus haplotype test was not markedly more significant than a 2-SNP omnibus haplotype test of rs10757283 and rs10811660, p=2.7x10-15. In comparison, the best single SNP rs7018475 was associated with p=6x10-9. rs10757283 and rs10811660 are correlated (r2=0.26) and define three clades of haplotypes that have been previously demonstrated to be associated with T2D. Our results highlight the potential for haplotype-based analysis to elucidate the complex underlying genetic architecture of the T2D susceptibility loci.

425W

Relationship between Diabetes Risk and Admixture in Post-Menopausal African American and Hispanic American Women. *L. Qi[1], R. Nassir[2], R. Kosoy[2], L. Garcia[1], J. Curb[3], L. Tinker[4], B. Howard[5], J. Robbins[2], M. Seldin[2].* 1) Dept of Public Health Sciences, Univ California, Davis, Davis, CA; 2) Univ California, Davis, Davis, CA; 3) University of Hawaii, Honolulu, HI; 4) Fred Hutchinson Cancer Research Center, Seattle, WA; 5) MedStar Health Research Institute/Georgetown University, Washington, DC.

In the United States, type 2 diabetes is more prevalent in African Americans and Hispanic Americans than in European Americans. To assess whether continental admixture is correlated with diabetes risk in these admixed groups, we conducted an admixture analysis using 16,476 women from the Women's Health Initiative (WHI), who self identified as African American (AFA) or Hispanic American (HA). Self-reported diabetes treated with pills or insulin shots at baseline and during following up were ascertained based on the WHI questionnaire. We genotyped 92 ancestry-informative markers and used STRUCTURE analysis to estimate the proportion of sub-Saharan African (AFR), Amerindian (AMI) and European (EUR) admixture. Cox regression models were used to examine the association between genetic admixture and diabetes risk, with and without accounting for socioeconomic status (SES), and adiposity measures including body mass index (BMI) and waist hip ratio (WHR). Neighborhood SES was obtained using a standardized geocoding protocol and a summary measure of each participant's neighborhood SES was estimated from tract-level data. AFR admixture was significantly associated with diabetes risk in AFA women when adjusting for entry age alone (HR = 3.08, $p < 0.0001$), and after further adjusting for neighborhood SES (HR = 2.36, $p < 0.0001$), and adiposity measures (BMI or WHR) (HR = 2.02 or 2.23, $p < 0.0001$). In HA women, AMI admixture had significant associations with diabetes risk when adjusting for entry age alone (HR = 2.50, $p < 0.0001$), and this association remained significant after further adjustment for SES (HR = 1.97, $p = 0.0003$), and BMI (HR = 2.03, $p = 0.0002$). In HA women, AFR admixture was not correlated with diabetes risk ($p > 0.5$) while EUR admixture appeared to have a protective effect against diabetes. In addition, in both AFA and HA women, SES showed significant negative association with diabetes risk while BMI or WHR had significant positive associations with diabetes risk, with and without adjusting for genetic admixture. Thus, admixture, SES and BMI/WHR each independently contribute to diabetes risk after accounting for each of the other factors, emphasizing the importance of considering both genetic and environmental causes in the etiology of type 2 diabetes. The data provide additional support to the hypothesis that differences in ethnic origins may be critical to etiologic and therapeutic studies.

Genetic role on sleep disorder. *M. Falah[1], M. Asghari[1], M. Houshmand[2], M. Farhadi[1].* 1) 1Department & Res Centr, Gen, Tehran, Iran; 2) National Institute for Genetic Engineering and Biotechnology, Tehran, Islamic Republic of Iran.

Sleep is one of the great mysteries of science. In the adult population, about one third is suffering from temporary sleep disturbances. About one in ten is suffering from a chronic sleep disorder which is also affecting the persons mood and efficiency daytime. Sleep disorder commonly involve genetic susceptibility, environmental effect, and interactions between these factors. These days, the hereditary of sleep patterns has been shown in studies of monozygotic twins, and electroencephalogram patterns offer a unique genetic fingerprint which may assist in the identification of genes involved in the regulation of sleep. Genetic factors are also thought to play a role in sleep disorder for instance: - Narcolepsy is a disabling sleep condition and research has revealed it has a complex hereditary pattern. Researchers discovered that a specific gene causes symptoms in mice and dogs that looked like the symptoms that were associated with narcolepsy in humans. The narcolepsy gene produces a protein in the brain (called orexin, or hypocretin) that promotes wakefulness. A reduction in this wakefulness-promoting protein or in the receptors for this protein may underlie narcolepsy in humans. - Another sleep disorder is Sleep Apnea, an extreme form of snoring in which an individual's airway becomes partially or completely blocked, leading to repetitive awakenings. This is a complex pattern because there are likely to be multiple genes involved. Genes influence how fast or slow our internal clock runs and, as a result, how closely it—and our body's functions—align with the 24-hour day. Changes in these genes, were known as mutations, from one generation to the next can affect the clock's timing, and the results of this change were shown as in advanced sleep phase syndrome (ASPS) and delayed sleep phase syndrome (DSPS). Gene profiles of sleep impairment are consisted of: Bmal1, NPAS2/Clock, Dec2, 5-HT1a, Orexin /Hcrtrt2 and Ube3A...etc Those who carry the mutation sleep on average two hours less a night — but still function perfectly well. While the mutation is probably rare, it offers the strongest evidence yet of the role genes play in our need for sleep. We expect a long road still ahead before scientists solidly understand sleep because it's a complex phenotype. If we can understand this biological pathway, perhaps we can come up with a therapeutic compound. Maybe we can help people sleep less in a safe way.

Sequencing of Whole Blood Cell RNA: Duplex Specific Nuclease Treatment for Removal of Abundant RNA Species. *K. Fitch[1], S. Luo[2], P. Beineke[1], H. Tao[1], M. Wu[1], S. Rosenberg[1], J. Wingrove[1].* 1) CardioDx, Inc, Palo Alto, CA; 2) Illumina, Inc, Hayward, CA.

Background: RNA sequencing using Next Generation Sequencing methods (NGS) is rapidly replacing microarrays to measure changes in gene expression. However, sequencing of whole blood RNA can be confounded by the high abundance of RNAs such as hemoglobin. We describe the use of Duplex-Specific Nuclease (DSN) to remove high abundance RNAs, and compare RNA sequence data from treated RNA to that obtained by microarray and RT-qPCR. Methods: RNA was purified from whole blood collected in Paxgene tubes from consented donors. RNA from multiple individuals was combined into 5 independent pools. Total RNA was fragmented, converted to cDNA and then subjected to adaptor ligation and PCR. Amplified cDNA from the first pool was either treated with 2 units of DSN for 5 hours, or left untreated; the four remaining pools were treated with DSN as described above. cDNA was then sequenced on the Illumina GAII platform using standard Illumina protocols. Results: Sequencing of untreated cDNA resulted in 257,709 reads per kilobase of exon model (RPKM) for HBA1 sequence, 25% of the total reads sequenced. Treatment with DSN reduced this to 926 RPKM for HBA1, effectively reducing the amount of HBA1 by 99.6%. Comparable results were seen for HBA2 and HBB (99.7 and 99.8% reductions respectively). Comparison of the four treated pools to microarray and RT-qPCR data derived from the same samples showed good concordance (median r2 value of 0.547, 17,069 genes; median r2 value of 0.841, 176 genes respectively). DSN treatment also reduced the levels of other high abundance genes such as histone, ribosomal and ubiquitin components as compared to microarray and sequence data by linear regression. Conclusions: Treatment of whole blood total RNA with DSN appears to be an effective way to reduce high abundance transcripts, prior to RNA sequencing, improving the depth of the transcriptome revealed. In addition, better correlation was observed between RNA sequencing and RT-qPCR data than between microarray and RT-qPCR data.

Increased African Ancestry and Decreased Lung Function in Puerto Rican and African American Children with Asthma and Mediation by Environmental Risk Factors. *K.A. Drake[1], C.R. Gignoux[1], L.A. Roth[1], S. Sen[1], S. Thyne[1], P. Avila[2], L. Borrell[3], H.J. Farber[4], R. Kumar[5], W. Rodriguez-Cintron[6], J. Rodriguez-Santana[7], D. Serebrisky[8], M. Lenoir[9], K. Meade[10], E. Brigino-Buenaventura[11], E.G. Burchard[1].* 1) Univ CA, San Francisco, San Francisco, CA; 2) Northwestern Univ, Chicago, IL; 3) City Univ of New York, NY, NY; 4) Texas Children's Hospital, Houston, TX; 5) Children's Memorial Hospital, Chicago, IL; 6) VA Medical Center, San Juan, PR; 7) Centro de Neumologica Pediatrica, San Juan, PR; 8) Jacobi Medical Center, NY, NY; 9) Bay Area Pediatrics, Oakland, CA; 10) Children's Hospital Research Center Oakland, Oakland, CA; 11) Kaiser Foundation Research Institute, Oakland, CA.

Genetic ancestry has been shown to be associated with many phenotypes including lung function, and may be a useful clinical proxy in some cases. However, the underlying causes of these associations are unidentified population-specific genetic and environmental variables. An increase in African ancestry was previously reported to be associated with a decrease in lung function as measured by forced expiratory volume in one second (FEV_1) in several healthy African American adult populations. FEV_1 decreased by anywhere between 2.39 and 8.14 mL per percentage increase in African ancestry depending on the population. This finding demonstrated that African American individuals were being misclassified based on predictive lung functions that did not account for ancestry, but it was unclear whether the association was coming from an increase in African ancestry or a decrease in European ancestry. We replicated this association in 540 Puerto Rican children with asthma and 437 African American children with asthma. Global ancestry in these populations was determined from 400 ancestry informative markers using the program ADMIXTURE. The Puerto Rican children and African American children had 35% and 77% African ancestry, respectively, although there was wide variation in both populations. FEV_1 decreased 6.03 mL for every percentage increase in African ancestry ($p=0.0001$) in our Puerto Rican population and 6.79 mL ($p<0.00001$) for every percentage increase in our African American population, adjusting for age, age^2, height^2, BMI, recruiting site, sex, and Native American ancestry if appropriate. The fact that Puerto Ricans are admixed with three ancestral populations allowed us to determine that an increase in African ancestry specifically is associated with a decrease in FEV_1. We demonstrated the use of graphical causal inference models to estimate the mediating effect of environmental variables on this ancestry-lung function association. We estimated the proportion of the total effect of African ancestry on FEV_1 that was due to a child's second hand smoke exposure; in Puerto Ricans this proportion was 0.5% (95% CI: -3.1%-5.6%) and in African Americans it was 0.8% (95% CI: -4.7%-4.5%). Although these data indicate that the association between African ancestry and FEV_1 is not being driven by second hand smoke exposure, we discuss how the proportion of the association owed to other causal environmental and genetic risk factors may be identified using this methodology.

429W

Genetic vectors - consolidated genotyping data, in association study of rheumatoid arthritis. *I. Sandalov[1], L. Padyukov[2].* 1) Condensed Matter Physics, Royal Institute of Technology, Kista-Stockholm, Sweden; 2) Rheumatology Unit, Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

The highlight of modern genetics is an exponential growth of data and increasing complexity of relations between found genetic variations and the phenotype. We suggested to look on genotyping data as on an ensemble of spin chains and to analyze the data as a quantum system. In this approach SNP is considered as a spin with three states corresponding to possible genotypes. Each person is characterized by single genetic vector (GV), which is a combination of genotypes or a multi-spin state. This consolidation of genotypes in GVs integrates multiple genetic variants in a single statistical test and excludes ambiguity of biological interpretation for allele and haplotype associations. To examine the validity of the approach, we analyzed 1,820 rheumatoid arthritis (RA) cases and 947 healthy controls from the Swedish EIRA study. GVs were constructed from 8 SNPs in HTR2A locus and HLA-DRB1 shared epitope (SE) alleles. When empirical GVs were used for analysis of the structure of the study population we observed stratification for 338 GV subgroups. Among those, 36 GVs were represented only in control group (5.81% of all healthy individuals), while 127 GVs were found only in RA group (14.9% of all RA cases). Two- and three-point statistical correlations for genotypes, chosen from contrast GVs, were evaluated and used for a detection of the genotype-genotype interactions. We replicated our findings in independent study of RA (NARAC) and found that 131 GVs coincide and contain vast majority of individuals in both study populations. The correlators for both cohorts show that interaction between one set of the genotypes (rs2070040, AG; rs977003, AA or CC) favors the development of RA, whereas for another set of genotypes (rs2070040, TT and rs977003, AC), as well as for rs977003, AC genotype at the absence of SE, it plays the protective role ($p<10^{-10}$). This method can be applied for the analysis of moderately associated loci from GWAS for selection individuals with either contrasting GVs or for optimization of putative “functional” combinations of the genotypes. Additionally, by using our approach, the interactions along the locus (including LD measures) or more extended interactions for combined sets from different loci are possible to assess.

Novel approaches for discovery and replication in large scale association studies. *D.V. Zaykin, C-L. Kuo.* Dept Biostatistics, NIEHS/NIH, Res Triangle Park, NC.

We report methods for estimating the proportion of false discoveries among top R association results in large-scale association studies. Our approach gives an estimate of such proportion (R-FDR) for any given study, as well as its expected value. R-FDR estimate can be used to prioritize association results for replication, while the expected R-FDR can be used for sample size calculation in planning studies. Our approach incorporates effect size distribution as well as linkage disequilibrium through accurate approximations for probabilities of ranks of true associations. Genes can be weighted differentially or organized into “tiers”, depending on whether they belong to a candidate pathway. One important difference with conventional approaches is that we directly control FDR for a given number of top hits, rather than controlling FDR for a fixed significance threshold.

431W

Interpreting familial whole-genome sequencing data for the identification of genetic variants influencing epilepsy susceptibility. *E.K. Ruzzo[1, 3], E.L. Heinzen[1, 3], R. Wedel[2], K.V. Shianna[1], D. Ge[1], R. Ottman[2, 3], D.B. Goldstein[1, 3].* 1) Center for Human Genome Variation, Duke University School of Medicine, Durham, North Carolina 27708, USA; 2) G. H. Sergievsky Center and Departments of Epidemiology and Neurology, Columbia University, and Division of Epidemiology, New York State Psychiatric Institute, New York, NY, USA; 3) Epigen Consortium.

Epilepsy is highly heritable, yet the genetic contribution to the vast majority of cases remains elusive. Due to extreme locus heterogeneity, classic case-control sequencing study designs may fail to uncover epilepsy susceptibility variants in small, heterogeneous samples. In this study, we exploited multiplex epilepsy families to reduce heterogeneity and sequenced multiple affected related individuals to reduce the number of candidate variants. Our familial study design enables multiple levels of evaluation for each of the millions of identified variants, prior to detailed candidate gene analyses or follow-up genotyping: i) comparison to sequenced control genomes (>300) ii) identification of shared familial variants iii) prioritization of variants falling in linkage peaks and iv) overlap of variants or affected genes across families or in sporadic epilepsy cases. This multilevel approach shrinks the pool of candidate variants to be genotyped to assess familial cosegregation and enrichment in large case-control cohorts. In this study, we performed whole-genome or exome sequencing of 56 epilepsy patients from 29 multiplex families, all sequenced to high coverage (>30x). Following alignment of the short-sequence reads, variant calling, quality control filtering, and the multi-level evaluation outlined above, we identified a set of 367 candidate single nucleotide variants (SNVs) that were exceedingly rare, or completely absent outside affected family members, and likely to impact the encoded protein product. Importantly, candidate variants were genotyped in a much larger cohort of 1,000 epilepsy patients and 2,500 controls using a custom-genotyping chip. Variants still enriched or exclusively found in cases vs controls were evaluated for familial cosegregation. We found that no single variant explained a large number of families, indicating that distinct genetic etiologies exist. Several variants were shared within a family, rare or absent in controls, and seen in additional sporadic cases. Of particular interest are: a stop gain in USP45 (emerging evidence supports the importance of ubiquitination in neuronal function), and nonsynonymous variants in RBM15 (CNS expressed RNA binding protein) and PKD1 (seizures observed in patients with microdeletions encompassing PKD1). These variants are currently being tested for cosegregation. We continue to utilize this familial approach for the discovery of novel genetic variants that increase epilepsy susceptibility.

Chronic Rhinosinusitis in Cystic Fibrosis Heterozygotes. *A. Powers[1], W. Regelmann[2], J. Phillips[2], C. Milla[3], X. Wang[4,5].* 1) Fairview Health Services, University of Minnesota Medical Center Fairview, Minneapolis, MN; 2) Dept. of Pediatrics, University of Minnesota Medical Center, Fairview, Minneapolis, MN; 3) Dept. of Pediatrics, Stanford University, Palo Alto, CA; 4) Dept. of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 5) National Eye Institute, NIH, Bethesda, MD.

Cystic fibrosis (CF) is the most common life-threatening autosomal recessive disorder in the Caucasian population, with an incidence of one in 2000-4000 live births and a prevalence of approximately 30,000 affected individuals in the US. CF clinical presentation includes sino-pulmonary symptoms. Chronic inflammation of sinuses and nasal mucosa starts in early stages of the disease. Chronic rhinosinusitis (CRS), defined as persistent inflammation involving nasal and paranasal mucosa, is an almost invariable feature of CF. However, CRS is the most prevalent chronic condition in the United States and can be seen in isolate or other systemic conditions besides CF. Genetics play a very important role in many of these systemic conditions. While these systemic conditions, and specifically CF, may not be accountable for the majority of CRS patients, the genetic contributing factors of these conditions may contribute significantly to the etiology of CRS in general. Previously, a higher frequency of CF carriers was found in the general CRS patients and a higher CRS incidence was found in CF obligate carriers in the greater Maryland area. To verify these findings in a different geographical area, we conducted a similar survey study with parents of CF patients visiting University of Minnesota Medical Center, Fairview (UMMC). Biological parents of any patient visiting the CF Clinic at UMMC were invited to participate by the genetic counselor. A study invitation letter, IRB approved consent form, and study questionnaire were provided if interested. Detailed questions regarding sinus conditions were adopted from previously used surveys. One hundred fifty four parents completed the survey. Forty three individuals met the criteria for CRS, therefore having self-reported CRS. This accounts for about 28% of the participating obligate CF carriers. It was estimated that 13% to 14% of US population had self-reported CRS. Incidence of CRS in the CF carrier population was increased in Minnesota, which is consistent with the previously demonstrated results. The CF carrier frequency is approximately one in 28 in the N. American Caucasian population. All states in the US now have CF newborn screening and carrier testing is frequently offered as part of routine prenatal care. A controlled comparison of CRS frequency in appropriate controls is warranted to help determine if therapeutic strategies used in CF patients may aid CRS treatment in parents and other CF carriers.

A Note on Robust TDT-Type Test under Informative Parental Missingness. *J. Chen[1], K. Cheng[1,2,3].* 1) Biostatistics Center and Graduate Institute of Biostatistics, China Medical University, Taipei, Taiwan; 2) Biostatistics Center and College of Public Health, China Medical University, Taichung, Taiwan; 3) Graduate Institute of Statistics, National Central University, Chungli, Taiwan.

Many family-based association tests rely on the random transmission of alleles from parents to offspring. Among them, the transmission/disequilibrium test (TDT) may be considered to be the most popular statistical test. The TDT statistic was proposed to evaluate nonrandom transmission of alleles from parents to the diseased children. However, in family studies, parental genotypes are not always available. Quite often, the offspring genotype affects the severity of offspring phenotype or/and the age at onset and in turn affects the parental missingness. In such case, the nonrandom transmission of alleles may also occur even when the gene and disease are not associated. As a consequence, the usual TDT or its variations would produce excessive false positive conclusions in association studies. In this note, we propose a TDT-type association test which is not only simple in computation but also robust to the joint effect of population stratification and informative parental missingness. The test statistic does not rely on any model and also allows for having different mechanisms of parental missingness across subpopulations. We use a simulation study to compare the performance of new test and the TDT and point out the advantage of the new method.

434W

Bioinformatic analysis of protein turnover of intronless gene products. *T.O. Onabanjo, R.J. Slater, E.A. Bryson, N.C. Madu, R. te Boekhorst.* School of Life Sciences, University of Hertfordshire, Hatfield, United Kingdom.

Most Eukaryotic genes are interrupted by introns, while prokaryotic genes are entirely intronless. This seems to support the so called `introns-late hypothesis' that introns emerged in the course of evolution in Eukaryotes. However, many eukaryotic histone and GPCR genes are predominantly intronless and there are intronless genes among those coding for proteins associated with transcription regulation, DNA replication and DNA repair. Thus the overall efficiency of such processes may be significantly influenced by rapid transcription of these genes and the translation and turnover of the resulting proteins. Given the importance of DNA repair proteins in preserving the integrity of the genome and the likely need for this process to be rapid and efficient, we investigated whether there was any difference between the half-life of DNA repair proteins encoded by intronless genes and genes with introns. Our study identified 170 DNA repair proteins in the human genome, out of which only 4.1% were encoded by intronless genes. TermiNator was used to predict the N-terminal residue after posttranslational modifications and the half-life of the proteins from the N-end rule. There was no significant difference between the half-life of proteins resulting from intronless and intron containing DNA repair genes. A similar result was obtained using Protparam when predicted protein stabilites were compared. We also analyzed the entire human genome using TermiNator and found no significant difference in the half-life of proteins resulting from intronless and intron containing genes. These findings indicate that the evolutional advantage that introns bring by enabling alternative splicing is so great that it justifies the extra time and energy spent on transcribing them, even when the resulting proteins are only required for a short time.

The Influence of Real-Life Topologies on Boolean Models of Gene Regulatory Networks. *C. Darabos[1], F. DiCunto[2], M. Tomassini[3], P. Provero[2], M. Giacobini[2], J.H. Moore[1].* 1) Dartmouth Medical School, Lebanon, NH, USA; 2) University of Torino, Torino, Italy; 3) University of Lausanne, Lausanne, Switzerland.

Gene-on-gene regulations are key components of every living organism. Dynamical abstract models of genetic regulatory networks (GRNs), such as Kauffman's random Boolean networks (RBN), help explain the genome's evolvability and robustness by the structural topology of the network formed by genes, as vertices, and regulatory interactions, as edges. In the original RBN model, the network was a random structure, and extensions studied other synthetic topologies, such as scale-free network. In this work, we use two regulatory-networks modules of biological organisms, yeast and mouse embryonic stem cell, as support for Boolean network models to study how real topology compares to artificial ones. Additionally, we propose a threshold-based dynamic Boolean update function (replacing the original RBN's random function) in which the promoting and repressing effect of each gene product interaction is taken into consideration. In order to investigate the dynamical behavior of these two study case models, we visualized the phase transition between order and chaos into the critical regime using Derrida plots. We also proposed a complementary measure, the criticality distance that allows us to discriminate between different regimes in a quantitative manner. Moreover, we portray the entire state spaces of the two real-life GRNs using RBN-specific statistical measurements (attractor state space). Simulation results on two real-life genetic regulatory networks show that there exist a set of parameters in both update functions that allow “organic” systems to operate in the critical regime, and that these values are comparable in both case studies. The analyze of the attractor space hints at “cell specialization” in the case of ES cells, and cell cycle in yeast. Finally, we use a third real-life regulatory network, along with its inferred Boolean update functions to validate the results obtained, and we show a 91% accuracy of our threshold-based update function. The update function confers additional realism to the model, while actually reducing the complexity and solution space, thus making it easier to investigate.

Compensatory amino acid changes as a signal of human disease. *D. Jordan[1,2], I. Adzhubey[2], S. Sunyaev[2].* 1) Biophysics Program, Harvard University, Cambridge, MA; 2) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School.

Human disease mutations of high penetrance sometimes correspond to wild type amino acid variants in vertebrate orthologs. This observation has previously been interpreted as a result of compensatory amino acid changes. We analyzed a large dataset of well-annotated mutations involved in Mendelian diseases using new comparative genomics data on 46 vertebrate species. We observed that over 8% of mutations correspond to wild type amino acids in vertebrate species. We tested whether these cases can be explained by compensatory effects of other amino acid changes in these species. For a large fraction of observations, the presence of a human disease variant in vertebrate orthologs is accompanied by a synchronous change at several other amino acid sites. This observation is limited to disease mutations and is in sharp contrast to human neutral sequence variants. We show that a simple statistic based on co-evolving sites can differentiate between neutral and pathogenic mutations that are observed as wild-type amino acids in vertebrate orthologs. We analyze this result to distinguish true compensatory changes from fast-evolving sequence regions and alignment or mapping errors. This analysis quantifies the error produced by models of evolution and population genetics that treat multiple sites as evolving independently in a constant evolutionary landscape. We also conclude that using a co-evolution statistic like that reported here can greatly increase accuracy of computational predictions of the pathogenic effect of human missense mutations based on comparative genomics data.

Impact of genetic variants on coding genes: genomic sequence and protein structure conservation. *E. Khurana[1, 2], L. Habegger[2], A. Abyzov[1, 2], M. Gerstein[1, 2, 3].* 1) Department of Molecular Biophyics & Biochemistry, Yale University, New Haven, CT; 2) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 3) Department of Computer Science, Yale University, New Haven, CT.

Several genomic variants are known to be associated with diseases, while many variants occur in healthy humans. In order to understand the underlying differences between these two kinds of variants, we computed and compared several properties of the two sets of variants: disease-causing variants from Human Gene Mutation Database (HGMD) and those reported in three different populations of healthy individuals in pilot phase of the 1000 Genomes Project. Firstly, in order to check which coding sites are most prone to mutation in healthy individuals, we computed the selection pressure at each coding site. This was done by using a maximum likelihood approach and a phylogenetic tree with gene alignments from multiple species. We find that most missense single nucleotide polymorphisms (SNPs) with high-allele frequencies occur at sites evolving neutrally. Moreover, we are also able to identify ~200 sites that are evolving under positive selection and are polymorphic amongst humans. Secondly, it has been reported before that evolutionary conservation is an essential feature that helps to identify damaging SNPs - in order to test the hypothesis that the same is true for small insertions and deletions (indels), we computed evolutionary conservation scores for small in-frame deletions associated with diseases as well as for those observed in healthy humans. We find that disease-associated deletions are significantly more conserved amongst species and hence evolutionary conservation promises to be an essential marker for identification of damaging in-frame deletions. Finally, we extended our analysis from genomic sequence to protein structure. Protein structures are assigned to a specific SCOP family (Structural Classification of Proteins) if they share similar structure and function, even though they might not share a similar genomic sequence. Structural alignment of all proteins within each SCOP family reveals that SNPs associated with diseases occur at residues which show significantly more structural conservation, i.e. regions on three-dimensional protein structure which are less plastic amongst the family. Thus, our results provide insights about human genomic variants that are polymorphic in healthy individuals vs those that cause diseases, and hence should further aid studies which try to identify and understand genetic variants causing diseases.

Genetic structure of Jewish populations on the basis of genome-wide single nucleotide polymorphisms. *N.M. Kopelman[1], L. Stone[1], D.G. Hernandez[2], D. Gefel[3], A.B. Singleton[2], E. Heyer[4], M.W. Feldman[5], J. Hillel[6], N.A. Rosenberg[7].* 1) Porter School of Environmental Studies, Tel Aviv University, Ramat Aviv, Israel; 2) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, Maryland, USA; 3) Department of Medicine, Barzilai Hospital, Ashkelon, Israel; 4) Muséum National d'Histoire Naturelle - Centre National de la Recherche Scientifique-Université Paris 7, Paris, France; 5) Department of Biology, Stanford University, Stanford, California, USA; 6) Robert H Smith Institute of Plant Sciences and Genetics, Faculty of Agriculture, The Hebrew University of Jerusalem, Rehovot, Israel; 7) Department of Human Genetics, University of Michigan, Ann Arbor, Michigan, USA.

The Jewish population forms a genetically structured population, due to historical migrations and diverse histories of the various Jewish communities. Discerning the ancestry and population structure of different Jewish populations is important for understanding the complex history of the Jewish communities as well as for research on the genetic basis of disease. Using >500,000 genome-wide single-nucleotide polymorphisms, we investigated patterns of population structure in 438 samples from 30 Jewish populations in the context of additional samples from non-Jewish populations. The collection of Jewish populations studied incorporates a variety of populations not previously included in other genomic population structure studies of Jewish groups (e.g. NM Kopelman et al. 2009 BMC Genet 10:80; G Atzmon et al. 2010 AJHG 86:850-859; DM Behar et al. 2010 Nature 466:238-242; SM Bray et al. 2010 PNAS 107:16222-16227; JB Listman et al. 2010 BMC Genet 11:48). We identify fine-scale population structure within the Jewish samples, including notable distinctions separating Ashkenazi, Mizrahi, Sephardi, and North African populations. Additionally, we identify distinctions within major regional groups, including a separation among the North African populations of Libyan, Moroccan, and Tunisian Jewish samples and a separation among the Mizrahi populations of Bukharan, Georgian, Iranian, and Iraqi Jewish samples. These results supply enhanced information regarding Jewish population structure, providing a basis for further detailed analysis of the genetic history of Jewish populations.

Estimating a date of mixture of ancestral South Asian populations. *P. Moorjani[1,2], N. Patterson[2], P. Govindaraj[3], L. Singh[3,4,5], K. Thangaraj[3,5], D. Reich[1,2,5].* 1) Dept Gen, Harvard Medical School, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Centre for Cellular and Molecular Biology, Hyderabad, India; 4) Genome Foundation, Hyderabad, India; 5) These authors co-directed the project.

Linguistic and genetic studies have shown that most Indian groups have ancestry from two genetically divergent populations, Ancestral North Indians (ANI) and Ancestral South Indians (ASI). However, the date of mixture still remains unknown. We analyze genome-wide data from about 60 South Asian groups using a newly developed method that utilizes information related to admixture linkage disequilibrium to estimate mixture dates. Our analyses suggest that major ANI-ASI mixture occurred in the ancestors of both northern and southern Indians 1,200-3,500 years ago, overlapping the time when Indo-European languages first began to be spoken in the subcontinent. These results suggest that this formative period of Indian history was accompanied by mixtures between two highly diverged populations, although our results do not rule other, older ANI-ASI admixture events. A cultural shift subsequently led to widespread endogamy, which decreased the rate of additional population mixtures.

The Influence of Whole Genome Duplication and Subsequent Diversification on Environmental Robustness and Evolutionary Innovation in Gene Regulatory Networks. *Q. Pan, C. Darabos, A. Tyler, J. Payne, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Whole genome duplication and subsequent diversification in biological systems constitute powerful mechanisms for the discovery of new phenotypes and for the protection of these phenotypes against environmental perturbation. Here, we use Random Boolean Networks to investigate the influence of these genetic mechanisms on the relationship between evolutionary innovation and environmental robustness in gene regulatory networks. We find that whole genome duplication is highly deleterious in ancestral environments, but provides fitness advantages in novel environments, which come at the cost of reduced environmental robustness. We then show that the subsequent diversification of duplicated networks, via the loss of regulatory interactions, can partly negotiate this tradeoff, improving evolutionary innovation and environmental robustness. The results of this study provide a foundation for understanding the role of robust gene regulatory networks in the genotype-phenotype mapping relationship.

441W

The Effect of Assortative Mixing on the Robustness of Gene Regulatory Networks. *D. Pechenick, J. Payne, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Gene Regulatory Networks (GRNs) comprise collections of genes and regulatory rules that describe gene expression in cells. GRNs are robust in that perturbation, for example knocking out a gene, doesn't necessarily yield a different expression profile. GRNs are also evolvable in that new phenotypes can be realized through mutation. Populations of GRNs can achieve both robustness and evolvability by occupying large neutral spaces, which consist of all the different genotypes that are accessible by point mutations and lead to the same phenotype. Here we investigate how assortativity, a structural property of networks, influences neutral space size. Assortativity describes the extent to which nodes that possess a certain number of connections are themselves connected to nodes with the same number of connections. We use Boolean Networks to model GRNs, where nodes represent genes and edges represent regulatory interactions. The expression states of genes are either on or off, and gene expression for all genes is updated simultaneously at discrete time points according to deterministic regulatory rules, which we define as a network's genotype. As gene expression states are updated they eventually repeat to form a cycle, called an attractor, which we define as a phenotype. We use random walks to estimate the size of a network's neutral space, which we use as a proxy for robustness. We build Boolean Networks with multiple average degrees and degree distributions, with a range of different assortativity values. We find that positively assortative networks have higher mutational robustness than negatively assortative networks, and that this is most noticeable in chaotic networks with a constant input degree. In ordered and critical networks with varying degree distributions, which more closely resemble real-world biological GRNs, the effect of assortativity on mutational robustness is negligible. To explain these observations, we identify a simple mechanism that involves the dense core of interconnected genes that appears in networks with high but not low assortativity. While assortativity can influence mutational robustness for certain types of networks, it is unlikely that real GRNs evolve toward higher robustness by means of altering assortativity.

Bioinformatics tools for population genetics and genetic epidemiology: automatic data format conversion for population genetics and genetic epidemiology through a dynamic pipeline. *M.R. Rodrigues, W. Magalhaes, M. Machado, E. Tarazona-Santos.* Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil.

Population genetics and genetic epidemiology require data analyses using different software. Since most of these software are not compatible in terms of accepted input and output formats, solutions to allow interoperability are required. Manual modification of files is intractable when handling information of hundreds or thousands of individuals and SNPs. One solution to guarantee the interoperability of different software is to create conversion-specific scripts that automatically map the output format of one software into the input format of another. A more comprehensive approach is to combine these conversion-specific scripts through a pipeline to increased the number of possible conversions that are available to the user. For example, having a script (S_{AB}) that converts format A into format B and another script (S_{BC}) that converts format B into format C, when a conversion from format A into C is required we can combine scripts S_{AB} and S_{BC} in a pipeline to provide this conversion, instead of having to create a third conversion script. Therefore, here we propose a conversion pipeline to solve the interoperability problem. Currently, our format conversion pipeline handles data formats compatible with the following software: PolyPhred (for polymorphism identification from aligned row sequences reads), PHASE (to infer chromosome phase), DnaSP (population genetics analysis), Structure (population structure inferences), Sweep (natural selection inferences), Haploview (linkage disequilibrium analysis) and R-based tools for population genetics/genetic epidemiology such as HierFstat. The pipeline handles general file formats such as SDAT, NEXUS and PrettyBase. It is composed of 15 conversion tools implemented in Perl, which allow for 26 format conversions. Our pipeline extends an existing conversion pipeline (Machado et al. 2011, Investigative Genetics) with the addition of new conversion tools, and is implemented using a graph-based approach that allows us to generate conversion pipelines dynamically. The advantage of this dynamic approach is that it guarantees the extensibility of the pipeline, making it easy to add new conversion scripts (i.e. conversion scripts compatible with new formats created by the 1000Genomes Project, such as the SAM format, and with publically available script repositories such as BioPerl). Our format conversion pipeline is interactive and available online through a web interface. Supported by: CAPES, CNPq, NIH, FINEP-Epigen.

Genome of the Netherlands: family-based whole genome sequencing of 250 Dutch trio families. *C. Wijmenga[1], M. Swertz[1], H. Cao[2], L. Francioli[1,3], F. van Dijk[1], K. Ye[4], R. Chen[2], L. Karssen[5], J. Laros[4], B. van Schaik[6], J. Bovenberg[4], P.E. Slagboom[4], D.I. Boomsma[7], C.M. van Duijn[5], G.J. van Ommen[4], Y. Du[2], P.I.W. de Bakker[3] on behalf of the GoNL consortium.* 1) University Medical Center Groningen, the Netherlands; 2) BGI, Shenzhen, China; 3) University Medical Center Utrecht, the Netherlands; 4) Leiden University Medical Center, the Netherlands; 5) Erasmus University Rotterdam, the Netherlands; 6) Amsterdam Medical Center, the Netherlands; 7) Free University Amsterdam, the Netherlands.

The Genome of the Netherlands (GoNL) is a national collaboration aimed at establishing a map of Dutch genetic variation by whole genome-sequencing of 250 trio families (i.e. 1000 independent Dutch genomes) including 20 families with 2 offspring (10 families with monozygotic and 10 with dizygotic twin pairs). The trio families consist of unselected individuals of Caucasian origin. The families participate in prospective population-based cohorts and are equally distributed across 11 provinces of the Netherlands. This project is expected to reveal most of the genetic variation within the Dutch population with frequencies greater than 0.5%. This family-based design represents a unique resource to accurately reconstruct haplotypes as we can infer phase, to better characterize structural variation, and to establish the rate of *de novo* mutational events. This resource will also serve as a reference panel for imputation in the available genome-wide association studies in Dutch cohorts (>100,000 samples) to refine association signals and to test for association to rare population-specific variants. In collaboration with BGI, GoNL has completed sequencing of genomic DNA of all 250 Dutch trio families (770 individuals) on Illumina HiSeq at an average coverage depth of 12x. We observed >99.0% SNP concordance when we compared the GoNL data with immunochip data comprising some 200,000 SNPs including ~50,000 rare variants (MAF<5%). Principal component analysis of the immunochip data showed a clear North-South gradient within the Netherlands. We have performed in-depth analysis on chromosome 20 using 20 trio's (60 samples). We observed 16,700 non-overlapping sites that appear unique to the Netherlands when compared to the 1000 Genomes Project phase 1 data. More than 90% of these sites have allele count <3. Extrapolating from these data, we expect to reveal many more low-frequency variants that were unobserved in the European 1000 Genomes data. The resource will be made available to the community, and are expected to help in the interpretation of medical sequencing projects.

Automated determination of phased genotypes from family HLA typing data. *N. Leahy, A. Madbouly, L. Gragert, C. Malmberg, J. Paulson, M. Maiers.* Bioinformatics, National Marrow Donor Program, Minneapolis, MN.

Assigning HLA haplotype phase through family typing is helpful in the search process of selecting donors for hematopoietic stem cell transplants and is useful for population genetic studies. Manual segregation of informative pedigrees to assign phase is laborious and error-prone, but the absence of high resolution HLA typing presents challenges to automation. We developed an algorithm that will identify haplotypes within a group of related individuals in the presence of ambiguous data. Family data was used to generate phase information for all available family members at HLA-A, -B, -C, -DRB1 and -DQB1 loci. All alleles were considered for broad HLA typings. The algorithm performed all possible pair-wise comparisons within a single family and scored comparisons based on completeness, agreement with other comparisons and probability the pair shares at least one haplotype. Resolved haplotypes were reported for all family members along with occurrences of homozygosity, missing data and both or neither alleles shared at a locus. The results were compared to phased genotypes determined by manual segregation. Our algorithm was evaluated with three datasets consisting of 1) 401 and 2) 2566 mother-child pairs (802 and 5132 individuals, respectively) and 3) a dataset of 419 families (1398 individuals) where family size ranged from 2 to 10 with a mean family size of 3.34 and median of 3. Individuals in the first set were typed at up to three loci: HLA-A, -B and -DRB1. Individuals in the other two sets were typed at up to all five loci. The automated pedigree analysis was fully consistent with manual segregation. In the first dataset phased genotype information was obtained in 76.6% of individuals for three loci, 18.3% for two and 3.7% for one while 1.5% could not be resolved. In the second, phase information was obtained in 0.2% for five loci, 10.4% for four, 40.2% for three, 39.9% for two and 8.0% for one while 1.3% remained unresolved. In the third, information was obtained in 16.9% for five loci, 13.9% for four, 37.7% for three, 19.0% for two, 8.4% for one and 4.1% unresolved. Our tool for automated pedigree analysis is significantly faster compared to the manual segregation method. Direct observation of genotype phase information would be useful in the validation of haplotype inference methodologies. Future developments will combine information from family HLA typing with population HLA frequencies to infer the most likely HLA alleles for untyped loci.

445W

A web application for calculating allelic killer immunoglobulin-like receptor (KIR) haplotype frequencies and linkage disequilibrium statistics. *D. Roe, C. Vierra-Green, M. Maiers.* Bioinformatics Research, National Marrow Donor Program, Minneapolis, MN., U.S.A.

Killer immunoglobulin-like receptors (KIRs) are expressed on natural killer cells and some T cells. They are ligands for Class I human leukocyte antigen (HLA) proteins and help regulate the immune response to them. As such, they have been associated with the outcomes of some types of hematopoietic stem cell transplants and the occurrence or progression of several diseases. Its ~200 Kb genetic region is part of the Leukocyte Receptor complex on chromosome 19 (19q13.4). It is very polymorphic allelically and structurally, as its haplotypes have undergone numerous insertions, deletions, and rearrangements. Most of its genotypes are structurally ambiguous; even some structural haplotypes are ambiguous if gene copy number is not considered. Haplotypes are categorized in two ways: into centromeric/telomeric regions (designated by a `c' or `t') depending on chromosome position and A/B (designated by a `A' or `B') depending on the presence of `activating' versions of the KIR genes. For example, a haplotype consisting of the first A centromeric region and the second telomeric region is indicated by cA01~tB02. This polymorphism complicates the imputation of haplotype frequencies from unphased genotypes, which can be valuable for understanding the inheritance and diversity of these gene regions. Haplotype frequencies are often a prerequisite for many techniques in population genetics. We have developed a web tool that uses an expectation maximization algorithm to predict structural and allelic haplotype frequencies and their corresponding linkage disequilibrium statistics. Input consists of a collection of unphased genotypes and a set of structural centromeric and telomeric reference regions into which the genotypes must fit. The algorithm utilizes a decision matrix for resolving paralogous genes and generates predictions for the centromeric, telomeric, and combined regions. We demonstrate its use on a set of 506 samples of Northern European ancestry, each with three-digit allele-level typings for 14 KIR genes. Five haplotypes constitute 90% of the predictions: cA01~tA01(46%), cA01~tB01(13%), cB01~tA01(8%), cB01~tB01(10%), cB01~tA01(13%). These results may be used to impute allelic haplotypes from structural ones, thereby potentially increasing the power and resolution of association studies.

Haplotype Diversity and Linkage Disequilibrium of the Dyslexia Candidate Gene *DCDC2* in 90 Populations: Patterns for Alphabetic and Logographic Languages. *B.M.P. Bowen[1], S. Kosmaczewski[1], N. Powers[1], P. Paschou[2], W.C. Speed[1], J.R. Gruen[1], K.K. Kidd[1].* 1) Genetics, Yale University, New Haven, CT; 2) Department of Molecular Biology and Genetics, Democritus University of Thrace, Kimmeria, Greece.

Doublecortin Domain-Containing 2 (*DCDC2*) has been associated with dyslexia in English, German, and Italian-speaking populations. A comparison of allele frequencies across HapMap populations for SNPs in the LD blocks spanning *DCDC2* showed a high failure rate for a SNP in East Asian populations. This led us to hypothesize that the high failure rate was due to a deletion in intron 2 that is associated with dyslexia in European populations. We genotyped 2800 individuals from diverse populations and found that the deletion frequency was five times higher in Asian populations than in European populations. Given the association of *DCDC2* with reading ability in populations with alphabetic languages, we decided to investigate whether there are differences in the genetic architecture of *DCDC2* in populations with alphabetic versus logographic languages (English compared to Chinese, for example). We combined genotype data from the HapMap, HGDP, and Kidd lab on 90 populations including more than 3,000 individuals originating from Africa, Europe, Asia, the Pacific, and the Americas. In total we used 43 SNPs across *DCDC2* to build haplotypes using fastPHASE and estimated pairwise linkage disequilibrium across the gene at varying intensities using Haplot to identify core haplotypes. We then focused on 15 SNPs in intron 2 of *DCDC2* and found a haplotype in East Asian populations that accounts for a considerable proportion of the genetic variation that exists in this population. These results suggest that underlying genetic variation might have contributed to the differential development of alphabetic versus logographic written language in some populations.

***PLIN4* variant associated with muscle strength in young females.** *F. Orkunoglu-Suer[1], H. Gordish-Dressman[1], P. Clarkson[2], P. Thompson[3], T. Angelopoulos[4], P. Gordon[5], N. Moyna[6], K. Panchapakesan[1], M. Abdel-Ghani[1], L. Pescatello[7], P. Visich[8], R. Zoeller[9], E. Hoffman[1], J. Devaney[1].* 1) Research Cntr for Genetic Med, CNMC, Washington, DC; 2) Dep of Kinesiology, U.of Massachusetts, Amherst, MA; 3) Division of Cardiology, Henry Low Heart Center, Hartford Hospital, Hartford, CT; 4) Center for Lifestyle Medicine and Department of Health Professions, University of Central Florida, Orlando, FL; 5) Department of Physical Medicine and Rehabilitation, School of Medicine, University of Michigan, Ann Arbor, MI; 6) School of Health and Human Performance, Dublin City University, Dublin 9, Ireland; 7) Department of Kinesiology & Human Performance Laboratory, University of Connecticut, Storrs, CT; 8) Human Performance Laboratory, Central Michigan University, Mount Pleasant, MI; 9) Department of Exercise Science and Health Promotion, Florida Atlantic University, Davie, FL.

Background: Prelipin 4 (PLIN4) is a protein that coats intracellular lipid storage droplets and plays a key role in the cellular deposition and mobilization of triacylglycerol facilitating free fatty acid uptake. *PLIN4* expression in humans is the highest in adipose tissue but also shows expression in skeletal muscle. Human (*PLIN4*) has been localized to 19p13.3, within a region previously linked to urinary albumin excretion. **Methods:** In our current study, we hypothesize that a variant, located in the 3'UTR (rs8887) of the *PLIN4* gene that has been shown to modulate obesity phenotypes, would be associated with subcutaneous fat volumes, skeletal muscle volume and muscular strength phenotypes in young adults. In addition, we hypothesized that rs8887 genotype would be linked with fat, muscle and strength response to a 12-week resistance training intervention in these young individuals. To explore these hypotheses, we genotyped the rs8887 variant in our cohort of young individuals (FAMUSS; n= 755) that have undergone a mentored 12-week strength training protocol on the non-dominant arm. Genotype/phenotype associations prior to and following the 12-week exercise intervention were tested using an analysis of covariance model with age and weight as co-variates. **Results:** Females with a copy of rare allele (A allele) for rs8887 had significantly lower pre-intervention measures of isometric strength for the upper arm (GG: n=125; 69.7 ± 2.1 kgs; GA/AA: N=313; 63.2 ± 1.3 kgs; p = 0.011). We did not see any other associations with any of our measured phenotypes in females or males. **Conclusion:** Our data suggests that the PLIN4 variant rs8887 modules muscle strength in females but does not have an effect on the response of subcutaneous fat, muscle, and strength response to a resistance training intervention. The rare allele (A allele) for rs8887 affects the binding of miR-522, which has been shown to have importance in the development of fetal tissue. We need to explore the role of miR-522 in skeletal muscle plasticity and confirm our results in additional populations with similar phenotypes.

Role of Haplotypes on Chromosome 6p in the Susceptibility to Psoriatic Arthritis (PsA). *F.J. Pellett[1], F. Siannis[3], V.T. Farewell[3], P. Rahman[2], V. Chandran[1], D.D. Gladman[1].* 1) Rheumatology, Toronto Western Research Institute, Toronto, Ontario, Canada; 2) Memorial University, St. John's, Newfoundland, Canada; 3) MRC Biostatistics Unit, Cambridge, United Kingdom.

Introduction: PsA, an inflammatory arthritis associated with psoriasis (Ps), is associated with alleles of the HLA-B and -C loci on 6p. The Tumour Necrosis Factor (TNF)-(gene is implicated in PsA while corneodesmosin (CDSN) is a proposed candidate gene for Ps. Both genes are in the HLA region. We aimed to investigate whether the association with PsA was related to linkage with HLA alleles. Methods: Genomic DNA from 204 PsA patients and 101 healthy controls from Toronto (TO), an admixed population, and 235 patients and 102 controls from Newfoundland (NF), a founder population, was tested. Molecular HLA typing of the HLA-B and C loci was performed using the reverse line blot technique (RELI SSO). SNPs at positions 238,308, 857, 863 and 1031 of the TNF-(gene promotor and 619, 1215, 1236 and 1243 of the CDSN gene were genotyped by time of flight mass spectrometry using the Sequenom platform. Chi- square analysis was used to test for association of any SNP with either PsA susceptibility or specific HLA alleles. Haplotype analysis was performed using the haplo.stats program. Results: No association with any of the SNPs was seen in either patient group compared to their respective controls. However, associations were seen with specific HLA-B and/or -C alleles. At TNF-238, the minor A allele was strongly associated with HLA-B*57 ($p<0.000001$); at CDSN-1215, the minor G allele with HLA-B*13 and C*06 ($p<0.000001$) and at TNF-308, the minor A allele with HLA-B*08 ($p<0.000001$). There were distinct SNP haplotypes extending from the TNF locus to the CDSN locus associated with specific HLA-B and -C alleles. These haplotypes were seen in both control and patient groups. The TNF/CDSN SNP haplotype associated with HLA-B*57 and HLA-C*06 was increased in both patient groups while that with HLA-B*38 and HLA-C*12 was increased in the Toronto patients compared to controls. The TNF/CDSN haplotype associated with HLA-B*07 and HLA-C*07 was decreased in both patient groups. Conclusion: The results suggest that the SNP haplotypes are conserved across this chromosome region. The previously reported TNF/CDSN SNP association with Ps/PsA is probably due to association between the HLA-B*57 HLA-C*06 haplotype with Ps/PsA. The effect of these SNP haplotypes on disease susceptibility and progression in PsA requires further investigation.

ASSOCIATION ANALYSIS OF THE 5-HTTLPR POLYMORPHISM OF THE SEROTONIN TRANSPORTER GENE WITH TYPE 2 DIABETES MELLITUS AND INCREASED BODY MASS INDEX. *V. Peralta Leal[1], E. Leal Ugarte[1], JP. Meza Espinoza[1], IP. Davalos Rodriguez[3,4], A. Bocanegra Alonso[5], RI. Acosta Gonzalez[5], E. Gonzales[2], S. Nair[2], J. Duran Gonzalez[2].* 1) Facultad de Medicina e Ingeniería en Sistemas Computacionales, Universidad Autónoma de Tamaulipas, H. Matamoros Tamaulipas, México; 2) Department of Biological Sciences and Center of Biomedical Studies, University of Texas at Brownsville, Brownsville, Texas 78520; 3) División de Genética, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México; 4) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, México; 5) Clinical Analyses Department, Unidad Académica Multidisciplinaria Reynosa-Aztlán, Universidad Autónoma de Tamaulipas, México.

Background: The 5HTTLPR Serotonin transporter polymorphism has been associated recently with changes in eat behavior, body weight and diabetes development and Mexico is one of the countries with the highest number of obese and diabetic individuals. The aim of this study is to identify an association of the 5-HTTLPR polymorphism of the SLC6A4 gene with type 2 diabetes and/or higher body mass index. Methods: From a Mexican-Mestizo population, 138 individuals diagnosed with type 2 diabetes and 172 unrelated controls were included in this study, for a subsequent analysis, all subjects were grouped according their body mass index values in overweight/obese (>25) and non-obese (<25). Polymerase Chain Reaction was performed for identification of the 5-HTTLPR alleles L and S as previously described. Conclusions: In the present study we didn't found an statistical association between the 5-HTTLPR polymorphism and type 2 diabetes in Mexican population (P= 0.12); interestingly, analysis of L allele and increased body mass index shows an association in the analyzed individuals after adjusting for age, sex and type 2 diabetes (P=0.02, OR 1.74).

Genetic variant of autophagy related 5 homolog (*ATG5*) is associated with asthma in the French Canadian founder population. *A.H Poon[1,2], S.M Tse[3], A.A Litonjua[3,4], S.T Weiss[3,5,6], Q. Hamid[1], C. Laprise[1,2].* 1) Meakins-Christie Laboratories, McGill University Health Centre, Montreal, Quebec, Canada; 2) Department of Sciences fondamentales, Université du Québec à Chicoutimi, Chicoutimi, PQ, Canada; 3) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 4) Division of Pulmonary and Critical Care Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 5) The Partners Center for Personalized Genetic Medicine, Partners Health Care; Massachusetts, USA; 6) Department of Medicine, Harvard Medical School, Boston, MA, USA.

RATIONALE: We hypothesized that variants of genes in the autophagy pathway are associated with asthma. We conducted a family-based association study to investigate whether single nucleotide polymorphisms (SNPs) in the unc-51-like kinase 1 (*ULK1*), sequestosome 1 (*SQSTM1*), microtubule-associated protein 1 light chain 3 beta (*MAP1LC3B*), beclin 1 (*BECN1*) and autophagy related 5 homolog (*ATG5*) genes are associated with asthma. **METHODS**: We investigated 51 SNPs in 5 candidate genes in an asthma family-based study from northeastern Quebec, Canada (Saguenay-Lac-Saint-Jean familial collection (SLSJ)). A total of 1338 individuals (483 nuclear families) with known asthma status were included in the analysis. Probands were recruited if they fulfilled at least 2 of the following 3 criteria: (1) a minimum of 3 clinic visits for acute asthma within 1 year, (2) 2 or more asthma-related hospital admissions within 1 year, or (3) steroid dependency, as defined by either 6 months of oral or 1 year of inhaled corticosteroid use. SNPs which spanned±10 kilobase (kb) of the candidate genes were chosen. Association between SNPs and asthma was assessed using the family-based association test statistic (FBAT) under an additive model, with $p<0.05$ as evidence of statistical significance. Replication of association was carried out in non-Hispanic Caucasian participants of the Childhood Asthma Management Program (CAMP). **RESULTS**: Of 1338 individuals, 336 were either probands or affected siblings. Of this group, the mean age was 16.45 (standard deviation (SD) +/-9.43) years. 77.1% was atopic. The mean (SD) forced expiratory volume in 1 second (FEV_1) % predicted was 94.1(20.1)%. After Bonferroni correction, SNP rs12212740 of ATG5 was statistically significant ($p = 0.0002$). SNP rs12212740 was not associated with asthma in CAMP, however, it was associated with FEV_1 (adjusted for age, sex and height^2) ($p<0.05$). In the SLSJ cohort, rs12212740 was associated with adjusted FEV_1($p=0.007$), and the direction of association was consistent with that observed for CAMP. **CONCLUSION**:SNP rs12212740 of *ATG5*, is associated with asthma and FEV_1 in the SLSJ study and with FEV_1 in the CAMP cohort. **Funding sources**: Richard and Edith Strauss Foundation, Canada Research Chair on Genetic Determinants of Asthma; and the CAMP Genetics Ancillary Study is supported by U01 HL075419, U01 HL65899, P01 HL083069, R01 HL086601, and T32 HL07427 from the NHLBI, National Institutes of Health (NIH).

Tumor necrosis factor-alpha and IL4 genes polymorphism is not associated with smoking-related COPD in Northern India population. *R.K. Shukla[1], S. Kant[1], S. Bhattacharya[2], B. Mittal[3].* 1) Pulmonary Medicine, CSMMEDICAL UNIVERSITY, (ERSTWHILE KGMC), LUCKNOW, INDIA, India; 2) Physiology, CSMMEDICAL UNIVERSITY, (ERSTWHILE KGMC), LUCKNOW, INDIA, India; 3) Depratment of Genetics, Sanjay Gandhi Post Graduate of Medical Sciences, Raebarely Road, LUCKNOW, INDIA, India.

Background: Chronic Obstructive Pulmonary Disease (COPD) is driven by abnormal inflammatory reactions in response to inhaled particles and fumes. Therefore, inflammatory mediators are postulated to be of distinct importance. Susceptibility to COPD is, in part genetically determined. A single nucleotide polymorphism (SNP) in tumor necrosis factor- alpha (TNF-(308) has been inconsistently associated with COPD and its phenotypes interleukin- IL- 4 (70bp VNTR) has also been reported to be associated with COPD. In the present study we have explore the association with northern Indian population. Material & Methods: We analyzed the genetic variants TNF-(-308 G>A and IL4 (70bp VNTR) in 412 subjects, all the study subject were diagnosed by pulmonary function test (FEV1 /FVC ratio <70%). 204 COPD patients (148 patients with tobacco smoke related COPD and 56 patients with non tobacco smoke related COPD), and 208 healthy controls. Genomic DNA from peripheral blood lymphocytes was used for genotypic analysis by polymerase chain reaction. Results: TNF-(-308 A allele frequency was not significantly different between the population control subjects and the smoking-related (9.0 % vs.12.5%, P= 0.47), or non smoking-related COPD patients (6.6% vs. 4.5 %, p= 0.38) However, significant differences were observed between smoker COPD vs non smoker population controls (12.5% vs.4.55%, P= 0.025).In case of IL4 (70bp VNTR), allele 1 and allele 2 were also not significantly different among population control subjects, smoking related COPD and non smoker COPD patients. Conclusion: We found that the TNF-(-308 A allele may play a role in the susceptibility to smoking-related COPD, and IL4 (70bp VNTR) alleles were not associated with Smoking related COPD, although the determinants between smokers susceptible to the development of COPD and those resistant to it cannot be explained by a single gene polymorphism.

452W

A unified model of Meiosis combining Recombination, Nondisjunction, Interference and Fertility. *H.R. Johnston IV[1], D.J. Cutler[2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322.

Male and female recombination rates differ greatly across the broad scale of human chromosomes. The cause of this observation has yet to be identified. To this end, we have created a unified model of meiosis that combines knowledge of recombination, non-disjunction, interference and fertility. The model we create is based on the observation that chiasmata are the mechanism that enables the normal segregation of chromosomes during meiosis. Non-disjunction is the result of a failed segregation event. In our model, non-disjunction occurs both when no chiasmata are present between pairs of non-sister chromatids as well as when multiple chiasmata are present close together between pairs of non-sister chromatids. Other elements of our model include having no chiasmata occur between sister chromatids as well as concluding male meiosis immediately while arresting female meiosis between birth and the mother's age at conception. Using this framework, we assume female chiasmata are evenly distributed across a chromosome. Male chiasmata, however, follow a beta-distribution with a higher density of events near the telomeres. We also allow female chiasmata to dissolve over time at a rate which is Laplace distributed with a mean dissolving age of 49 years and a variance of 72 years. The number of chiasmata in any female meiosis is Poisson distributed with mean 80 chiasmata. Finally, the mean distance apart at which closely spaced recombination events cause a non-disjunction event is exponentially distributed with mean 350 Kb for two-strand double recombination events, 99 Kb for three-strand doubles and 58 Kb for four-strand doubles. Our model correctly predicts the rate of fertility, trisomy 21 occurrences and trisomy 13 occurrences for each maternal age. The recombination rates of each simulated chromosome match closely to the available deCODE recombination maps. In addition, we exactly match the observed 40 recombination events per female meiosis as shown in Broman, at al. As a result, we can conclude that the rates of known trisomies are simply the result of the size of their respective chromosomes. Our model will enable us to address additional questions, such as the potential cause of the beta-distribution of male recombination events, in the future.

453W

New deletions missed by current PCR techniques could lead to errors in UGT2B17 genotyping for doping tests in sports and association studies. *L. Wang[1, 2], G. Bademci[1], A.L. Torres[1], C. Jauregui[1], S. Zuchner[1,2], W.K. Scott[1,2], G.W. Beecham[1,2], E.R. Martin[1,2], J.M. Vance[1,2].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine.

BACKGROUND: UDP glucuronosyltranserases (UGTs) are a family of proteins that catalyze the glucuronidation of endogenous and exogenous lipophilic compounds, including steroids, bile acids, xenobiotic drugs, and environmental pollutants. The glucuronidated derivatives are more easily excreted via the urine or bile. Among UGTs, UGT2B17 is the most important player in steroid hormone metabolism. The genomic location of UGT2B17 spans 31 Kb on chromosome 4, within a 117 kb region that is frequently deleted in humans. CNV of UGT2B17 has been associated with prostate cancer and osteoporosis, and has an impact on the doping tests in sports. Furthermore, CNV of UGT2B17 generates minor histocompatibility antigen and is associated with the risk of graft-versus-host disease in stem cell transplantation. Therefore, accurately genotyping the UGT2B17 CNV is of broad clinical interest. Previously, a PCR-based method has been developed to genotype UGT2B17 deletion. We sought to compare this method with CNV analysis based on SNP array and quantitative PCR (qPCR). METHODS: For the PCR analysis, the primers C (amplifying a 316 bp region within exon 1 of UGT2B17) and J (amplifying an 884 bp region spanning the deletion breakpoints) were used as described before. For the SNP array analysis, the Illumina Infinium 610-quad BeadChip and PennCNV were used to determine CNV using an existing GWAS study on Parkinson disease. For the qPCR analysis, the TaqMan® Copy Number Assay (Hs03185327_cn) targeting the intron 1 - exon 1 border of UGT2B17 and the CopyCaller™ Software were used to estimate copy number for UGT2B17. RESULTS: In total, 530 independent non-Hispanic white samples were analyzed using all three different methods. Discordant UGT2B17 CNV genotypes were found for 21 (PCR vs SNP array), 15 (PCR vs qPCR), and 11 (SNP array vs qPCR) individuals. Interestingly, there are 13 individuals with concordant UGT2B17 CNV genotypes based on qPCR and SNP array CNV analysis, but were assigned a different CNV genotype by the PCR-based method. CONCLUSION: The qPCR seems to be the most robust CNV test for the UGT2B17 deletion. Our data suggest that genetic variations around breakpoints of the 117 Kb deletion encompassing the UGT2B17 gene interfere with the PCR-based genotyping method. Although the frequency is low, the PCR-based method could lead to misinterpretation of doping test results and mismatch for minor histocompatibility antigen.

Signatures of selection in human transcription factor binding sites and prediction of functional consequences of noncoding mutations. *A. Siepel, L. Arbiza, B.A. Aksoy, M.J. Hubisz, B. Gulko, I. Gronau, A. Keinan.* Biol Stats & Comput Biol, Cornell University, Ithaca, NY.

By comparing patterns of polymorphism within a species with patterns of divergence between species, it is possible to characterize the extent and modes by which natural selection has shaped present-day genomes. This approach has been used for decades to study human protein-coding sequences, but applications in noncoding regions have so far been limited. We have combined the complete genome sequences of 45 unrelated individuals recently produced by Complete Genomics with chromatin immunoprecipitation and sequencing (ChIP-seq) data for 47 transcription factors from the Encyclopedia of DNA Elements (ENCODE) project, to enable the first systematic genome-wide study of polymorphism and divergence of human regulatory elements. We have developed a new probabilistic modeling approach that allows us to contrast patterns of polymorphism and divergence in short noncoding functional elements with those in neutrally evolving flanking regions. Simulation experiments demonstrate that our methods effectively distinguish positive and negative selection, are robust to population structure, bottlenecks, and population growth, and are much less strongly biased by the presence of weak negative selection than are standard McDonald-Kreitman methods. We show that the binding sites of most transcription factors have experienced significant levels of selection, in some cases at least as strong as with nonsynonymous sites in protein-coding regions. Negative selection dominates, in general, but the binding sites of certain transcription factors (notably, FOXP2 and GATA-1) have also been strongly influenced by positive selection. In many cases, binding sites are strongly enriched for signatures of selection (both positive and negative) near genes whose Gene Ontology (GO) categories are compatible with the functions of the transcription factor of interest. We also examine the relationships between signatures of selection and various local features of interest, such as the expression levels of nearby genes, position relative to the proximal promoter region, and histone modifications. Finally, we show how our methods can be adapted to predict the functional consequences of mutations in noncoding regions across the genome. We expect these methods to be useful in interpreting the potential function of noncoding loci identified in genome-wide association studies.

Locally Linear Embedding (LLE) for Human Population Structure Studies. *H. Siu[1], L. Jin[1], M. Xiong[2].* 1) MOE Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, 200433, China; 2) Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030, USA.

The dimension of the population genetics data produced by next-generation sequencing platforms is extremely high. It is increasingly recognized that the high dimension reduction that can reduce the noises and effectively extract useful population genetics information from the data holds a key to the success of population structure and historical inference from next-generation sequencing data. This motives us to use locally linear embedding (LLE) that projects high dimensional genomic data into low dimensional, neighborhood preserving embedding, as a general framework for population structure and historical inference. To facilitate application of the LLE to population genetic analysis, we systematically investigate several nice properties of the LLE and reveal the connection between the LLE and principal component analysis (PCA). Identifying a set of markers and genomic regions which could be used for population structure analysis will provide invaluable information for population genetics and association studies. In addition to identifying the LLE-correlated or PCA-correlated structure informative markers and genomic regions enriched with these markers, we have developed a new statistic that integrates genomic information content in a genomic region for collectively studying its association with the population structure and lasso algorithm to search such regions across the genomes. We applied the developed methodologies to low coverage pilot dataset in 1000 Genomes Project and PHASE III Mexico dataset of the HapMap released in May, 2010 and demonstrated that the LLE has higher power to separate populations than PCA. We observed that 25.09%, 44.95% and 21.41% of common variants and 89.2%, 92.4% and 75.1% of rare variants were the LLE-correlated markers in CEU, YRI and ASI, respectively. We also identified 3,575 genomic regions enriched with the LLE-correlated SNPs, 3,675 genomic regions enriched with the PCA-correlated SNPs and 1,898 structure informative genomic regions that were search by lasso algorithm. We characterize the genotype frequency and linkage disequilibrium (LD) patterns of the structure informative genomic regions and interestingly observed that 24.65%, 53.38% and 57.55% of identified selection regions by Tajima D test were overlapped with the structure informative genomic regions detected by the lasso, LLE and PCA enrichment analysis, respectively.

Integrative SNP Genotyping for Parallel Sequencing in Population Genomics Studies. *Y. Wang[1], J. Yu[1], A. Sabo[1], R. Gibbs[1], O. Thousand Genomes Consortium[2], F. Yu[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) 1000 Genomes Consortium.

Parallel sequencing is highly promising for population genomics studies. We analysis 1000 Genomes Project Phase I dataset by an integrative SNP Genotyping Pipeline (SNPTools) which consists the following components and innovations: Effective Base Depth (EBD) statistics summarizes sequencing details and enables statistical modeling on sequencing data; Variance ratio based site scoring statistics discovers SNP sites with high sensitivity and specificity; BAM-specific Binomial Mixture Modeling (BBMM) captures the heterogeneity of sequencing data and generates robust and raw genotype likelihoods from sequences; Novel imputation engine refines raw genotype likelihoods by utilizing LD information and produces high quality genotype and haplotype calls; An integration component that combines multiple existing data sources. We found the 1000 Genomes Project Phase I (1) low-pass (~5X) data has >98%; sensitivity and specificity in SNP site discovery measured by corresponding HapMap, OMNI and Axiom datasets; (2) low-pass only data achieves ~99.5%; overall genotyping accuracy (3) the variation of genotyping error rates across chromosomes are largely explained by recombination rate (4) Integration of multiple data sources (e.g. exome sequences and microarrays) in to low-pass data shows comparable accuracy against traditional microarray technologies. (5) Although the entire low-pass dataset is large (~25T), it can be processed in reasonable time (<1 month). These evidences support the utility of parallel sequencing for large scale population genomics studies at reasonable cost.

457W

Amylase gene copy numbers and salivary amylase activity in ethnically diverse populations from Ethiopia. *C.C. Elbers[1], S.R. Thompson[1], A. Ranciaro[1], D.W. Meskel[2], G. Belay[2], S.A. Tishkoff[1].* 1) Department of Genetics, School of Medicine, University of Pennsylvania, Philadelphia, USA; 2) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia.

Starch is an important carbohydrate in the human diet, especially among agricultural societies. The catabolism of starch into simple sugars is initiated by the salivary enzyme amylase. It is known that the enzymatic activity of salivary amylase shows significant variation among individuals, which is influenced by both environmental and genetic factors. Salivary amylase (*AMY1*) gene copy numbers are correlated with amylase activity. It has been suggested that *AMY1* copy numbers have been under positive natural selection based on the observation that high-starch consuming populations have more *AMY1* copy numbers compared to low-starch consuming populations.

DNA, saliva and phenotype data were collected from 760 unrelated individuals from 17 diverse Ethiopian ethnic populations. Together, the samples represent high genetic, phenotypic and dietary diversity, and include populations practicing agriculture, pastoralism and hunting-gathering. We assessed the association between copy numbers in the *AMY1* gene and salivary amylase activity using linear regression. Analyses were adjusted for the potential confounders of age, sex, smoking and fasting status.

The mean *AMY1* copy number was 6.6 with a range of 2 to 17. *AMY1* gene copy numbers were positively correlated with salivary amylase enzyme activity ($r = 0.45$; $p = 2.83 \times 10^{-32}$) among all Ethiopians. The correlation differed per ethnic group, ranging from $r = 0.34$ in the Agaw population to $r = 0.74$ in the Sheko population. Compared to agriculturalists, pastoralists had fewer *AMY1* copy numbers (6.4 ± 0.1 vs 6.0 ± 0.2; $p = 0.007$) and lower salivary amylase enzyme activity (77.4 ± 3.4 U/ml vs 59.3 ± 4.5 U/ml; $p = 0.01$). Populations that traditionally have a high-starch diet have more *AMY1* gene copy numbers and higher amylase activity compared to low-starch consuming populations. However, *AMY1* copy numbers cannot entirely explain amylase activity in all populations and, therefore, follow-up studies on additional genetic and environmental factors influencing amylase activity are needed.

Characterizing Genes Associated with both Complex and Mendelian Diseases. *W. Jin[1], S. Xu[1], P. Qin[1], L. Jin[1,2].* 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shangh; 2) Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai 200433, China.

Genetic disorders have been traditionally classified as either Mendelian or complex diseases. This nosology has greatly benefited genetic counseling and development of gene mapping strategies. However, we found that 54.1% (524 of 968) of the Mendelian diseases genes in hand-curated OMIM database (hOMIM) also involved in complex diseases according to genetic association database (GAD), and those genes underlying both Mendelian and complex disease have never been systematically analyzed. In this study, we classified human genes into five categories: Mendelian and complex diseases (MC) genes, Mendelian but not complex diseases (MNC) genes, complex but not Mendelian diseases (CNM) genes, essential genes and OTHER genes. Our analysis showed that MC genes on average associated with 1.77 Mendelian diseases and 5.83 complex diseases, which are significantly higher than other disease genes (P<2.8×10-6). Analysis showed that MC genes involved in more complex networks than MNC and CNM genes, but less than essential genes. We also found that MC genes encode the longest proteins, and have the most transcripts among all gene categories. Interestingly, although expression level of MC genes is similar to that of essential genes, tissue specificity of MC genes is significantly higher than that of any other gene categories (P< 7.5×10-5). Further analysis showed that MC genes were under stronger long-lasting purifying selection than CNM genes. However, compared with the other gene categories, MC genes were also under stronger recent positive selection similar with CNM genes. And over-representing of CNVs in CNM genes indicates the important role of CNVs in genetic basis of complex disease. Comparative analysis of the representing pattern of CNVs in different gene categories also suggested that MC genes seemly have been under both purifying and positive selection. Analysis showed that disease genes exhibited different relative evolutionary rate in different timescales. Based on this elaborate classification, we not only characterized the genes underlying both Mendelian and complex diseases, but also gained some new insights on the other four kinds of genes.

459W

A Map of Copy Number Variations in Chinese Populations. *H. Lou[1], S. Li[2], Y. Yang[2], X. Zhang[2], B. Wu[2,3], L. Jin[1,2,3], S. Xu[1].* 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences and Max Planck Society (CAS-MPG) Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shangh; 2) Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, China; 3) Children's Hospital Boston, Harvard Medical School, Boston, MA, USA.

It has been shown that the human genome contains extensive copy number variations (CNVs). Investigating the medical and evolutionary impacts of CNVs requires the knowledge of locations, sizes and frequency distribution of CNVs within and between populations. However, CNV study of Chinese minorities, which harbor the majority of the genetic diversity of Chinese populations, has been underrepresented considering the same efforts in other populations. Here we constructed, to our knowledge, a first CNV map in 7 Chinese populations representing the major linguistic groups in China with 1,440 CNV regions identified using Affymetrix SNP 6 Array. Considerable differences in distributions of CNV regions between populations and substantial population structure were observed. We showed ~35% of CNV regions in minority ethnic groups are not shared by any two populations under comparison and suggested that the contribution of minorities to genetic architecture of Chinese population cannot be ignored. We further identified highly differentiated CNV regions between populations and genes enriched in these regions. For example, a common deletion in Dong and Zhuang (44.4% and 50%) was not observed in Han Chinese, which overlaps two keratin-associated protein genes contributing to the structure of hair fibers. Interestingly, the most differentiated CNV deletion between CEU and YRI reported in previous studies containing CCL3L1 gene, was also the highest differentiated regions between Tibetan and other populations. Besides, by joint analyzing CNVs and SNPs we found a CNV region containing gene CTDSPL with near perfect LD between flanking SNPs in Tibetan while not in other populations except CHD. Furthermore, we found the SNP taggability of CNVs in Chinese populations was much lower than that in European population. Our results suggested the necessity of a full characterization of CNVs in Chinese populations, and the CNV map we constructed serves as a useful resource in further evolutionary and medical studies.

Human amylase gene copy number variation in Korea and Mongolia population. *H.Y. Son[1], C.H. Park[1], J.S. Seo[1,2], J.I. Kim[1,2].* 1) Dept. of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul, Korea; 2) Genomic Medicine Institute, Medical Reseach Center, Seoul National University, Seoul, Korea.

Copy number variations (CNVs) have recently been considered as important human genomic variant, which associated with phenotypic difference and disorder. The copy number of salivary amylase genes (AMY1) have shown to be related with ethnic difference of starch diet. Here, we compared AMY1 copy number in 2 groups of 1039 Koreans(531 Ansan, 508 Sihwa) and 2 groups of 811 Mongolians(400 Dashvalvar, 411 Orkhontuul). We estimated copy number by TapMan real-time PCR method. The average of copy number was 6.27 and 6.39 in Korean and 5.83 and 6.49 Mongolian populations, respectively. The low copy group(Mongol Dashvalvar, 5.83) show significant difference than others. In addition, comparison of AMY1 copy number with body mass index(BMI) and waist hip ratio revealed significant association in Mongol population. These results suggest that lower copy number of AMY1 may be related with obesity in low starch diet population.

461W

The population genetics of native Peruvian populations: evolutionary inferences and biomedical implications. *E. Tarazona-Santos[1], L. Pereira[1], M. Scliar[1], G.B. Soares-Souza[1], R. Zamudio[1], L.W. Zuccherato[1], F. Kehdy[1], W. Magalhaes[1], M.R. Rodrigues[1], G. Bertorelle[2], E. Hollox[3], S.J. Chanock[4], R.H. Gilman[5, 6, 7].* 1) Dept Biol Geral, CP 486, Univ Federal Minas Gerais, Belo Horizonte, MG, Brazil; 2) Universita degli studi di Ferrara, Ferrara, Itália; 3) Univeristy of Leicester, Leicester, UK; 4) National Cancer Institute, US; 5) Johns Hopkins School of Public Health, US; 6) Asociación Benéfica PRISMA, Peru; 7) Universidad Cayetano Heredia, Peru.

Peru has the largest Native American population in South America. In the Andes, populations derive from a unique complex of societies that evolved during the last 10000 years along the Andes and its adjacent coast. During PreColumbian times, they reached a level of socioeconomic development unmatched elsewhere in South America. Smaller populations are settled in the Amazonian region, and in the hereafter called transition area between the Andes and the Amazonas. A mestizo population of millions is also settled in current Peruvian cities. We are studying the population genetics of Peruvians, addressing evolutionary inferences and biomedical implications of their diversity. We summarize three results: (1) Using 20kb resequenced from neutral inter-genic regions, we made inferences about the history of Andeans (Quechua) and a population from the transition area (Shimaa). These populations derived from an ancestral population with an effective size (N_e) of ~6000 individuals that split about 1025 years ago. At this time the N_e of Quechuas (N_e=5000) was five times larger than the N_e of the Shimaas, the former showing an evidence of a posterior demographic expansion, and the latter of a bottleneck. Thus, Andean and transition-area populations, even if they speak languages from different families and being culturally differentiated, share very recent ancestral populations. (2) Populations considered as mestizo have very high Native American ancestry. A sample (n=297) from Lima, genotyped for 106 AIMs, has 78.4% of Native American ancestry, suggesting that the Peruvian population is a potential target for large epidemiological studies in Native Americans. (3) We identified genes with variants that are common in Native Americans and rare elsewhere. The FCGR3B CNV locus has an idiosyncratic high frequency of deletions in our native samples. This variant has been elsewhere associated with lupus erythematosus and rheumatoid arthritis, two diseases associated with Native American ancestry. On the basis of the genotyping of 1442 SNPs on 411 genes, we determined that the following genes, that on the basis of recent GWAS are associated with complex diseases, show a differentiated haplotype structure in Native Americans: CASR, CAV1, CYP19A1, DRD2, FUT2, IL13, IL15, IL6R, IL7R, KRT23 and SCARB1 are highly differentiated from Africans/Europeans; ADH1C, APOB, CASR, CCND1, CDKN2A, CDK5, CYP19A1, ESR1, IGF2, IL1RN, LEPR and SCARB1 are highly differentiated from Asians.

Development of Human Variation Database in Japanese Integrated Database Project. *A. Koike[1], N. Nishida[2], M. Kawashima[2], M. Yoshida[1], I. Inoue[3], S. Tsuji[4], K. Tokunaga[2].* 1) Cent Res Lab, Hitachi, Ltd, Kokubunji, Japan; 2) Dept Human Genetics, Univ. Tokyo; 3) Dept. of Mol. Life Sci. and Mol. Med., Nat. Inst. of Genet; 4) Dept Neurology, Univ. Tokyo.

Recent progresses in SNP typing and massively parallel sequencing technologies enabled us to explore disease related loci/variations on a genome-wide scale in a cost-effective high-throughput manner and have been successful for identifying disease related loci/variations. To date, our organization has created a repository database for SNP-based genome-wide association studies (GWAS) (https://gwas.lifesciencedb.jp/) to achieve continuous and intensive management of GWAS data and data-sharing among researchers and has widely called for data submission. In this study, we have extended the GWAS database to a Human Variation Database to accumulate variations including short/long insertions/deletions and structural variations mainly in Japanese or Asian population, which were detected by various measurements including massively parallel sequencers. In the database, variations related to disease susceptibility, virus resistance, and drug response are registered along with statistical genetic results and simple clinical characteristics to clarify the locus specific characteristics. Since some genes are widely known to be related to multiple diseases, variations and diseases are made to be cross-searchable to shed light on relationships among various diseases. Given that high-throughput data can suffer from relatively high error rates caused by multiple factors, quality control is carried out and reliability scores are assigned to variations. Variations in healthy Japanese individuals are also systematized so as to be useful for exploitation of disease-related variations. In the database, variation positions and statistical results along with other information such as genes, ncRNAs, and conservation scores are presented by a graphic viewer to facilitate understanding of biological functions of disease-related variations. Comparison between various study results obtained by different institutions with different populations and their meta-analysis are also available. The same data are also managed as a distributed annotation system (DAS) to invoke useful data from other databases. In this presentation, we introduce the overview of database structure and methods for variation detection, quality filtering, and statistical genetic analysis and data management policies. Establishing the contribution of candidate genes to the development of ESKD in Puerto Rico. *Y.M. Afanador[1], A.V. Washington[1, 2], J.C. Martínez-Cruzado[1], T.K. Oleksyk[1].* 1) Department of Biology, University of Puerto Rico, Mayaguez Campus, Mayaguez, PR 00680; 2) Department of Anatomy, Universidad Central del Caribe School of Medicine, Bayamon, PR 00960.

Kidney disease is the ninth leading cause of death in Puerto Rico. Dialysis treatment for End Stage Kidney Disease (ESKD) in the island is estimated to be approximately 4,000 patients annually, and close to 24% of them die every year. Focal Segmental Glumerulosclerosis (FSGS) and Diabetic Nephropathy are among primary causes of ESKD, accounting for 30 and 40% of disease occurrence, respectively. FSGS is reported to be the most common primary glomerulopathy in the United States where it is most common among individuals of African ancestry, while Type 2 Diabetes Mellitus (T2DM) is more widespread among Hispanic populations. Both contribute to ESKD among Puerto Ricans.

The purpose of this study was to establish the relative contribution of the genetic factors associated with T2DM, FSGS, or ancestry to ESKD in Puerto Rico. We created a panel of 16 SNPs found in 12 candidate genes and a panel of Ancestry Informative Markers (AIMs), and used them to genotype 144 ESKD patients and 2x set of matched controls using TaqMan Open Array System (ABI). We report associations of these candidate genes as well as the relative ancestry contribution of European, African and Native American ancestries to ESKD. Hispanics are the highest growing minority population in the US. As a highly admixed population, Puerto Ricans may prove to be a useful model for studying the genetic basis for kidney disease, especially in Hispanic populations, which carry a greater risk of acquiring the disease compared to non-Hispanic whites.

A Genome Wide Search for Type 2 Diabetes Susceptibility Genes in Arab Families. *H. Alsafar[1], H. Cordell[2], O. Jafer[3], S. Jamieson[4], K. Khazanehdari[3], J. Blackwell[4,5], G. Tay[6].* 1) Khalifa University of Science, Technology & Resear, Abu Dhabi, United Arab Emirates; 2) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, United Kingdom; 3) Molecular Biology and Genetics Laboratory, Central Veterinary Research Laboratory, Dubai, United Arab Emirates; 4) Telethon Institute for Child Health Research, Centre for Child Health Research, The University of Western Australia, Subiaco, Western Australia; 5) Cambridge Institute for Medical Research and Department of Medicine, School of Clinical, Medicine University of Cambridge, Cambridge, United Kingdom; 6) Centre for Forensic Science, The University of Western Australia, Crawley Western Australia.

Type 2 Diabetes (T2D) is currently the fastest growing debilitating disease in the world. In the United Arab Emirates (UAE), it has been estimated that one out of five people between the ages of 20 to 79 lives with this disease. Due to an increasing prevalence of T2D in the region, lifestyle management strategies with an emphasis on prevention are required. Determining genetic risk factors can also make an important contribution to understanding the processes leading to disease. A genome wide association study (GWAS) using a family based association test (FBAT) in an extended family of 178 members from the UAE (66 diabetic and 112 healthy individuals) were genotyped using the Illumina Human 660 Quad chip array was undertaken in order to identify gene(s) and mechanisms associated with disease. The study revealed 21 new association signals from single nucleotide polymorphisms (SNPs) within five genes (RBM47, KCTD8, GABRB1, SCD5 and PRKD1). Six SNPs within PRKD1 on chromosome 14 were found to be most strongly associated with T2D in this Arab population. It has been suggested that PRKD1, a serine/threonine kinase, plays an important role in insulin secretion. The strongest statistical evidence for this new association signal was from rs10144903 in intron 1 of PRKD1, with the overall estimate of effect returning an odds ratio of 3.72 (95% confidence interval, 1.28-10.82; p-value = 3.92E-06). This study is the first GWAS for T2D in families of Arab descent, and these findings may provide important insights into the pathogenesis of T2D in Middle Eastern populations. Comparative analysis with other ethnic groups could assist in dissecting the mechanisms that cause the disease.

Influence of Ethnicity in Association with UCP2 -866G/A, PGC1((Gly 482 Ser) and mtDNA 10398G/A Polymorphisms in Orissa Population Groups. *A. Behura[1,2], R.N.K. Bamezai[2], G.B.N. Chainy[1].* 1) Department of Biotechnology, Utkal University, BHUBANESWAR, Orissa, India; 2) National Center of Applied Human Genetics, School of Life Sciences, JNU, New Delhi India.

Type 2 Diabetes (T2D) involves complex interplay of both genetic and environmental factors leading to two distinct defects in insulin secretion and insulin action. In this study, we explored a total of 1205 individuals (508 cases and 697 controls) belonging to Orissa population, to elucidate the role of some of the polymorphisms of the candidate genes: UCP2 -866G/A, mtDNA 10398G/A and PGC1((Gly 482 Ser). These polymorphisms are suggested to be associated with T2D susceptibility in literature and are mainly involved with the activity of pancreatic beta cells, affecting glucose-stimulated insulin secretion. India exhibits different ethnic population structure comprising various caste groups existing from ages which have mostly remained endogamous. Thus to assess the impact of ethnicity, these individuals were further stratified on the basis of respective caste groups i.e. (Brahmins, Kshatriya, OBC and SCs). Genomic DNA was extracted by phenol-chloroform method and PCR-RFLP procedure was used for genotyping. Binary logistic regression was applied to test the association of risk factors with T2D after adjusting for age, sex and BMI. In total population UCP2-866 AA+GA vs GG (p=0.003), mtDNA 10398 A/G (p=1.8E-9) and PGC1(GG+GA vs AA (p=7.86E-12) significantly provided risk towards T2D. Caste based stratification revealed UCP2-866 AA+GA vs GG significantly provided risk only in Kshatriyas (p=0.005) and mtDNA 10398A/G in Brahmins (p=0.002), Kshatriyas (p=0.00005) and OBC (p=0.003). While in PGC1(GG+GA vs AA, all the caste groups: Brahmins (p=0.0002), Kshatriyas (p=0.0003), OBC (p=0.006) and SCs (p=0.01) are significantly associated with T2D. Thus the present investigation concludes that differential pattern of association of polymorphisms is observed for different caste groups, suggesting the putative role of ethnicity. Thus, for risk calculation and proper medical intervention, knowledge of the ethnicity and nature of variation in risk factors need serious attention.

466W

Exceptions to the "One Drop Rule"? DNA evidence of African ancestry in European Americans. *J.L. Mountain[1], J.M. Macpherson[1], C.B. Do[1], B.T. Naughton[1], R.A. Kittles[2], N. Eriksson[1].* 1) 23andMe, Inc, Mountain View, CA; 2) Institute of Human Genetics, University of Illinois at Chicago, Chicago, IL.

Genetic studies have revealed that most African Americans trace the majority (75-80%, on average) of their ancestry to western Africa. Most of the remaining ancestry traces to Europe, and paternal lines trace to Europe more often than maternal lines. This genetic pattern is consistent with the "One Drop Rule," a social history wherein children born with at least one ancestor of African descent were considered Black in the United States. The question of how many European Americans have DNA evidence of African ancestry has been studied far less. We examined genetic ancestry for over 77,000 customers of 23andMe who had consented to participate in research. Most live in the United States. A subset of about 60,000 shows genetic evidence of fewer than one in 16 great-great-grandparents tracing ancestry to a continental region other than Europe. They are likely to consider themselves to be entirely of European descent. We conducted two analyses to understand what fraction of this group has genetic evidence of some ancestry tracing recently to Africa. We first identified individuals whose autosomal DNA indicates that they are predominantly of European ancestry, but who carry either a mitochondrial (mt) DNA or Y chromosome haplogroup that is highly likely to have originated in sub-Saharan Africa. Of the 60,000 individuals with 95% or greater European ancestry, close to 1% carry an mtDNA haplogroup indicating African ancestry. Of approximately 33,000 males, about one in 300 trace their paternal line to Africa. We then identified the subset of these European Americans who have estimates of between 0.5% and 5.0% of ancestry tracing to Africa. This subset constitutes about 2% of this set of individuals likely to be aware only of their European ancestry. The majority (75%) of that group has a very small estimated fraction of African ancestry (about 0.5%), likely to reflect African ancestry over seven generations (about 200 years) ago. We estimate that, overall, at least 2-3% of individuals with predominantly European ancestry have genetic patterns suggesting relatively deep ancestry tracing to Africa. This fraction is far lower than the genetic estimates of European ancestry of African Americans, consistent with the social history of the United States, but reveals that a small percentage of "mixed race" individuals were integrating into the European American community (passing for White) over 200 years ago, during the era of slavery in the United States.

African genome sequencing reveals diversity and origin of the "European" 17q21.31 inversion polymorphism. *K. Meltz Steinberg[1,2], F. Antonacci[1,2], J.M. Kidd[1,5], C.D. Campbell[1,2], P. Sudmant[1,2], L. Vives[1,2], M. Malig[1,2], L. Scheinfeldt[3], W. Beggs[3], M.P. Donnelly[4], K.K. Kidd[4], S.A. Tishkoff[3], E.E. Eichler[1,2].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Howard Hughes Medical Institute, University of Washington, Seattle, WA; 3) Department of Genetics and Biology, University of Pennsylvania, Philadelphia, PA; 4) Department of Genetics, Yale University, New Haven, CT; 5) Department of Genetics, Stanford University, Stanford, CA.

The 17q21.31 inversion polymorphism represents one of the most dynamic and evolutionarily complex regions of the human genome. The two haplotypes exist in direct (H1) and inverted (H2) orientation and show no recombination over nearly 2 Mb resulting in extended linkage disequilibrium. The two haplotypes are among the most ancient in the human species diverging 2.3 million years ago. Interestingly, the H2 is found primarily in individuals of European/Mediterranean descent where changes in the flanking duplication architecture predispose carriers to the 17q21.31 microdeletion syndrome. We recently identified a 205 kb duplication associated with 30% of European H1 haplotypes while a smaller 155 kb duplication in the same region is fixed in European H2 haplotypes. We sought to study the architecture and genetic diversity of this region in more detail using next-generation sequencing, arrayCGH and fluorescence *in situ* hybridization. We sequenced a Massai human genome, analyzed copy number variation from 542 African genomes for this region, and genotyped 821 unrelated African individuals from 23 geographically diverse ethnic groups with variable modes of subsistence. We identify eight new structural haplotypes (3 related to H2 and 5 related to H1). These vary dramatically in size from 1.08 to 1.5 Mb and differ based on orientation, gene organization and duplication architecture. We find that the H2 haplotype is absent from the Western African populations but is enriched in hunter-gatherer groups from Eastern and Central Africa (San Bushman, Pygmies, Hadza and Sandawe). In addition, the H2-specific duplication is polymorphic in Africans. SNP genotyping and copy number estimates from over 1500 unrelated individuals from worldwide populations support the hypothesis that the nonduplicated H2 represents the ancestral state and demonstrate that the H1 duplication is specific to Europe. We estimate that the evolutionary age of the H2 duplication is significantly older (850,000 years) when compared to the H1 duplication (320,000 years old). Remarkably, most Europeans (60%) carry either the H1 or H2 duplication, which is virtually absent (<5%) in most other continental groups. Our results support the hypothesis that the H2 haplotype without extensive duplication is the ancestral haplotype, the H1- and H2-specific duplications emerged independently, and the duplications arose prior to the human migration out of Africa.

Positive and balancing selection acting on the lectin-like oxidized low density lipoprotein receptor 1 (*OLR1*) intronic regions. *I.M. Predazzi[1], A. Rokas[2], N. Schnetz-Boutaud[1], N.D. Williams[1], A. Tacconelli[3], A. Deinard[4], J.L. Haines[1], G. Novelli[5], G. Sirugo[3], S.M. Williams[1].* 1) CHGR, Vanderbilt University, Nashville TN 37232, USA; 2) Department of Biological Sciences, Vanderbilt University, Nashville, TN 37235, USA; 3) Unità di Genetica Medica, Ospedale San Pietro FBF, Rome, Italy; 4) Department of Anthropology, University of Minnesota, Minneapolis, MN; 5) Department of Biopathology, Tor Vergata University of Rome, Italy.

The lectin-like oxidized low density lipoprotein receptor 1 (*OLR1*) is the principal endothelial scavenger receptor for oxidized low density lipoproteins (ox-LDLs). *OLR1* also plays a role in innate immunity through its function as an endothelial receptor for the outer membrane protein peptide A (OmpA) of *Klebsiella* and *Chlamydia pneumoniae*. Several associations have been reported between OLR1 and phenotypes related to atherosclerosis. A non-synonymous variant in exon 4 alters the function of the receptor, changing the positive isopotential surrounding the active site; in addition, *OLR1* introns (especially intron 4) and 3'UTR contain SNPs that associate with alternative splicing of the mRNA, leading to an isoform, lacking part of the functional domain. Despite these interesting functional data, the importance of *OLR1* variations in relation to disease remains unclear. Under the hypothesis that regions that confer functional differences and hence affect disease risk are non-neutral, we tested for evidence of both ancient (inter-specific) and recent selection (intra-specific) across the whole gene as well as focusing in regions that have been previously associated with function. We sequenced the entire coding region and crucial intronic regions in a sample of 48 non-human primates from 12 species, combined them with 7 reference primate sequences and performed interspecies tests for ancient selection in coding and non-coding regions (dN/dS and McDonald-Kreitman tests). We also tested for recent selection by analyzing genetic structure in haplotypes from the four principal HapMap populations (CEU, YRI, JPT and CHD) using Analysis on Molecular Variance (AMOVA) and Tajima's D. We found evidence of ancient selection in *OLR1* intron 4 but not in the coding region. Intra-specific analyses indicated evidence of balancing selection (particularly in the CEU sample, Tajima's D = 4.04) and with significant genetic structuring (Fst = 0.117; $p < 0.001$). Analyses only including an LD block containing intron 4, indicated more population differentiation (Fst = 0.270; $p < 0.001$) and comparable levels of balancing selection (Tajima's D = 3.50). Intron 4's involvement in alternative splicing, suggests that this may have been the target of both ancient and recent selection. These data suggest that selection is operating on a non-coding region within a disease risk locus, and may be taking place at different evolutionary time points, both ancient and recent.

A likelihood framework to model gene expression evolution through a phylogeny. *R.V. Rohlfs[1], P. Harrigan[1], D. Brawand[2,3], M. Soumillon[2,3], A. Necsulea[2,3], H. Kaessmann[2,3], R. Nielsen[1,4].* 1) Department of Integrative Biology, University of California, Berkeley, Berkeley, CA; 2) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 3) Swiss Institute for Bioinformatics, Switzerland; 4) Bioinformatics Center, University of Kopenhagen, Kopenhagen, Denmark.

Despite fascinating theoretical results about the important role of gene expression changes in recent primate and human evolution, experimental exploration of these hypotheses has been limited by the unavailability of robust gene expression data across species. Recent technological innovations, specifically the development of RNA-Seq, have facilitated the collection of reliable gene expression data across tissues and species. These data enable comparative evolutionary analysis of gene expression, allowing exploration of long-standing hypotheses regarding the role of gene expression in adaptation. We have implemented a statistical model for the evolution of gene expression through a phylogeny based on an Ornstein-Uhlenbeck process. This model accounts for phylogenetic relationships between species, constraints on gene expression, and the possibility of directional selection on gene expression level. Observed gene expression data can be fit to various models, including unconstrained neutral expression evolution, constrained expression evolution, and constrained expression evolution with lineage-specific directional selection. The likelihood of the data under different models in this framework can be compared to test hypotheses regarding gene expression evolution and selection. We have demonstrated the validity of these methods through simulation studies and applied the framework to study an RNA-Seq dataset quantifying expression in six tissues and in a panel of mammalian species, with an emphasis on primates and humans. Our analyses confirm that expression evolution is better modeled by accounting for phylogenetic structure between species. We show that a large portion of the genes considered appear to be under evolving with constraints on expression level, implying widespread negative selection. Further, our analysis suggests that the expression levels of some genes may have been subject to direction selection, specifically along the human and primate lineages. For instance, the gene showing the most evidence for selection in the primate lineage, COL25A1, is down-regulated in primates and has previously been found to be involved with Alzheimer's disease and to cause atypical behavior when over-expressed in animal models.

470W

Evidence for extensive ancient admixture in different human populations. *J. Wall[1], S. Kim[1], C. Gignoux[3], A. Woerner[2], F.L. Mendez[4], K. Veeramah[2], M.F. Hammer[2, 4].* 1) Inst Human Gen and Dept Epidemiology and Biostatistics, Univ California, San Francisco, San Francisco, CA; 2) ARL Division of Biotechnology, University of Arizona, Tucson, AZ; 3) Department of Bioengineering and Therapeutic Sciences, Univ California, San Francisco, San Francisco, CA; 4) Dept of Ecology and Evolutionary Biology, Univ Arizona, Tucson, AZ.

We generated whole-genome sequences from four Biaka pygmies and analyzed them along with the publicly available genomes of 69 individuals from a range of different ethnicities. We scanned each of the 73 genomes for regions with unusual patterns of genetic variation that might have arisen due to ancient admixture with an `archaic' human group. While a majority of the most extreme regions were really misalignment errors, we did find hundreds of regions that likely introgressed in from archaic human ancestors, and we estimate the amount and the timing of these ancient admixture events. These regions were found in the genomes of both sub-Saharan African and non-African populations. While Neandertals are a natural source population for ancient admixture into non-Africans, the source for ancient admixture into sub-Saharan African populations is less obvious.

471W

Positive Selection, Purifying Selection, and Neo-Functionalization in Human Disease-Related Zinc-Finger Proteins. *G.J. Wyckoff[1], J.H. Laity[2], L.S. Feng[2], A. Solidar[3].* 1) Div Molec Biol & Biochem, Univ Missouri-Kansas City, Kansas City, MO; 2) Div. Cell Bio. and Biophysics, Univ Missouri-Kansas City, Kansas City, MO; 3) Vassa Informatics, Kansas City, MO.

Neofunctionalization, defined as the creation of novel functions from existing genetic functionality, is one of the cornerstones of molecular evolutionary genetics. Without this process, the genetic toolkit would be limited to a small set of functions derived early in evolutionary time, or to those functions that arose via completely independent, random mutation of silenced genes (functional recapture) or from changes to non-functional segments that have become functional due to random changes. However, while neo-functionalization often involves the processes of random mutation, duplication, and positive selection, many different scenarios have been examined. Here, we examine a set of Cys2-His2 (C2H2) zinc-finger proteins. The zinc finger containing family of proteins is a large and relatively diverse group; over 1200 members can be found in Genbank. C2H2 Zinc finger proteins are well represented in this group, and are usually found functioning in traditional roles of mRNA- or DNA-binding . However, a portion of C2H2 zinc fingers have been found that act in tandem to form metal-responsive elements, and these zinc fingers operate only in tandem where one finger stabilizes the other finger so it can perform DNA or RNA-binding functions. These “two-finger” zinc fingers, far from being disparate beads on a string, are functionally interconnected. This represents a novel, regulatory function after a random mutation produced what appears to be a neutral mutation; the novel, selected function apparently only came into being after an internal duplication of a zinc-finer domain within an already functional protein. Further, we show that this new function is under a large degree of purifying selection, and the position of the initial random mutation appears to be “locked in” over evolutionary time, both within and between zinc-finger proteins. These genes are especially relevant, as members within this family have essential roles in development, and many have been implicated in genetic disorders and cancers.

472W

A population genetics analysis of MetaboChip data comparing African-American and European-descent populations. *W.S. Bush[1], K.E. North[2], S. Buyske[3], B. Voight[4], D.C. Crawford[1], the PAGE study.* 1) Ctr Human Gen, Vanderbilt Univ, Nashville, TN; 2) Department of Epidemiology and Carolina, Center for Genome Sciences, University of North Carolina Chapel Hill Chapel Hill, NC; 3) Department of Statistics & Biostatistics, Rutgers University, Piscataway, NJ; 4) The Broad Institute of Harvard and MIT, Boston, MA.

Studying the genetic differentiation of human sub-populations can provide valuable clues about the underlying causes of disease and differences in their prevalence. To date, most population genetic studies have been conducted using reference samples from the International HapMap Project or 1000 Genomes Project (1KGP), each of which provide extensive coverage of either common or complete variation, but both of which have limited sample sizes. The Population Architecture using Genomics and Epidemiology (PAGE) study is a network of several population-based studies of diverse populations, including the Atherosclerosis Risk in Communities (ARIC), the Multiethnic Cohort, and the Women's Health Initiative. The goals of PAGE are several-fold including the generalization and characterization of genome-wide association study (GWAS)-identified variants and genomic regions in African Americans. To this end, we typed the Illumina MetaboChip, a custom BeadChip of ~200K variants that targets GWAS-identified variants as of 2010, rare variants from the pilot 1KGP, and fine-mapping variants for ~250 regions associated with metabolic diseases in 5,897 African American PAGE participants. These PAGE MetaboChip data provide an unprecedented opportunity to compare the allele frequencies of common and less frequent SNPs in thousands of individuals. In this work, we explore differences between African Americans and European-descent populations to identify variants that show evidence of population divergence and evolutionary pressure. Using Wright's fixation index (Fst), 3632 SNPs with Fst > 0.15 indicating moderate population differentiation. Of these, 12 SNPs have been related to phenotypes in previous GWAS studies, including Crohn's disease, height, freckles and skin pigmentation, coronary heart disease and hypertension, rheumatoid arthritis, celiac disease, and colorectal cancer. This work provides further insight into the genetic architecture of metabolic traits, and highlights loci that may have arose due to environmental adaptations.

473W

A comparative study of genetic and epigenetic regulatory mechanisms in primates. *C.E. Cain[1], A.A. Pai[1], R. Pique-Regi[1], J.F. Degner[1], M. Myrthil[1], N. Lewellen[1], J.K. Pritchard[1,2], Y. Gilad[1].* 1) Department of Human Genetics, University of Chicago, 920 E. 58th Street, Chicago IL 60637; 2) Howard Hughes Medical Institute, University of Chicago, 920 E. 58th Street, Chicago IL 60637.

Changes in gene regulation are thought to play an important role in adaptation and speciation, especially in primates. However, the extent to which changes in different regulatory mechanisms underlie gene expression evolution is not yet known. To address this gap, we investigated the contribution of changes in different genetic and epigenetic regulatory mechanisms to inter-species differences in gene expression levels. Specifically, we collected gene expression data and obtained genome-wide profiles of epigenetic markers, transcription factor binding, and markers of chromatin state in lymphoblastoid cell lines (LCLs) from humans, chimpanzees, and rhesus macaques. We found strong evidence for the conservation of histone modification localization and DNA methylation patterns. Regardless of species, highly expressed genes are more likely than lowly expressed genes to have epigenetic profiles characterized by presence of the histone modification H3K4me3 and absence of DNA methylation at their proximal promoters. Moreover, we observed an enrichment of inter-species differences in epigenetic marks in genes that are differentially expressed between species. We found evidence for regulatory changes due to turnover in transcription factor binding due to inter-species differences in the transcription factor protein (trans mechanism) or to the binding sites (cis mechanism). By obtaining profiles of multiple epigenetic modifications and markers of chromatin state in the same samples, we are able to achieve a more comprehensive understanding of the combinatorial patterns that underlie differences in gene expression levels between primates.

474W

RANTES gene polymorphism in HIV-infected South African population. *N. Chin'ombe, M. Skelton, C. Dandara.* IIDMM, Human Genetics, University of Cape Town, Observatory 7925, Cape Town, South Africa.

Introduction Several host restriction gene polymorphisms have been linked to susceptibility to HIV infection. Limited information on these polymorphisms is available in the African population. The RANTES (regulated upon activation normal T cell expressed and secreted), a well-characterized AIDS restriction gene, encodes a ligand for CCR5. A single nucleotide polymorphism (In1.1C) in the intron of RANTES has previously been shown to reduce the expression of the gene, thereby increasing the chance of HIV infection and accelerated disease progression. Objective To investigate frequency of RANTES In1.1C gene polymorphism in the South African population infected with HIV. Methods DNA was isolated from blood of HIV-infected patients and health control subjects. Polymerase chain reaction was used to amplify the RANTES allele. Restriction fragment length polymorphism method was used to determine the genotypes (In1.1 T/T, T/C and C/C) of the RANTES. Results Out of the 281 South African individuals infected with HIV, 7 (2.5%) were homozygous to the RANTES In1.1C allele, 92(32.7%) were heterozygote carriers (In1.1T/C) and 182 (64.8%) had the normal allele (In1.1T/T). The allele frequency for the RANTES In1.1C was 0.19 in this population. In the control population (n = 95), 2.2% carried the In1.1C/C genotype and the allele frequency was 0.16. Conclusion The RANTES In1.1C allele is present in the South African population.

Analysis of the genetic basis of disease in the context of human migration. *E.C. Corona[1], R.C. Chen[1], C.P. Patel[1], A.M. Morgan[1], M.S. Sikora[2], C.B. Bustamante[2], A.B. Butte[1].* 1) Biomedical Informatics, Stanford University, Stanford, CA; 2) Genetics, Stanford University, Stanford, CA.

Genetic diversity across different human populations can inform on our current understanding of the genetic-basis of disease. The effects of migration on the emergence or regression of the genetic contribution to complex disease susceptibility have never been comprehensively studied and contrasted. We estimate the genetic contribution to disease susceptibility of 173 diseases in 1043 unrelated individuals across 51 populations of the Human Genome Diversity Panel. The genetic risk of each disease is estimated for all populations by combining all known genome-wide association studies published with each population's genetic substructure. By incorporating a phylogenetic tree establishing worldwide relationships across the 51 studied populations, we estimate when and where genetic risk of each disease underwent differentiation exceeding what is expected by genetic drift. We observe that genetic risk of Type 2 Diabetes underwent strong differentiation towards decreased risk in the ancestral population common to Native Americans and East Asians. Membranous Nephropathy underwent differentiation towards decreased risk gradually as populations migrated Eastward. Alzheimer's disease underwent differentiation towards decreased risk solely in two East Asian populations (Dai and Cambodia). This analysis represents the first comprehensive characterization of disease susceptibility differentiation associated with migration events. We anticipate that by highlighting groups of populations that show differences in disease susceptibility along migration trajectories, our findings will enable detailed analysis pertaining to the driving forces behind population differences in the genetics-basis of disease susceptibility.

Conserved SNPs are enriched for disease-susceptability loci and eQTLs in LCLs. *P. Evans, E. Gamazon, N. Cox.* Gen Med, Univ Chicago, Matteson, IL.

Finding functional variation in the human genome has the potential to increase our ability to find the genes responsible for a number of complex diseases. Much work has already been done on annotating the genome but little is still known about functional elements outside of genes. However, if we can restrict our searches of genomic variation to only variants that are functional then we can greatly reduce the penalty for multiple testing as most variation should play no role in disease. This has been done for many new gene-based tests. One example is using eQTL information from a given tissue to link functional variation to specific genes. This has the limitation that the information garnered may not be informative unless you are looking in the relevant tissue-type for a given disease. One solution to this problem is to use nontissue-dependent types of information to find variation that is likely to be functional. One possible alternative are SNPs that reside within evolutionarily conserved elements within the genome. Over long enough time lines, non-functional sites in two related species should vary between genomes, while elements that are functional will remain constant as purifying selection removes any variants that arise in these elements. Therefore by looking between sequences of two or more species that are suitably divergent, we can find elements that are likely to be functional. This would allow us to find functional SNPs that would not be dependent on tissue type, although some of these conserved elements may have regulatory functions that are tissue-specific. We have used the conserved elements defined by Pollard et al, Genome Research 2010, to find SNPs in HapMap in these conserved elements. SNPs in conserved elements are highly enriched for eQTLs in lymphoblastoid cell lines, showing that these SNPs are likely to have function. SNPs from the NHGRI catalog of published GWAS containing reproducibly associated SNPs for a variety of diseases are also enriched for SNPs in conserved elements, indicating these SNPs are also relevant for disease.

Genetic of LCT gene in Amerindian populations from Brazil. *D.C. Friedrich[1], S.M. Callegari-Jacques[2], F.M Salzano[1], M.L. Petzl-Erler[3], L.T. Tsuneto[3], M.H. Hutz[1].* 1) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil; 2) Department of Statistics, UFRGS, Porto Alegre, RS, Brazil; 3) Department of Genetics, UFPR, Curitiba, PR, Brazil.

The LCT gene encodes lactase enzyme, which is responsible for the digestion of lactose. During early childhood, lactase level declines dramatically but some people maintain lactase secretion during their whole life, a condition known as lactase persistence (LP). LP is due to mutations in the LCT gene enhancer, located 13Kb upstream the gene. In Europeans, the -13910T allele is associated with LP. In Africans this polymorphism is almost absent while other mutations in this same region were related to LP. The LCT gene is highly polymorphic in human populations, a total of 36 haplotypes have been described, but so far Amerindians were not investigated for these polymorphisms or for the presence of LP mutations. In this study, the LCT gene and the presence of LP allele were characterized in four Native Brazilian populations. The sample consisted of 316 individuals from Guarani-Kaiowá, Guarani-Ñandeva, Kaingang, and Xavante populations. Twelve polymorphisms were genotyped by PCR-based methods or by sequencing. The -13910T allele associated with LP varied from 0.5% in the Xavante to 7.6% in the Guarani-Ñandeva, and the frequencies differ significantly between Kaingang and Xavante, Xavante and Guarani-Ñandeva, and between Guarani groups. The -13910T frequency is probably of European origin and its prevalence correlates with non-native admixture proportions previously described for these populations. The LCT gene was highly polymorphic in this ethnic group, 15 haplotypes were observed with a heterogeneous distribution among these Native Brazilian groups. All populations had significant differences in haplotype frequencies. The Guarani-Kaiowá presented an excess of LCT A, E, and U haplotypes, while the C was scarcity. An excess of the A haplotype was also observed in the Guarani-Ñandeva. The Xavante showed an excess of C, and a lack of A, and E haplotypes, whereas the Kaingang did not differ from the average haplotype frequencies. Multidimensional Scaling using F_{ST} distance showed a gradient on the distribution of these four populations, the Xavante was the most isolated and Guarani-Kaiowá was closer to Asian and Southern European populations. In each population, the LP -13910T allele occurred in a different haplotype. The absence of new mutations in the -13Kb enhancer, the absence of pastoralism reports in these groups, and LCT haplotype distribution in present day-Amerindians suggest that drift was the main factor that explains the high heterogeneity observed.

Human genes with unusually recent or ancient common ancestors. *M. Hu, Y. Xue, C. Tyler-Smith.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Which genetic changes have contributed to the characteristics specific to modern humans is a question of great interest to biologists. Among other approaches, this question could be addressed by identifying regions that share a very recent common ancestor among all humans. We performed a genome-wide scan for regions with a recent coalescent time (<200,000 years) using published high-coverage genome sequences of 11 unrelated individuals from European, Asian and African populations, applying the genetree* package. However, due to the lack of consistency of those genome sequences produced by different platforms, data had to be heavily filtered so the global distribution of the coalescent times across the genome was skewed to younger ages. We are applying the same approach to a diverse collection of high-coverage whole genome sequences from 54 unrelated humans released by Complete Genomics Inc. (http://www.completegenomics.com/), which have higher data consistency. We also calculate the divergence/diversity ratio among those genomes compared to other primates. Regions with high divergence/diversity ratios or recent common ancestors may have contributed significantly to the evolution of modern humans. On the other hand, regions sharing very ancient common ancestors (>2 million years ago) among humans may have entered our gene pool from other species of archaic hominin, or undergone balancing selection, where maintaining a high level of polymorphism for a long period has been advantageous. Our scan of the 11 genomes also unveiled regions in the human genome with potential ancient common ancestors, and we are also looking for ancient regions in our scan on the new 54 genomes. Our preliminary results point to some novel genes showing evidence of potential balancing selection. *Bahlo, M. & Griffiths, R. C. Inference from gene trees in a subdivided population. Theor Popul Biol 57, 79-95 (2000).

Population history and paternal gene flow in the Ch'orti' Maya of Eastern Guatemala. *A.E. Justice, S.M. Johnson, M.H. Crawford.* Department of Anthropology, University of Kansas, Lawrence, KS.

Ch'orti' Maya is spoken mainly in Eastern Guatemala, western Honduras, and El Salvador. The Ch'orti' Maya have occupied eastern Guatemala and western Honduras for ~2,000 years. When the Spanish invaded the Ch'orti' in 1524, there were approximately 120,000 Mayans inhabiting the region. During the 19th and early 20th century German, French, and U.S. investors moved to the region. As a result of the introduction of African slaves in the 1500s, the attempted Ladinoization of the Indians from the 1700s through 1940s, and the negativity associated with being an Indian into the 1990s, there was cultural and biological admixture among the Indians, Africans, and Europeans. This study aims to characterize the source and level of admixture within the Ch'orti' Maya while making inferences into their historical relationships with surrounding Central Americans. DNA was extracted from 21 males residing around Jocotán, Chiquimula, Guatemala. Y SNPs were characterized using HyBeacons® PCR probes, and STRs (DYS-19, 385 a/b, 389 I/II, 390, 391, 392, 393, 438, and 439) were characterized using AFLP on an Applied Biosystems ABI Prism 3130 for haplogroup assignment. Haplotype diversity, locus diversity, and MPD were computed to characterize the intra-population variation. Slatkins Rst, R-matrix analysis, and SAMOVA were used to highlight the relationship among populations in Central America. Native American haplgroups are present in the majority of the sample, (62% haplotype Q1a3a, and 10% Q1). The majority of non-native admixture is from Europe, most likely the Iberian Peninsula (Haplogroups R1b, I, and J). The Ch'orti exhibit higher than expected haplotype diversity compared to surrounding populations, but average gene diversity and MPD. The difference in diversity measures for the Ch'orti' is likely the result of a high occurrence of low frequency haplotypes. Regardless of their geographic proximity and historical relationship to Honduran Native Americans, the Ch'orti' have a closer relationship to the paternal lineages present in El Salvador natives and Panamanian natives. Despite a long history of colonization and slavery, the Ch'orti' retain a majority of Native American Y lineages. However, the effects of colonization, including population decline and forced migration, have had an effect on the genetic structure of these paternal lineages. These events are reflected in the presence of Mediterranean Y Haplogroups and a high occurrence of low frequency haplotypes.

Genetic affinities of Lakshadweep Islanders. *S. Justin Carlus[1], K. Gopal[1], A. Mishra[1], P.S. Gireesha[2], A. Rastogi[3], A.J. Francis[1], R. Tamang[1], A.G. Reddy[1], L. Singh[1,4], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, India; 2) Yogi Vemana University,Kadapa, Andhra Pradesh, India; 3) Amity Institute of Biotechnology, Amity University, Noida, India; 4) Genome Foundation, Hyderabad, India.

The Indian subcontinent is legendary for the cultural, linguistic and genetic diversity of its inhabitants. Lakshadweep is one of the union territories of India, consisting of 36 islands located in the Arabian Sea. Till date there is no genetic study that has been carried out on the populations of this islands. Therefore, we have undertaken this study to establish the genetic affinities of the Lakshadweep islanders. About 5 ml of blood samples from 880 healthy and unrelated individuals inhabited in different Islands of Lakshadweep (Kavaratti, Agatti, Kiltan, Andrott, Kalpeni, Minicoy and Chetlat Islands) were collected with informed written consent. We have typed with the uniparentally inherited Y-chromosome and mitochondrial DNA (mtDNA) markers. Based on the mutations observed, we have assigned haplogroup to every individual. Our results showed that all the samples fell under the Indian- and WestEurasian-specific haplogroups; M and N, respectively. Further analysis showed that existence of several sublineages of Macrohaplogroups M (M2, M25, M3, M3a, M33a, M4, M4'30 and M5) and N (U2, U7, U9 R5, R7 and R9). In order to establish the paternal lineages, we screened with 12 Y-chromosomal biallelic markers viz. M9, M175, M45, M82, M69, M70, M173, M62, M124, M17, M89 and APT. Haplogroups M17-R1a and M172-J2 were observed in high frequency. Additionally, haplogroups such as M69-H, M11-L and M124-R2 were noticed in significant proportion. There are some M45-P*, M9-K*and M89-F* derived samples in less frequencies. Our mtDNA and Y-chromosomal DNA analysis revealed the existence of WestEurasian and Indian gene pool among the Lakshadweep populations.

Inferences of demographic history and selection in Bornean and Sumatran Orangutan genomes. *J.L. Kelley[1], X. Ma[1], K.E. Eilertson[2], R.N. Gutenkunst[3], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Statistical Science, Cornell University, Ithaca, NY; 3) Molecular and Cellular Biology, University of Arizona, Tucson, AZ.

Analysis of genetic variation in orangutans, our most distantly related Great Ape, can provide insight into forces that shape the Great Ape genome. To understand recent orangutan demographic history, we first analyze the Bornean and Sumatran Orangutan joint site frequency spectrum from 10 individuals. Five individuals from each species were sequenced with a median read depth of over 8x. Model-fitting using DaDi indicates that the two populations diverged 400,000 years ago, similar in time to the human-Neanderthal split. Our demographic inference shows that the Sumatran population has a current effective population size four times larger than the Bornean population. Additionally, the distribution of selection coefficients we infer from the frequency spectrum of non-synonymous polymorphisms is consistent with the previously estimated distribution in humans. To identify particular genes under selection, we further apply a generalized linear mixed model to estimate genome-wide variability among coding sites in the genome. Of the over 7,200 annotated orthologs queried using SNIPRE (selection inference using Poisson random effects), only 32 are best explained by a model of positive selection between orangutans and humans. Nearly 50% of loci have negative selection coefficients between human and orangutan, suggesting that constraint and conservation are predominant drivers of gene evolution in Great Ape genomes. The distribution of deleterious alleles between the two species, as measured by variation at conserved sites, is surprisingly similar given their different demographic histories. Together, these findings suggest that although the diets and environments experienced by orangutan and human are quite different, similar pressures may have acted on both orangutan and human genomes.

Comparing genetic diversity and evolutionary implication of 439 obesity-related genes between populations in the Human Genome Diversity Panel (HGDP). *J. kim[1], M. Lee[1], Y. Yoo[2], J. Sung[1].* 1) Graduate School of Public Health, Seoul National University, Seoul, Korea; 2) Department of Mathematics Education, Seoul National University, Seoul, Korea.

BACKGROUND: Obesity and its complications are important risk factors of many common diseases and have become a priority problem in global health. Genome-wide association (GWA) studies have accumulated a list of genes responsible for obesity, but only a part of genes are replicated across populations. Previous studies have indicated population differences in susceptibility to obesity and to complications of obesity. To explain this difference, a “thrifty gene hypothesis” has been proposed, without being vindicated by objective evidence. Recent deluge of GWA studies has revealed hundreds of obesity-related genes, which provide targets for systematic population genetic evaluation. OBJECTIVE: We identify genes that show significant population differences in allele frequency across populations of HGDP, and for those different genes we test evidence for selection. METHOD: We examine 439 obesity related gene regions that have been replicated by independent genome-wide association studies using Human Genome Diversity Panel (HGDP) and Korean Association Resource (KARE) project samples. SNP genotypes in these regions obtained from 500~600k genome-wide arrays are used. With HGDP data, we select top 30 genes that show largest population differences in allele frequencies. For these 30 genes, extended haplotype homozygosity (EHH) and cross population extended haplotype homozygosity (XP-EHH) tests were performed to evaluate the presence or degree of positive selection in seven populations including East Asians, Europeans, Sub-Saharan Africans. RESULTS : Several obesity genes showed substantial variation in allele and haplotype frequency patterns across populations groups and we found evidence for possible positive selection in some populations. For MCHR1 gene, one core haplotype (4 SNPs) is most frequent in Americans (89%), but not in Other population (0~17%). In addition, this haplotype contains rs133072 that is replicated in previous GWAS and demonstrated relatively long range LD with slow EHH decays in Americans but not in other population groups suggesting positive selection in Americans. For ALDH2 gene, similar result is found in East Asians. CONCLUSION: We identified some obesity related genes with different SNP frequency distribution patterns and found some evidences for positive selection in some populations for those genes. This result may help to reveal the cause of obesity.

Ascertainment Bias in Microsatellites: Impact on Estimates of Mutation Rates. *M. Kimmel, B. Li.* Departments of Statistics and Bioengineering, Rice University, Houston, TX, USA.

Microsatellite loci play an important role as markers for identification, disease gene mapping and evolutionary studies. Mutation rate, which is of fundamental importance, can be obtained from interspecies comparisons, which however are subject to ascertainment bias. This bias arises when a locus is selected based on its large allele size in one species (cognate species 1), in which it is first discovered. This bias is reflected in average allele length in any non-cognate species 2 being smaller than that in species 1. This phenomenon was observed in various pairs of species, including comparisons of allele sizes in human and chimpanzee. Various mechanisms were proposed to explain ascertainment bias. Here, we examine the framework of a single-step asymmetric and unrestricted stepwise mutation model with genetic drift. Analysis is based on coalescence theory. The mechanism of ascertainment bias in this model is a tighter correlation of allele sizes within a cognate species 1 than of allele sizes in two different species 1 and 2. We present computations of the expected bias, given the mutation rate, population sizes of species 1 and 2, time of separation of species 1 and 2, and the age of the allele. In particular, we show that when the past demographic history of the cognate and non-cognate taxa are different, the rate and directionality of mutations will impact the allele sizes in the two taxa differently than the simple effect of ascertainment bias. This effect may exaggerate or reverse the effect of difference in mutation rates. We reanalyze literature examples, and conclude that despite the bias, the microsatellite mutation rate in human exceeds that in chimpanzee.

Lactase persistence: New variants and evidence for function. *A. Liebert[1], T. Danielsen[2,3], A. Krüger Olsen[2,3], J.T. Troelsen[2,3], D.M. Swallow[1].* 1) Research Department of Genetics, Evolution and Environment, University College London, Darwin Building, Gower Street, London WC1E 6BT, UK; 2) Department of Sciences, Systems and Models, University of Roskilde, Universitetsvej 1, DK-4000 Roskilde, Denmark; 3) Department of Cellular and Molecular Medicine, University of Copenhagen, Panum Institute, Building 6.4, Blegdamsvej 3B, DK-2200 Copenhagen N, Denmark.

Background The ability to digest lactose in milk in adulthood differs between people. Only 35% of the world population show the phenotype of lactase persistence (LP), as lactase expression is usually down regulated after weaning. LP is at highest frequency in Northern Europe where it is caused by a mutation upstream of the lactase gene (*-13.910*T* in intron 13 of the adjacent *MCM6* gene). However, *-13.910*T* is absent in many milk drinking pastoralist groups in Africa where several other putative causal alleles have been identified. These nucleotide substitutions are located within 100 bases of each other, in a region that has been shown *in vitro* to have enhancer function. Four of the variants have been studied functionally so far but there is patchy information on the distribution of these and the other variants. *Aims and methods* We have examined the distribution of *-13910*T* around the periphery of Europe and the extent of spread of the African alleles out of Africa, as well as searching for new functional variant alleles. We have sequenced DNA from individuals from 40 populations of Europe, Asia and the Middle East, and conducted transfection and gel shift assays on some of the variants. *Results -13910*T* is the predominant derived allele throughout the whole of Europe while this and the alleles first described in Africa are present together in the Middle East, although other rare alleles were also found. In all, we identified a total of 17 variants in the enhancer region, of which 8 are described here for the first time. We selected 3 variants that had not previously been studied and showed that they also have function *in vitro*. The altered binding of transcription factors to probes containing these derived alleles has been confirmed by supershift and/or competition experiments. Higher enhancer activity has also been shown in reporter gene assays. *Conclusion* Many different mutations in the enhancer region appear to alter lactase gene activity.

Studying the impact of Old World diseases on Native American populations via ancient DNA. *B. Llamas[1], L. Quintana-Murci[2], A.L. Hughes[3], A. Cooper[1], W. Haak[1].* 1) Australian Centre for Ancient DNA, University of Adelaide, Adelaide, SA, Australia; 2) Genome and Genetics, Institut Pasteur, 75015 Paris, Fance; 3) Department of biological Sciences, University of South Carolina, Columbia, SC 29208, USA.

There is good evidence to suggest that prior to the arrival of the Spanish in 1492, South and Central American populations were the largest of any in the world. However, censuses performed by Spanish functionaries less than a century later show a drastic decline in both population size and distribution. Several accounts estimate that up to 95% of the indigenous population of the Americas died between the period of initial contact and the beginning of population recovery. Consequently, contact between the Eastern and Western Hemispheres in the sixteenth century represented an adaptive transition that shaped modern human biocultural diversity on a global scale.

We propose to use ancient DNA techniques to explore the selective pressures exerted by new pathogens on human populations. Our project aims are: i) to generate the first real-time picture of the genetic changes induced by epidemics in human populations using ancient DNA from a large number of specimens from pre- and post-Contact Native populations from South and Central America; and ii) to describe the genetic diversity of Native populations prior to European contact to test the hypothesis that they were immunologically `naïve' to Old World diseases, and suffered very high levels of mortality as a consequence.

Ongoing research efforts include mitochondrial and Y-chromosome genotyping using multiplex SNP analysis, the development of DNA capture methods targeting immunogenes in ancient DNA libraries, and the use of Next Generation Sequencing platforms.

Major outcomes expected from this project are a better comprehension of the biological impact of colonisation on indigenous groups, as well as a better understanding of the parameters and driving forces behind human evolutionary history.

486W

Phylogenetics and phase: Comprehensive mapping of human genetic variation associated with the age of onset of late-onset Alzheimer's disease. *M.W. Lutz[1,2], D.G. Crenshaw[1,2], A.M. Saunders[1,3], I. Grossman[4], O. Chiba-Falek[1,2], D.K. Burns[4], A.D. Roses[1,2,3,4].* 1) Deane Drug Discovery Institute, Duke University, Durham, NC; 2) Institute for Genome Policy and Sciences, Duke University, Durham, NC; 3) Neurology, Duke University Medical School, Durham, NC; 4) Zinfandel Pharmaceuticals, Inc, Durham NC.

The unique nucleotide content of each of the two homologous chromosomes that an individual carries (genetic phase) has been shown to have a profound effect on allele-specific gene expression and protein function that may contribute to clinical phenotypes or disease. Analysis of phylogenetic trees and networks is a powerful approach to investigate the relationships between phased sequence data and phenotype, particularly when mechanisms of reticulate evolution are incorporated into the analysis. We analyzed data available from two late-onset Alzheimer's disease (LOAD) association studies: 1) Lescai et al. (2010) reported association for three APOE promoter SNPs (-219, -491 and -427) and; 2) Roses et al. (2010) reported association for a poly-T length polymorphism in TOMM40 locus (rs10524523 referred as “523”). A phylogeny was constructed from DNA sequences in the TOMM40-APOE linkage disequilibrium (LD) region (Chr19 50,092,405 - 50,101,584, NCBI version 36) from LOAD patients and controls. Analysis revealed that the three SNPs in the APOE promoter were in linkage with specific “523” alleles. The major findings were: 1) The T allele of -219 always maps to a major clade on the phylogenetic tree that is associated with a higher risk for LOAD and an earlier age of onset for LOAD relative to the other major clade; and 2) the T allele of -219 always co-occurs with either a Long “523” allele (20-29 Ts) linked to APOE ,4 or a Very Long “523” allele (>29 Ts) linked to APOE ,3 while the -219 G allele co-occurs with Short “523” alleles (<20 Ts). A specific SNP in TOMM40 (rs8106922) was found as the most significant variant which separates the two major clades of the tree, while “523” remains the variant most highly associated with differences in age of onset of LOAD. Other SNPs, including the APOE promoter polymorphisms, map uniquely to specific “523” alleles. Our results demonstrate that phylogenetic analysis can reconcile results of independent studies of phased sequence data and the age of onset of LOAD and provide a comprehensive mapping of human genetic variation associated with LOAD age of onset. These data further demonstrate the importance of using phylogenetic analysis with phased sequence data for other disease gene identification studies.

From Essentiality to Redundancy: Evolutionary Genetics Dissection of the Human Interferon Families. *J. Manry[1,2], E. Patin[1,2], G. Laval[1,2], S. Fornarino[1,2], L.B. Barreiro[3], M. Tichit[4], M. Fumagalli[5], M. Sironi[5], Y. Itan[6], J.L. Casanova[6], C. Bouchier[4], L. Quintana-Murci[1,2].* 1) Human Evolutionary Genetics, Department of Genomes and Genetics, Institut Pasteur, Paris, France; 2) Centre National de la Recherche Scientifique, Paris, France; 3) Department of Pediatrics, University of Montréal, Montréal, Canada; 4) Pasteur Genopole, Institut Pasteur, Paris, France; 5) Scientific Institute IRCCS E. Medea, Bosisio Parini, Italy; 6) St Giles Laboratory of Human Genetics of Infectious Diseases, New York, USA.

Detecting how natural selection has acted upon genes involved in host defense and immunity-related processes can provide insights into the mechanisms that mediate the eradication of infection. Interferons (IFNs) are helicoidal cytokines that play a key role in innate and adaptive immune responses. Most IFNs present an antiviral activity and are intercellular mediators able to modulate several major biological functions, such as cell proliferation and differentiation, or lymphocyte activation. Given the multiple genes that encode IFNs, it is now a priority to delineate those that are essential with respect to those that are more redundant in the immune response. Through the resequencing of the 27 genes encoding the human IFNs and their receptors in a panel of individuals from different ethnic backgrounds, our population genetics data revealed that some members of the type-I IFN family, with the most extreme cases being *IFNA6* and *IFNA8*, as well as the only member of the type-II IFN family, *IFNG*, fulfill essential functions in host defense. By contrast, the fact that other type-I IFNs, such as *IFNA10* and *IFNE1*, accumulate missense and nonsense mutations at high population frequencies suggests higher redundancy and pseudogenization. Finally, type-III IFNs appeared to be mainly targeted by recent positive selection, especially among non-African populations, owing to increased resistance to viral pressure. Taken together, our evolutionary data reveal that the different members of the human IFN families differ in their biological relevance, given their varying essential or adaptive behaviors, suggesting that some genes may represent better targets for clinical studies than others.

Transmission distortion observed in human pedigrees. *W.K. Meyer[1], C. Ober[1, 2], R.R. Hudson[3], M. Przeworski[1,3,4].* 1) Dept. of Human Genetics, University of Chicago, Chicago, IL; 2) Dept. of Obstetrics and Gynecology, University of Chicago, Chicago, IL; 3) Dept. of Ecology and Evolution, University of Chicago, Chicago, IL; 4) Howard Hughes Medical Institute, University of Chicago, Chicago, IL.

Children of a heterozygous parent are expected to carry either allele with equal probability. Exceptions can occur, however, due to meiotic drive, competition among gametes, or viability selection, processes which we collectively term “transmission distortion” (TD). Although there are a number of well-characterized examples of these phenomena, the existence of transmission distortion in humans remains unknown. We therefore performed a genome-wide scan for regions experiencing transmission distortion within human populations. To this end, we applied the transmission disequilibrium test (TDT) to nuclear families belonging to three large sets of pedigrees of European descent that have been genotyped on genome-wide single nucleotide polymorphism (SNP) arrays: the Framingham Heart Study (FHS), a founder population of European origin (HUTT), and a subset of the Autism Genetic Resource Exchange (AGRE). Genotyping error is an important confounder in this type of analysis. In the FHS and HUTT, despite extensive quality control, we did not find sufficient evidence to exclude genotyping error as the source of the strongest signals. In the AGRE, however, many TD signals extend across multiple SNPs, a pattern highly unlikely to arise from genotyping error. These point to several promising candidate regions, notably a locus on chromosome 10q26.13 displaying strong evidence for transmission distortion and the signature of recent positive selection. Focusing on paternal transmissions, we also detected a signal in 6p21.1, a region that had been previously been suggested as experiencing TD from the analysis of a small sample of European males. In signals derived from maternal transmissions, we found a strong enrichment for genes involved in cell junctions. We found no strong maternal TDT signals near centromeres or telomeres, the chromosomal regions predicted to be most susceptible to meiotic drive in females. These results demonstrate the existence of ongoing segregation distortion or strong viability selection in contemporary human populations and suggest the involvement of cell junction-related loci in maternal distortion.

Impact of restricted marital practices on genetic variation in a distinctive endogamous population. *T.J. Pemberton[1,2], F-Y. Li[1,3], E.K. Hanson[4], N.U. Mehta[1,5], G. Mendoza-Fandino[1,5], J. Ballantyne[4], J.W. Belmont[3], N.A. Rosenberg[2,6,7], C. Tyler-Smith[8], P.I. Patel[1,5,9].* 1) Institute for Genetic Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) National Center for Forensic Science, University of Central Florida, Orlando, FL; 5) Department of Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA; 6) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 7) Life Sciences Institute, University of Michigan, Ann Arbor, MI; 8) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 9) Center for Craniofacial Molecular Biology, Herman Ostrow School of Dentistry, University of Southern California, Los Angeles, CA.

Social stratification in India is evident as social classes that are defined by endogamous groups known as castes. Within a caste, there exist endogamous groups known as *gols* (marriage circles), which comprise a small number of exogamous *gotra* (lineages). Thus, while consanguinity is strictly avoided and there is some randomness in mate selection within the *gol*, gene flow is limited with populations outside of the *gol*. Gujarati Patels practice this form of “endogamic exogamy.” We have analyzed genetic variation in one such group, the Chha Gaam Patels (CGP), which comprises Patels from six villages. Population structure analysis of 1,200 autosomal loci offers support for distinctive multilocus genotypes in the CGP with respect to both non-Gujaratis and other Gujaratis, and indicates that individuals from the six villages are genetically extremely similar. Analysis of Y-chromosomal and mitochondrial haplotypes provides support for both patrilocal and patrilineal practices within the *gol*, and a low-level of female gene flow into the *gol*. Time to the most recent common ancestor estimates based on Y-chromosomal haplotypes are consistent with historical accounts of the settlement of the six villages by Patels between 1155-1575 CE. Our study illustrates how the practice of *gol* endogamy has likely created isolated groups of individuals throughout India and thereby introduced fine-scale genetic structure into the population of India.

Patterns of shared polymorphism between humans and chimpanzees. *S. Pfeifer[1], E. Leffler[2], A. Fledel-Alon[2], A. Auton[3], R. Bowden[1,3], O. Venn[3], S. Melton[2], Z. Iqbal[3], I. Turner[1], L. Segurel[2], R. Hernandez[4], J. Maller[1,3], J. Broxholme[3], R. Bontrop[6], G. Lunter[3], P. Humburg[3], S. Myers[1,3], P. Donnelly[1,3], M. Przeworski[2,5], G. McVean[1,3].* 1) University of Oxford, Department of Statistics, 1 South Parks Road, OX1 3TG Oxford, United Kingdom; 2) University of Chicago, Department of Human Genetics, 920 East 58th Street, Chicago, IL, 60637, United States; 3) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, OX3 7BN Oxford, United Kingdom; 4) University of California, Department of Bioengineering and Therapeutic Sciences, San Francisco, CA 94143-0912, United States; 5) Howard Hughes Medical Institute, 920 East 58th Street, Chicago, IL, 60637, United States; 6) Biomedical Primate Research Centre, Lange Kleiweg 161, 2288 GJ Rijswijk, Netherlands.

Genetic polymorphisms that are shared between related species may result from either recurrent mutation or the maintenance of ancestral variation. As part of a project to map genetic variation in our closest living relatives, we have sequenced 10 Western chimpanzees (*Pan troglodytes verus*) to 8-10X and have identified over 4 million high confidence SNPs and short indels in regions of orthology to humans. We find that approximately 1% of polymorphic sites in chimpanzees are also variable among the 60 individuals from the Yoruba population sequenced as part of the 1000 Genomes Project; roughly two times the number expected by chance. Approximately two thirds of shared polymorphic sites also share the same alleles and of these over 60% represent mutations at putative CpG sites. However, even after accounting for known sequence context effects and local mutation rate variation, we still find a strong excess of certain mutation types, not all at CpG sites, indicating substantial heterogeneity in mutation rates at very fine scales and/or ancient-shared polymorphism. By characterising patterns of genetic variation and linkage disequilibrium (LD) around shared sites and, more specifically, searching for closely-sited variants in strong LD in both species we assess the evidence for shared ancient polymorphism.

Evolutionary dynamics of co-segregating gene clusters associated with complex diseases. *C. Preuss, M. Stoll.* Genetic Epidemiology , Leibniz Institute for Arteriosclerosis Research, Muenster, NRW, Germany.

With the advent of the HapMap project and the 1000 Genomes project, genetic variation accounting for disease susceptibility and population specific differences within the human genome have become more tractable. Recent studies suggest that gene order and single nucleotide polymorphisms (SNPs) associated with complex traits are not randomly distributed throughout the genome, but tend to cluster in regions of long-range linkage disequilibrium (LD). Here, we analyzed the distribution of disease-associated SNPs based on pilot data from the 1000 Genomes project, a set of publicly available GWAS data and meta-analyses for three HapMap populations (CEU, AFR, ASN). We observed distinct clustering of disease-associated SNPs in regions of long-range LD, which harbor genes involved in immunity i.e. the interleukin cluster on 5q31 or RhoA on 3p21. In-depth analysis of these genomic regions using integrated haplotype scores (iHS) and LD patterns revealed strong signs of recent selective sweeps for disease variants within immune clusters. Interestingly, disease-associated SNPs are common in populations under positive selection but absent from chromosomes in populations without signs of recent selection. Our data suggest that clustering of immune genes is the result of continuing selection pressure (adaptive or positive) throughout the evolution leading to physical clustering to facilitate a rapid adaptation of the immune system to changing environments and challenges. As a result, genomic regions of long-range LD evolved, which facilitated hitchhiking of susceptibility variants for common, complex diseases with an inflammatory background such as Crohn's disease (CD), type I diabetes and rheumatoid arthritis.

Rate and Molecular Spectrum of Spontaneous Mutations in the Human Genome Inferred from Rare Variants Found by Sequencing 202 Drug Target Genes in 14,000 Individuals. *V.M. Schaibley[1], M. Zawistowski[2], D. Wegmann[3], D. Kessner[3], M.G. Ehm[4], J.C. Whittaker[4], S.L. Chissoe[4], V.E. Mooser[4], M.R. Nelson[4], G. Abecasis[2], J. Novembre[3], S. Zöllner[2], J.Z. Li[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 3) Department of Ecology and Evolutionary Biology, University of California, Los Angeles, CA; 4) Quantitative Sciences, GlaxoSmithKline.

Understanding the rate, variability, and genomic context of spontaneous mutation in human populations is fundamental to understanding our evolutionary history. One approach to studying spontaneous mutation is to examine extremely rare variants in humans, which have arisen recently and are largely unaffected by natural selection, biased gene conversion and population demographic history. Because rare variants are for the most part immune to these confounding factors, we can characterize mutations throughout the genome, particularly within coding regions, where common variants are influenced by selection. In collaboration between GlaxoSmithKline and the University of Michigan, we have sequenced the exons of 202 genes in 14,000 individuals. In all, we discovered >34,000 variants with an allele frequency <= 0.001. Using these variants, we analyzed the overall mutation rate, the rates for specific types of mutation (e.g. A:T>G:C, G:C>A:T, etc.) as well as their correlation to specific genomic features which have previously been shown to impact mutation, including GC content, recombination rate, and adjacent nucleotide context. Regions of high GC content show decreased rates of mutation for most mutation subtypes, although the strength of this association is often confounded by read depth differences due to GC content. Still, mutations toward G or C nucleotides have weak yet significant negative correlations with GC content, suggesting that mutations that increase the overall GC content may be suppressed in GC-rich regions. Recombination has been previously shown to affect mutation along the human chimpanzee lineage. In rare variants, we show that local recombination rate or distance to recombination hotspot has little impact on the overall mutation rate or those of subtypes, suggesting that recombination has not had a significant influence on the mutation pattern in these variants. We also examined the mutation rate for specific types of mutations depending on the nucleotides surrounding the variant site and found that the adjacent nucleotide context impacts the mutation rate. These results show that local genomic context has substantial and specific effects on spontaneous mutation. The ability to examine extremely rare variants provides a new opportunity to study mutation as a fundamental process in biology without previous limitations, and generates precise estimates of local mutation rates for better interpretations of medical resequencing data.

Evolutionary genetics evidence for strong differences in the biological relevance of host microbial sensors. *E. Vasseur[1], S. Pajon[1], J. Manry[1], B. Crouau-Roy[2], L. Quintana-Murci[1].* 1) UP Human Evolutionary Genetics, CNRS URA 3012, Institut Pasteur, Paris, France; 2) Evolution et Diversité Biologique, UMR CNRS 5174, Université Paul Sabatier, Toulouse, France.

Microbial sensors, or pattern-recognition receptors (PRRs), are responsible for the detection of pathogens by the host, and constitute key actors of the innate immune system. Detecting how natural selection has targeted immunity-related genes has proven to be a useful tool for identifying genes playing an essential role in host defence. Here, we studied the levels of naturally-occurring variation of two major families of intracellular PRRs; the NOD-like Receptors (NLRs) and the RIG-I-like receptors (RLRs), which are mainly involved in the sensing of bacteria and viruses, respectively. To this end, we resequenced the 24 genes encoding these receptors in a panel of individuals (HGDP-CEPH) representing the major continental populations and used this dataset to perform a number of inter- and intra-specific neutrality tests. Our results revealed that the NALP subfamily of the NLRs, probably the least known family of PRRs, has been globally targeted by strong purifying selection. Indeed, amino-acid altering variation at 9 out of the 14 NALPs has been strongly constrained since the human/chimpanzee divergence. This suggests that most NALPs fulfil an essential function, thus constituting excellent candidates to be further studied in the context of infectious and autoimmune diseases. By contrast, such selective constraints have been relaxed for the remaining NLRs (i.e. some NALPs and 6 of the 7 NODs) and the 3 RLRs, which in turn seem to evolve more adaptively. Specifically, we found signatures of local positive selection targeting the RLRs MDA5 and LGP2 as well as the NLR CIITA among Eurasian populations, and identified at least 3 non-synonymous mutations as putative targets. More generally, when comparing the patterns of diversity and selection depicted at the major families of PRRs - the NALPs, the NODs, the RLRs and the TLRs - a clear pattern emerged. Among the families of PRRs specialised in the sensing of nucleic acids particularly from virus, the endosomal TLRs fulfil a more essential role than RLRs. Likewise, among the PRR families specialised in the sensing of products principally from bacteria, parasite and fungi, the intracellular NALPs appear to fulfil more crucial functions with respect to most NODs and the cell-surface TLRs. Our data allow us to propose a general hierarchical model, which indicates strong differences in the relative biological importance of PRRs and pave the way for future biochemical, immunological and clinical genetics studies.

A SNP in EDAR is associated with a number of phenotypes of epidermal appendages - a population study in China. *S. Wang[1], Y.G. Kamberov[2], J. Tan[3], P. Gerbault[4], L. Tan[1], Y. Yang[3], S. Li[3], B.A. Morgan[5], D.E. Lieberman[6], M.G. Thomas[4], C.J. Tabin[2], L. Jin[3], P.C. Sabeti[1].* 1) FAS Ctr Systems Biol, Harvard Univ, Cambridge, MA; 2) Harvard Medical School, Department of Genetics, Boston, MA; 3) MOE Key Laboratory of Contemporary Anthropology, Fudan University, Shanghai, China; 4) Department of Genetics, Evolution and Environment, University College London, U.K; 5) Massachusetts General Hospital, Cutaneous Biology Research Center, Charlestown, MA; 6) Department of Human Evolutionary Biology, Harvard University, Cambridge, MA.

Ectodysplasin-A Receptor (*EDAR*) is involved in the development of epidermal appendages, including hair, sweat glands and teeth. The derived allele of SNP rs3827760 in *EDAR* was previously reported to be under strong positive selection in East Asian populations. In order to uncover the adaptive mechanism of this high frequency allele in East Asia, we carried out a systematic study in different ethnic groups in China with various allele frequency. rs3827760 is associated with a number of phenotypes, including sweat gland density, shovel-shaped incisor, and Carabelli's cusp. Through haplotype analysis of 280 SNP within 1cM of rs3827760 in 52 worldwide populations, we inferred the age of the derived allele and its associated long-range haplotype. It falls into late Pleistocene, and should predate the prehistoric colonization of the Americas. Using Approximate Bayesian Computation, and by incorporating paleoclimate data, we reconstructed the scenarios of the arising and spreading of the derived allele in East Asia. A model, in which selection coefficient depending on humidity, provided the best fit to real data. This finding, together with the genetic association of rs3827760 with sweat gland density, provides evidence that the local adaptive mechanism probably involved an advantage of thermoregulation in the humid weather in East Asia.

Parental Age and Assisted Reproductive Technology in Autism Spectrum Disorders , Attention Deficit Hyperactivity Disorder, and Tourette Syndrome in the a Japanese populationPopulation. *T. Shimada[1], H. Kuwabara[2], Y. Kano[2], K. Kasai[1], N. Kato[3], T. Sasaki[4].* 1) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Department of Child Psychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Department of Neuropsychiatry, Showa University School of Medicine, Tokyo, Japan; 4) Division of Physical and Health Education, Graduate School of Education, University of Tokyo, Tokyo, Japam.

We investigated whether advanced parental ages and assisted reproductive technology (ART) are risk factors in autism spectrum disorders (ASD), attention deficit hyperactivity disorder (ADHD), and Tourette syndrome (TS). Clinical charts of were reviewed in Japanese outpatients with ASD (n=552), ADHD (n=87), and TS (n=123) were reviewed. Parental ages of individuals with ASD, ADHD, or TS wasere compared with parental age in the general population of Tokyo (GP) after adjusting for year of birth years. Paternal and maternal ages were significantly higher in persons with ASD and ADHD, but not those with in TS. Logistic regression analysis revealed indicated that both maternal and paternal age were associated with ASD after controlling for the other parent's age, gender, singleton or multiple birth, gestational age, birth weight, and birth order. In cases where the presence or absence of ART could be ascertained (ASD n=467; ADHD n=64; TS n=83), Tthe frequency rate of ART in cases of 467 persons with ASD subjects (4.5%) was 1.8 times of the expected frequency expected in the GP, while ART was not observed present in cases of 64 persons with ADHD and 83 TS subjects. These preliminary results remain tentative pending replication with larger, community-based samples.

GENETIC AND CLINICAL ANALYSIS OF SPINOCEREBELLAR ATAXIA TYPE 8 REPEAT EXPANSION IN A SICILIAN PEDIGREE. *F. Cavalcanti[1], P. Tarantino[1], M. Sframeli[2], F. Annesi[1], E.V. De Marco[1], M. Caracciolo[1], M. Gagliardi[1,3], A. Gambardella[1,4], C. Rodolico[3], A. Quattrone[4,5], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone (CS), Italy; 2) Department on Neurosciences, Psychiatry and Anaesthesiology, University of Messina, Messina (ME), Italy; 3) University of Magna Graecia, Catanzaro (CZ), Italy; 4) Institute of Neurology, Department of Medical Sciences, University of Magna Graecia, Catanzaro (CZ), Italy; 5) Neuroimaging Research Unit, Institute of Neurological Sciences, National Research Council, Catanzaro (CZ), Italy.

Spinocerebellar ataxia type 8 (SCA8) is the first example of dominantly inherited ataxia reported to be caused by a dynamic mutation of the untranslated CTA/CTG trinucleotide repeat. Although it is typically described as an automal dominant condition the SCA8 expansion exhibits variable penetrance and considerable intergenerational instability with a maternal transmission bias. The repeat lengths most often associated with ataxia range from 80 to 250. In this study we describe the clinical and genetic features of a Sicilian family affected by SCA8. We obtained clinical and genealogical information from seven people of a three generation pedigree. All family members signed an appropriate informed consent form and genetic studies were performed. Blood samples were obtained from all subjects and genomic DNA was extracted by standard methods. Triplet expansion in SCA8 was detected by PCR amplification with fluorescent primers. PCR products were separated onto a capillary sequencer. The proband of the family, a 41-year women, at the age of 37,has been diagnosed clinically with ataxia. The initial symptom, was gait instability, and she progressively experienced manifestation of limb and gait ataxia, dysarthria. Molecular analysis of the family members revealed no evidence of SCA1-SCA17. However, in three members of seven examined, a heterozygous CAG repeats expansion in ATXN8 gene was detected. We investigated the presence of the SCA8 triplet expansion in a Italian family, we found 3 subjects (1 patient with ataxia, 1 patient with parkinsonism and 1 unaffected subject) with abnormally expanded CTA/CTG repeats. In this study we confirmed the reduce penetrance of disease and the marked heterogeneity of the SCA8 clinical picture.

GRIK2, IL1B, NEDD8 and NEDD9 genes may act as modifiers of the Machado Joseph Disease/ SCA 3 phenotype. *V.E. Emmel[1], K.C. Donis[2], T.C. Gheno[1], J.A.M. Saute[3], L. Vedolin[6], L.B. Jardim[1 2 5], M.L. Sraiva-Pereira[1 2 4].* 1) Genetic Identification Laboratory, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil; 2) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Porto Alegre, RS, Brazil; 3) Neurology Service, Hospital de Clínicas de Porto Alegre, Brazil; 4) Department of Biochemistry, Universidade Federal do Rio Grande do Sul, Brazil; 5) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Brazil; 6) Neuroradiology Center, Hospital Moinhos de Vento, Porto Alegre, Brazil.

Machado-Joseph disease is a neurodegenerative disease caused by expansion of a polyglutamine tract in ataxin-3 that is coded for by ATXN3 gene. CAG length is inversely correlated with disease age at onset but is responsible for about 45-60% its variation in Machado-Joseph disease. **Aims**: to investigated if single-nucleotide polymorphisms in candidate genes BAX (rs1805419), CRYAB (rs14133), GRIK2 (rs2227281), IL1B (rs16944), ITPR1 (rs17786144), NEDD8 (rs2144487), and NEDD9 (rs760678) would modify age at onset, severity of disease, and volumes of infratentorial structures at MRI, in a large group of Brazilian patients with Machado-Joseph disease. **Methods**: DNA samples of 273 Brazilian MJD patients (119 families) were studied. Specific SNPs were determined by qualitative real time PCR using the TaqMan® PCR Assay (Applied Biosystems). A subgroup of 100 patients were clinically evaluated by NESSCA score: disease severity was defined as the quotient NESSCA/disease duration. MRI was done in 30 individuals. The normalized volumes of the brainstem, midbrain, pons, medulla oblongata, and cerebellum of SCA3 patients were measured on fluid-attenuated inversion recovery (FLAIR), using semi-automated segmentation techniques and voxel count volumetry using the software ImageJ. **Results**: significant associations were found between GRIK2 polymorphism (rs2227281) and cerebellum volume (P=0.006), IL1B polymorphism (rs16944) and age at onset (P=0.042), NEDD8 polymorphism (rs2144487) and pons volume (P=0.023), and a NEDD9 polymorphism (rs760678) and disease severity (P=0.003). The effect of combined protective genotypes for AO was investigated, and combined genotypes for GRIK2 (CC) + NEDD8 (GG) (P=0.008) and IL1B (AA) + NEDD8 (GG) (P=0.055) are associated with increased AO when compared with any other genotype combination. **Conclusions**: These results suggest that polymorphisms in GRIK2, IL1B, NEDD8, and NEDD9 genes may contribute to the phenotypic expression of Machado-Joseph disease.

Residual Age of Disease Onset Variance in Spinocerebllar Ataxias in a Cuba and US Cohort. *K.P. Figueroa[1], H. Coon[1], C.M. Gomez[2], H.L. Paulson[3], S.L. Perlman[4], N. Santos[9], J.D. Schmahmann[5], L. Velázquez Pérez[9], G.R. Wilmot[6], T.A. Zesiewicz[7], S.H. Subramony[8], T. Ashizawa[8], S.M. Pulst[1], Clinical Research Consortium for Spinocerebellar Ataxias (CRC-SCA).* 1) Neurology, University of Utah, Salt Lake City, UT; 2) University of Chicago, Chicago, IL; 3) University of Michigan, Ann Arbor, MI; 4) University of California Los Angeles, Los Angeles, CA; 5) Harvard University, Boston, MA; 6) Emory University, Atlanta, GA; 7) University of South Florida, Tampa, FL; 8) University of Florida, Gainesville, FL; 9) Centro para la Investigación y Rehabilitación de las Ataxias Hereditarias, Holguín, Cuba.

Disorders caused by the expansion of a coding CAG DNA trinucleotide repeat, collectively referred to as polyglutamine (polyQ) diseases, show a strong inverse correlation between CAG repeat length and age of disease onset (AO). The square of the correlation coefficient (r2) in polyQ disease ranges in most studies from 0.6 to 0.8. Despite the overall good inverse correlation between AO and repeat length in all polyQ diseases, there is tremendous variability of AO within each repeat class. This variation suggests that other factors, in addition to the mutant allele itself, exist that influence disease onset and progression. The Clinical Research Consortium for Spinocerebellar Ataxias (CRC-SCA) is an NIH-funded multi-site clinical research group. As of 6-1 2011, clinical data and CAG genotypes have been collected from 168 patients. Age of onset was considered the first sign of disease usually manifested by unsteadiness of gait. A comparison group consisted of 326 patients were recruited from the SCA2 founder population in Holguin, Cuba. We examined the age of onset and SCA2 CAG repeat length in 326 Cuban SCA2 patients from a founder population and 168 US patients from the CRC-SCA (34 SCA1, 26 SCA2, 67 SCA3, 41 SCA6). Linear and log(AO) correlations with CAG repeat length were computed. For the Cuban SCA2 population, GLM and GENMOD were used to estimate variance explained by repeat adjusted for family membership. For the Cuban cohort, the mutant SCA2 CAG repeat allele explained 69% of AO variance in the entire sample, but this decreased to 50% when adjusted for pedigree structure. Analysis of affected first degree relatives (parents & sibs) indicated that half of the residual variance was explained by shared genetic factors. In contrast, the r2 for the CRC-SCA cohort was 0.26 (SCA2), 0.34 (SCA3), and 0.22 (SCA6). Only SCA1 (r2: 0.54) showed an r2 close to values previously reported. The values for r2 in the Cuban SCA2, and US SCA1 cohorts are similar to prior reports for other polyQ diseases including Huntington disease. However, the values for SCA2, SCA3, and SCA6 are much lower than previously reported. Initial results of the first US multi-center study of spinocerebellar ataxias appear to show significant differences compared to pedigree or founder population-based single-center studies. The amount of variance attributable to the CAG repeat may be smaller than assumed by prior studies when geographically diverse unrelated individuals are included.

Introduction. The Spinocerebellar Ataxia type 17 (SCA17) is an autosomal dominant polyglutamine disease caused by expansion of a trinucleotide repeat encoding glutamine (CAG or CAA) in the general transcription factor TATA box-binding protein (TBP; 600075). It is characterized by ataxia, pyramidal and extrapyramidal signs, cognitive impairments, psychosis, seizures, dementia, a clinical phenotype and mode of inheritance similar to Huntington disease. Material and Methods. A female aged 33 year-old was studied clinically due to SCA (gait ataxia, dysmetria, severe dysarthria and aggression; MRI revealed moderate cerebellar atrophy. Laboratorial studies were performed with 5mL of peripheral blood to isolate patient's DNA by GeneCatcher Kit (Invitrogen). The molecular analysis was made by identification of expansion repeats in tandem by RED assay with probes to analyze the repeats.RED products were identified by Southern Blot and sequencing. Results. Molecular analysis revealed a number of expansion repeats of 34/52 (exp).Discussion. In previous studies done in Mexico the frequency of SCA17 was 2.8 percent. This is the first time that it is detected a patient affected by SCA17 in Northwest Mexico.

Screening *ANO10* mutations in a Japanese cohort of cerebellar ataxia. *K. Ishikawa[1], M. Furuki[1], H. Matsuo[1], T. Yamashita[2], H. Mizusawa[1].* 1) Dept Neurology, Tokyo Med & Dental Univ, Tokyo, Japan; 2) Department of Neurology, Kumamoto University, Kumamoto, Japan.

Autosomal-recessive cerebellar ataxia (ARCA) is a group of rare heterogeneous neurodegenerative disorders. Its cardinal clinical feature is progressive cerebellar ataxia, although various phenotypes such as pyramidal tract signs, ocular apraxia, peripheral neuropathy, or spinocerebellar long tract signs may accompany. Molecular backgrounds of ARCA are complicated and the currently known mutations are responsible for only a small portion of those patients. Recently, Vermeer and others identified mutations in anoctamin 10 (*ANO10*), a gene encoding a putative calcium-activated chloride channel, in three European ARCA families (Vermeer S. et al. Am J Hum Genet 87, 813-819, 2010). To clarify whether *ANO10* mutations are also present in Japanese patients, we screened this gene in our families with ARCA. Based on clinical features of European ANO10 patients, 4 patients from different families were identified as candidates among our cohort of 225 families with adult onset ataxias of unknown cause. Mutation screening was performed by amplifying each of 15 exons with polymerase chain reaction (PCR) followed by direct nucleotide sequencing. We found a novel, homozygous single-nucleotide deletion in exon 6, resulting in frameshift and premature translation stop, in one patient. The same mutation was not seen in 50 control subjects. Clinical features of this patient were late-onset cerebellar ataxia with gaze-evoked nystagmus and exaggerated tendon reflexes. The remaining three patients were negative with *ANO10* mutation despite that their clinical phenotypes are indistinguishable from those of the patient with mutation. We conclude that mutations in *ANO10* are also seen in Japanese, and should be screened in patients with late onset cerebellar ataxia with hyper-reflexes and nystagmus.

A Genome-wide Expression Profiling to unravel effect of missense mutations in SCA28 patients. *C. Mancini[1], P. Roncaglia[3], N. Lo Buono[1], A. Brussino[1], C. Cagnoli[1], F. Maltecca[7,8], H. Krmac[4], T. Limongi[6], G. Stevanin[5], S. Forlani[5], G. Casari[7,8], A. Funaro[1], A. Durr[5], N. Migone[1,2], S. Gustincich[4], A. Brusco[1,2].* 1) Department of Genetics, Biology and Biochemistry, University of Torino, Italy; 2) SCDU Medical Genetics, S.Giovanni Battista Hospital, Torino, Italy; 3) European Bioinformatics Institute, Cambridge, United Kingdom; 4) Neurobiology Sector, SISSA/ISAS, Trieste, Italy; 5) CRICM, UPMC/Inserm UMR_S 975, CNRS UMR 7225 GHU Pitié-Salpêtrière, Paris, France; 6) Italian Institute of Technology (IIT), Genova, Italy; 7) Human Molecular Genetics Unit, Center for Genomics, Bioinformatics, and Biostatistics, Milano, Italy; 8) San Raffaele University, 20132 Milano, Italy.

SCA28 is an autosomal dominant ataxia associated with oculomotor anomalies, due to *AFG3L2* gene missense mutations. The encoded protein is a member of the mitochondrial m-AAA protease (ATPases Associated with a variety of cellular Activities), and forms an hexameric complex in the Inner Mitochondrial Membrane, which exerts proteolytic activity and protein quality surveillance functions. We performed a whole genome expression profiling (based on Affymetrix Human Genome U133A 2.0 Chip Array) using lymphoblastoid cell lines (LCLs) from four SCA28 patients (mutations p.T654I, p.M666V, p. M666T and p.G671R), and six unrelated healthy controls matched for sex and age. We found 117 probes whose expression was statistically different, 60 of which up-regulated (Fold Change - FC = 1.5-16) and 57 down-regulated (FC = 0.7-0.1).The differentially expressed genes (n=88) were clustered, in five functional categories: (1) Cell Growth and Metabolism; (2) Apoptosis activation; (3) Oxidative Stress Response; (4) Cell Adhesion and Membrane Components; (5) Calcium Binding Proteins. To verify these pathways, we performed functional experiments on seven patients' LCLs which showed: 1) a delayed growth compared to controls ($p<0.005$), and an increased number of cells (> 15%) in G0/G1 phase ($p<0.001$); 2) an increased mortality of patients' cells due to apoptosis (AnnexinV/Propidium Iodide test) ($p<0.05$); 3) normal intracellular ROS levels in basal conditions (DCFH-DA test at FACS analysis). We also evaluated the respiratory chain activity in LCLs mitochondria, measuring ATP synthesis after treatment with specific respiratory chain blocking agents. No significant difference compared to controls was measurable, likely because an impairment in ATP production is absent or below detectable levels. We did not find mitochondrial DNA large deletions by long-range PCR. In conclusion, whole genome expression profiling in SCA28 LCLs allowed to identify several altered pathways that may be related to the disease. It is conceivable that the activation of the G1-S checkpoint and apoptosis is due to a cell cycle checkpoint surveyor responding to an abnormal cellular stress coming from the mitochondria. In more sensible cell types or tissues, such as Purkinje cells in cerebellum, this may result in a detectable alteration leading to the disease.

503W

Generation and characterization of transgenic rat models of spinocerebellar ataxia type 17 (SCA17). *H. Nguyen, A. Kelp, O. Rie) , P. Bauer.* Dept Med Gen, Univ Tuebingen, Tuebingen, Germany.

Spinocerebellar ataxia 17 (SCA17) is an autosomal-dominant, late-onset neurodegenerative disorder caused by CAG repeat expansions and consecutive polyglutamine (polyQ) expansions in the TATA-box-binding protein (TBP), an ubiquitously expressed transcription factor. To further investigate this devastating disease, we generated a transgenic rat model of SCA17, which carries a full human cDNA fragment of the TBP gene with 64 CAG repeats under the control of the murine prion protein promoter (PrP-TBP64Q). We obtained ten founders and were able to establish five lines with transmission of the transgene. On the basis of the mRNA expression level and the protein level as well as the distribution of TBP in the different brain regions we chose one of these five lines (line 8.4) for further characterization. This line shows a strong expression of the mutant TBP protein in the cerebellum and a moderate expression in the olfactory bulb, brainstem and cortex. Transgenic SCA17 rats exhibited a progressive phenotype with significantly lower body weight, ataxia, motor dysfunction and premature death around 10 months of age. At this time point neuropathological changes, such as misshaped Purkinje cells and corkscrew like dendrites were observed in the cerebellum of heterozygous transgenic SCA17 rats compared to wildtype littermates. Our results indicate that this model will be a valuable tool for investigating pathogenesis and for preclinical trials.

A novel mouse model of spinocerebellar ataxia type 6 develops distinct Purkinje cell degeneration. *T. Unno[1], H. Mizusawa[1], K. Watase[2].* 1) Dept. of Neurology and Neurological Science,Tokyo Medical and Dental Univ. Grad. Sch. of Medicine, Bunkyoku, Japan; 2) Dept. of Center for Brain Integration Research, Tokyo Medical and Dental Univ. Grad. Sch. of Medicine.

Spinocerebellar ataxia type 6 (SCA6) is a dominantly inherited neurodegenerative disorder caused by small CAG repeat expansions within P/Q-type voltage-gated calcium channel ($Ca_v2.1$) gene (*CACNA1A*). *CACNA1A* undergoes alternative splicing such that one splice variant translates the polyglutamine tract from a CAG repeat tract residing in the last coding exon (exon47). The mutant allele produces the channel with an abnormally long polyglutamine tract (EXP-$Ca_v2.1$) and confers a toxic gain-of-function. For the elucidation of molecular pathways involved in SCA6 pathogenesis, it would be helpful to dissect the mammalian models that develop cerebellar Purkinje cell (PC) degeneration mirroring that seen in the disease. In an effort to engender such animals by enhancing the expression of mutant channels, here we created two novel knockin mouse models of SCA6 (named as Sca6-MPI-11Q and Sca6-MPI-118Q) carrying a splice-site mutation so that only the MPI-type splicing occurs from the exon47 locus. The animals were designed to express humanized MPI channels with either 11 or 118 polyglutamine tract. Immunoblot analysis using cerebellar extracts confirmed that these mice indeed expressed humanized $Ca_v2.1$ channel protein. Homozygous SCA6-MPI-118Q developed gait ataxia as early as 6 weeks of age while homozygous SCA6-MPI-11Q mice were indistinguishable from their wild-type littermates even at 1 year of age. Neuropathological examination of the cerebella of 6-week-old homozygous SCA6-MPI-118Q mice revealed that mutant PCs developed cytoplasmic inclusions concomitant with marked neuritic changes such as reduced dendritic arborization and axonal swelling. Many of these PCs were found to have irregularly shaped nuclei. The number of remaining PCs progressively declined as the SCA6-MPI-118Q mice aged. Interestingly, the cytoplasmic inclusions mostly co-localized with a couple of lysosome marker proteins such as cathepsin B and D. These results suggested that homozygous Sca6-MPI-118Q mice developed distinct PC degeneration and faithfully reproduced many features of SCA6. Lysosome may play a role in the inclusion formation in SCA6.

Genotype-Phenotype correlations in Spastic Paraplegia type 7. *K.L.I. van Gassen[1], C. van der Heijden[1,2], E.J. Kamsteeg[1], H. Scheffer[1], B.P. van de Warrenburg[2].* 1) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 2) Department of Neurology, Donders Institute for Brain, Cognition, and Behavior (Centre for Neuroscience), Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Spastic Paraplegia type 7 (SPG7) is an autosomal recessive neurodegenerative disorder mainly characterized by a progressive bilateral lower limb spasticity. Complex features, often of cerebellar origin, may also be observed. Many different *SPG7* mutations have been observed, but no genotype-phenotype correlations have been found so far. From a total of more than 700 patients referred for SPG7 testing, we identified 60 patients with mutations in the *SPG7* gene. We identified 13 previously unreported mutations and detected a high recurrence rate of several earlier reported mutations. Since the phenotype of SPG7 is quite variable we here investigated a possible genotype-phenotype correlation.

We were able to collect detailed clinical data of 48 patients. Patients were ranked based upon age at disease onset, pure vs. complex phenotype, ataxia vs. no ataxia and missense vs. NUL-mutations, the latter defined as at least one allele that presumably does not lead to a protein product. A generally complex phenotypic presentation occurred in 65% of all patients and was associated with a younger age of onset (p=0.065). Ataxia was observed in 53% of all patients. We found that NUL-mutations were significantly ($p<0.05$) associated with the co-occurrence of cerebellar ataxia, which was independent from age at disease onset. The c.1409G>A (p.Arg470Gln) mutation, which was found homozygously in two sibs, was associated with a specific complex phenotype that included optical nerve atrophy.

In this large Dutch SPG7 cohort, we have identified the first genotype-phenotype correlation by observing a significant association between the cerebellar phenotype of SPG7 and *SPG7* NUL-alleles. There is thus an overlapping phenotypic presentation with its biological counterpart *AFG3L2*, which when mutated causes spinocerebellar ataxia type 28, possibly suggesting that abnormal levels of the SPG7 protein impact the function of the mitochondrial AAA-protease complex in the cerebellum. In addition, a missense mutation in exon 10 resulted in concomitant optical nerve atrophy, which suggests deleterious interactions of this *SPG7* gene variant with its substrate *OPA1*, the mutated gene product in optic atrophy type 1. Functional studies are required to investigate these interactions.

506W

A novel Ataxin-7 variant associated with slurred speech, clumsiness, learning difficulties, pes cavus and ataxia. *J. Warner[1], J. Pagan[1], D. FitzPatrick[1], M. Porteous[1], A. Diamond[1], P. Kennedy[3], D. Wilcox[2].* 1) S.E Scotland Gen Service, Western Gen Hosp, Edinburgh, United Kingdom; 2) Medical Genetics, Duncan Guthrie Institute of Medical Genetics, Yorkhill Hospital, Glasgow, United Kingdom; 3) Institute of Neurological Sciences, Southern General Hospital, Glasgow, United Kingdom.

We describe a three generation family with ataxia, dysarthria, dyspraxia and learning difficulties. The male proband presented with slowly progressive slurred speech, deteriorating memory, marked cerebellar signs and pes cavus (onset age 7). Genetic testing of the dominant cerebellar ataxia genes was requested. Screening of the SCA1, SCA2, SCA3, SCA6 and FRDA genes failed to reveal any pathogenic expanded repeats. PCR amplification using primers flanking the ataxin-7 CAG repeat gave one apparently normal repeat size in combination with a smaller product than any previously described repeat. Sanger dideoxy sequencing identified the variant c.110_139del; p.Glu37_Glu46del (accession number NM_000333.3). This in phase deletion ablates the first poly proline stretch of the ataxin-7 SH3 domain. An SH3P12 gene product has been shown to colocalise with Ataxin-7 in brain. The likely pathogenic variant is present in the proband's mother and sister who both have similar symptoms and signs. We present detailed clinical descriptions including MRI of affected family members. Further in vitro studies of this variant may throw light on ataxin 7 function.

507W

Non-AUG initiated homopolymeric proteins in microsatellite expansion disorders. *T. Zu[1], N. Doty[1], B. Gibbens[2], M. Swanson[1], L. Ranum[1].* 1) Dept Mol Genet & Microb, Univ Florida, Gainesville, FL; 2) Univ Minnesota.

For a group of neurological diseases caused by microsatellite expansions, mutations within or outside of predicted coding or non-coding regions are thought to cause disease by protein gain-of-function, protein loss-of-function or RNA gain-of-function mechanisms. In the absence of AUG or other known alternative start codons, we discovered that the canonical rules of translation do not apply for CAG•CTG expansions and that CAG and CTG trinucleotide repeats express homopolymeric expansion proteins in all three frames. This Repeat-Associated Non-AUG (RAN) translation occurs in mammalian tissue culture and in lentiviral-vector transduced cells and tissues. We now demonstrate that RAN-translation can occur across a variety of disease-causing microsatellite expansion motifs including CAG, CTG and CCTG, and that the hairpin structures are required. Additionally, we show non-AUG transcripts are associated with polyribosomal fractions and that RAN-translation occurs without frameshifing or RNA editing. RAN-translation results in the accumulation of polyGln, polyAla and polySer in HEK293T and neuronal N2a and T98 cells but not in several cell-free translation systems. These results suggest that specific cellular factors increase this novel type of translation initiation. Mass spectrometry of RAN-translated polyAla protein identified homopolymeric peptides with N-terminal alanine or N-terminal-acetylated alanine. Additionally, we show that RAN translation across human spinocerebellar ataxia type 8 (SCA8) and myotonic dystrophy type 1 (DM1) CAG-expansion transcripts results in the accumulation of SCA8 polyAla and DM1 polyGln expansion proteins in multiple organ systems in affected patients and mice. More specifically, the SCA8-Ala protein has been detected in the Purkinje cell soma and dendrites in SCA8 human and mouse and the DM1 CAG-polyGln protein is found in skeletal muscle and cardiomyocytes in affected human and DM1 mouse tissue. Infiltrating apoptotic (caspase-8 positive) leukocytes have been identified in thromboses within mouse cardiac tissue suggesting polyGln toxicity in DM1 cells. Understanding the mechanisms underlying RAN-translation has the potential to dramatically change ideas about the complexity of the proteome and how perturbations at this novel level impact biology and disease.

508W

A SNAP25 promoter variant is associated with schizophrenia and a disturbed SNAP25b/SNAP25a expression ratio in patients. *A. Dumaine[1,2,3], A. Meary[1,2,3,4], P.M. Llorca[3,5], C. Lancon[3,6], F. Schurhoff[1,2,3,4], A. Szoke[1,2,3,4], M. Leboyer[1,2,3,4], S. Jamain[1,2,3].* 1) Psychiatrie Génétique, Inserm U955, CRETEIL, France; 2) Université Paris Est, Faculté de Médecine, UMR-S 955, Créteil, 94000, France; 3) Fondation FondaMental, Créteil, 94000, France; 4) AP-HP, GHU (Chenevier-Mondor), Pôle de Psychiatrie, Créteil, 94000, France; 5) CHU Clermont-Ferrand, Hopital Gabriel Montpied, Service de Psychiatrie, Clermont Ferrand, 63000, France; 6) AP-HM, Hopital Sainte Marguerite, Service de Psychiatrie, Marseille, 13000, Marseille.

There is compelling evidence in favor of a common genetic vulnerability to schizophrenia and bipolar disorder. In a recent study, we identified one variation in the promoter region of the gene encoding the synaptosomal associated protein SNAP25, which was significantly more frequent in patients with an early-onset form of bipolar disorder as compared with healthy controls. This variation was also associated with an increased level in prefrontal cortex of SNAP25b, the major isoform of SNAP25 in adulthood. SNAP25 is a presynaptic plasma membrane protein essential for the triggering of vesicular fusion and neurotransmitter release and for which altered protein levels have been already reported in patients with schizophrenia. In the current study, we genotyped this promoter variant of SNAP25 in a sample of 288 schizophrenic patients consecutively admitted in three French university-affiliated psychiatry departments and 137 unaffected controls, with no personal or family history of axis I psychiatric disorders. In addition, we analyzed the expression level of the two SNAP25 isoforms in the dorsolateral prefrontal cortex of 33 schizophrenic patients and 30 controls from the Array Collection of the Stanley Medical Research Institute. We showed that this bipolar disorder-associated variation was more frequent in patients with schizophrenia as compared with controls (p=0.0009). Although no difference in expression level was observed neither for SNAP25a nor for SNAP25b between patients with schizophrenia and controls, we found a significant difference for the ratio SNAP25b/SNAP25a between genotype categories in patients (p=0.04). The `AA' genotype carriers had a lower ratio than the `AC' and `CC' genotypes carriers. We found similar results using ANOVA with Postmortem interval, Refrigerator Interval, Brain pH and Sex as covariates. This association was not found in controls. Our results suggest that a variation in SNAP25 might be a common vulnerability factor to schizophrenia and bipolar disorder. Moreover, the SNAP25b/SNAP25a ratio is crucial during brain development and switch at puberty, a high-risk period for schizophrenia onset, with SNAP25b becoming the major isoform. According to our results, we thus assume that this switch might be impaired by the promoter variant of SNAP25, increasing the vulnerability to schizophrenia.

509W

Evaluating the NLGN3 gene alternative splicing pattern and its potential role in autism. *Z. Talebizadeh, R. Aldenderfer.* Dept Pediatrics, Children's Mercy Hosp, Kansas City, MO.

An increased prevalence of autism in males suggests a role for the X chromosome. Evaluating X chromosome inactivation (XCI) in autistic females has been recommended by us and other groups. Despite some interesting hypotheses (e.g., imprinting and epigenetic mechanisms), it is not yet clearly understood if and how XCI might be important to understanding the mechanism of autism. One way to tackle this important topic is to assess if autistic females with X-inactivation skewness (XIS) have a unique genomic profile. Exploring such a question first requires knowing how this gene regulatory process is connected with other genomic processes. X chromosome inactivation is a DNA methylation process. Previously we have shown the trend of a higher degree of XIS in autistic females compared to non-autistic females. We also reported on the potential role of aberrant alternative splicing in X-linked neuroligin genes in autism. More recent findings have shown a cross link between DNA methylation and alternative splicing. These lines of evidence prompted us to systematically evaluate alternative splicing of NLGN3 in relation to autistic females' XCI status. We evaluated the expression level of multiple alternative splicing transcripts for NLGN3, an X-linked autism gene, in autistic females with and without XIS. Subjects were ascertained from the Autism Genetics Resource Exchange (AGRE). XCI status was determined using blood-derived genomic DNA. TaqMan gene expression experiments for multiple NLGN3 splice variants were conducted using RNA from AGRE lymphoblastoid cell lines. In addition to the two known NLGN3 variants, we identified three novel splice variants for this gene. A distinct, statistically significant pattern was detected in the expression level of examined alternatively spliced NLGN3 isoforms for autistic females with XIS compared to those without XIS and controls. This is the first study to evaluate the expression level of NLGN3 at the alternative splicing level taking into consideration the X-inactivation status of autistic females. Our study indicates that NLGN3 undergoes complex splicing resulting in multiple splice variants. Furthermore, our expression data demonstrates that autistic females with XIS may represent a more homogeneous subset of this highly heterogeneous population. Applying such a stratification method may provide a way to better understand underlying genetic and epigenetic mechanism in autism.

GJB2 (Connexin26) is associated with age-related hearing impairment in humans and mice. *C-C. Wu[1,2], J-H. Hwang[3,4], Y-C. Lu[1], Y-H. Lin[1], P-J. Chen[3], W-S. Yang[2,3], M-F. Chen[5], I-S. Yu[6], S-W. Lin[6], H-C. Lin[7], C-C. Kuo[7], Q. Chang[8], X. Lin[8], Y-L. Lee[9,10], T-C. Liu[1], C-J. Hsu[1].* 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institute of Clinical Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Otolaryngology, Buddhist Dalin Tzu-Chi General Hospital, Chiayi, Taiwan; 5) Health Management Center, National Taiwan University Hospital, Taipei, Taiwan; 6) Transgenic Mouse Models Core (TMMC), Division of Genomic Medicine, Research Center For Medical Excellence, National Taiwan University, Taipei, Taiwan; 7) Department of Physiology, National Taiwan University College of Medicine, Taipei, Taiwan; 8) Department of Otolaryngology, Emory University School of Medicine, Atlanta, GA, USA; 9) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 10) Research Center for Genes, Environment and Human Health, College of Public Health, National Taiwan University, Taipei, Taiwan.

Age-related hearing impairment (ARHI), the most common form of hearing impairment in humans, is a complex disease caused by an interaction between environmental and genetic factors. It has been postulated that genes leading to monogenic hearing impairment might also be susceptibility genes for ARHI. The purpose of this study is to investigate the association between ARHI and variant alleles of GJB2, of which the mutations are the most important cause of monogenic hearing impairment worldwide. A total of 1481 volunteers (all were Han Chinese, aged 40 to 80 y) were included in the clinical analyses, and their audiological phenotypes were determined according to the Zlow, Z4-tone and Zhigh scores converted from their original frequency-specific hearing thresholds. Seven sequence variants in the coding region of GJB2, including c.79G>A, c.109G>A, c.235delC, c.299_300delAT, c.341A>G, c.368C>A and c.608T>C, were genotyped and then correlated to the audiological phenotypes under the assumption of various inheritance models. We identified an association between GJB2 variant alleles and ARHI in the clinical cohort, with the strongest association between the c.109G>A allele and ARHI under the assumption of the co-dominant model ($p<0.001$, for Zlow, Z4-tone and Zhigh). The pathogenetic effects were then confirmed in a knock-in mouse model segregating the c.109G>A variant: mice homozygous for c.109G>A (Gjb2tm1Dontuh/tm1Dontuh mice) developed pre-senile hearing deterioration, revealed compromised gap-junction-mediated metabolite transfer in the inner ear sensory epithelium, and appeared more vulnerable to noise exposure. The association between GJB2 and ARHI supports the hypotheses that genes responsible for monogenic hearing impairment and genes regulating the potassium homeostasis in the inner ear might contribute to ARHI.

Microarray technology and GhostMiner software in modelling genetic risk factors of neurometabolic disturbance in patients with Parkinson's disease. *M. Bodzioch[1], K. Lapicka-Bodzioch[1], J. Slawek[3,4], A. Roszmann[3,4], M. Rudzinska[2], A. Szczudlik[2], A. Slowik[1].* 1) Dep. of Neurogenetics, Jagiellonian University Medical College, Krakow, Poland; 2) Chair of Neurology, Jagiellonian University Medical College, Krakow, Poland; 3) Department of Neurology, St. Adalbert Hospital, Gdansk, Krakow, Poland; 4) Department of Neurological and Psychiatric Nursing, Medical University of Gdansk, Gdansk, Poland.

Introduction: Parkinson's disease (PD) is a mutlifactorial disease with a plentitude of genetic and environmental determinants. Most studies have focused on a limited number of genetic variants and only developed simple risk models.

Goals: To genotype multiple variants in genes involved in neurometabolism and to develop complex models of susceptibility to PD.

Materials and methods: Using the OpenArray technology, we genotyped 128 single nucleotide polymorphisms (SNP) in genes involved in neural signalling and neurometabolim, including those encoding neuroprotective humanin peptides, in 190 PD patients and 196 healthy controls (including 44 sib pairs). The genotype data were analyzed with the GhostMiner software package.

Results: The decision tree algorithm with a separability of split value method was used to create a precise statistical model, differentiating with a very high accuracy (accuracy coefficient = 0,974) the affected and non-affected. The model comprises 57 logical rules, which enable correct classification of nearly all study participants into the PD group (26 rules) and healthy controls (31 rules). The highest differentiating value was attributed to genetic variants in humanin receptors - FPR1 and FPR3, genes involved in neurotransmission - COMT, HTR3A, HTR1B, ALDH5A1 and DRD1, as well as mediators of lipid metabolism - NIPSNAP3A and ABCA1. Sex and neurodegeneration-associated genes, LRRK1 and MAPT, were also important.

Conclusions: Bioinformatic analyses of data sets including multiple gene variants result in more complex but also more precise genetic risk models of susceptibility to PD.

Supported by the N R13 0038 04 grant from the Polish Ministry of Science and Higher Education.

Pathway analysis approach for interpreting nicotine dependence GWAS. *O. Harari, J.C. Wang, L.J. Bierut, P.A.F. Madden, A.M. Goate, NAG and SAGE collaborators.* Department of Psychiatry,Washington University School of Medicine, St Louis, MO.

The identification of the genetic architectures of complex traits, such as Nicotine Dependence, requires the analysis of multiple genetic risk factors [1]. Gene Ontology (GO) analysis exploits the concept that susceptibility alleles for a trait are distributed among sets of genes that share in common biological characteristics [2]. This approach allows us to examine thousands of putative signals conferring small risk, complementing standard analysis of the top most significant findings [1]. We analyzed two Genome-wide association studies (GWAS): the Study of Addiction: Genetics and Environment (SAGE) consisting of 1,294 cases (Fagerström Test for Nicotine Dependence score⁄ 4) and 2,071 controls [3]; and the Australian twin-family study (OZ-GWAS) which includes 1,935 and 2,262 nicotine dependent and non-dependent subjects respectively [4]. We evaluated the cigarettes per day phenotype GWAS signals by employing the gene overrepresentation method [2] and selected those terms that resulted significant for both studies. We considered both the genotyped SNPs and the imputed ones, to circumvent the different genotyping platforms employed in each study (i.e. Illumina 370K chip for the majority of the samples for OZ-GWAS and Illumina 1M chip for SAGE). Also, we estimated the statistical significance of the identified terms by the gene set enrichment analysis method [1]. We found significant several GO terms (GO:0015464, GO:0007271, GO:0005892, GO:0035095, GO:0042166, and GO:0004889) that group cholinergic receptors. Importantly, these terms were also statistically significant for the Atherosclerosis Risk in Communities GWAS (7221 subjects). Additionally, we found other terms significant for the 3 studies (GO:0007606, GO:0007608, and GO:0004984) that group genes involved in the sensory perception of chemical stimulus.

Transplantation of P75 down-regulated rat bone marrow stromal cells promotes functional behavior in a rat model of spinal cord injury. *Z. Hajebrahimi[1,2], H. Edalat[2], M. Tavallaei[3], M. Movahedin[4], S. Amiri[2], S.J. Mowla[2].* 1) Department of physiology, Aerospace Research Institute, Tehran, Iran; 2) Department of Molecular Genetics, School of Biological Sciences, Tarbiat Modares University, Tehran, Iran; 3) Molecular Biology Research Center, Baqiyatallah Medical Sciences University, Tehran, Iran; 4) Department of Anatomy, School of Medical Sciences, Tarbiat Modares University, Tehran, Iran.

It is hoped that stem cells will provide an inexhaustible source of neurons for therapies aimed at cell replacement or neuroprotection in disorders affecting the brain and spinal cord. Bone marrow stromal cells (BMSCs) which are capable of differentiating into neural cells, has been employed for cell and gene therapy of neurodegenerative diseases, including spinal cord injury (SCI). One of the main difficulties of cell transplantation into central nervous system (CNS) is the high proportion of cell death specifically after neural differentiation. P75 receptor, known as the death receptor, has been shown to cause apoptosis of neural cells after binding to neurotrophines. Our previous data revealed a significant reduction of apoptosis in engineered neural-like cells derived from BMSCs after inhibition of p75 expression by siRNA approach. Thus, here we have examined whether p75-siRNA expressing rat BMSCs (rBMSCs) are able to survive at the site of implant, and if they can improve functional behavior after grafting into lesion site of spinal cord injured rats. Our findings demonstrate that p75 siRNA expressing rBMSCs (labled with fluorescent carbocyanine dye DiI) could effectively integrate into host tissue and survive in injured rat spinal cord for at least 4 weeks. Additionally, functional recovery was obviously observed in these genetically modified rBMSC treated SCI animals, compared with control (intact rBMSCs) and untreated ones. Thus, rBMSCs that endogenously express p75 siRNA could be a good candidate for treatment of SCI.

Genetic factors associated with the predisposition to late onset Alzheimer disase. *A. Alpman Durmaz[1], E. Kumral[2], B. Durmaz[1], H. Onay[1], F. Ozkinay[1], O. Cogulu[1], S. Pehlivan[3], M. Orman[4], C. Ozkinay[1].* 1) Deparment of Medical Genetics, Ege University, Izmir, Turkey; 2) Department of Neurology, Ege University, Izmir, Turkey; 3) Department of Biology, Gaziantep University, Gaziantep, Turkey; 4) Department of Biostatistics and Medical Informatics, Ege University, Izmir, Turkey.

Alzheimer disease is a progressive, irreversible neurodegenerative disorder characterized by loss of memory and cognitive skills with an incidence of 6-8% between the ages of 70-85. More than 90% of cases are sporadic and have later age of onset. Many studies have shown a genetic predisposition for late onset Alzheimer disease (LOAD). The most studied genetic factor that has been found to be associated with LOAD is apolipoprotein E gene besides other susceptibility genes involved in vascular pathologies, homocysteine metabolism, and neuronal growth and differantiation such as methylenetetrahydrofolate reductase (MTHFR), angiotensin-converting enzyme (ACE), APOB and brain derived neurotrophic factor (BDNF). In this study Factor V Leiden (G1691A) and H1299R, prothrombin G20210A, Factor XIII V34L, B-fibrinogen -455G>A, PAI-1 5G/4G, HPA1 b/a, MTHFR C677T, MTHFR A1298C, APOE, ACE I/D, BDNF C270T and G196A polimorphisms were evaluated in 100 LOAD patients and 100 age matched healthy controls. Factor V Leiden A allele, APOE4 allele, MTHFR CC (A1298C) and BDNF TT (C270T) genotypes were significantly higher in LOAD patients compared to the control group (p=0.05, p<0.001, p=0.04 , p=0.03, respectively). There were no significant associations between other genotypes and allel frequencies. Mini-Mental State Examination (MMSE) scores and age at onset of the patients were also evaluated for each and combined genotypes. Age at onset was significantly lowered by about approximately 4 and 5 years in patients carrying BDNF TT (C270T) and MTHFR TT (C677T) genotypes, respectively. As a conclusion Factor V, APOE, MTHFR and BDNF genes may be associated with LOAD and BDNF and MTHFR alleles may play a in the age at onset of the LOAD.

Genome-wide association analysis of age-at-onset in Alzheimer's disease. *M.M. Barmada[1], F.Y. Demirci[1], R.L. Minster[1], M.M. Carrasquillo[2], V.S. Pankratz[2], S.G. Younkin[2], A.J. Saykin[3,4], R.A. Sweet[5,6], E. Feingold[1], S.T. DeKosky[7], O.L. Lopez[6], M.I. Kamboh[1].* 1) Human Genetics, GSPH, Univ Pittsburgh, Pittsburgh, PA; 2) Neuroscience, Mayo Clinic College of Medicine, Jacksonville, FL; 3) Radiology and Imaging Sciences, SOM, Indiana Univ, Indianapolis, IN; 4) Medical and Molecular Genetics, SOM, Indiana Univ, Indianapolis, IN; 5) Psychiatry, SOM, Univ Pittsburgh, Pittsburgh, PA; 6) Neurology, SOM, Univ Pittsburgh, Pittsburgh, PA; 7) Neurology, SOM, Univ Virginia, Charlottesville, VA.

The risk of Alzheimer's disease (AD) is strongly determined by genetic factors and recent genome-wide association studies (GWAS) have identified several disease susceptibility loci and genes. In addition to the disease risk, age-at-onset (AAO) of AD has also strong genetic component with an estimated heritability of 42%. Identification of genes that influence the AAO of AD may help to understand the biological mechanisms that regulate the onset of the disease. Here we report the results of a GWAS focused on identifying genes for the AAO of AD. We performed a 3-stage analysis on a total of 2,222 AD cases. As expected, the most significant associations were observed in the *APOE* region on chromosome 19 where several SNPs surpassed the conservative genome-wide significant threshold (*P*<6.22E-08). The most significant SNP outside the *APOE* region was located in a gene on chromosome 4q31 (*P*= 4.95E-07) and there were 17 additional significant SNPs in this region at *P*<1E-04. The associated gene is expressed in the cerebral cortex and thus is a strong potential candidate for affecting the AAO in AD. Confirmation in additional well-powered samples will be necessary in order to establish these findings.

Autosomal dominant leukodystrophy (ADLD) is a slowly progressive demyelinating disease, with onset in the 4th to 6th decade of life. It is characterized by autonomic dysregulation, pyramidal signs, cerebellar dysfunctions, and symmetrical primary myelin loss in the central nervous system. Duplication of the lamin B1 gene (*LMNB1*) has been implicated as the cause of disease. Eleven ADLD families of different ethnic origins have been published so far, but the duplication breakpoint has been characterized at the nucleotide level in only three. Here, we characterize the *LMNB1* duplication in eight patients with ADLD originating from Italy (n=3), France (n=3), Brasil (n=1) and North America (n=1). A custom array-CGH allowed us to define the extent of the duplications, which ranged from 128 to 474 Kb. Seven duplications were unique, proving their origin from separate mutational events. Two French families, coming from the same geographic region, shared the same duplication, and are therefore likely to have a common ancestor. The largest duplication boundaries extend centromerically up to *GRAMD3* (also involving *ALDH7A1* and *PHAX*), and telomerically up to *MARCH3*. Using long-range PCR and sequencing, the duplication breakpoints were characterized in six patients; a microhomology region was found in two, an insertion in two, and a microduplication in one, suggesting microhomology-mediated, break-induced replication (MMBIR) as a possible mechanism of origin. We studied the expression of the *LMNB1* alleles using a primer extension assay of the SNP rs1051644 in the 3'UTR (c.*239C>T); lymphoblastoid cell lines of three different patients showed a 2:1 ratio of the duplicated allele vs. the non-duplicated allele on both genomic DNA and cDNA. This proves that the duplication increases *LMNB1* expression by only 50%, whereas published real-time PCR data show several fold increases in *LMNB1* expression. In cell models, lamin B1 overexpression alters the transcription of many genes, and we suggest this may affect the real-time experimental results. In summary, we define seven novel *LMNB1* duplications in ADLD patients. Expression analysis experiments using primer extension suggest that in lamin B1 duplication carriers the gene and protein levels are increased approximately 50%. Quantification of the LINE-1 copy number in postmortem brains of psychiatric disorder patients. *M. Bundo[1], T. Miyauchi[2], A. Komori-Kokubo[2], K. Kasai[3], T. Kato[2], K. Iwamoto[1].* 1) Dept. of Molecular Psychiatry, Grad. Sch. Med., Univ. Tokyo, Tokyo, Japan; 2) Lab. for Molecular Dynamics of Mental Disorders, RIKEN BSI, Wako, Japan; 3) Dept. of Neuropsychiatry, Grad. Sch. Med., Univ. Tokyo, Tokyo, Japan.

Some retrotransposons have the activity of moving through the genome, resulting in the generation of variations in the human genome. Recently, it has been shown that one of the well-characterized retrotranposons, the LINE-1 (long interspersed nuclear element 1), possess the retrotranspose activity in neural progenitor cells. Interestingly, copy number of the LINE-1 was higher in brains compared with other tissues, and that it was differed among brain sub-regions. These findings implicate that aberrant LINE-1 activity might be associated with the pathophysiology of psychiatric diseases such as schizophrenia. Here, we quantified the copy number of the LINE-1 in genomic DNA derived from postmortem livers and brains of patients with psychiatric diseases. Postmortem samples were obtained from the Stanley Medical Research Institute. Samples consist of 15 schizophrenia, 15 bipolar disorder, 15 major depression and 15 controls. Copy number of the LINE-1 was determined by realtime PCR method, according to the previous report (Coufal et al, Nature 2009). There were significant increases in brain LINE-1 content in the ORF2 probes in schizophrenia, but not differed in the 5' UTR probe. These results indicate that the increased insertion of the incomplete reverse-transcribed LINE-1 in schizophrenia. Confounding factors such as age, gender, postmortem interval, and sample pH did not affect the LINE-1 content in brains. These results suggest that aberrant retrotranposon activity in the neural progenitor cells may be associated with the pathophysiology of schizophrenia.

A novel putatively autism-associated adenosine A3 receptor (A3AR) variant causes dysregulation of and altered physical association with the serotonin transporter. *N. Campbell, C.-B. Zhu, K. Lindler, R.D. Blakely, J.S. Sutcliffe.* Center for Molecular Neuroscience, Vanderbilt Univ, Nashville, TN.

Autism is a neuropsychiatric disorder expressed across a spectrum of abnormalities that includes deficits in social interactions and development of language, along with patterns of rigid-compulsive behaviors. Autism spectrum disorders (ASDs) affect approximately 1 in 110 individuals, with studies pointing to a highly complex genetic etiology. Recent discoveries have highlighted the importance of rare genetic variation that cause or confer susceptibility for ASDs, and that multiple loci within particular gene networks can have coding or structural variants. The serotonin network is one strongly implicated in autism, and rare autism-associated variants in the serotonin transporter (SERT) lead to increased activity and dysregulation. Therefore, we hypothesized that SERT regulatory proteins will harbor rare genetic variation that alter SERT function consistent with previously seen mechanisms. We tested this hypothesis on the adenosine A3 receptor locus (ADORA3). The adenosine A3 receptor (A3AR) is an attractive target as it has been show to be active in 5-HT clearance and has a role in modulating SERT activity. Initial reporting from sequencing ADORA3 exons in autism probands revealed carriers of an undocumented and functional variant (Leu-90Val) leading to increased SERT activity. He we report a second variant (Val171Ile) identified in cases (3/184) and not seen in controls (0/305). This nonsynonymous change affects a highly conserved position in the protein and is predicted to be damaging. To address this variant functionally, we co-expressed the variant (3AR with SERT in CHO cells and found SERT stimulation (i.e. 5HT uptake) to be unresponsive with a selective A3AR agonist (IB-MECA). In this report, we further demonstrate a modest overall excess of rare nonsynonymous variants in the ADORA3 gene in ASD cases vs controls; the physical association between Val171Ile-A3AR and SERT to be decreased; and a lower SERT surface expression upon IB-MECA stimulation of Val171Ile-A3AR. Here, we discuss our latest findings on the significance of this A3AR variant and its consequences for disruption of 5-HT homeostasis.

The use of aripiprazole in the management of schizophrenia associated with 22q11.2 deletion syndrome. *E. Chow[1,2,3], A.S. Bassett[2,3].* 1) Clinical Genetics Service, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 2) Clinical Genetics Research Program, Ctr Addiction & Mental Hlth, Toronto, ON, Canada; 3) University of Toronto, ON, Canada.

Aripiprazole is an atypical antipsychotic medication that works as a partial dopamine agonist. It has been shown to be as effective against psychotic symptoms associated with general population schizophrenia as other atypical antipsychotic medications, with a response rate of about 75%. Unlike other atypical antipsychotic medications, it is not associated with significant weight gain or adverse metabolic effects. Aripiprazole has been approved for general use in Canada since the fall of 2009. 22q11.2 deletion syndrome (22q11DS) is the most common microdeletion syndrome in humans, and is associated with a 25% risk of developing schizophrenia in adulthood. We studied the use of aripiprazole in 5 patients with 22q11DS and schizophrenia, and compare their experiences to those in two patients with schizophrenia and other genetic or neurodevelopmental syndrome. In the 5 adult patients with 22q11DS (2 M, 3 F) and stable DSM-IV schizophrenia, their average age at time of initiation of aripiprazole was 29.4 years. The most common reason for starting aripiprazole was excessive weight gain or metabolic changes associated with the atypical antipsychotic medication(s) used previously. The median starting dose for aripiprazole was 5 mg daily, about half of the recommended starting dose. The median maximum daily dose reached was 25 mg, in the recommended therapeutic range. On average, the patients were treated with aripiprazole for 3.2 months, and an average weight loss of 2.9 kg occurred during treatment. However, 4 of the 5 patients decompensated into psychosis when switched to aripiprazole, requiring hospitalization and discontinuation of the medication. The remaining patient's psychotic symptoms were not affected by the use of aripiprazole. In contrast, in two other patients (one with Fragile X syndrome, one with a non-verbal learning disability syndrome) who also suffered from DSM-IV schizophrenia, both responded well to an average daily dose of 25 mg of aripiprazole, with complete resolution of psychotic symptoms, and remained on the medication after 18 months. Although the sample size is small, these preliminary data suggests that unlike other patients in the general population, and unlike patients with other genetic conditions, aripriprazole may not be an effective antipsychotic medication in patients with 22q11DS, even if its use is associated with less weight gain and less metabolic changes than other atypical antipsychotic medications.

Identification of Bipolar Disorder Genes by Exome Sequencing. *C. Cruceanu[1], R.G. Lafrenière[2], D. Spiegelman[2], P. Grof[3], M. Alda[4], G.A. Rouleau[2,5], G. Turecki[1].* 1) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Center of Excellence in Neuroscience of the Université de Montréal (CENUM), Montreal, Quebec, Canada; 3) Mood Disorders Centre of Ottawa, Ottawa, Ontario, Canada; 4) Department of Psychiatry, Dalhousie University, Halifax, Nova Scotia, Canada; 5) Centre de Recherche du Centre Hospitalier de l'Université de Montréal (CRCHUM), and Department of Medicine, University of Montreal, Montreal, Quebec, Canada.

Bipolar disorder (BD) is a complex psychiatric condition characterized by alternating manic and depressive episodes. In spite of the strong support for the role of genetics in BD, molecular studies have by-and-large had minimal success in identifying disease-causing genes. This is likely because of high levels of heterogeneity in the sample sets used, but the problem may be minimized by focusing on a well-defined sub-phenotype of BD. Our group has led efforts to characterize BD patients that respond positively to Lithium (Li) therapy, and shown that Li-response clusters in families and can predict symptom recurrence. Research in BD genetics to date has consisted of linkage and genome-wide association studies, which presume that common variants in a small subset of genes are the cause for BD. However, the minimal success in finding specific genes suggests that BD is caused by highly penetrant rare variants in a large number of different genes. Our research focuses on a well-defined clinical subtype of BD (Li-responsive) to minimize clinical heterogeneity, and we are using massively-parallel next-generation sequencing to resequence the exomes of over 200 affected individuals from multi-generational family units with Li-responsive BD. Focusing on the exome allows us to restrict our analysis to rare and potentially highly penetrant (e.g. protein-truncating or missense) variants across a large majority of genes. To identify relevant BD susceptibility genes we prioritized variants present in the affected and missing from the unaffected individuals within a family. Subsequently, we consolidated these findings across familial units, hoping to identify genes that contain an excess of rare, potentially deleterious mutations in BD cases. To validate candidate variants we used Sanger sequencing in our families as well as an extended sample set of non-familial Li-responsive BD cases. By focusing on highly penetrant rare variants, rather than common variants, we hope to have narrowed in on the key genes and biochemical pathways that play an important role in this disorder and can lead directly to clinically relevant diagnostic and therapeutic applications.

Genome-Wide Search for Pleiotropic Genetics Effects on Obesity and Brain Structure in Mexican American Individuals. *J.E. Curran[1], A.M. Winkler[2,3], R.L. Olvera[4], M.A. Carless[1], T.D. Dyer[1], J.W. Kent Jr.[1], P. Kochunov[5], M.C. Mahaney[1], A.G. Comuzzie[1], P.T. Fox[5], L. Almasy[1], R. Duggirala[1], D.C. Glahn[2,3], J. Blangero[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Olin Neuropsychiatry Research Center, Institute of Living, Hartford, CT; 3) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 4) Department of Psychiatry, University of Texas Health Science Center at San Antonio, San Antonio, TX; 5) Research Imaging Institute, University of Texas Health Science Center at San Antonio, San Antonio, TX.

Obesity is a common, chronic disorder reaching pandemic proportions worldwide and now represents an immediate major public health problem. Obese individuals are at a greater risk of decreased longevity and increased morbidity from various diseases including diabetes, coronary heart disease, stroke, hypertension, arthritis and some common forms of cancer. Given the role of the neural networks in satiety and appetite regulation, it is becoming clear that the brain plays a significant role in obesity. In this study, we performed the first genetic analyses searching for evidence of pleiotropy acting on both brain anatomy (obtained from MRI) and BMI in a large cohort of Mexican American individuals from large extended pedigrees. We identified multiple brain phenotypes that exhibit significant genetic correlation with BMI. Our most significant results show a highly significant overall genetic correlation ($p = 5.3\times10^{-4}$) between entorhinal cortex thickness and BMI. The entorhinal cortex is proximal to the hippocampus and is very closely related to hippocampal function, including memory function. Given this evidence for obligate genetic pleiotropy influencing these two phenotypes, we performed genome-wide bivariate association analysis using 932,000 SNPs to localize quantitative trait loci influencing these two phenotypes. Using this novel bivariate procedure (implemented in SOLAR), we localized two putative QTLs that cannot be found via standard univariate analyses, showing the power-increasing benefits of multivariate analysis. A locus in the region of 7q23 near the ataxin 7-like 1 gene was detected ($p = 3.4\times10^{-7}$) with a focal effect on entorhinal cortex. Ataxin-related genes have been previously implicated in neuronal function, hypophagia, and obesity which suggests that we have identified an interesting empirical candidate gene. A second putative locus was mapped to 14q11 near the *MAP45* gene ($p = 7.9\times10^{-7}$). The sentinel marker evidencing this QTL shows additional pleiotropic effects on major depression-related phenotypes (e.g., Beck depression inventory, $p = 0.0007$) which is interesting given the strong relationship between obesity and depression. Our results strongly support a role for the medial temporal lobe, which includes the hippocampus and entorhinal regions, in obesity and document, for the first time, that pleiotropic genetic effects help determine the brain/obesity relationship.

522W

Network analysis reveals functional convergence between genes involved in Alzheimer's disease and molecular targets of lithium. *S.D. Detera-Wadleigh, F.J. McMahon.* NIMH/NIH, Bethesda, MD 20892-3719.

Our previous analysis of biological networks generated by molecular targets of lithium showed a striking enrichment of apoptosis functional clusters and neurotrophin signaling (Gupta et al 2011), a possible functional signature for lithium's efficacy as a mood stabilizer. Inhibition of GSK3) is one of the best-documented responses to lithium. This effect has aroused interest in lithium as a potential therapeutic agent for Alzheimer's disease (AD). Since GSK3 seems to be important in the amyloid-tau cascade thought to play a role in AD pathogenesis, inhibition of GSK3 by lithium could slow the progression of disease processes leading to AD. Motivated by this idea, we explored evidence for a functional convergence between genes involved in AD and molecular targets of lithium. We performed separate network analysis on APP and presenilin 1 (PSEN1), two genes that have been shown to play a causative role in early-onset familial AD (EOFAD). We implemented 2 network tools, MiMI on Cytoscape (www.cytoscape.org) and STRING 8.3 (http://string-db.org/). Functional annotation to identify significantly enriched pathways and functional clusters was performed using DAVID (http://david.abcc.ncifcrf.gov/tool.jsp). We found that the most enriched functional cluster in both APP and PSEN1 gene networks was regulation of apoptosis/regulation of programmed cell death, reminiscent of the highly-enriched functional cluster generated by molecular targets of lithium. We extended this analysis to genes involved in late-onset AD (LOAD), including APOE and 11 genes well-supported by GWAS (e.g., Naj et al 2011; Hollingsworth et al. 2011; Wijsman et al. 2011). Functional annotation showed that the LOAD network recruited SH3 domain-containing molecules, complement activation, plasma lipoprotein particle remodeling, regulation of cholesterol transport, and positive regulation of apoptosis as the topmost enriched clusters. These results suggest that regulation of apoptosis is a functional link between EOFAD, LOAD, and molecular targets of lithium.

523W

Imprinted small nucleolar RNA in autism spectrum disorders. *A. Eran[1,2], K. Vatalaro[1], E.N. Brown[2], I.S. Kohane[2,3,4], L.M. Kunkel[1,4].* 1) Department of Genetics, Children's Hospital Boston, Boston, MA; 2) Health-Science and Technology, Massachusetts Institute of Technology, Cambridge, MA; 3) Department of Informatics, Children's Hospital Boston, Boston, MA; 4) Department of Pediatrics, Harvard Medical School, Boston, MA.

Autism Spectrum Disorders (ASDs) are highly heritable neurodevelopmental disorders of mostly idiopathic etiology. The most common cytogenetic abnormalities associated with ASD are duplications of the imprinted 15q11-13 locus. Two small nucleolar RNA (snoRNA) clusters are transcribed from the paternal allele, HBII-52 and HBII-85, both highly expressed in the brain. The precise function of these snoRNAs is unknown, but HBII-52s have been shown to regulate splicing and adenosine-to-inosine (A-to-I) RNA editing of the serotonin receptor HTR2C, a functional and positional candidate for ASD. For an initial examination of 15q snoRNAs in ASD and their impact on HTR2C editing, we used ultradeep (>5000x) sequencing to interrogate HBII-52 and HBII-85 snoRNAs from postmortem cerebella of 25 individuals with ASD and neurotypical controls. The 454 platform was used to sequence 57 of 71 known HBII snoRNAs, as well as HTR2C editing and splicing, in cases and controls. We report differential expression and sequence variation of HBII-52 and HBII-85 snoRNAs in individuals with ASD and neurotypical controls, as well as their correlation with HTR2C editing and splicing. This study represents a first large-scale characterization of these snoRNAs in human subjects. Our results suggest that snoRNA-mediated regulation of A-to-I editing may be part of the complex epigenetic basis of ASD.

Active and passive MDMA (`ecstasy') intake induces differential transcriptional changes in the mouse brain. *N. Fernàndez-Castillo[1,2,3], M.J. Orejarena[4], M. Ribasés[5,6], M. Casas[5,7], P. Robledo[4,8], R. Maldonado[4], B. Cormand[1,2,3].* 1) Genetics Department, University of Barcelona, Barcelona, Spain; 2) The Biomedical Network Research Centre on Rare Diseases (CIBERER), Barcelona, Spain; 3) Biomedicine Institute of the Universitat de Barcelona (IBUB), Spain; 4) Neuropharmacology lab, Department of Experimental Sciences and Health, University Pompeu Fabra, PRBB, Barcelona, Spain; 5) Department of Psychiatry, Hospital Universitari Vall d'Hebrón, Barcelona, Spain; 6) Psychiatric Genetics Unit, Vall d'Hebron Research Institute, Barcelona, Spain; 7) Department of Psychiatry and Legal Medicine, Universitat Autònoma de Barcelona, Spain; 8) Neuropsychopharmacology Program, IMIM (Hospital del Mar Research Institute), PRBB, Barcelona, Spain.

3,4-methylenedioxymethamphetamine (MDMA, “ecstasy”) is a recreational drug widely used by adolescents and young adults. Although its rewarding effects are well established, there is controversy on its addictive potential. We aimed to compare the consequences of active and passive MDMA administration on gene expression in the mouse brain since all previous studies were based on passive MDMA administration. We used a yoked-control operant intravenous self-administration paradigm combined with microarray technology. Transcriptomic profiles of ventral striatum, frontal cortex, dorsal raphe nucleus and hippocampus were analyzed in mice divided in contingent MDMA, yoked MDMA and yoked saline groups, and several changes were validated by qRT-PCR. The comparison of contingent MDMA and yoked MDMA versus yoked saline mice allowed identification of differential expression in several genes, most of them with immunological and inflammatory functions, but others being involved in neuroadaptation. Interestingly, the Lcn2 gene, coding for lipocalin2 that mediates astrocytosis under inflammatory conditions, was highly upregulated (between 30 and 60 times over the control expression) in all four brain regions in mice after contingent or yoked MDMA administration. In the comparison of contingent MDMA versus yoked MDMA intake, hippocampus and the dorsal raphe nucleus showed statistically significant changes. The altered expression of several genes involved in neuroadaptative changes and synapse function, which may be related to learning self-administration behaviour, could be validated in these two brain structures. In hippocampus, downregulation of the genes Bzrap1, Nlgn2 and Axin2 was identified in the contingent mice, and Camk2a, Kalrn, Egr-3 and Ddn were all upregulated in the dorsal raphe nucleus of contingent mice. In conclusion, our study shows a strong effect of MDMA administration on the expression of immunological and inflammatory genes in all the four brain regions studied. In addition, experiments on MDMA self-administration suggest that the dorsal raphe nucleus and hippocampus may be involved in active MDMA seeking behaviour, and show specific alterations on gene expression that support the addictive potential of this drug.

525W

Expression analysis in dental pulp stem cells of idiopathic autistic patients reveals alterations in important processes for neurogenesis. *K. Griesi-Oliveira[1], D.Y. Sunaga[1], L.A. Cruz[1], E. Vadasz[2], M.R. Passos-Bueno[1].* 1) Biosciences Institute - University of Sao Paulo, Sao Paulo, SP, Brazil; 2) Psychiatric Institute - School of Medicine - University of Sao Paulo, Sao Paulo, SP, Brazil.

The investigation of autism spectrum disorders (ASD) causes is hampered by the genetic heterogeneity of these neurodevelopmental diseases. However, it has becoming evident that, although genetically heterogeneous, all the different ASD-related genetic alterations should be implicated in common molecular pathways or biological processes. In this scenario, the search for differentially expressed genes (DEGs) between ASD patients and controls is a good alternative to examine the molecular etiology of such disorders. In the present study, we employed genome-wide expression analysis to compare the transcriptoma of dental pulp stem cell (DPSC) of idiopathic autistic patients and control samples. Among the 404 differentially expressed genes (DEGs) identified, 335 (83%) are expressed in nervous tissue, showing that DPSC are good source of material to explore expression differences in ASD patients. Functional annotation analysis revealed that the ASD DEGs are enriched for gene ontology categories related to nervous system development and function. The great majority of these genes are involved in the formation of axons and dendrites, particularly, genes implicated in cell adhesion and regulation of cytoskeleton dynamics, suggesting that these mechanisms can be a common core undelaying ASD etiology. Notably, “Axonal guidance signaling” was the most significantly enriched canonical pathway found in our analysis, a pathway that was already pointed as implicated in ASD etiology by functional annotation analysis of genes compromised by ASD-specific CNVs. We also verified that most of the functionally relevant DEGs can be combined in a large network of functional relations, where they also interact with others genes that are part of canonical pathways already implicated in ASD, such as PTEN and Glutamatergic signaling. We identified 83 drugs that target the genes in this network, which are, therefore, a source of molecules that can be used for future in vitro drug screening studies for ASD. The use of cellular reprograming to investigate ASD patients' neurons can be employed to verify the effects of these drugs as well as the role of the identified pathways in neuronal phenotype.

526W

Association of SNPs in the FKBP5 gene region with hippocampal and amygdala volume in a healthy control sample. *L. Gschwind, C. Vogler, D. de Quervain, A. Papassotiropoulos.* Molecular Neurosciences, University of Basel, Basel, Basel, Switzerland.

Background: FKBP5 has been reported to play a role in response to antidepressant treatment and in post-traumatic stress disease (PTSD). Furthermore, hippocampal and amygdala volume have been linked to the risk of developing depression, PTSD and a variety of other psychiatric disorders. We hypothesized that the implication of FKBP5 in psychiatric diseases might be mediated through effects of genetic variation on differences in amygdala and hippocampal volumes. Therefore, we examined whether single nucleotide polymorphisms (SNPs) in the FKBP5 gene region are associated with hippocampal and amygdala volume differences in a sample of healthy young subjects. Methods: We used automated segmentation procedures of structural magnetic resonance images to determine measures of hippocampal volume in 329 healthy young Swiss individuals. Hippocampal and amygdala volumes were corrected for age, gender and intra-cranial volume. Genetic variation in FKBP5 and additionally 20kb up- and downstream of the gene was assessed through 46 SNPs represented on the Affymetrix Genome-Wide Human SNP Array 6.0. Genetic associations were tested under the assumption of a dominant and an additive model using the Plink software package. Results: None of the investigated SNPs withstood multiple testing corrections. The number of SNPs reaching nominal significance of association with hippocampal or amygdala volumes corresponds to the number of nominally significant results that are expected by chance if an (-error rate of 5% is assumed. Conclusion: In a group of 329 healthy young individuals, which is sufficiently powered to detect medium effect sizes, we could not reveal a potential influence of FKBP5 on hippocampal and amygdala volume. It is unlikely that the impact of FKBP5 on psychiatric diseases is mediated through volumetric effects of FKBP5 genetic variation in brain regions related to psychiatric disease.

527W

A new locus for autosomal dominant Charcot-Marie-Tooth disease type 2 maps to chromosome 10p13-14. *M. Gu[1], W. Xu[1], L. Sun[1], W. Guo[1], J. Ma[2], S. Chen[2], Z. Wang[1].* 1) Dept Med Gen, E-Institutes of Shanghai Universities, Shanghai Jiao Tong Univ Sch Med, Shanghai, China; 2) Dept Neurology, Rui-Jin Hospital Affiliated to Shanghai Jiao Tong Univ Sch Med, Shanghai, China.

Charcot-Marie-Tooth disease (CMT) is one of the most common inherited neurological disorders with a prevalence estimated at 1/2500. Mutant alleles underlying CMT can segregate in an autosomal dominant, recessive, or X-linked manner. On the basis of clinical manifestation and electrophysiological properties, CMT has been divided into two main types: a demyelinating form (CMT1) affecting the glia-derived myelin and an axonal form (CMT2) affecting axon. CMT2 is characterized by distal muscle weakness and atrophy, mild sensory loss, and normal or near-normal nerve conduction velocities. Here, we report a six-generation pedigree of CMT including 8 patients, from Shandong Province, China. After informed consent was signed, 29 members in the family took part in our research. All patients presented muscle weakness and a predominating weakness of distal parts of the lower limbs, no significant sensory impairments were observed. The electrophysiological examinations show that both of motor nerve conduction velocities (MCV) and sensory nerve conduction velocities (SCV) were normal, but some compound motor action potentials (CMAP) were decreased at upper limbs. MCV were lower than normal one, but SCV was normal. CMAPs were greatly reduced at lower limbs. All evidence supported the diagnosis of CMT2. Some known loci including CMT2A, CMT2B, CMT2D, CMT2E, CMT2F and CMT2L were excluded by linkage analysis. A genome-wide scanning was carried out, and the results revealed linkage of CMT2 to a locus at chromosome 10p13-14. The fine mapping and haplotype analyses localized this novel locus to 5.41 Mb intervals between microsatellite markers D10S585 and D10S1477. The maximal two-point LOD score of 4.56 for marker D10S506 at a recombination fraction (7) of 0 strongly supported linkage to this locus. Thus, CMT2 neuropathy in this family represents a novel genetic entity. In the ALEXA-Seq data viewer (http://obiweb.bcgsc.ca/solexa/ALEXA/Sutent/genes), more than 70 genes have been mapped at above-mentioned region, twenty of them functionally similar or related to known genes which are being sequenced. We are looking forward to identifying a novel causing gene in the pedigree with CMT2.

528W

Variants in the 15q25 locus are associated with schizophrenia diagnosis. *K.J. Jackson[1], A.H. Fanous[1,2,3], J. Chen[1], K.S. Kendler[1], X. Chen[1].* 1) Dept Psychiatry, Virginia Commonwealth University, Richmond, VA; 2) Washington VA Medical Center, Washington, DC; 3) Georgetown University Medical Center, Washington, DC.

The 15q25 locus, which contains the CHRNA5/CHRNA3/ CHRNB4 genes, coding for (5, (3 and) 4 nicotinic receptors respectively, is the most significant candidate region to date associated with smoking behavior and nicotine dependence (ND). It is well known that rates of tobacco smoking are much higher in patients with schizophrenia (_80-90%) compared to the general population (_20-30%), though the underlying mechanism for this comorbidity is unclear. One hypothesis is that there are common genetic factors that predispose to both ND and schizophrenia. To explore this hypothesis, we examined the association between schizophrenia diagnosis, negative symptoms, and 5 variants in the 15q25 gene cluster (rs951266, rs16969968, rs1051730, rs8040868, rs17477223) in 7 schizophrenia datasets (n=9,448). Results from each study were used to perform a meta-analysis. Two variants were significantly associated with schizophrenia diagnosis (rs8040868, rs17477223). After inclusion of 3 bipolar sets into the meta-analysis (total n=15,780), four markers were significant after correction for multiple testing (rs951266, rs16969968, rs8040868, rs17477223). No significant association was found with the presence of negative symptoms. Gene expression analysis was also conducted using the SNPExpress database. Preliminary results indicate an association between genotypes of the rs1051730 variant and CHRNA5 expression in brain and peripheral blood mononuclear cells. A follow-up meta-analysis using publically available post-mortem brain expression data (n= 632) from the Myers Lab (http://labs.med.miami.edu/myers/LFuN/papers.html) and Stanley Medical Research Institute (http://www.stanleyresearch.org) also suggest a marginal association with the rs1051730 variant and CHRNA5 expression. Taken together, these results suggest that variants in the 15q25 gene cluster are associated with risk for schizophrenia diagnosis, and may influence CHRNA5 expression in the brain. Because the direction of the association is the same as what was found for ND, these results also support the notion that there are genetic mechanisms common to schizophrenia, ND, and potentially bipolar disorder. Future studies involve elucidation of potential gene x gene interactions with the (5, (3 and) 4 nicotinic receptor genes and (7, (4, and) 2 nicotinic receptor genes, as these genes have also been found to be associated with schizophrenia, and may contribute to maintenance of smoking behavior.

Genomewide Association Study Implicates NDST3 in Schizophrenia and Bipolar Disorder. *T. Lencz[1,2,3], S. Guha[1], C. Liu[4], J. Rosenfeld[1], P. DeRosse[1], L. Cheng[5], J. Badner[5], J. Kane[1,2,3], A. Lee[2,3], P. Gregersen[2,3], I. Pe'er[6], A. Malhotra[1,2,3], A. Darvasi[7].* 1) Dept Psychiatry Res, Zucker Hillside Hosp, Glen Oaks, NY; 2) Feinstein Institute for Medical Research, Manhasset, NY; 3) Hofstra University School of Medicine, Hempstead, NY; 4) Dept of Psychiatry, University of Illinois at Chicago, Chicago, IL; 5) Dept of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 6) Dept of Computer Science, Columbia University, New York, NY; 7) Dept of Genetics, Institute for Life Sciences, Hebrew University, Jerusalem, Israel.

Background Schizophrenia and bipolar disorder are major psychiatric disorders with high heritability and overlapping genetic variance, yet few susceptibility loci have been identified and replicated in large-scale studies. **Methods** We performed a genome-wide association study (GWAS) in an ethnically homogeneous cohort of 904 schizophrenia cases and 1640 controls drawn from the Ashkenazi Jewish (AJ) population, and sought to replicate our top result in 10 case-control cohorts (6 schizophrenia and 4 bipolar disorder cohorts containing a total n=20,446 subjects) drawn from multiple ethnicities. We also examined the relationship between alleles at our top GWAS SNP and expression of a neighboring gene in 119 postmortem cerebellar tissue samples. **Results** In our Ashkenazi GWAS discovery cohort, we identified a genome-wide significant risk locus at chromosome 4q26 (rs11098403, $P = 6.55 \times 10^{-9}$). This SNP demonstrated significant association across the 10 replication cohorts regardless of diagnosis or ethnicity (heterogeneity I2=0), resulting in a meta-analytic $P = 7.82 \times 10^{-10}$ (OR=1.12, 95%CI=1.08-1.16). Additionally, this intergenic SNP was significantly associated with postmortem cerebellar expression of the neighboring gene NDST3, which encodes an enzyme critical to heparan sulfate binding. **Conclusions** Our study suggests a possible role of NDST3 in susceptibility to schizophrenia and bipolar disorder. Heparan sulfate binding is critical to neurite outgrowth, axon formation, and synaptic processes thought to be aberrant in major psychiatric disorders.

Analysis of the *FBXO7* gene in early-onset parkinsonism. *Y. Li[1], M. Funayama[1,2], H. Yoshino[1], H. Tomiyama[2,3], N. Hattori[1,2,3].* 1) Research Institute for Diseases of Old Age, Graduate School of Medicine, Juntendo University, Tokyo, Japan; 2) Department of Neurology, Juntendo University School of Medicine, Tokyo, Japan; 3) Department of Neuroscience for Neurodegenerative Disorders, Juntendo University School of Medicine, Tokyo, Japan.

Background and Objectives: Mutations in the *FBXO7* gene located within the *PARK15* locus on chromosome 22q12-q13 have recently been identified in European patients with autosomal recessive early-onset parkinsonism-pyramidal syndrome, however, it has been detected in only three European families. To clarify the distribution and frequency of *FBXO7* mutations, we investigated *FBXO7* gene mutations in Japanese patients with early-onset parkinsonism. **Methods:** All coding exons and exon-intron boundaries of the *FBXO7* gene were sequenced in 110 Japanese patients (age at onset; 11 to 50 years, mean ±SD; 33.3±8.2 years) with early-onset parkinsonism. None of the subjects had mutations in the *parkin* gene and the *PINK1* gene. **Results:** None of pathogenic mutations in the *FBXO7* gene were detected. **Conclusions:** Our study suggests that *FBXO7* mutation is rare among Japanese patients with early-onset parkinsonism.

Mesial temporal lobe epilepsy gene expression profiling: a comprehensive gene set enriched-based analysis. *I. Lopes-Cendes[1], J.F. Vasconcellos[1], C.V. Maurer-Morelli[1], C.S. Rocha[1], C.L. Yasuda[2], H. Tedeschi[2], E.D. Oliveira[2], F. Cendes[2].* 1) Department of Medical Genetics, Faculty of Medical Sciences, State University of Campinas, and CINAPCE Program, Campinas, SP, Brazil; 2) Department of Neurology, Faculty of Medical Sciences, State University of Campinas, and CINAPCE Program, Campinas, SP, Brazil.

Gene Set Enrichment Analysis (GSEA, http://www.broadinstitute.org/gsea/index.jsp) is a web tool for interpreting gene expression profiles, whose analysis is based on the enrichment of gene sets (groups of genes that share common biological function, chromosomal location and/or regulation). Mesial temporal lobe epilepsy (MTLE) is one of the most common forms of human epilepsy, and causes both neuronal loss and synaptic reorganization in the hippocampus. MTLE is largely described as a sporadic disease; however, we and others have shown that MTLE can also have familial recurrence. The present study applied GSEA to interpreted data from gene expression profiles obtained from hippocampal tissue of MTLE patients with positive and negative family history (FH) of MTLE, compared to normal controls. Transcriptional profiling by microarray analysis revealed that patients with MTLE and a positive-FH had 170 differentially expressed genes and patients with a negative-FH had 341, when compared to control samples. GSEA of the gene expression profile from patients with positive-FH demonstrated 7 enriched gene sets ($p<0.05$ and FDR q-value<0.05), which are involved in cellular proliferation, MYC and AKT1 signaling pathways, inhibition of DNA methylation and histone deacetylation, and synthesis of myelin constituents. MYC is associated with apoptotic induction in neurons, while AKT1 indirectly mediates neuron apoptosis through the regulation of FKHR and Bim. Epigenetic modifications, such as DNA methylation, may be involved in the pathogenesis of epilepsy. Finally, myelin constituents may present a differential expression profile due to neuronal plasticity following brain tissue lesion. GSEA of the gene expression profile from patients with negative-FH demonstrated 5 enriched gene sets ($p<0.05$ and FDR q-value<0.05), which are mainly involved in oxidative stress and electron transport chain. Oxidative stress was identified as an important mechanism in the etiology of seizures, and induces neuronal death. The electron transport chain may play an indirectly role in the pathogenesis of epilepsy, through the production of reactive oxygen species. In conclusion, our data shows for the first time the application of GSEA in epileptic tissue and the results support previous experimental data indicating the complex nature of the mechanisms involved in the pathogenesis of MTLE. A frequentist enrichment approach links bipolar affective disorder to genes involved in long term potentiation phenotypes. *S. Meader[1], L. Winchester[2], E. Domenici[3], C. Francks[4], J. Ragoussis[2], C. Webber[1].* 1) MRC Functional Genomics Unit, Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford OX1 3QX, United Kingdom; 2) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, United Kingdom; 3) Biomarker & Pathway Analysis, F. Hoffmann-La Roche Ltd, CH-4070 Basel, Switzerland; 4) Max Planck Institute for Psycholinguistics, Wundtlaan 1, 6525 XD Nijmegen, The Netherlands.

Copy number variants (CNVs) have been identified repeatedly as a cause of neurological disorders. However, despite several major studies, there have been few reports that have causally implicated CNVs in the occurrence of bipolar affective disorder. We examined a novel set of CNVs identified among 888 patients diagnosed with type I or type II bipolar disorder. When compared to matched controls, we found that the CNV burden within these patients was significantly increased.

We developed a novel and statistically-robust frequency-based approach to determining functional gene enrichments in case/control CNV data which is demonstrably free from functional gene length biases. Using phenotypic data from >5,000 mouse gene knockouts and considering each of 444 reasonably populated behavioural and nervous system phenotypes, we asked whether the orthologues of the genes yielding that phenotype in mice were significantly more frequently affected among individuals with bipolar disorder compared to individuals without the disorder.

Among the bipolar patients, we identified a significant association of genes whose mouse orthologues, when disrupted, result in an *abnormal long term potentiation phenotype* (3.2-fold enrichment; $p < 4 \times 10^{-5}$; FDR < 5%). This enrichment identifies 17 bipolar candidate genes whose protein-coding sequence is disrupted by deletions within the case population, two of which have been previously associated with bipolar disorder.

To confirm the relevance of this specific phenotypic association, we formed a wholly independent set of 39 bipolar candidate genes taken from the recent literature. Among those mouse orthologues for which phenotypic information was available, the phenotype *abnormal long term potentiation* was found to be the most specific among those phenotypes most significantly enriched (6.7-fold enrichment; $p < 2 \times 10^{-4}$; FDR < 5%). Ongoing analysis exploiting detailed patients records is revealing the segregation of this novel signal with both disorder type and onset, and treatment outcome. Taken together, our findings support a significant role for copy number variation in bipolar affective disorder, and demonstrate the utility of mouse phenotypic data in gaining functional insights into, and identifying the genes underlying, neurological disease.

CACNA1C is associated with memory function in healthy young adults. *A. Milnik[1,4], B. Auschra[1,2,3], D.J.-F. de Quervain[3,5], A. Papassotiropoulos[1,2,3].* 1) Division of Molecular Neuroscience, Department of Psychology, University of Basel, Basel, Switzerland; 2) Life Sciences Training Facility, Department Biozentrum, University of Basel, Basel, Switzerland; 3) University Psychiatric Clinics, University of Basel, Basel, Switzerland; 4) University Department of Neurology, University Medical Center Magdeburg, Magdeburg, Germany; 5) Division of Cognitive Neuroscience, Department of Psychology, University of Basel, Basel, Switzerland.

Background: An association of single nucleotide polymorphism (SNP) rs1006737 with depression and schizophrenia and disease-related cognitive phenotypes has been shown previously. This SNP is located within CACNA1C, which encodes for the alpha subunit of the L-type voltage-dependant calcium channel. Imaging studies have shown impaired hippocampal function during memory recall in carriers of the disease-associated allele. However, no association between this SNP and memory performance in healthy subjects has been hitherto shown, possibly due to small effect and sample sizes. Method: We analyzed behavioral and genetic data of 1471 young healthy participants carefully characterized for episodic and working memory performance and for additional psychological traits (e.g. personality, depression, anxiety). Results: Young healthy risk-allele carriers have significantly impaired episodic memory performance, albeit the effect size is modest. No association with working memory performance or additional psychological traits was observed. Conclusion: We observed a significant association of CACNA1C SNP rs1006737 with memory function in a large group of young healthy adults and hypothesize that increased CACNA1C-related vulnerability to psychiatric disorders is moderated through impaired memory capacity.

534W

Intragenic CNVs identified by exon-level microarray analysis in individuals with autism plus epilepsy. *A. Moreno-De-Luca[1], E.B. Kaminsky[1], D.H. Ledbetter[2], C.L. Martin[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Geisinger Health System, Danville, PA.

Autism spectrum disorders (ASD) and epilepsy are two of the most common, heterogeneous and heritable neurodevelopmental disorders. Both conditions can present with a wide range of co-morbidities that often include cognitive and developmental impairments. ASD and epilepsy have both been associated with multiple genetic etiologies, such as single gene mutations and copy number variants (CNVs); however, the specific cause remains elusive in most cases. The prevalence of epilepsy in individuals with ASD (~30%) and vice versa (~30%) is significantly higher than that of either individual disorder in the normal population (<1%), suggesting the existence of shared genetic and molecular mechanisms that may account for their co-occurrence. The causative role of large CNVs harboring multiple genes has been well established in individuals with ASD and epilepsy. However, the relevance of small intragenic imbalances has yet to be determined. To explore the contribution of exonic CNVs to the ASD/epilepsy phenotype, we custom-designed an oligonucleotide copy number microarray with whole genome plus exon-level targeted coverage of >1,200 known and candidate ASD and epilepsy genes. We tested 144 individuals with ASD plus epilepsy from the Autism Genetic Resource Exchange who previously screened negative for any large (>250 kb), pathogenic CNVs. We identified 6 families with exonic deletions and 8 with exonic duplications (9.7% yield). To establish the inheritance pattern of the deletion cases, we performed parental microarray analysis and showed that two siblings inherited a deletion in *CNTNAP2* from their father. Three additional cases also had inherited deletions in *LIN7C* (mat), *CHRM3* (mat) and *OR1C1* (mat). These results suggest incomplete penetrance, variable expressivity or a familial benign CNV. In one case with a deletion in *ADAM22*, the inheritance could not be determined since the father was unavailable. Interestingly, we identified a *de novo* deletion of exon 24 in *EHMT1* in an individual with clinical features similar to those of Kleefstra syndrome (ASD, epilepsy, craniofacial dysmorphic features, scoliosis, and clinodactyly), suggesting a potential pathogenic role for this exonic CNV. Our results highlight the contribution of exonic CNVs to ASD plus epilepsy and support further investigations to continue unraveling the underlying shared pathophysiological pathways.

Characterization of VCP R155H Homozygote Mouse Model Exhibits Pathology Typical of IBMPFD and ALS. *A. Nalbandian[1], E. Dec[1], S. Donkervoort[1], H. Yin[2], G.D. Watts[3], C. Smith[4], V. Caiozzo[5], A. Wang[2], T. Mozaffar[2], J. Weiss[2], V. Kimonis[1].* 1) Department of Pediatrics, University of California, Irvine, CA; 2) Departments of Neurology, University of California Irvine, CA; 3) School of Medicine, Health Policy and Practice, University of East Anglia, Norwich, Norfoik, UK; 4) Department of Neurology, University of Kentucky Medical School, Lexington, KY; 5) Department of Orthopedic Surgery, University of California, Irvine, CA.

Inclusion body myopathy associated with Paget disease of bone and frontotemporal dementia (IBMPFD) is a progressive, fatal, genetic disorder with variable penetrance, predominantly affecting three main tissue types: muscle (IBM), bone (PDB) and brain (FTD). IBMPFD is caused by mutations in the ubiquitously expressed valosin containing protein (VCP) gene, a member of the AAA-ATPase super-family. It has been reported that VCP is involved in a plethora of distinct cellular processes including homotypic membrane fusion, transcription activation, nuclear envelope reconstruction, DNA repair, post-mitotic organelle reassembly, cell cycle control, apoptosis and endoplasmic reticulum associated degradation of proteins (ERAD), which is capable of destroying both integral membrane proteins and luminal proteins. The majority of individuals develop IBM with progressive proximal muscle weakness. VCP mutations have been seen in 2-3 % of familial amyotropic lateral sclerosis (ALS) and 15% of individuals with VCP hereditary inclusion body myopathy have an ALS phenotype. Cellular and animal models indicate pathogenic disturbances in IBMPFD tissues including ERAD, autophagy, apoptosis, and mitochondrial dysfunction. In the current study, we aim to characterize the R155H homozygote mouse model and to utilize this as a useful tool for investigating the pathogenesis of IBMPFD and ALS. Homozygosity of the R155H mutation is lethal and these animals die by 14 to 21 days of age, the cause(s) of which remains undetermined. Preliminary histological results have shown pathology of the heart and muscle. These mice are smaller and reveal abnormal muscle architecture of the skeletal muscle and large vacuoles in the cardiac muscle fibers. Thus, elucidating the basic molecular signaling cascades involved in IBMPFD and ALS diseases and improving protein homeostasis will ultimately lead to strategies and therapies.

haplogroup U indicates proneness to autism but on the contrary, haplogroup H is likely to be the least affected mtDNA variant. *F. Piryaei[1], M. Houshmand[1,2], O. Aryani[2], S. dadgar[2], Z.S. Soheili[1].* 1) Medical genetics, National Institute of Genetic Engineering and Biot, Tehran, Iran; 2) Special medical center, Tehran, Iran.

Autism is a disorder of neural development characterized by impaired social interaction and communication, and by restricted and repetitive behaviour which appears to result from developmental factors that affect many or all functional brain systems. Autism is noticeably suggested to be affected by mitochondrial dysfunction since Brain function crucially depends on ATP production so that over 95% of total brain ATP is provided via oxidative phosphorylation. Employing direct sequencing of mtDNA fragments, the objectives of this study was to investigate probable mutations within mtDNA genes which might be causative in autism in 24 affected individuals and to compare the distribution of those individuals and 100 control subjects among mitochondrial haplogroups. 9 nucleotide substitutions were identified including G8251A, G8269A, A8271G, C8472T, C8684T, G8697A, A8701G, A8836G and G8865A in patients. G15928A and A16149C were observed in two groups as A16149C was a novel substitution. A15973G was another novel detected mutation observed in patients. Sequencing of the D loop resulted in different haplogroups. Distribution of affected and control groups among different haplogroups revealed that in all probability haplogroup U indicates proneness to autism. On the contrary, haplogroup H is likely to be the least affected mtDNA variant.

Hereditary sensory & autonomic neuropathies (HSANs) are a heterogeneous group of disorders characterized by variable sensory and autonomic dysfunction due to peripheral nerve involvement. HSAN2 is a rare autosomal recessive and progressive disease with onset in the 1st decade of life. We previously established that mutations in the nervous system-specific HSN2 exon of WNK1 cause HSAN2. Mutations in WNK1/HSN2 were shown to cause HSAN2 in familial cases. The clinical and pathological data suggest that HSAN2 is characterized by abnormal development and/or degeneration mainly of sensory fibers. First, we screened for human nervous system proteins that bind to HSN2 exon using a yeast two-hybrids approach (Y2H). Positive clones were isolated based on their activation of reporter genes and the cDNAs from positive clones were rescued, sequenced and analyzed using NCBI BLAST. Following this Y2H screen, a list of potentially interesting interactors was generated and the interactions validated using co-immunoprecipitation (Co-IP) and Western blots using commercial antibodies recognizing the interactors identified. From these results, we are focusing on some specific partners of HSN2 who seems to have an important role in this disease. This project will lead to a better understand of the pathological mechanisms leading HSANII.

538W

Penalized regression to detect multiple genetic associations with motor symptom progression in Parkinson's Disease. *S.L. Rhodes[1], M. Creek[2], J. Sinsheimer[2,3,4], B. Ritz[1].* 1) Dept Epidemiology, UCLA Sch Public Hlth, Los Angeles, CA; 2) Dept Biostatistics, UCLA Sch Public Hlth, Los Angeles, CA; 3) Dept Human Genetics, Geffen School of Medicine at UCLA, Los Angeles, CA; 4) Dept Biomathematics, Geffen School of Medicine at UCLA, Los Angeles, CA.

Idiopathic Parkinson's disease (PD) is characterized by a highly variable progressive decline in motor function such that some patients become wheelchair bound within a few years while others remain without major restriction for longer periods. While current therapies treat the symptoms, no treatment prevents the neurodegeneration or the progressive decline in motor function. Few studies have investigated predictors of motor decline despite its significant impact on quality of life for PD patients. Recognized predictors include age of symptom onset, motor symptom subtype, and dementia prior to or concomitant with PD diagnosis; but, to date, no genetic predictors of progression have been identified. Given the complex etiology of PD, we hypothesized that subjects with an increased number of genetic variants in recognized PD candidate genes would be at increased risk for more rapid decline of motor function. To test this hypothesis used two complementary approaches, (1) we constructed an allelic dosage score, and (2) built models using lasso penalized regression, a continuous model selection that tests the effects of all variants simultaneously. The lasso approach allows discovery of gene-gene interactions where two-way, three-way, and even higher order interactions can be considered. This study was approved by the UCLA Human Subjects Committee and all subjects provided written informed consent. 228 incident PD patients had sufficient baseline and follow-up data to contribute to the analysis. We observed no differences between rapid and slow progressors for gender, family history of PD, duration of disease prior to baseline, interval between baseline and follow-up, or PD motor subtype. Similar to prior observations, rapid progressors were older at symptom onset than slow progressors ($p=0.018$); dementia at baseline was an exclusion criteria and thus could not be assessed. Consistent with our hypothesis, we observed a significant increase in the number of risk SNPs in rapid progressors compared with slow progressors ($p<0.001$). Furthermore, we observed a cluster of genes related to metal and iron metabolism associated with faster progression of motor symptoms. If replicated in animal models and other PD studies, these findings suggest an avenue of investigation for new therapeutics aimed to slow the progression of motor function decline in PD.

539W

Increased sociability and social interaction in mice lacking glutamate receptor interacting proteins. *R. Rose[1], R. Mejias[1], A. Adamczyk[1], R. Huganir[2], T. Wang[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, Johns Hopkins University, Baltimore.

Glutamate receptor interacting protein 1 and 2 (GRIP1/2) are homologous and neuron-enriched scaffolding proteins that interact directly with the C-termini of glutamate receptors 2/3 (GluA2/3) via its PDZ domains 4-6 (PDZ4-6). GRIP1/2 play an important role in regulating GluA2/3 trafficking and neuronal plasticity. Loss of GRIP1/2 was found to impair activity dependent GluA2 recycling in neurons. Gain-of-function GRIP1 variants clustered around PDZ4-6 have recently been reported to alter GluA2 recycling and contribute to the severity of deficits in social interaction in autistic patients. To understand the role of GRIP1/2 in social function and autism spectrum disorders, we characterized the social behavioral phenotype of adult Grip1/2 double knockout (DKO) mice. Grip1/2 DKO mice were generated by crossing Grip2 conventional KO with Grip1 conditional (neuron-specific deletion via nestin-cre expression) KO mice. Grip1/2 DKO mice and wild type (wt) control mice were matched for age, sex, and strain background. Compared to wt, Grip1/2 DKO mice were found to have a significant increase in sociability towards stranger mice (time with stranger mice in seconds: wt: 44±5; DKO, 81±8, $p=0.0022$; $n=10$); in preference for social novelty towards novel versus familiar mice (time with novel mice in seconds; wt: 35±3; DKO: 59±6, $p=0.0024$; $n=10$); and in male-male social interactions in open arena (time of social interaction in seconds; wt: sniffing, 18.9±1.1; following, 7.1±0.7; DKO: sniffing, 38.6±1.9; following, 12.6±1.9; $p<0.001$; $n=10$). These results strongly support a role of GRIP1/2 in modulating social behaviors and implicate glutamate-signaling disturbance in social behavioral disorders including autism.

540W

Deletion of MAOA and MAOB in male siblings with severe mental retardation and autistic phenotype. *M. Saito, T. Yamagata, Y. Shiba, N. Nakashima, M. Nagashima, E. Jimbo, M.Y. Momoi.* Dept Pediatrics, Jichi Med Univ, Shimotsuke, Japan.

Copy number variation (CNV) took major place on the pathogenesis of autism spectrum disorder (ASD). On the array complementary genomic hybridization (aCGH) analysis for CNV detection in ASD patients, we detected deletion of *monoamine oxidase (MAO) A* and *MAOB* in the siblings with severe mental retardation and ASD. Patient 1 was five-year-old boy. He could sit without support and spoke only several words. He was hypotonic and showed impaired sociability, stereotypic movements, excitability, self-injury and insomnia. Patient 2 was a three-year-old brother of patient 1. He could sit, but could not speak any words. Other symptoms were resembled with patient 1. Both patients were not blind. On array CGH analysis using Agilent Human genome aCGH 44K in patient 1, about 600kb deletion on Xp11.3 was detected. In this deleted region, only *MAOA* and *MAOB* were existed. In patient 1 and 2, *MAOA* and *MAOB* deletion was confirmed by PCR analysis designed to amplify several exons of each gene on genomic DNA. *NDP*, the gene for Norrie disease that showed blindness and mild mental retardation, were not deleted on aCGH analysis and the expression of *NDP* was confirmed by RT-PCR. MAO catalyzes serotonin and catecholamine. Therefore, serotonin and catecholamine levels in cerebrospinal fluid (CSF), serum and urine were analyzed. CSF serotonin level were markedly elevated to 3,000pg/ml (normal <10) in both patients, and 5-HIAA was <1.0ng/ml (24.6±1.8). Catecholamine level was mildly elevated such as CSF norepinephrine 409pg/ml(180±17), and urine dopamine 1.88mg/gCr (0.77±0.22) in patient 1. *MAOA* were reported to relate with ASD from the association study with 5' VNTR or SNPs on *MAOA*. However, mutations of *MAOA* were detected on the patients with mild mental retardation and anti-social behavior. Mutation of *MAOB* showed no symptoms. Deletion of *MAOA, MAOB* and *NDP* caused severe mental retardation and blindness. Deletion of *MAOA* and *MAOB* were reported in only one sibling with severe developmental delay and stereotypical hand movements, and our patients showed similar phenotypes with them. From our results, these symptoms such as severe mental retardation, ASD, exitability and hypotonia were considered to be caused by serotonin toxicity from the loss of catalyzing ability of MAO.

541W

Genome-wide linkage analysis suggests oligogenic regulation of brain auditory responses. *E. Salmela[1], H. Renvall[2], M. Vihla[2], J. Kere[1,3], R. Salmelin[2].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Brain Research Unit, Low Temperature Laboratory, Aalto University, Finland; 3) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden.

All sounds entering the ear produce robust auditory evoked responses (AERs) in the human brain. AERs are variable between individuals but typically stable over time for a given individual, and they have been widely used to probe cortical functions in both healthy and clinical populations. However, little is known about their underlying molecular mechanisms.

To study the possible genetic determinants of the AERs in a normal population, we have measured AERs from 113 pairs of healthy siblings using magnetoencephalography (MEG). The subjects were presented with 1 kHz tones in alternating ears, and the responses were recorded with a 306-channel Elekta Neuromag neuromagnetometer. The subjects were also genotyped on Affymetrix 250K *StyI* SNP arrays, yielding genotypes for ca. 150,000 single-nucleotide polymorphisms (SNPs) after filtering.

In both cerebral hemispheres, the amplitudes of the responses at ~100 ms (N100m) to both ipsi- and contralateral stimuli were highly heritable ($h^2 > 0.70$). A variance component-based analysis revealed linkage for the right- but not for the left-hemispheric amplitudes: a significant linkage of the ipsilateral amplitudes to a region on chromosome 2q37 (LOD = 3.32, $p < 0.04$ based on 330 permutations with Merlin), and a suggestive linkage of the contralateral amplitudes to the same region (LOD = 3.01, $p < 0.15$); additional suggestive linkage peaks were seen on chromosome 3p12 (LOD = 2.55, $p < 0.44$) for the contralateral and on chromosome 8q24.3 (LOD = 3.27, $p < 0.06$) for the ipsilateral amplitudes. Several of the highlighted regions contain functionally plausible genes, and further analyses of them are ongoing. Overall, the results demonstrate the potential of genetic analysis in linking macroscopic cortical phenotypes with molecular-level processes controlled by specific genes.

542W

Copy Number Variants and Agenesis of the Corpus Callosum: A Significant Etiologic Mechanism that Overlaps with Autism. *E. Sherr[1], S. Sajan[2], L. Fernandez[1], E. Rider[1], S. Esmaeeli[1], J. Glessner[3], H. Hakonarson[3], S. Christian[2], W. Dobyns[2].* 1) Departments of Neurology & Pediatrics, Univ California, San Francisco, San Francisco, CA; 2) Center for Integrative Brain Research, University of Washington, Seattle, WA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Background: One major causative hypothesis for autism is that alterations in long-range cortical connectivity underlie the pleiotropic clinical manifestations. Agenesis of the corpus callosum (AgCC) is a common CNS malformation in which many individuals have autism or have deficits on the autism spectrum. Like autism, the genetics of AgCC is likely to be complex and prior small reports from our lab and others have suggested that de novo copy number variants (CNV's) may play an important causative role. Hypotheses: We hypothesized that AgCC patients would have a significant number of large candidate CNV's and that these CNV's may overlap with those identified in autism. Methods: We identified patients with AgCC by a comprehensive radiological and clinical review of our IRB approved AgCC cohort (n>500). Blood samples were obtained from the proband and both biological parents, when available. DNA was extracted and run on an Illumina 610 Quad Chip array. Data were analyzed using PennCNV. CNV's that were selected for analysis contained greater than 9 SNPs, were longer than 30 kb, had a PennCNV confidence level above 10 and contained one or more genes. Manual curation and merging of contiguous large CNVs were conducted. Results: 271 patient samples were run and high quality data were obtained from 96%. These data were compared against 1953 ethnically matched controls that were run and analyzed on the same platform. We compared both CNVs binned by size and grouped by associated genes. Rare deletion CNV's larger than 500 kb and gene rich (>20) were significantly associated with AgCC patients as compared to controls (OR = 14.33; p = 0.000016). A complex deletion-duplication on chromosome 8p was recurrent in the AgCC cohort and at other loci, both the deletion and reciprocal duplication were found both with AgCC. We also analyzed the enrichment of genes within CNVs previously associated with autism and found that CNV deletions in AgCC patients were significantly correlated with CNVs duplications in autism (OR = 9.74; p = 0.0062). Conclusions: Large CNV's are commonly found in AgCC patients and there is a specific enrichment of autism genes with AgCC CNV's. These data support a strong etiologic link between autism and AgCC and likely shared molecular and developmental pathways.

543W

A genetic study associating brain volume abnormalities with serotonin system gene variants in pediatric obsessive-compulsive disorder. *V.M. Sinopoli[1,2], K. Wu[1], F. MacMaster[4], P. Easter[4], J. Kennedy[3], G. Hanna[5], D. Rosenberg[4], A. Arnold[1,2].* 1) University of Toronto, Toronto, ON, Canada; 2) Hospital for Sick Children, Toronto, ON, Canada; 3) Centre for Addiction and Mental Health, Toronto, ON, Canada; 4) Wayne State University, Detroit, MI, USA; 5) University of Michigan, Ann Arbor, MI, USA.

Background: Obsessive-compulsive disorder (OCD) is a heritable and common neuropsychiatric disorder of unknown etiology. A number of candidate gene studies have been conducted; serotonergic system genes being of particular interest, since serotonergic medications are highly efficacious in treatment of this disorder. Genetic variations attributed to the serotonin transporter gene (SLC6A4), serotonin receptor 2A gene (HTR2A), and serotonin receptor 1B gene (HTR1B), have been implicated. In addition, studies have attributed the disorder to regional volumetric brain abnormalities, with the striatum (caudate and putamen) being among the most consistently associated regions. Purpose: This study attempts to associate serotonergic system gene polymorphisms with volumetric brain region abnormalities in a clinical, pediatric OCD sample. Methods: Genetic and structural magnetic resonance imaging (sMRI) brain data were collected from a clinic-based, pediatric sample of 20 medication-naïve OCD patients, ages 7 to 17, at Wayne State University in Detroit, Michigan. Association analysis was conducted for SLC6A4, HTR2A, and HTR1B, which have been previously implicated in OCD. A total of 40 single nucleotide polymorphisms (SNPs), spanning each gene, were examined and tested for association with volumes of brain regions with `a priori' evidence of association with OCD: thalamus, anterior cingulate cortex (ACC), orbitofrontal cortex (OFC), and caudate. Results: In HTR2A, the C allele of single nucleotide polymorphism (SNP), rs1923886, was found to be significantly associated with reduction in volume of the left putamen (adjusted P-value of 0.035). The same SNP was nominally associated with total and right putamen volume (not significant after adjustment for multiple comparisons). Conclusions: We identified an association between volume of the putamen, a component of the striatum, with a specific genetic variant in children with OCD. These results were consistent with previous neuroimaging findings implicating the striatum in OCD pathophysiology. Regional brain volumes provide potentially valuable endophenotypes (intermediate phenotypes) that may be associated with decreased heterogeneity compared to complex behaviours, thereby facilitating the identification of specific genotypic associations.

Multi-variant analysis of "dopamine pathway" genes in skiers and snowboarders reveals no association with sensation seeking behaviours. *C.J. Thomson[1], S.R. Carlson[2], J.R. Rupert[1].* 1) Kinesiology, Univ British Columbia, Vancouver, BC, Canada; 2) Department of Psychology, University of Minnesota Duluth, Duluth, Minnesota, U.S.A.

The personality trait sensation seeking (SS) involves a desire to seek out new and thrilling experiences and has been associated with risky behaviours ranging from substance abuse to high-risk sports (*e.g.*, surfing, skiing). Approach-related traits, of which sensation seeking is one, are to some extent regulated by the neurotransmitter dopamine. Genes involved in dopamine synthesis, transport, and metabolism have been investigated in numerous studies of approach-related traits, externalizing disorders (*e.g.*, attention deficit hyperactivity disorder and conduct disorder), and substance abuse; however, few studies have measured sensation seeking specifically, and none have investigated the trait in a sporting context. We predicted that variants in genes contributing to the dopamine pathway would associate with sensation seeking behaviour in athletes. To test this, we developed a reliable questionnaire to evaluate SS behaviours in the context of skiing and snowboarding (the CSSQ-S). We administered this questionnaire, along with the commonly used Zuckerman-Kuhlman Personality Questionnaire (ZKPQ) that includes the Impulsive Sensation Seeking subscale (ImpSS) to a sample of male and female skiers from Western Canada (N = 575). Using DNA isolated from buccal cells, 32 SNPs in eight genes that encode proteins related to dopamine synthesis or function (*DRD1, DRD2, DRD3, DRD4, DAT1, COMT, MAO-B, DBH*) were genotyped. Many of the SNPs we examined had been previously explored in association with other externalizing phenotypes. Alleles at four genes (*DRD1* rs251937, *DRD2* rs6277 and rs1800497, *DRD3* rs167771, and *DAT1* rs27072 and rs463379) were associated with ImpSS score and/or CSSQ-S score (p < .05); however, these associations were not significant when the results were corrected for number of tests (*i.e.*, post FDR correction). While our data did support a correlation between skiing behaviour (as measured by the CSSQ-S) and SS in general (as measured by the ZKPQ), we did not find any evidence that alleles at the SNPs we examined were associated with SS behaviour in our cohort of skiers/snowboarders.

Comparative analysis of Dopamine D4 Receptor (DRD4) rare variants in Schizophrenia and Attention Deficit and Hyperactivity Disorder (ADHD): Further evidence of allelic heterogeneity contribution to ADHD etiology. *L. Tovo-Rodrigues[1], L.A. Rohde[2], T. Roman[1], A. Salatino-Oliveira[1], J.P. Genro[1], F.B. Kohlrausch[1], C. Kieling[2], C. Zeni[2], G.V. Polanczyk[3], M. Schmitz[2], E.S. Gama[2], M.I. Lobato[2], M.H. Hutz[1].* 1) Department of Genetics, UFRGS, Porto Alegre, RS, Brazil; 2) HCPA, Porto Alegre, RS, Brazil; 3) Department of Psychiatry, USP, São Paulo, SP, Brazil.

The dysregulation of the dopaminergic system has been implicated in the pathophysiology of ADHD and Schizophrenia. Some studies have suggested that the susceptibility genes underlying both disorders might partially overlap. DRD4 is one of the most variable genes in the human genome. Its third exon contains a VNTR of 48bp and differences of single nucleotide polymorphism inside the repeats. VNTR polymorphism can vary from 2 to 11 and 7 repeat has been suggested as a susceptibility allele for psychiatry diseases. However, association studies have shown conflicting results. As an excess of rare variants was observed in ADHD probands, these inconsistences could be explained by the presence of the mutation sites inside VNTR. This study aims to compare the VNTR sequence variability of 4R and 7R alleles in predominantly Euro-Brazilian ADHD, schizophrenic and control subjects. Out of 650, 208 and 330 genotyped ADHD, schizophrenic and control individuals respectively, all 7R and some 4R homozygous individuals were resequenced, comprising 132 ADHD alleles, 68 schizophrenia alleles, and 74 control alleles. DNA was amplified and PCR product was sequenced. Haplotypes were estimated using a Bayesian method implemented in PHASE2.1 software. Fisher's Exact Test was used to compare DRD4 variants distribution among the three groups. A total of 17 haplotypes were observed in this sample. When only 4R variants are considered, no difference were observed among groups (P=0.124). Considering 7R allele, a difference was observed among groups (P=0.009). The frequency of rare variants in ADHD, schizophrenia and control groups were 0.210 (33 variable sites), 0.000 and 0.033 (6 variable sites) respectively. Multiple comparison followed by Bonferroni correction revealed an excess of rare variants in ADHD when compared to control (P=0.042) and schizophrenia groups (P=0.014) while no difference was observed between control and schizophrenia groups (P=0.927). In conclusion, this study indicates the major effect of DRD4 exon 3 VNTR rare variants and allelic heterogeneity is on ADHD genetic susceptibility. Probably this finding is exclusive to this disorder and could not be extended to other psychiatry conditions. It is likely that all previous studies of the DRD4/ADHD association modestly underestimated the relative risk by only examining repeat length rather than DNA sequence.

546W

Mutation Screening of Microtubule Genes in Sporadic and Familial Patients with Bilateral Perisylvian Polymicrogyria. *S.S. Tsuneda[1], F.R. Torres[1], M.M. Guerreiro[1], C.A. Guimarães[1], V.C. Terra-Bustamante[2], M.A. Montenegro[1], F. Cendes[1], I. Lopes-Cendes[1].* 1) Unicamp, Campinas, SP, Brazil; 2) USP, Ribeirão Preto, SP, Brazil.

Polymicrogyria (PMG) is a malformation caused by abnormal brain cortex organization, characterized by multiple small gyri with abnormal cortical lamination. The most common site for PMG is the Sylvian fissure (80%), of which 40%; are bilateral. In these patients, the cerebral cortex on the border and in the depth of the Sylvian fissure is thickened and abnormally infolded, more vertically oriented and may be extending more posterior up to the parietal lobes, characterizing the syndrome called bilateral perisylvian polymicrogyria (BPP). Approximately 28 familial cases of BPP have been described, from which 75%; are compatible with an X-linked heritance pattern. Our group has recently described a candidate locus for BPP on chromosome Xq27.2-27.3. However, most patients with BPP are sporadic and mutations in microtubule genes, acting in microtubules dynamics, such as TUBA1A, TUBB2B, TUBA8A and WRD2, have been recently implicated with several types of cortical malformations. Among them, only TUBA1A has been related to BPP, in a single family. The objective of the present study is to search for mutations in TUBA1A, TUBB2B, TUBA8A and WRD2 genes in familial and sporadic patients with BPP. Genomic DNA obtained from 26 unrelated patients with BPP was used as template for polymerase chain reactions (PCR) with primers for coding regions and intron/exon boundaries of the candidate genes. Amplicons were submitted to automatic sequencing and the chromatograms obtained were compared to nucleotide sequences in the NCBI database. We identified four base substitutions in TUBA1A gene: c.453G>C, c.510T>C, c.522G>A and c.541G>A. The first three sequence variations have been already described as synonymous substitutions. However, c.541G>A has not been yet reported and was identified in three unrelated patients. This base change results in the translation of an isoleucine for a valine at the position 181 of the protein. Preliminary analysis with SNPs&GO ans SIFT algorithms show that this aminoacid substitution is probably neutral. Since both aminoacids (isoleucine and valine) have a very similar structure, raising the possibility of a non-pathogenic mutation. However, further experiments, including the investigation of a large number of control subjects are under way, in order to better investigate the possible role of this newly described sequence variation in the etiology of BPP. Financial support: CNPq, FAPESP and EMBRAPA.

Rare deletions at the *NRXN3* locus in individuals with Autism Spectrum Disorder. *A.K. Vaags[1,2], A.C. Lionel[1,2,3,4], D. Sato[1,2], J.L. Howe[1,2], C.R. Marshall[1,2], S. Lamoureux[1,2], I.E. Drmic[5], L. Senman[5], C. Chrysler[6], A. Thompson[6], C. Russell[6], D. Pinto[1,2], A. Prasad[1,2], S. Walker[1,2], W. Roberts[5,7], P. Szatmari[6], S.W. Scherer[1,2,3,4].* 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, ON, Canada; 2) Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 4) The McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 5) Autism Research Unit, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Offord Centre for Child Studies, Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Ontario, Canada; 7) Bloorview Kids Rehabilitation, University of Toronto, Toronto, Ontario, Canada.

The three members of the human neurexin gene family, *NRXN1*, *NRXN2* and *NRXN3*, encode neuronal adhesion proteins with important roles in synapse development and function. Recent research has implicated rare exonic copy number variants (CNVs) and point mutations at the *NRXN1* and *NRXN2* loci in Autism Spectrum Disorder (ASD) and other neurodevelopmental disorders. Illumina 1M and Affymetrix 6.0 microarray analysis of 1,600 ASD cases and their family members identified rare CNVs within the *NRXN3* gene. We now present clinical characterization of four subjects, from two unrelated families, with rare deletions at 14q24.3-31.1 overlapping exons of the *NRXN3* gene. Deletions with similar breakpoints to those seen in the probands were not observed in high-resolution microarray data from 8,427 population-based controls. The main phenotypic features in our subjects include characteristic behaviors associated with Asperger's syndrome and ASD, the severity of which, were correlated with the extent of the *NRXN3* deletion. These cases are now undergoing exome-sequencing to identify additional genetic changes that may contribute to ASD. In addition, Sanger sequencing of the coding region of the *NRXN3* gene in 350 ASD cases identified four individuals with *NRXN3* point mutations. Of note, these changes were also present in their unaffected siblings and thus may not be directly associated with the development of an ASD phenotype. This is the first report of ASD subjects with exonic deletions at the *NRXN3* locus, and adds to the evidence linking rare genetic variants affecting the neurexin gene family, with risk for neurodevelopmental disorders.

Expression-based *in silico* screening of candidate therapeutic compounds for mesial temporal lobe epilepsy. *J.F. Vasconcellos[1], C.V. Maurer-Morelli[1], C.S. Rocha[1], C.L. Yasuda[2], H. Tedeschi[2], E.D. Oliveira[2], F. Cendes[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences, State University of Campinas and CINAPCE Program, Campinas, SP, Brazil; 2) Department of Neurology, Faculty of Medical Sciences, State University of Campinas and CINAPCE Program, Campinas, SP, Brazil.

Mesial temporal lobe epilepsy (MTLE) is one of the most common forms of human epilepsy, whose pathological hallmarks are neuronal loss and synaptic reorganization in the hippocampus. The Connectivity Map (C-MAP, http://www.broadinstitute.org/cmap/index.jsp) is a web tool for gene expression signature screening *in silico* (represented by a set of genes with up- or down-regulated labels) that potentially reveals interactions among drugs, genes and diseases, providing information to identify potential drugs and targets based on gene expression analysis. MTLE is largely described as a sporadic disease; however, we and others have recently shown that MTLE can also segregate in families. The present study was conducted to investigate new potential therapeutic targets for the treatment of patients with MTLE based on their gene expression signatures through the C-MAP analysis. Transcriptional profiling by microarray analysis revealed that patients with MTLE and a positive family history [(+)FH] of MTLE had 170 differentially expressed genes and patients with a negative family history [(-)FH] had 341, when compared to healthy controls. C-MAP analysis of patients with (+)FH gene signature demonstrated a negative correlation with IL-6 and glycogen synthase kinase-3 inhibitors (connectivity score -0.692 and -0.568, respectively). IL-6 activation in epilepsy may play a role protecting the central nervous system (CNS) from seizure-induced damage, while glycogen synthase kinase-3 activates WNT pathway and may contribute to the regulation of neuronal survival and homeostasis in the CNS. C-MAP analysis of patients with (-)FH gene signature demonstrated a negative correlation with the signatures for TNF-(/NF-k) and HSP90 inhibitors (connectivity score -0.697 and -0.238, respectively). These inhibitors mediate the inactivation of main cell survival pathways. Interestingly, there was no overlap between the molecules from the C-MAP database that had a significant negative correlation in the (+)FH MTLE gene signature and those compounds which were identified in the (-)FH MTLE gene signature group. In conclusion, our data demonstrate for the first time the use of an *in silico* approach to search for potential molecular targets for the treatment of patients with MTLE based on its gene expression signature. Furthermore, the C-MAP revealed a clear difference in the gene expression profiles of MTLE patients with and without familial recurrence of the disease. Supported by: FAPESP.

White Matter Lesion on Brain MRI can be Diagnostic for ATR-X syndrome: The Study of Brain MRI/CT findings in ATR-X syndrome Patients in JAPAN. *T. Wada[1], H. Ban[2], K. Enomoto[3], K. Kurosawa[4], N. Aida[5], ATR-X Syndrome Network Japan.* 1) Pediatric Neurology, Kanagawa Children's Med Center, Yokohama, Japan; 2) Pediatrics, Himeji Red Cross Hospital, Himeji, Hyogo, Japan; 3) Pediatrics, Tokyo Medical and Dental University, Tokyo, Japan; 4) Genetics, Kanagawa Children's Med Center, Yokohama, Japan; 5) Radiology, Kanagawa Children's Med Center, Yokohama, Japan.

X-linked a-thalassemia/ mental retardation (ATR-X) syndrome (MIM#301040) is among X-linked mental retardation syndromes, which is due to mutations of ATRX gene, and is characterized by boy/male patients, central hypotonic facies, severe cognitive dysfunction, HbH disease (a-thalassemia), genital abnormality, skeletal abnormality, and autistic and/or peculiar behavior. More than 200 patients in the world, including more than 70 Japanese cases, have been diagnosed as ATR-X syndrome. ATR-X syndrome seems a rare disease, however, we estimated that the prevalence of ATR-X syndrome is 1/ 30,000-40,000 newborn boys, which is much higher than that have been reported formerly. So more patients should remain to be diagnosed. Since 2010, we have established ATR-X syndrome Japan Network for patients and their families, and we have surveyed ATR-X syndrome patients in Japan. In this study, we investigate the brain MRI and/or CT findings of 25 Japanese ATR-X patients who had ATRX gene mutations. The MRI/CTs of all other than five patients showed nonspecific brain atrophy. Interestingly, the T2 and FLAIR MRI of seven patients, which we could analyze precisely, showed high intensity of the white matter around the trigones with/without multiple small spherical foci that parallel CSF intensity, and some patients were misdiagnosed as a leukodystrophy or white matter disease. These findings did not seem to correlate with their clinical severity of the patients. The sequential MRIs of another patient, who had infantile spasm at 1 year old, showed progressive brain atrophy and ventricular enlargement. We should consider ATR-X syndrome as differential diagnosis in patients with intellectual disabilities, whose T2 or FLAIR MRI shows high intensity regions in white matter, especially around the trigones. And we propose these findings as associated (<50) features or supporting features of the diagnostic criteria of ATR-X syndrome or ATRX gene mutation positive patients with atypical ATR-X syndrome features. We are now establishing the diagnostic criteria, which facilitate further clinical study of individuals with proven ATR-X molecularly, and assist in the evaluation of those who appear to have clinical features of ATR-X with no ATRX mutations. We should evaluate brain MRI of more patients to validate these findings and update the consensus for it in the near future.

Association of candidate genes conferring susceptibility to schizophrenia in a sample from Indonesia with 1097 cases and 1112 controls reveals association with rs1344706 located in the ZNF804A gene. *D. Wildenauer[1], N. Dai[1], W. Qin[1], M. Wildenauer[1], A. Kusumawardhani[2], S. Schwab[3], Indonesia Schizophrenia Genetic Consortium.* 1) CCRN Sch Psychiatry, UWA, Claremont, Australia; 2) Department of Psychiatry, University of Indonesia; 3) Department of Psychiatry, University of Erlangen-Nuremberg.

Schizophrenia is a complex genetic disorder with heritability of up to 80%. World-wide prevalence (life time risk) is on average about 1%. We hypothesize that genes conferring risk for schizophrenia are present in all populations and can therefore be detected in populations with different ethnic background. However, population specific susceptibility alleles may exist. Identification of these alleles may aid in gene identification in schizophrenia as well as in characterization of the reported differences in course and outcome between developing and developed countries. We have consecutively ascertained a sample of 1097 individuals with schizophrenia and 1112 non-psychiatric controls in five Mental State Hospitals in the area of Jakarta, Indonesia. Diagnosis was made according to the DSMIV criteria by psychiatrists, trained in the use of a structured interview (DIP) in Bahasa Indonesia translation. In addition, from previous studies we have a sample of 124 families from Indonesia with 2 or 3 affected siblings with parents (318 affected, 686 individuals in total) available. This family sample revealed genome-wide significance for a schizophrenia locus on chromosome 3p26-21. Using a TDT based approach we obtained some evidence for association for SNP rs 1703183 which is located in the linked area in the region of the GRM7 (Metabotropic Glutamate Receptor 7) gene. For our current association studies based on the sample of 1097 case and 1112 controls we have followed up this initial finding. In addition, we followed up on findings from GWAS studies in Caucasian samples, i.e rs2958182 (TCF4, chr18q), rs1344706 (ZNF804A, chr2), rs795009 (SYN2, chr3p), and rs2660304 (MIR137, chr 18). In order to assess homogeneity of our case control sample, we characterized all samples in respect to ethnicity, sampling error and genotyping quality, using a DNA test panel with 360 evenly spaced SNPs (Illumina). Evidence for association was obtained for rs1344706 (ZNF804A) with a P-value of 0.006 (chi2 test). Genotype distribution was also statistically significantly different between cases and controls (P=0.027). The odds ratio was 1.179 (95% confidence interval 1.047 - 1.327). Controls revealed a T-allele frequency of 0.488, cases a frequency of 0.529, which is different from Caucasian samples, but similar to Han Chinese samples. Our results support a potential role of ZNF804A in the etiology of schizophrenia and may confirm that this is not population specific.

551W

Loss-of-function mutation of collybistin is responsible for X-linked mental retardation associated with epilepsy. *T. Yamamoto[1], K. Shimojima[1], M. Sugawara[1], M. Shichiji[1,2], S. Mukaida[3], R. Takamaya[3], K. Imai[3].* 1) Inst Integrated Medical Sci, Tokyo Women's Med Univ, Tokyo, Japan; 2) Department of Pediatrics, Tokyo Women's Medical University, Tokyo, Japan; 3) National Epilepsy Center, Shizuoka Institute of Epilepsy and Neurological Disorders, Shizuoka, Japan.

Microarray-based comparative genomic hybridization analysis identified a 737-kb microdeletion of Xq11.2 including the cdc42 (cell division cycle 42) guanine nucleotide exchange factor (GEF)-9 gene (ARHGEF9), encoding collybistin which plays a pivotal role in formation of postsynaptic glycine and gamma-aminobutyric acid (GABA)A receptor clusters, in a male patient with severe mental retardation and epilepsy. No overlapping deletion with this was identified in the database of genomic copy number variations. A cohort study of ARHGEF9 nucleotide sequence identified a nonsense mutation in another male patient with severe mental retardation and epilepsy. This mutation affects one of the 3 transcript variants of ARHGEF9, which was confirmed to be expressed in the brain by RT-PCR. Although this nonsense mutation was shared with the patient's mother, it was not observed in 100 normal individuals. Both male patients suffered epileptic seizures after 1 year of age. Brain magnetic resonance imaging revealed mild frontal atrophy in the first patient and right frontal polymicrogyria in the second patient. Three previously reported mutations of ARHGEF9 consisted with a missense mutation in a male patient with hyperekplexia and two chromosomal disruptions in 2 female patients. The common phenotypic effects of all ARHGEF9 mutations were mental retardation and epilepsy. Therefore, ARHGEF9 is likely to be responsible for syndromic X-linked mental retardation associated with epilepsy.

552W

Variants in NRG3 at 10q23.1 correlated with a subtype of schizophrenia with severe delusions. *M. Zeledón[1,2,3], M. Taub[4], N. Eckart[1,2], R. Wang[3], M. Szymanski[1,2], P. Chen[5], A. Pulver[3,6], D. Avramopoulos[1,3], A. Sawa[3], D. Valle[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Medical Institute, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins Medical Institute, Baltimore, MD; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 5) Department of Medical Genetics, National Taiwan University Hospital, Taipei City, Taiwan; 6) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

Schizophrenia (SZ) is a disabling psychiatric disease affecting 1% of the world's population. Previously, we reported a linkage peak (NPL of 4.7) at 10q22 in the Ashkenazi Jewish (AJ) population and followed this up with a fine mapping association study that found significant association between a phenotypic quantitative trait “delusion” and 3 SNPs in intron 1 of NRG3 (Chen et al., AJHG 84:21, 2009). Two other groups have replicated our findings in outbred samples. To identify causative variants in the 162kb LD block covering the 5' end of NRG3 and containing the 3 associated SNPs we performed Illumina sequencing of this LD block in 47 AJ SZ patients at the extremes of the delusion trait distribution. We found 5 variants in a 10kb segment of intron 1 with significant frequency differences (including 2 of the previously reported SNPs) and an inherited 1.8kb microdeletion 21.5kb upstream of the transcription start site. An individual homozygous for the deletion allowed us to unambiguously define the deletion haplotype which includes the risk alleles for all 5 associated SNPs. The deletion frequency among the AJ SZ patients with the highest delusion scores (MAF=10.1% n=69, 7 deletion carriers) was higher than in patients with the lowest delusion scores (MAF=0%, n=67, Fisher's exact p=0.013). We tested the correlation between delusion scores and deletion frequency for 658 AJ SZ patients across the range of delusion scores, and found the deletion significantly correlated with higher delusion factor scores (p genotype effects=0.0069). Due to its location 5' of the transcription start site, this deletion may be perturbing regulation of NRG3 expression. Alternatively, it may tag a haplotype containing the causative variant(s). In this regard, preliminary data on RNA from 180 temporal lobe samples show that one of the 5 delusion associated SNPs (rs10748842) is also strongly associated with the use of alternative NRG3 transcription start sites in adult brains. Our data suggest that the deletion or, more likely, one of the associated SNPs perturb expression of NRG3 isoforms and lead to increased risk for a high-delusion SZ phenotype. Understanding how variation in this region affects NRG3 regulation will allow us to decipher the mechanistic pathways leading to risk for SZ or modifications of the SZ phenotype.

553W

GWAS scoring routines and serial, permutated enrichment analyses reveal a substantial polygenic component to the risk of alcohol dependence, with biological ontologies implicated in both European-American and African-American subjects. *M. Zlojutro[1], D.M. Dick[2], A. Agrawal[3], K.K. Bucholz[3], M. Schuckit[4], S. Kuperman[5], J. Kramer[6], J.A. Tischfield[7], J.I. Nurnberger, Jr.[8], V. Hesselbrock[9], B. Porjesz[10], L. Bierut[3], H.J. Edenberg[8], L. Almasy[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Virginia Commonwealth University, Richmond, VA; 3) Washington University School of Medicine, St. Louis, MO; 4) University of California, San Diego VA Medical Center, San Diego, CA; 5) University of Iowa College of Medicine, Iowa City, IA; 6) Department of Psychiatry, University of Iowa College of Medicine, Iowa City, IA; 7) Human Genetics Institute of New Jersey, Rutgers University, Piscataway, NJ; 8) Indiana University School of Medicine, Indianapolis, IN; 9) University of Connecticut Health Center, Farmington, CT; 10) Department of Psychiatry, SUNY Downstate Medical Center, Brooklyn, NY.

Alcohol dependence (AD) is a complex disorder in which both genetic and environmental factors affect susceptibility. Linkage, candidate gene and genome-wide association studies (GWAS) have identified several genes associated with AD, although explaining only a small fraction of the overall risk. To better understand the polygenic structure of the hereditary component underlying AD risk, we developed a series of scoring routines for aggregating genotypic information. Routines were delineated by P-value thresholds, both in cumulative and non-cumulative manners, and weighted by AD odds ratios derived from case-control GWAS data for European-American (EA; n=1,274) and African-American samples (AA; n=457) from the Collaborative Study on the Genetics of Alcoholism (COGA). Scores, representing hundreds or thousands of SNP variants, were calculated in population-matched target samples from the Study of Addiction: Genetics and Environment (SAGE) GWAS data. In addition, SNPs used in the various scoring routines were annotated to gene locations and tested for gene enrichment of biological pathways and ontologies using a permutated approach. SAGE scores explained a significant, yet small percentage of the variation in AD status, with peak values occurring at P-value thresholds of <0.05 and <0.30 for EA and AA target samples, accounting for 0.73% (P= 1.64 ×10-3) and 2.14% (P=2.08×10-4) of the variation, respectively. For non-cumulative routines, significant scores were observed at 0.50<P<0.55 and 0.55<P<0.60 for EAs and AAs, indicating that a substantial polygenic component underlies AD, involving thousands of common alleles, many of small effect. The COGA-derived scoring routines were also applied in the alternate population target samples, which showed no significant evidence of association, suggesting that population-specific alleles play an important role in AD risk. However, gene enrichment analysis of the various routines found several biological ontologies and pathways enriched in both the EA and AA samples. These include glucocorticoid receptors (significantly enriched for routines with P-value thresholds <0.20) and Maf transcription factors (P thresholds <0.35), as well as chloride transport (0.30< P thresholds <0.55) and glycine metabolism (0.30< P thresholds <0.85) that include gene variants of much smaller effect. These results underscore the complex, polygenic nature of AD and provide key insights into its underlying etiological mechanisms.

554W

RAAS pathway genes in susceptibility to Intracranial aneurysm in Indian population. *M. Banerjee[1], L.V Koshy[1], S. Sathyan[1], H.V. Easwer[2], S. Premkumar[3], J.P. Alapatt[3], R.N. Bhattacharya[2].* 1) Dept Human Molec Gen, Rajiv Gandhi Ctr Biotech, Trivandrum Kerala, India; 2) Dept. Neurosurgery, SCTIMST, Trivandrum Kerala, India; 3) Dept. Neurosurgery, Calicut Medical college, Calicut, Kerala, India.

Intracranial aneurysm (IA) is a fairly common condition that is often asymptomatic until the time of rupture, resulting in Aneurysmal subarachnoid hemorrhage (aSAH), ensuing significant morbidity and mortality. It is the cause for an estimated five to 15 percent of all strokes. The reported prevalence rate of intracranial aneurysms in India varies from 0.75 to 10.3 percent as determined in angiographic and autopsy studies. Current evidence supports the concept, that the pathogenesis of intracranial aneurysms has a multifactorial origin, where the essential defect of the arterial wall may, at least in part be genetically determined. Hypertension is one of the most common population attributable risk factor for aSAH in Indian population. Renin-Angiotensin-Aldosterone System (RAAS) plays a very prominent role in regulation of blood pressure by influencing vascular volume, homeostasis and vascular tone. The genes that encode components of the RAAS are thought to play a role in determining genetic susceptibility to essential hypertension, and may also be viewed as a candidate pathway for IA. The mechanism of decreased expression of local RAAS could be attributed to mutations in genes that encode components of the RAAS systems, thereby conferring a genetic susceptibility to IA. These genetic mutations could act as effect modifiers that could interact with environmental risk factors like hypertension to influence the presence or absence of IA, or even the rupture of IA. In the present study we focused on six primary blood pressure-regulating genes of the RAAS: renin (REN), angiotensionogen (AGT), angiotensin I-conveting enzyme (ACE), angiotensin II receptor, subtype 1 (AGTR1) , cytochrome b-245 alpha polypeptide (CYBA) and endothelin-1(EDN1) as potential candidate genes. The most significant association was seen with EDN1 -2212G/A polymorphism, which was also found in genotypic and haplotypic combination. ACE 2350G/A polymorphism also revealed significant association. Gene x gene interactions also supported the interaction among these risk conferring alleles of EDN1 and ACE while the gene x environment interactions were independent of EDN1. The genetic risk indicated by a 5' regulatory region of EDN1 -2212G/A, and epigenetic risk indicated by a miRNA binding region of the AGTR1 1166A/C, interacted independently with a common denominator ACE 2350G/A for developing IA. Our results indicate novel genetic and epigenetic interactions of RAAS pathway genes.

Common genetic susceptibility to autism spectrum disorder (ASD) and dyslexia (DYS). *M.L. Cuccaro[1], D. Ma[1], E.R. Martin[1], J.L. Haines[2], J.R. Gilbert[1], M.A. Pericak-Vance[1].* 1) Dept Med, Univ Miami Sch Med, Miami, FL; 2) Center for Human Genetics Research, Vand Univ, Nashville, TN.

Autism spectrum disorder (ASD) is a neurobehavioral phenotype with a strong genetic component. A common finding in ASD is an increased prevalence of other neurobehavioral disorders (e.g., epilepsy, intellectual disability, and learning disabilities) in affected individuals and first-degree relatives. For example, in families with both ASD and epilepsy, we found an increased rate of dyslexia (DYS) in first-degree family members vs. families with ASD alone. This supports the emerging model that select genetic variants give rise to diverse neurobehavioral phenotypes. We hypothesize that DYS genes will be more strongly associated with both ASD and DYS in the subset of families with DYS relatives compared to the ASD-only families. To test this hypothesis, we examined whether variants in DYS genes tend to have p-values ranked lower among the ASD+DYS families compared to the ASD-only families. We first identified nine high-profile DYS candidate genes (KIAA0319, CMIP, DYX1C1, CNTNAP5, DOCK4, DCDC2, PCSK6, SLC2A3, GRNI2B) based on the existing literature. Then, from our overall ASD data set (ascertained based on DSM-IV/ADI-R criteria) we identified a subset of DYS families (N=33). Using family history data, a family was classified as DYS if at least one non-ASD individual within the nuclear family was positive for DYS (36 parents; 3 siblings). Using data from high-density SNP arrays, family-based association analysis was carried out using Combined Association in the Presence of Linkage test (CAPL) treating individuals with ASD and DYS as affected and all others as unaffected. In addition, CNV detection was carried out on samples and high-confidence CNVs were detected by two distinct algorithms. There were 673 SNPs falling in the nine candidate gene regions. Fifty-five SNPs presented a p-value of less than 0.05 [0.001-0.049]. A total of 542 case-unique CNVs were identified among the 37 DYS individuals (two dropped due to QC) who were genotyped using Illumina 1M chip. However, none of the nine candidate genes appear to be disrupted by these CNVs. An investigation of CNVs from a unique subset of eight patients who had both ASD and DYS did not identify any shared CNVS. While none of the association results survived multiple testing corrections, we did observe a greater frequency of significant p-values in DYS candidate genes than expected by chance in our DYS subset (8.2% vs. 5%). This suggests that DYS genes may be involved in risk for both ASD and DYS.

Direct genetic effects of putative functional SNPs in CRH pathway genes associated with anxious temperament in rhesus macaques. *G.L. Fawcett[1,2], M. Raveendran[2], J.A. Oler[5], A.S. Fox[5], S.E. Shelton[4], D.M. Muzny[2], R.A. Gibbs[1,2], N.H. Kalin[4,5], J. Rogers[1,2,3].* 1) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX 77030; 2) Human Genome Sequencing Center, Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX, 77030; 3) Southwest National Primate Research Center, San Antonio, TX 78245; 4) Department of Psychiatry, The HealthEmotions Research Institution, University of Wisconsin-Madison, Madison, VI 53719; 5) Department of Psychology, Waisman Laboratory for Brain Imaging and Behavior, University of Wisconsin-Madison, Madison, WI 53705.

Children who exhibit extreme anxiety in the face of novel challenges are predisposed to developing clinical anxiety problems as adults. The corticotrophin releasing hormone (CRH) pathway has been implicated in mediating individual variation in later risk of anxiety and depression. Various lines of evidence demonstrate that increased activity in the CRH pathway results in elevated anxious behavior. Using a well validated rhesus monkey model to assess anxiety, brain metabolic rates in the amygdala and anterior hippocampal regions were shown to be associated with anxious temperament (AT), a composite behavioral phenotype including blood cortisol measurements, freezing behavior, and vocalization behavior among juveniles in response to a brief mildly stressful challenge. Both AT and hippocampal metabolic rates during assessment of anxious behavior show strong heritability (h^2=0.50 and h^2=0.52, respectively). Additionally, we have previously associated an intronic SNP (*SNP9111*) in *CRHR1* with AT in this population (n_220). In our current work, 447 rhesus macaques from a single pedigree were resequenced (Sanger) for four genes (*CRH*, *CRHR1*, *CRHR2*, and *CRHBP*). Using measured genotype analysis in SOLAR, we replicated the association of *SNP9111* with AT. Of particular interest, we identified a putative functional nonsynonymous SNP (*SNP5043*) in strong linkage disequilibrium with *SNP9111* that is significantly associated with AT (p=0.002). *SNP5043* is located in exon 6 of *CRHR1*, the sole exon in *CRHR1* displaying significant conservation only within higher order primates. Several other SNPs and indels in other genes in the CRH pathway also showed significant association with AT; one in *CRH* (*SNP3155*) was detected as probably damaging using Polyphen-2. We conclude that a complex genetic architecture composed of direct effects in multiple genes contributes to the strong heritability for AT in this rhesus macaque model. Efforts to characterize the direct genetic and possible epistatic contributions to AT and its neural substrates are underway to gain further insight into the childhood risk to develop anxiety and depression.

Association Study of Five Genes and Early-Onset Generalized Anxiety Disorder. *Y. Feng[1], K. Manassis[2], D. Avery[2], CL. Barr[1, 2].* 1) Genetics & Development Division, Toronto Western Hospital, Toronto, ON, Canada; 2) Hospital for Sick Children, Toronto, ON, Canada.

Introduction: Anxiety disorders are common with the prevalence of the group of disorders estimated as high as 25% in the population. Twin studies indicate moderate heritability for anxiety disorders with a very high genetic correlation (.99) with major depressive disorder. Here we investigate the relationship of five genes (AVP, AVPR1B, CRH, GABRD, and NTRK3) to early-onset anxiety in a sample of families with children/adolescents with generalized anxiety disorder (GAD). We focused on markers we previously identified as associated with childhood-onset depression because of the genetic overlap indicated from family and twin studies. Methods: We genotyped 17 markers in those five genes in 161 families with a child/adolescent proband (165 affected children) with a diagnosis of GAD and tested for association using the Transmission Disequilibrium Test (TDT). Results: We found evidence for biased transmission of the alleles of the SNP rs1870393 in the CRH gene (p=0.022) and a trend for alleles of the SNP rs2376803 in the GABRD gene (p=0.059). Conclusions: While preliminary, these results support the role of hypothalamic-pituitary-adrenal (HPA)-axis and GABAergic system in early-onset generalized anxiety disorders. Further studies are in progress to determine the nature of this association.

Increased exonic de novo mutation rate in probands affected with schizophrenia. *S.L. Girard[1], J. Gauthier[1], A. Noreau[1], L. Xiong[1], S. Zhou[1], L. Jouan[1], A. Dionne-Laporte[1], D. Spiegelman[1], E. Henrion[1], O. Diallo[1], J.Y.J. Bao[2], A.H.Y. Tong[2], C.H. Lin[2], B. Millet[3], N. Jaafari[3], R. Joober[4], P. Dion[1], S. Lok[2], M.-O. Krebs[3], G.A. Rouleau[1].* 1) CENUM, Universite de Montreal, Montreal,; 2) Genome Research Centre, The Li Ka Shing Faculty of Medicine, University of Hong Kong; 3) Université Paris Descartes, Faculté de Médecine Paris Descartes, Paris, France; 4) Douglas Mental Health University Institute, Department of Psychiatry, McGill University, Montréal.

Schizophrenia (SCZ) is a severe psychiatric disorder that profoundly affects cognitive, behavioral and emotional processes. The wide spectrum of symptoms and clinical variability in SCZ suggest a complex genetic etiology, which is consistent with the numerous loci thus far identified by family linkage, copy number variation (CNV) and association studies. While SCZ heritability may be as high as ~80%, the genes responsible for much of this heritability remain to be identified. Using high-throughput sequencing technologies, we sequenced the exome of 14 patients with schizophrenia and their parents. We identified 15 de novo mutations (DNMs) in 8 probands, which is significantly more than expected considering the previously reported DNM rate. In addition, 4 of the 15 identified DNMs are nonsense mutations, which is more than expected by chance. Our study supports the notion that DNMs may account for a fraction of the heritability reported for SCZ while providing a list of genes possibly involved in disease pathogenesis.

559W

Evaluation of Candidate Genes for Autism using Vineland Adaptive Behavior scales-II as covariates in APL-OSA. *J. Jaworski[1], I. Konidari[1], p. Whitehead[1], E. Martin[1], M. Cuccaro[1], J. Gilbert[1], J. Hussman[2], M. Pericek-Vance[1], J. Haines[3], R. Chung[1].* 1) MIHG, University of Miami - Miller School of Medicine, Miami, FL; 2) Hussman Foundation, Ellicott City, Maryland; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Autism is a complex disorder of neurodevelopment and is characterized by social impairments, language problems, and interfering repetitive behavior. Although a broad range of methods have implicated a number of candidate genes to be associated with Autism, no single gene has shown consistent replication across datasets and methods. Genetic heterogeneity can be one of the reasons that causes this inconsistency. If clinically derived traits are correlated with genes responsible for a subset of families with autism, they can be used to dissect the entire sample and identify the homogeneous subset. The Vineland Adaptive Behavior scales (VABS-II)is a widely used measure of adaptive functioning and has been used as a quantitative trait in prevous studies of ASD. The VABS-II consists of four domains (Communication, Daily Living, Socialization, and Motor Skills) and the Adaptive Behavior Composite score, an overall index. APL-OSA is an association method that can identify a genetically homozygous subset of families based on a trait-related covariate. Every individual from each family is assigned a domain score and the single marker association is evaluated from lowest to higher scoring families. The subset of families with the largest association statistic is selected and a permutation procedure is used to test the relationship between the family-specific covariate values and the association statistics. The dataset consisted of 428 Autistic Caucasian multiplex families with a total of 1585 individuals of which 708 were affected. SNPS of various candidate genes were typed for the dataset using the Illumina1Mduo chip. Using the Adaptive Behavior Composite score as a covariate yielded a significant SNP, RS757775 (p-value 0.03) within the candidate gene OXTR on chromosome 6. In addition, another SNP in the OXTR gene was significant for the communication skills domain (RS6443206, p-value 0.02). Both observations were observed as the covariate was sorted from low to high indicating a deficiency in the domain. Although the markers did not pass multiple testing corrections, this gene had previously been seen to be associated with autism as well as the VABS and IQ. We have independently replicated previously reported association with the OXTR gene and autism. The use of the VABS-II domain scores with APL-OSA on other candidate genes for autism could lead to the discovery of more genes associated with the disease.

560W

Evidence of imprinting at the autosomal recessive intellectual disability gene, TRAPPC9, and a possible role for CNVs at this locus in autism. *L. Kaufman[1], M. Ishida[2], K. Nakabayashi[3], A. Mir[4], G. Moore[2], J. Mill[5], S. Lewis[6], B. Fernandez[7], M. Ayub[8], J. Vincent[1].* 1) Neurogenetics, Univ Toronto, Toronto, Canada; 2) Institute of Child Health, University College London, 30 Guilford Street, London WC1N 1EH; 3) Department of Maternal-Fetal Biology, National Research Institute for Child Health and Development, Tokyo 157-8535, Japan; 4) Department of Bioscience, COMSATS Institute of Information Technology, Islamabad, Pakistan; 5) King's College London, MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, De Crespigny Park, London, UK; 6) Department of Medical Genetics, UBC, Vancouver, BC, Canada; 7) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St John's, Newfoundland, Canada; 8) School of Medicine and Health, Durham University, Durham, UK.

TRAPPC9 is a gene that has been implicated in autosomal recessive intellectual disability (ID). Its protein product, NIBP, is an activator of the NF-2b transcription factor and may be involved in cellular trafficking. Many ID genes have been implicated in autism and we hypothesized that *TRAPPC9* mutations may contribute to the autism phenotype as well. Unique CNVs overlapping *TRAPPC9* have been identified in 7 individuals with varying neurodevelopmental phenotypes. Four of these CNVs are maternally inherited, one is paternally inherited, and two are of unknown inheritance. Two are duplications, five are deletions, and all of them overlap exons of the gene. We have validated two of these CNVs, a deletion and duplication, using qPCR. *TRAPPC9* displays a recessive inheritance pattern in individuals with ID, however, it is partially paternally imprinted in mouse brain. Two other genes at the same locus, *Kcnk9* and *Eif2c2,* are also imprinted in mouse brain. Our group has confirmed preferential maternal expression (~80%) of *Trappc9* in mouse brain using a pyrosequencing assay and has demonstrated that expression is relatively consistent across brain regions and development periods. We also found that imprinting is specific to NPCs and neurons. Imprinting status in humans is still unknown, however, we hypothesized that maternally inherited CNVs may contribute to an observable phenotype by disrupting the dosage of the gene. To assess if maternally inherited truncating mutations have an effect on phenotype we reassessed unaffected carriers from an ID family with a *TRAPPC9* mutation. We found that unaffected carriers with a maternally inherited mutation were phenotypically normal, whereas those with a paternally inherited mutation were borderline ID. It is also possible that CNVs overlapping *TRAPPC9* result in the disruption of imprinting at this locus. No imprinting control region (ICR) is known for this locus however, *Peg13*, a paternally expressed, non-coding RNA that overlaps intron 17 of *Trappc9* in mice, has been proposed as a potential candidate. While there is no known homolog in humans, mRNAs that are proximally similar to *Peg13* have been identified. CNVs overlapping *TRAPPC9* have been identified in individuals with autism, however it is unclear if and how they contribute to the phenotype. Further studies, including the analysis of *TRAPPC9* imprinting in human brain and identification of an ICR will allow for better insight into the role of this genetic variation.

561W

Response to Antidepressants is associated with Polymorphisms in the Leptin Gene and reduced Leptin availability. *S. Kloiber[1], S. Ripke[2], B. Puetz[1], J. Hennings[1], P. Weber[1], M. Ising[1], M. Uhr[1], EB. Binder[1], B. Muller-Myhsok[1], F. Holsboer[1], S. Lucae[1].* 1) Dept Psychiatry, Max Planck Inst, Munich, Germany; 2) Center for Human Genetic Research, MGH Simches Research Center Boston, MA, USA.

Leptin, one of the key players in weight regulation, has been shown to exert antidepressant-like effects. Therefore we analyzed genetic variants in the leptin gene, leptin mRNA-expression, and leptin plasma concentrations in a sample of depressed inpatients from the Munich Antidepressant Response Signature (MARS) project. SNPs in the leptin gene were associated with response to antidepressant treatment. Results remained significant after correction for multiple testing and could be partially replicated in a second sample. Diminished leptin mRNA expression and decreased leptin levels could be linked to unfavorable treatment outcome. Our data thus point towards a role of leptin in antidepressant treatment response.

Targeted sequencing of *ALDH2* and ADH cluster loci shows differences in distribution of rare SNPs in European American alcohol dependent subjects and controls. *J.B. Listman[1], H. Zhao[2,3], X. Chen[3,8], H.R. Kranzler[4,5], J. Gelernter[1,3,6,7].* 1) Department of Psychiatry, Yale U Sch Med, New Haven, CT; 2) Department of Epidemiology and Public Health, Yale U Sch Med, New Haven, CT; 3) Department of Genetics, Yale U Sch Med, New Haven, CT; 4) Department of Psychiatry, U of Pennsylvania Sch Med, Philadelphia, PA; 5) VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 6) VACT Healthcare Center, West Haven, CT; 7) Department of Neurobiology, Yale U Sch Med, New Haven, CT; 8) Program in Computational Biology and Bioinformatics, Yale U Sch Med, New Haven, CT.

Genes encoding the main components of the ethanol metabolism pathway, alcohol dehydrogenase cluster loci (*ADH1a,1b,1c,4,5,6,7*) and aldehyde dehydrogenase 2 (*ALDH2*) harbor numerous common variants that affect drinking behaviors. Alcohol dependence (AD) has a heritability of 0.5-0.6 in populations of European ancestry but known risk alleles cannot account for this. Consistent with what is now known about rare and non-coding variant effects on complex phenotypes, we hypothesized that we could identify regions within the ADH cluster on chr4 and *ALDH2* on chr12 that are particularly sensitive to variation that affects risk for AD. We also hypothesized that some of the regions that are likely regulatory would be conserved in controls but show greater variation in the form of rare variants in cases. Samples from 16 European American (EA) AD cases and 8 EA AD controls were sequenced for the seven ADH cluster genes and *ALDH2* including introns, exons, 20kb upstream to the 5' end and 10kb downstream from the 3' end for a total of approximately 385kb. Regions were amplified using RainDance-designed primers and a droplet-based microfluidic PCR process. Twenty-four tagged samples were sequenced in two lanes of an Illumina GAII. Mapping was performed using the Burrows-Wheeler Alignment Tool with 3 mis-matches and no gaps allowed and SAMtools was used for genotype calling and SNP calling. We used Polyphen to test for potentially damaging non-synonymous variants and identified potential regulatory regions through UCSC Genome Browser ChIP-Seq and DNAse study data. We found differences between cases and controls in patterns of locations of novel rare SNPs. Consistent with the hypothesis, non-coding, putative regulatory regions of *ADH5* and *ADH7* contained multiple SNPs in 2/3 of cases but in no controls. SNPs in controls did not show clustering in a particular genomic region. Our preliminary findings require detailed follow-up.

563W

Single nucleotide polymorphism (SNP) fine mapping of the *AVRP1a* and *OXTR* region in families with autism: associations in the *OXTR/CAV3* locus. *A. Lori[1], I. Lee[2], J.F. Cubells[1,3], T. Lehtimäki[4], K. Puura[5], D. Skuse[2], L.J. Young[3], E.B. Binder[1,6].* 1) Departments of Human Genetics, Emory University School of Medicine; Atlanta GA, USA; 2) Behavioural and Brain Sciences Unit, University College London, Institute of Child Health, London, UK; 3) Departments of Psychiatry and Behavioral Sciences, Emory University School of Medicine; Atlanta GA, USA; 4) Dept of Clinical Chemistry, Tampere University and University Hospital, Tampere, Finland; 5) Dept of Child Psychiatry, Tampere University and University Hospital, Tampere, Finland; 6) Max-Planck Institute of Psychiatry, Munich Germany.

Autism spectrum disorders (ASDs) are neurodevelopmental disorders characterized by deficits in social behavior and communication, and by idiosyncratic interests and repetitive behaviors. Although highly heritable, few association studies have successfully identified genes that contribute to risk for ASDs. Vasopressin (AVP) and Oxytocin (OXT) and their receptors appear to play important roles in a social behaviors such as social attachment, and several studies have reported associations of the genes encoding these peptides and receptors with ASD, or with variation in human social cognitive function. We tested whether variation at *AVPR1A* and *OXTR1*, respectively encoding the AVP-1a receptor and OXT receptor, is associated with ASD in 170 families ascertained for ASD, from Finland and the UK. SNPs were selected using HAPMAP and SNP Browser. Criteria for selection included a minor allele frequency of >0.01 and pairwise r2 of 0.85 among validated SNPs. A total of 31 SNPs for *AVRP1A* and 62 SNPs for *OXTR1* were successfully genotyped using a Sequenom platform. A TDT analysis using PLINK was performed in the 170 families using single SNP and 2 and 3 SNP sliding window haplotype analyses. In the single SNP analyses, no association was observed for *AVRP1A* for any of the SNPs. In the *OXTR1* region, however, rs237865 associated with ASD with experiment-wide significance after correcting for multiple testing (p=0.0004). Two- and 3-SNP haplotypes including this SNP also showed significant associations (0.02 > p > 0.0002). The SNP is located in the 5' region of *Caveolin3* (*CAV3*) and 3' of *OXTR1* and ongoing eQTL analyses might resolve which genes' expression is affected by the associated polymorphisms. CAV3 is expressed in skeletal and smooth muscle, glial cells and early postnatal peripheral nerve. CAV3 is also involved in glucose homeostasis and obesity. Mutations within this gene cause neuromuscular and cardiac disorders, but also idiopathic elevation of serum creatine kinase, and sudden infant death syndrome. Further research is warranted to confirm associations between this locus and ASD, and to investigate the hypothesis that *CAV3* associates with metabolic dysfunction sometimes observed in patients with ASD, or whether the observed SNP association, if replicated, represents an association to functional variation at *OXTR1*.

564W

The SNP and haplotype analysis of CD200 gene with schizophrenia in a Japanese population. *F. Nishimura[1], A. Yoshikawa[1], M. Tochigi[1], Y. Kawamura[1,2], T. Umekage[3], T. Sasaki[4], K. Kasai[1], C. Kakiuchi[1].* 1) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 2) Yokohama Clinic, Kanagawa, Japan; 3) Division for Environment, Health and Safety, University of Tokyo, Tokyo, Japan; 4) Office for Mental Health Support and Graduate School of Education, University of Tokyo, Tokyo, Japan.

Introduction: Schizophrenia is one of the major mental disorders with approximately 1% prevalence rate. It is the most debilitating psychiatric disorder, inflicting much burden upon the patient, the family, and the society. The family, twin and adoption studies have established that the genetics play a significant role in the etiology of schizophrenia. On the basis of these studies, the heritability of schizophrenia is approximately 80%. However, genetic variants with decisive effect of schizophrenia have not been completely identified yet. We previously used DNA microarray analysis to examine the mRNA expression patterns in the lymphoblastoid cells derived from two pairs of monozygotic twins discordant for schizophrenia. We found the downregulation of the CD200 in all of the five independent replicates for each twin pairs. CD200 is expressed on B-cells and neurons and it downregulates microglia activation through CD200R. The notion that the immune system in schizophrenics may be involved in its susceptibility and the neuropathology of schizophrenia has recently been reported to be closely associated with the above-mentioned microglia activation. On the other hand, the upregulaion of CD200R1/CD200 pathway in the animal model of rheumatoid arthritis has been implicated. Interestingly, there is an inverse correlation between the occurrence of schizophrenia and rheumatoid arthritis. Hence, we considered CD200 as the possible common susceptibility gene for schizophrenia and rheumatoid arthritis. Method: 384 patients with schizophrenia diagnosed by DSM-IV criteria and 384 sex and age matched healthy control subjects were recruited. The objective of this study was clearly explained and written informed consent was obtained from all subjects. The study was approved by the Ethical Committee of the Faculty of Medicine, University of Tokyo. We selected the 23 tag SNPs from the JSNP database of Japanese population. We genotyped these SNPs by TaqMan Probe. We assessed the SNP and haplotype association. Results: The distribution of all 23 SNPs followed Hardy-Weinberg equilibrium in both the schizophrenia and control subjects. No significant association was observed in single SNPs and haplotype for CD200. Conclusion: We need further studies to analyze the CD200R which regulates microglia activation with CD200 and to determine the reason why CD200 expression was downregulated in the discordant monozygotic twins.

565W

Survey of effects of the DRD4 7R allele on Substance Use Disorder across schizophrenia, bipolar and other psychiatric phenotypes. *V.F.G Oliveira, A.K Tiwari, C.C Zai, M. Tampakeras, O. Likodi, B. Mackenzie, J.L Kennedy.* Neuroscience, CAMH, Toronto, Ontario, Canada.

Background: The D4 dopamine receptor gene (DRD4) contains a 48bp-tandem repeat polymorphism (VNTR) in exon 3 that impacts the length of the third cytoplasmic loop of the receptor protein. The DRD4 7R allele (7R) has undergone strong evolutionary selection in humans (Ding et al 2002). There is evidence supporting an association between the 7R allele and substance use disorders (SUDs). Psychiatric disorders are frequently complicated by substance abuse and this comorbidity is generally associated with more severe course of disease. A longstanding question has been: Is comorbid substance abuse arising from the same biological mechanisms involved in the primary psychiatric disorder, or does it have separate neural substrate? Genetic investigations may help resolve this issue. We propose that the DRD4 7R allele may play an important role in the comorbidity of SUDs and psychiatric disorders, and affect the age of onset. Methods: Overall, we had 344 schizophrenia (SCZ) and 613 bipolar (BD) European-Caucasian individuals, of which 105 were classified with alcohol abuse or dependence (lifetime) and 437 as smokers (lifetime) (DSM-IV criteria). Smoking status was assessed using the Fagerstrom test (schizophrenia) or similar sections from the SCAN interview (bipolar). The sample had >80%; power to detect an odds ratio as low as 1.7 (alcohol) and 1.49 (smoking). The DRD4 48bp repeat alleles were determined by PCR (Lichter et al., 1993) and sequence-based genotyping in an ABI 3130 platform. Results: Linear regression model indicated a trend toward a positive association between presence of the DRD4 7R allele and late age of onset for females, but not males, in SCZ while controlling for alcohol abuse/dependence (uncorrected p=0.021) and smoking (uncorrected p=0.027) variables. For bipolar individuals, 7R allele was not associated with age of onset while controlling for sex and alcohol abuse/dependence (p=0.632). For smoking, linear regression model indicated a positive association between presence of the 7R allele and age of onset (uncorrected p=0.009) while controlling for sex. Conclusions: The 7R allele may play a role in comorbid SUD in both schizophrenia and bipolar disorders. The results are somewhat limited by the modest sample size, and replication is required. DRD4 may influence risk for smoking in both SCZ and BP, but for alcohol abuse/dependence only in SCZ. Thus the risk effect of DRD4 is likely complex and in some cases disease specific.

566W

ApoE-SNCA-LRRK2 genes interaction in Parkinson's disease and controls. *A. Parsian[1], J.H. Zhao[2].* 1) Div Neuroscience & Behavior, NIAAA/NIH, Bethesda, MD; 2) MRC Epidemiology Unit, Cambridge, UK.

Our earlier reports of multiple variations in the ApoE, SNCA and LRRK2 genes have indicated that they are at most have modest increase of susceptibility to Parkinson's disease. In the current investigation, we focused on their interactions. The sample included 227 familial and 355 sporadic cases of Parkinson's disease and 236 unrelated controls. In the analysis we selected haplotypes showing increased risk according to haplotype specific analysis in SNCA as covariate to those in LRRK2 or repeat variation in ApoE in an interaction analysis both using R/haplo.stats, and vice versa for a pair of genes. As in our earlier report, haplotype 112 of 770-int4-Rep1 in SNCA has frequency of 0.04817 (haplo.em) and shows moderate significance (haplo.score) score statistic 2.53, asymptotic and simulated p values = 0.01; haplo.glm t-statistic=2.37 and p = 0.0182). In contrast, haplotypes 211212 and 212211 for rs10506151-rs10784486-rs1365763-rs1388598-rs1491938-rs1491941 in LRRK2 have score statistics -1.79 and -1.42 and t-statistic -1.79 (p = 0.0744) and -1.76 (p = 0.0794). The strongest evidence of statistical significance is the presence of SNCA haplotype 112 and haplotypes 222111 and 222221 in LRRK2 (both with t-statistic>5, p<0.0001), or presence of haplotypes 211212 and 212211 in LRRK2 with haplotype 122 in SNCA (t-statistic=1.77, p=0.078). However, such analysis between ApoE, LRRK2 and SNCA did not produce significant results. Given the recent successes of genome-wide association studies (GWASs) which largely indicate that SNPs established accounted for a small amount of phenotypic variations, it is hopeful that study of gene-gene interactions can help to identify further genotypic contributions to the “missing heritabilities”. Our results are in line with earlier reports that specific haplotypes in SNCA and LRRK2 might contribute to increased risks of Parkinson's disease.

567W

A polymorphism on CHRNA3 gene is associated with tobacco smoking in patients with ADHD in a Brazilian sample. *E.R. Polina[1], K.L. Silva[2], C.A.I. Salgado[2], E.H. Grevet[2], P. Belmonte-de-Abreu[2], C.H.D. Bau[1,2].* 1) Department of Generics, UFRGS, Porto Alegre, RS, Brazil; 2) Adult ADHD Outpatient Clinic, HCPA, Porto Alegre, RS, Brazil.

There is an important relationship between attention-deficit/hyperactivity disorder (ADHD) and tobacco smoking. Adults diagnosed with ADHD smoke at significantly higher rates than individuals in general population and have a threefold increased risk to become nicotine dependents. Some studies have shown that ADHD patients may smoke because of an improvement in attention and impulsivity control. Although the relationship between cigarette smoking and ADHD is not clear, it has been suggested that they may share a common neurotransmitter system. One theory is the “nicotinic receptor hypothesis” based on the finding that nicotinic receptors modulate the dopaminergic activity, which is involved in the underlying pathophysiology of ADHD. The CHRNA5-CHRNA3-CHRNB4 gene cluster located on chromosome 15q.25 has been associated with nicotine and alcohol dependence and lung cancer. This study aims to investigate a possible association between the polymorphism on nicotinic receptor gene and tobacco smoking in ADHD patients. We analyzed the polymorphism rs3743078 of the (3 nicotinic acetylcholine receptor subunit (CHRNA3), a transition C>G on intron 4, already associated with tobacco smoking. The sample comprises 435 Brazilians of European descent (188 smokers and 247 non-smokers) evaluated in the adult ADHD outpatient clinic of Hospital de Clínicas de Porto Alegre. The diagnostic of ADHD followed the DSM-IV criteria and tobacco smoking was evaluated with the Fagerstrom Test of Nicotine Dependence. TaqMan assay for allelic discrimination (Applied Biosystem) was used to determine SNP genotypes. Our results showed a significant association between the G allele and tobacco smoking in ADHD patients, after adjustment for gender (OR=2.455; P=0.002; 95% CI=1.378-4.371). These findings confirm, in patients with ADHD, the previous evidence for association between rs3743078 and nicotine dependence. Several other SNPs will be studied in this gene cluster in individuals with and without ADHD in order to verify how ADHD impact the relationships between nicotinic receptors and smoking. Future studies should also evaluate possible mediating effects of neuropsychological deficits in this association.

Homozygosity Mapping in 7 Pakistani Intellectual Disability Families Identifies 3 New Autosomal Recessive Loci. *MA. Rafiq[1], A. Mir[2], A. Noor[1], K. Mittal[1], E. Wiame[3], L. Kaufman[1], A. Mikhailov[1], F. Naeem[4], E. Van Schaftingen[3], T. Nasir[5], M. Ansar[6], M. Ayub[7], JB. Vincent[1,8].* 1) Molecular Neuropsychiatry, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Deaprtmrnt of Biosciences, International Islamic University, Islamabad, Pakistan; 3) de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 4) Lahore Institute of Research & Development, Lahore, Pakistan; 5) Mayo Hospital, Lahore, Pakistan; 6) Department of Biochemistry, Quaid-I-Azam University, Islamabad, Pakistan; 7) Tees, Esk and Wear Valleys NHS Foundation Trust United Kingdom; 8) Dept. of Psychiatry, University of Toronto, Toronto, Ontario, Canada;.

Intellectual disability (ID), or mental retardation (MR), is a neurodevelopmental disorder that has a devastating impact on the affected individuals and their families, as well as on health and social system. Here we report a study on non-syndromic autosomal recessive intellectual disability (NS-ARID) in consanguineous Pakistani families. Seven families (MR28, MR62, MR64, MR70, MR72, MR74 and PK11) were genotyped using Affymetrix 500K single-nucleotide polymorphism (SNP) microarrays. This approach allowed us to identify seven homozygous-by-descent (HBD) loci: 18q22.3-q23, 7p14.1-q11.22, 8q23.1-q24.21, 6q13-q16.2, 16q12.2-q21, 8p11.21-q13.2 and 11p11.2-q13.4.Three out of the seven loci mapped (8q23.1-q24.21, 6q13-q16.2 and 11p11.2-q13.4) overlap with previously reported studies and reduce the critical HBD region. Three other loci (18q22.3-q23, 16q12.2-q21 and 8p11.21-q13.2) have not been reported previously. We have sequenced DNA from four families (MR70, MR72, MR74 and PK11) by whole exome sequencing and exome data is being analyzed to discover disease causing mutations. Genes within the HBD region for family MR64 on 8q23.1-q24.21 have been sequenced and no causative mutation found so far. Sequencing of all genes within the HBD region discovered in family MR28 did not expose any exonic or splice junction changes. The remaining locus of MR62 (7p14.1-q11.22) family already mapped in patients with phosphoserine phosphatase (PSPH) deficiency, which is responsible for mental retardation and additional clinical phenotypes. Compound heterozygous mutations in the PSPH gene have been reported in patients with PSPH deficiency. We sequenced PSPH and found a homozygous missense mutation, Ala35Thr, in all affected members. This is first report of a homozygous change in PSPH. Studies to measure the effect of mutation on enzymatic activity reveal that the enzyme with the Ala35Thr, mutation has about a 5-fold reduced catalytic activity. The side chain of Ala35 is in a small hydrophobic pocket near the catalytic site. Threonine may make the side chain too bulky and polar to fit in the small pocket.

Association study shows positive correlation between inflammatory *IL1B* gene and mesial temporal lobe epilepsy with hippocampal sclerosis. *R. Santos[1], M. Silva[1], R. Secolin[1], C. Yasuda[2], T. Velasco[3], A. Sakamoto[3], F. Cendes[2], I. Lopes-Cendes[1], C. Maurer-Morelli[1].* 1) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas, Campinas, SP, Brazil; 2) Department of Neurology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, Brazil; 3) Department of Neurology, Psychiatry and Clinical Psychology, University of São Paulo, Ribeirão Preto, SP, Brazil.

The epilepsy syndromes presenting complex inheritance are still elusive when it comes to the identification of susceptibility genes even in the era of large genome wide association studies. Therefore, the use of candidate gene approach to study a more limited, but well characterized clinical sample still a valuable strategy. Several studies describe the inflammatory processes as a key point in the generation and progression of acute and chronic neurodegenerative diseases. The *IL1B* gene, which encodes a proinflammatory cytokine, has been associated to increased susceptibility to mesial temporal lobe epilepsy (MTLE) with mesial temporal sclerosis (MTS). The aim of this study was to investigate the association between *IL1B* gene with MTLE with magnetic resonance imaging (MRI) signs of MTS in a large group of patients. DNA samples were obtained from 204 unrelated patients with MTLE and MTS signs, as well as 204 unrelated controls, with no history of epilepsy. We selected seven SNPs within *IL1B* from HapMap database. SNPs were genotyped using the SNPlex^{TM} genotyping system (Applied Biosystems). Minor allele frequency (MAF>0.05), linkage disequilibrium (r^2>0.8) and Hardy-Weinberg equilibrium (HWE pvalue>0.05) were estimated using the HAPLOVIEW software. To evaluate the possibility of sample stratification we genotyped 86 additional SNPs distributed throughout the genome and located outside of the candidate genes loci. Statistical analysis was performed by logistic regression model and by Bonferroni correction for multiple comparisons. We found association between the SNP rs3730364 in the IL1B gene and MTLE [p=1.4x10^{-14}, OR=0.11; 95%CI: 0.06 - 0.21]. The genomic control indicated the absence of population stratification (Fst = 0.00821) between patient and control groups. Our association study shows a relationship between one SNP (rs3730364) in the IL1B gene and MTLE with MRI signs of MTS. However, rs3730364 do not appear to be a functional variant. Genomic control was critical to validate the groups as not stratified, giving robustness and reliability to our study. Although much progress has been made in the characterization of genes for the monogenic and rare forms of epilepsy the common epilepsy syndromes, usually showing complex inheritance remain a major challenge for gene identification, our study hopes to shed some light into this area.

570W

Exploring the contribution of ATP1A2 and SCN1A to genetic susceptibility in non hemiplegic migraine. *M.J. Sobrido[1,2], M. Camiña-Tato[2], A. Sampayo[3], J. Pardo[4], R. Cruz[2], A. Carracedo[1,2], P. Cacheiro[2].* 1) Fundación Pública Galega de Medicina Xenómica-SERGAS, Santiago de Compostela, Spain; 2) Genomic Medicine Group, University of Santiago de Compostela, CIBERER-ISCIII, Spain; 3) PAC Casa do Mar-SERGAS, A Coruña, Spain; 4) Neurology Department, Hospital Clínico Universitario, Santiago de Compostela, Spain.

Mutations in three genes have been identified in Familial Hemiplegic Migraine (FHM): CACNA1A (type I), ATP1A2 (type II), and SCN1A (type III). While most previous studies have found no evidence of association of CACNA1A polymorphisms with common forms of migraine, fewer data exist on ATP1A2 and SCN1A. Objectives: To analyze the role of genetic variants in the Na/K ATPase alpha-2 subunit (ATP1A2) and sodium channel voltage-gate type I alpha subunit (SCN1A) in common forms of migraine in a population from North-West Spain. Methods: We performed a case-control study of 641 subjects from Galicia, a region without significant population substructure. All patients were diagnosed by International Headache Society 2004 criteria for MO (188) and MA (145). Case and control groups were matched for age and gender. Recurrent headache was ruled out in control individuals and their first degree relatives. Genotyping was carried out with the SNPlex platform (Applied Biosystems, Foster City, CA) for 11 SNPs in ATP1A2 and 13 SNPs in SCN1A, with complete gene coverage based on HapMap haplotype blocks. Statistical analysis was performed using the R package SNPassoc. Single SNP association was assessed through Likelihood Ratio Test considering different genetic models. SNPs passing quality control threshold for genotyping rate (95% SNPs, 75% samples), MAF (0.10) and HWE in controls (alpha=0.05). While global case-control comparison did not show association, a statistically significant genotype association was observed in women for SNP rs13004083 under a recessive model (AA-AG vs. GG) for both migraine types (p=0.0025; OR 2.94, 95% CI 1.40- 6.18) and MA (p= 0.0031; OR 3.51, 95% IC 1.51- 8.16). Upon stratification by migraine type, the same genotype was associated with MA (p=0.0225; OR 2.17 95% CI 1.13-4.18). None of the individual associations remained significant after Bonferroni correction for multiple testing. Conclusions: A SNP located in the 5'-near SCN1A region, between SCN1A and SCN9A showed association with common migraine in a population of North-West Spain, particularly in women with MA. These data, together with previously reported nominal association of SCN9A and MA suggest that genetic variation in these voltage dependent sodium channel genes or in their proximity may play a role in common forms of migraine. CNS pathology in the mouse model of sialidosis recapitulates features of early stage Alzheimer's disease. *I. Annunziata[1], A. Patterson[1], D. Helton[1], S. Keilani[2], S. Gandy[2], A. d'Azzo[1].* 1) Department of Genetics, St. Jude Children's Research Hospital, Memphis, TN; 2) Mount Sinai Alzheimer's Disease Research Center, Mount Sinai School of Medicine, Mount Sinai, NY.

Lysosomal sialidase NEU1 catalyses the hydrolysis of sialo-glycoconjugates by removing their terminal sialic acid residues. In humans, primary or secondary deficiency of this enzyme leads to two clinically similar neurodegenerative lysosomal storage disorders: sialidosis and galactosialidosis. Mice deficient in Neu1 recapitulate the early-onset severe form of sialidosis. We have recently discovered that loss of Neu1 activity exacerbates the process of lysosomal exocytosis in various cell types by influencing the sialic acid content of Lamp-1. This increases the ability of a pool of lysosomes to dock at the PM and engage in lysosomal exocytosis. In this study we have investigated whether excessive lysosomal exocytosis underlies some of the neurological aspects seen in the brain of Neu1-/- mice. Histopathological examination of the brain of these mice revealed a progressive and time dependent formation of dystrophic neurites positive for APP/A) , particularly in the CA3 region of the hippocampus and the adjacent fimbria. The affected regions coincide with sites of high Neu1 expression in wild-type brain. This abnormality was paralleled by abnormal expression of oversialylated Lamp-1 and activated proteases, both features linked to excessive lysosomal exocytosis. These findings represent an example of a spontaneously occurring AD-like phenotype in a mouse model of a neurodegenerative disease and could contribute to the understanding of some of the pathological mechanisms of adult neurodegenerative conditions of unknown etiology. (This study was supported in part by NIH grant GM060950 and ALSAC of St. Jude Children's Research Hospital).

SCN1A mutation associated with intractable myoclonic epilepsy and migraine headache. *P. Frosk[1,3], A. Mhanni[1,3], M. Rafay[2].* 1) Genetics and Metabolism, Health Sciences Centre, Winnipeg, MB, Canada; 2) Section of Neurology, Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, MB, Canada; 3) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, MB, Canada.

SCN1A encodes the voltage-gated sodium channel NaV1.1. Its function is to propagate action potentials within the nervous system. Mutations in this gene have been associated with a number of seizure phenotypes including generalized epilepsy with febrile seizures plus (GEFS+), severe myoclonic epilepsy in infancy (SMEI), borderline SMEI (SMEB), intractable childhood epilepsy with generalized tonic-clonic seizures (ICEGTCS), and a number of cryptogenic focal and generalized epilepsies. The severe phenotypes are usually caused by *de novo* mutations in the gene and are less likely to be hereditary. When mutations are inherited, the spectrum of seizure phenotypes can be quite broad in the family even though patients have the same mutation. More recently cases of familial hemiplegic migraine have been found to be associated with mutations in this same gene. Here, we describe a child with speech and gross motor coordination delays, and intractable epilepsy, with primarily focal but also myoclonic seizures, and a mutation in SCN1A (c.3521C>G, p.T1174S). Interestingly the patient's mother, who suffers from frequent migraines with aura but has never had seizure, was found to also carry this mutation. A recent report describes this mutation in patients with familial hemiplegic migraine and without seizures but did describe a broader phenotype in one individual (coordination difficulties, multifocal action myoclonus, an abnormal electroencephalogram but no reported clinical seizures and later development of headache). Our patient's phenotype is unique because of the presence of intractable epilepsy. This suggests that the phenotypic consequences of some SCN1A mutations may be broader than previously thought and that lack of a family history of seizures does not preclude an inherited mutation.

Molecular pathogenesis for paroxysmal involuntary movements as a channelopathy: genetic analysis of human cases and an animal model. *C. Okada[1], H. Matsuo[1], S.E. Sander[2], M. Hamann[2], A. Richter[2], T. Hamada[3], A. Nakayama[1], Y. Utsumi[1], Y. Kawamura[1], H. Onoue[4], K. Kaida[4], Y. Kobayashi[3], K. Kamakura[4], N. Shinomiya[1].* 1) Dept. of Integrative Physiol. and Bio-Nano Med., National Defense Med. Col., Saitama, Japan; 2) Institute of Pharmacol. and Toxicol., Dept. of Veterinary Sci., Freie Univ., Berlin, Germany; 3) Dept. of Anat. and Neurobiol., National Defense Med. Col., Saitama, Japan; 4) Dept. of Internal Med., National Defense Med. Col., Saitama, Japan.

Paroxysmal dystonic choreoathetosis (PDC) is thought to be one of hereditary channelopathies, which is characterized by episodes of involuntary movements precipitated by caffeine, alcohol or emotional stress. We found a large Japanese family with PDC in which at least 17 members in 6 generations had been affected. Linkage analysis revealed that to chromosome 2q32-36 was the responsible locus of PDC in this family. Mutations in exon 1 of myofibrillogenesis regulator 1 (MR-1) gene which is located in PDC locus, were reported in several American PDC families. Sequence analysis showed that A7V mutation in MR-1 gene was found in all PDC-affected Japanese patients and this was also consistent with previously reported American PDC families (A7V and A9V). Since the effects of MR-1 mutation on its molecular function and intracellular localization were not clear, we first cloned distinct isoforms of MR-1 including MR-1L and MR-1S, and introduced A7V and A9V mutations into these isoforms. In spite of these disease-causative mutations, no change in the intracellular localization of MR-1 protein was found in MDCK cells, yet one isoform (MR-1L) showed clear localization to cytoplasmic membrane. An animal model of PDC (PDC hamster: dt^{sz}) has been reported. Clinical symptoms of dt^{sz} are similar to those of human PDC, but its causative gene remains unidentified. We determined the genome structure of hamster MR-1 gene and performed a mutational analysis using this model. Curiously, mutations similar to human PDC (A7V and A9V) were not detected in the MR-1 gene of dt^{sz} hamster. Therefore, we conducted a comprehensive analysis of alterations in gene expression of dt^{sz} and normal hamsters with a high coverage expression profiling (HiCEP) method. The expression profile of 109 genes in dt^{sz} hamster showed more than three-fold changes compared to normal hamster. These results imply that the causative gene of dt^{sz} may code a channel/transporter protein that is associated with MR-1 protein. Although further analysis of molecular functions and localization of PDC causative gene product will be needed, our approach will facilitate to understand the pathogenesis and will ultimately lead to the development of more effective therapies for basal ganglia disorders including other paroxysmal choreoathetosis, dystonic syndrome and Parkinson's disease.

22q11.2 deletion in a Brazilian schizophrenia patient revealed by MLPA and FISH techniques. *M.I. Melaragno[1], F.T. Bellucco[1], V.K. Ota[1], S.I. Belangero[1,3], M.C. Cernach[1], A. Gadelha[2,3], J. Mari[2], R.A. Bressan[2,3], M.C. Smith[1], D.M. Christofolini[1,4].* 1) Genetics Department, Universidade Federal de Sao Paulo, Sao Paulo, Brazil; 2) Department of Psychiatry, Universidade Federal de São Paulo, São Paulo, Brazil; 3) Interdisciplinary Laboratory of Clinical Neuroscience, Universidade Federal de São Paulo, São Paulo, Brazil; 4) Human Reproduction and Genetics Division, Department of Gynecology and Obstetrics, Faculdade de Medicina do ABC, Santo Andre, Brazil.

The most important known genetic risk factor for developing schizophrenia is the chromosomal 22q11.2 deletion, since about 25% of children with 22q11.2 deletion will develop schizophrenia in adolescence or adulthood. Moreover, in adult patients with schizophrenia it is estimated that the frequency of deletion is from 1:50 to 1:100. In this study a total of 158 adult unrelated schizophrenia patients, assessed according to DSM-IV were recruited from the Schizophrenia Program of Universidade Federal de São Paulo (UNIFESP), Brazil. The presence of 22q11.2 region copy number variation was investigated using multiplex ligation-dependent probe amplification (MLPA) technique using P250 DiGeorge kit and confirmed by fluorescence in situ hybridization (FISH). A typical 1.5 Mb 22q11.2 deletion, ranging from LCR22A to LCR22B, was detected in one patient, corresponding to 0.6% of prevalence in our sample, similar to literature data (0 % a 5,3 %). This patient is a 30 years and 10 months old man who presents learning disability and socialization difficulty. His first psychotic event occurred at 26 years old. The patient presented with a long face, short forehead, downslanting and short palpebral fissures, prominent nasal bridge with a bulbous nasal tip, hypoplastic alae nasi, long and discrete philtrum, small ear lobes with a thick edge of the helices, narrow and high palate and hyperchromic spot in the left hemithorax with irregular contours with the largest diameter of 10 cm suggesting nevi. Serum calcium levels were normal. Echocardiogram showed no structural heart abnormality. The patient presented neither nasal speech nor velopharyngeal insufficiency. Patient's parents were also investigated and presented normal karyotypes and FISH results. The patient here described met clinical criteria for 22q11deletion syndrome in adults, since he presents three major phenotypic findings of the syndrome such as, dysmorphic face, learning difficulties and psychiatric disorder. In our knowledge this is the first study investigating the presence of 22q11.2 deletion in a Brazilian sample of schizophrenia patients. Our work confirmed the prevalence of the 22q11.2 microdeletion in patients with schizophrenia and also that MLPA is a valuable and accurate diagnostic tool to investigate 22q11.2 rearrangements also providing information about deletion extension not accessed by standard FISH techniques. Financial support: FAPESP, CAPES and CNPq, Brazil.

Heritability analysis of behavioral traits in children of alcoholics. *V. Strumba[1], K. Shedden[3], R.A. Zucker[1], M. Burmeister[2].* 1) Addiction Research Center, University of Michigan, Ann Arbor, MI; 2) Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI; 3) Department of Statistics, University of Michigan, Ann Arbor, MI.

The main goal of our study is to identify genetic variants associated with behavioral traits associated with risk for Alcohol Use Disorder (AUD). The subjects are participants in the Michigan Longitudinal Study, which has been tracking children of alcoholic parents and SES-matched control families for over 25 years. Starting with the enrollment age of 3-5 years, children were assessed annually for a variety of traits including externalizing and internalizing behaviors, temperament, and comorbid symptomatology. As a first step in identifying gene-to-behavior associations, we need to identify the most powerful set of behavioral measurements for a genetic association test. Power for genetic studies requires at least part of the variance of the trait to be inherited. Therefore, we carried out heritability analysis of a variety of behavioral traits assessed in children of alcoholic parents at different developmental stages. To carry out heritability analysis we used data collected on full siblings from over 400 families. Due to the longitudinal nature of this dataset we used trait measures at all available time points. We tested item level data for each instrument used in the study as well as composite scores as trait measures where appropriate. In this analysis we identified a number of traits with low to moderate heritability, whereas other traits show no significant heritability. Among moderate, but highly significant, heritable traits we find four personality domains as measured by NEO-FFI: agreeableness (23%), consciousness (22%), extraversion (18%) and neuroticism (23%) with p-values <0.005. There is also significant heritability of behavioral problems measured by CBCL youth self report, such as anxiousness (23%), withdrawn (28%) and internalizing behavior problems (24%) with p-values <0.005. The set of traits with the best evidence for heritability will be used in the next step to test for association with genetic variants found in or near candidate genes known or suspected to be associated with alcohol and other drug use, as selected for a commonly used drug addiction panel of SNPs (Hodgkinson CA et.al. “Addictions biology: haplotype-based analysis for 130 candidate genes on a single array” Alcohol Alcohol. 2008 Sep-Oct; 43(5):505-15.). Supported by grants from the National Institute on Alcohol Abuse and Alcoholism (R37 AA 07065 (RAZ) and T32 07477 RAZ/KB), and from the National Institute on Drug Abuse (R01 DA 17732 (RAZ, MMH and JKZ).

Construction of in vitro model system to understand molecular mechanism of CGG repeat expansion in Fragile X syndrome. *Y. Nakayama[1], T. Seko[2], N. Sunamura[2], Y. Ogino[1], M. Kato[3], E. Nanba[1], M. Oshimura[2,4], H. Kugoh[2,4].* 1) Functional Genomics, The Center for Bioscience and Biotechnology, Yonago, TOTTORI, Japan; 2) Dept. of Biomed. Sci., Inst. of Regenerative Med., Tottori Univ; 3) Div. of Human Genomic Sci., Dept. of Mol. and Cellular Biology, Sch. of Life Sci.Faculty of medicine, Tottori univ; 4) Chromo. Eng. Res. Ctr., Tottori Univ.

Fragile X syndrome (FXS) is the most common inherited form of mental retardation. FMR1 gene on chromosome Xq27 region is responsible gene for FXS and (CGG)n triplet repeat has been found in its 5'UTR region. In FXS, CGG triplet repeat expands more than 200 triplets exclusively when Pre-Mutation (PM) allele between 45 to 200 CGG triplets is maternally transmitted. Following repeat expansion, CpG methylation across the promoter region of FMR1 gene occurs, leading to inactivation of FMR1 expression, and results in FXS phenotypes. However, the mechanisms of CGG repeat expansion and subsequent gene inactivation of FMR1 have not been fully elucidated. To date, several Knock-In (KI) mouse models with PM range CGG triplet repeat have been produced. Some showed CGG repeat expansion to Full-mutation (FM) range over 200 repeats in single generation, however, subsequent methylation at the FMR1 promoter region and gene silencing observed in human patients were not reproduced. These KI mice models suggested the importance of chromosomal context (cis element) for repeat expansion.

To develop a genomic model system to understand molecular mechanism of CGG triplet repeat expansion, CGG repeat region with suitable chromosome context and fully genomic reprograming activity to mimic germ cell environment should be important. In this study, to fulfill these conditions in vitro, we construct the human artificial chromosome (HAC) containing PM allele-derived CGG triplets with or without FMR1 promoter region (CGG-HAC). Then, as Embryonic Germ (EG) cells are well known to have dominant reprograming activity, CGG-HAC will be introduced into EG cells via microcell mediated chromosome transfer to see whether CGG expansion occurs and to see the effect of genomic reprogramming over CGG triplet repeat stability.

Further, to identify any specific protein(s) or non-coding RNA(s) may be associating CGG triplet repeat, we introduced lacO tandem repeats onto CGG-HAC. That enables us to harvest CGG-HAC with specific factors bound using lacO-lacI-mediated immunoprecipitation for further analysis. Thus, development of a novel method using HAC, termed chromosome immunoprecipitation (ChrIP), will be valuable to isolate chromatin-protein and/or chromatin-RNA complex toward molecular dissection of CGG repeat expansion mechanism in Fragile X syndrome.

Autism Spectrum Disorders associated with 17q12 Deletions Implicate the Acetyl-CoA Carboxylase Alpha Gene (ACACA). *D. Moreno-De-Luca[1], B.D. Pearce[2], O.Y. Ousley[3], C.L. Martin[1], D.H. Ledbetter[4], Simons Simplex Collection Genetics Consortium.* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 2) Department of Epidemiology, Rollins School of Public Health, Emory University, Alanta, GA, USA; 3) Emory Autism Center, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, GA, USA; 4) Genomic Medicine Institute, Geisinger Health System, Danville, PA , USA.

The 17q12 deletion is a recurrent copy number variant (CNV), which we previously identified as a very significant risk factor for autism spectrum disorders (ASD) and schizophrenia. There are 15 genes within this CNV; however, the specific gene or genes responsible for the behavioral phenotype remain unknown. We analyzed CNV data from 1,124 simplex ASD families from the Simons Simplex Collection (SSC) and identified three cases with genic deletions in 17q12. Two cases have the typical 17q12 deletion; in one case the deletion arose de novo, whereas in the other it was inherited from a father with macrocephaly and an elevated score on the Social Responsiveness Scale (SRS). The third case has a smaller deletion including only one of the 15 genes within the CNV region, ACACA, encoding acetyl CoA carboxylase alpha, the rate-limiting step in fatty acid synthesis. Downstream in this same pathway lies the 7-dehydrocholesterol reductase gene (DHCR7), mutations in which cause Smith-Lemli-Opitz syndrome (SLO) syndrome. Interestingly, most patients with SLO syndrome have ASD. The case with this smaller 17q12 deletion has ASD and macrocephaly, two of the most prominent features of individuals with recurrent 17q12 deletions. Moreover, he inherited this smaller deletion from his mother, who has macrocephaly, depression, and an elevated SRS score; however, two unaffected siblings without the deletion also have macrocephaly, therefore it is uncertain whether the macrocephaly in this family is related to the deletion. These findings support the pathogenic role of 17q12 deletions in ASD and implicate ACACA as a strong candidate gene responsible for the neuropsychiatric phenotype.

Defining the use of electronic medical records in genetic studies of multiple sclerosis. *M.F. Davis[1], J.L. McCauley[2], J.R. Oksenberg[3], S.L. Hauser[3], M.A. Pericak-Vance[2], J.L. Haines[1].* 1) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, Miami, FL; 3) Department of Neurology, School of Medicine, University of California, San Francisco, CA.

Multiple sclerosis (MS) is a neurodegenerative disease with complex genetic underpinnings and clinical heterogeneity. The HLA locus was identified as a critical genetic determinant of the disease in the 1970s, but no other genes or loci were discovered until the recent GWAS era. There are 23 confirmed loci in the published literature for MS at the present time. At Vanderbilt University, we have the unique opportunity to access BioVU, an opt-out DNA biobank. Over 120,000 leftover blood samples from outpatients have been collected and used to extract DNA, and each sample is linked to the individual's clinical data through a “synthetic derivative” of their de-identified electronic medical record (EMR). Currently, there are about 1000 samples with a diagnosis of MS in BioVU, and thousands of samples that can be used as controls. We have received access to the DNA samples and the synthetic derivative of all patients with MS and 2400 control subjects. We are undertaking a study to characterize the clinical information available from the EMR that can be used for genetic studies of MS. Previous studies have lacked access to long-term clinical information and few studies have analyzed the genetics of the various clinical aspects of MS. We are investigating the range and depth of information that can be extracted from the EMR, especially age of onset, progression (EDSS), first neurological symptom, and response to treatments, with the goal of performing genetic analyses using these sub-phenotypes to better understand the genetic heterogeneity of MS. As manual review of large numbers of medical records would be time-prohibitive and prone to human error, we are working to develop methods to extract this information using algorithms. Based on our preliminary manual review of 55 of these medical records, we estimate we will be able to extract an age of onset for 765 individuals, EDSS for 240 individuals, first neurological symptom for 655 individuals, and treatment information for 890 individuals. All of the samples we have extracted from BioVU have been genotyped on the Immunochip, which contains 196,524 SNPs representing genes implicated in autoimmune disorders, including MS. Once characterization of data available from the EMR is complete, we will perform association analyses with the sub-phenotypes identified.

Detection of a deletion in 20p in a schizophrenia patients. *C. Zai, M. Tampankeras, V. de Luca, A. Tiwari, V. de Oliveira, N. Freeman, B. MacKenzie, J. Kennedy.* Dept Neurogenetics, CAMH, Toronto, ON, Canada.

Schizophrenia is a severe chronic neuropsychiatric disorder that affects approximately 1% of the population. Its etiology remains unclear despite decades of research. We aimed to conduct a genome-wide association study on our sample of schizophrenia samples using the Affymetrix SNP6.0 platform. Analysis of raw data was carried out on Genotyping Console 2.1. Preliminary findings revealed a male patient of African ancestry with a possible deletion in the short arm of chromosome 20. The patient had no reported history of cannabis or alcohol abuse. Of note is a history of seizures. We are currently further characterizing this deletion and looking more in depth into the personal history and family history of medical conditions and other phenotypes, including history of suicide, of this patient.

580W

MLPA in proband and carrier analysis of Spinal muscular atrophy. *C. Arthi, B.R. Lakshmi.* MDCRC, Avinashilingam Deemed University for Women, Coimbatore, Tamil Nadu, India.

Spinal Muscular Atrophy (SMA) is one of the most common autosomal recessive disorder, affecting 1 in 10000 live births and with a carrier frequency of 1 in 50. The deficiency of the ubiquitous protein Survival Motor Neuron (SMN), coded by the SMN genes, SMN1 and SMN2 causes the disorder. In majority of cases, this deficiency is due to absence of the SMN1 gene. For accurate molecular diagnosis, the results of commonly used non-quantitative methods like conventional PCR-restriction fragment length polymorphism (PCR-RFLP) should be a confirmed by a quantitative analysis. Carrier analysis is also rendered difficult due to the presence of SMN2 copies. The present study analyses the usage of a recent, quantitative dosage analysis method viz, Multiplex Ligation Probe Amplification (MLPA), to estimate both homozygous and heterozygous absence of SMN1, SMN2 copy number and carrier analysis in a consanguineous family which led to genetic and reproductive counseling. A total of 47 patients clinically suspected for SMA were taken up for molecular diagnosis by both PCR-RFLP and MLPA. All the patients who had homozygous deletion of exon 7 (and 8) of SMNI gene by PCR-RFLP method showed the similar deletion status by MLPA. Three cases of heterozygous deletion of SMN1 exon 7 and 8 were identified by MLPA. Further sequence analysis of the SMN1 gene will be done to pick the mutation in the other SMN1 allele. Two patients detected for homozygous absence of SMN1 exon 7 by PCR-RFLP also had heterozygous deletion SMN1 exon 8 by MLPA. In a family where a male proband showed deletion of exons 7 and 8 of SMN1 gene by PCR-RFLP, the proband's sister was married to the maternal cousin. The couple visited the facility after the marriage requesting carrier diagnosis and counseling. MLPA was done for the proband, his parents, the sister and her husband (maternal cousin). On analysis both the parents of the proband were confirmed for their carrier status and the sister was also found to be a carrier of SMN1 exon 7 & 8 deletion. But the maternal cousin did not carry the mutation and genetic counseling was given to the family. Carrier analysis for SMA is not offered anywhere in our country and we observe that MLPA is a very useful and robust technique for carrier diagnosis in SMA. In a country where consanguineous marriages are common, such techniques offer valuable information towards alleviating and preventing such genetic disorders.

Copy number loss in Ashkenazi Parkinson's disease patients, non-carriers of founder *LRRK2* or *GBA* mutations. *A. Bar-Shira[1], M. Kedmi[1], I. Pe'er[4], N. Giladi[2,3], A. Orr-Urtreger[1,3].* 1) Genetic Inst, Tel Aviv Sourasky Med Ctr, Tel Aviv, Israel; 2) Movement Disorders Unit, Parkinson Center, Department of Neurology, Tel Aviv Sourasky Med Ctr, Tel Aviv, Israel; 3) Sackler Faculty of Medicine, Tel-Aviv University, Tel Aviv, Israel; 4) Department of Computer Science, Columbia University, NY, USA.

Parkinson's Disease (PD) is a complex disorder, associated with multiple genetic, environmental and age-related risk factors. The high level of copy number variation (CNV) identified in the general population, up to 12% of the human genome, suggests that CNVs could underlie some of the normal human variations including differences in cognitive, behavioral, and psychological features. An increasing number of human diseases result from recurrent DNA rearrangements that involve unstable genomic regions and abnormal dosage of gene(s). In PD, an abnormal copy number of the *alpha-synuclein* gene was associated with disease risk and severity (Singleton, Science 302:841, 2003). We aimed to determine whether specific CNVs are associated with disease risk and severity in our PD patient population. A pilot study was performed using Affymetrix SNP6.0 Array (~900K CNVs). Four study groups were analyzed: Ashkenazi PD patients with either *LRRK2* G2019S (75 samples) or founder *GBA* mutations (93 samples), PD-patients without these mutations (PD-NC,130 samples) and age- and sex-matched controls (128 samples). CNV changes were determined using the Genotype Console 2.1 (Affymetrix), Partek 6.3 and SVS V7.2.2 (Golden Helix). Initially, the identification of CNVs was done compared to an online HapMap database. In the 426 samples, 6595 CNVs were detected in the autosomal chromosomes: 3914 gain and 2681 loss events. Novel CNVs, which were not previously described, were also detected. For more reliable data, the above CNVs were filtered based on the average distance between the markers (number of CNV markers/length of CNV) and only CNV events with average distance of less than 10 Kb were selected. Here, 3582 gain events and 2157 loss events were detected. 1671 CNVs were in the controls and 4068 in PD-patients: 13.055 CNVs/individual in the control group and 13.65 in PD-patients. However, when dividing the patients according to the different carrier sub-groups, significant more loss events were detected among the PD-NC group (patients without founder *LRRK2* or *GBA* mutations) compared to the other groups. A candidate CNV on 8p23.2 was selected for validation-replication. Validation was fully achieved, but the replication step did not confirm its association with PD. Our results demonstrate that the Ashkenazi population is valuable for studying the complex genetic basis of PD, and suggest that additional CNVs studies are necessary to examine their potential involvement in PD.

Novel genomic imbalances detected by aCGH in patients with intellectual disability: searching for the key cognition genes. *M. Barbosa[1,2], F. Lopes[1], C. Bessa[1], G. Soares[2], J. Silva[2], T. Temudo[3], M. Rocha[2], C. Gomes[1], G. Barros[1], F. Duque[4], G. Oliveira[4], C. Marques[4], M. Reis-Lima[2], A.M. Fortuna[2], J. Pinto-Basto[5], J. Weiss[6], E. Sistermans[6], B. Ylstra[7], P. Maciel[1].* 1) Life and Health Sciences Research Institute (ICVS), Porto, Portugal; 2) Center for Medical Genetics Dr. Jacinto Magalhães, National Health Institute Dr Ricardo Jorge, Porto, Portugal; 3) Hospital Geral de St. António, Porto, Portugal; 4) Hospital Pediátrico de Coimbra, Coimbra, Portugal; 5) Center for Predictive and Preventive Genetics, IBMC, Porto, Portugal; 6) Department of Clinical Genetics, VU University Medical Centre, Amsterdam, The Netherlands; 7) Department of Pathology, VU University Medical Center, Amsterdam, The Netherlands.

The discovery of new genomic imbalances in patients with ID requires the differentiation of pathogenic copy number variations (CNVs) from benign variants. Whenever a new alteration is found, is important to prioritize the "best" candidate genes that may account for the ID phenotype, allowing the discovery of new ID causative genes. We have analyzed 130 patients with idiopathic ID (76 syndromic and 54 non-syndromic) by aCGH (Agilent 180K). The prioritization of candidate ID genes for each patient was based on bioinformatics analysis using the TS-CoExp Disease Gene Prediction web tool, leveraged with described/predicted protein function data from OMIM/PubMed. TS-CoExp predictions, based on conserved co-expression data, were performed for "Brain", "Brain and Central Nervous System", and also for all available co-expression networks, using a training set of 727 OMIM entries for which the keywords "mental retardation" or "intellectual disability" were present in the title and/or synopsis. We have discovered non-polymorphic genomic imbalances in 53 patients, of which 6 presented previously described microdeletion/microduplication syndromes, 20 had novel CNVs very likely to be pathogenic (VLP) and 27 presented smaller and less-likely pathogenic CNVs, the relevance of which needs to be further assessed. The novel VLP alterations included 1p36.21p36.23 del, 1q43-q44 del, 2p13.1-13.3 del, 2q11.2-q12.2 del, 2q11.2 dup, 3q22.1-q23 del, 5q35.3 dup, 6q25.3 deletion, 7q11.23 del, 7q33 del, 9q34.2-q34.3 dup, 9q33.2-q33.3 dup, 10q26.3 del, 12q24.21-24.2 del, 12q24.21 dup, 14q32.31-q32.33 dup, 16q24.3 dup, 20q13.12-q13.13 del and Xq24 dup. Among the genes prioritized by the TS-CoExp web tool are AKT3 (V-AKT murine thymoma viral oncogene homolog 3), SEMA4F (semaphorin 4F), CREG2 (cellular repressor of E1A-stimulated genes), RAB6B (RAB6B, member of the RAS oncogene family), SNX9 (shorting nexin 9), CNOT4 (CCR4-NOT transcription complex, subunit 4), RXRA (retinoid X receptor, alfa), EIF5 (eukaryotic translation initiation factor 5), EBF3 (early B-cell factor 3), MED13L (mediator complex subunit 13-like), ARFGEF2 (ADP-ribosylation factor guanine nucleotide exchange factor 2) and CUL4B (cullin 4B, for which only deletions and point mutations have been associated with ID so far). Our work contributes for the identification of new key genes implicated in cognition and, when mutated, in ID pathophysiology.

583W

Rare copy number variation at SEMA5A eQTLs is associated with autism. *Y. Cheng, L. Weiss.* Psychiatry, University of California, San Francisco, San Francisco, CA.

In a previous genome wide association study (GWAS), significant association with autism was detected near the SEMA5A gene, which has also shown evidence for reduced expression in autism (Weiss et al, 2009). Previously, 245 SEMA5A expression quantitative trait loci (eQTLs) were identified and shown to exhibit common polymorphism association with autism (Weiss et al., 2010, ASHG #294),. Here, we investigated rare copy number variants (CNVs) in these regions. From four datasets (Bucan et al, 2009; Marshall et al, 2008; Pinto et al, 2010; Szatmari et al, 2007), we obtained a list of autism-specific CNVs with less than 80% overlap with a reported variant in the Database of Genomic Variants (DGV , Iafrate et al, 2004). For each dataset, we calculated the total number of CNVs that overlapped with our eQTL regions and with random regions of the same length. This region sampling was repeated for 1,000 permutations to calculate a P-value. In the DGV, representing variation in the healthy population (69,694 CNVs >1kb reported in peer-reviewed literature), we observed 7% overlap (P= 0.23). Marshall et al. reported 277 CNVs from 427 probands (using 500K array and >1 algorithm) with 28% overlap (P<0.001). Bucan et al. reported 551 CNVs from 912 probands (Illumina 550K array, exonic CNVs), 22% of which overlapped our eQTLs (P=0.33). Szatmari et al. identified 209 CNVs from 173 probands (using 10K array and stringent thresholds), with 26% overlap (P=0.19). Pinto et al. reports 1,102 CNVs from 996 probands (1M array and CNVs >30kb called with >1 algorithm), which gives 18% overlap (P=0.01). The 372 records from Autism Chromosome Rearrangement Database (ACRD) has 27% overlap (P<0.001). The current analysis has some limitations, including differences in dataset size, array type, CNV calling algorithm and reporting criteria. For example, average size varies (0.1-4.6Mb), and exon-overlap might not be relevant for a CNV acting on regulatory sequence. Despite heterogeneity across studies, the proportion of overlap is 2.5- to 4-fold that seen in the DGV. In summary, our approach of defining an expression regulatory pathway for a SNP-associated candidate gene has revealed additional common, and now rare, variants associated with autism and may provide a framework for identifying which rare CNVs are likely to contribute to autism risk.

Attention problems and CNVs: A study of MZ twin pairs. *E.A. Ehli[1,2], A. Abdellaoui[3], Y. Hu[1], J.J. Hottenga[3], M. Kattenberg[3], C.E. van Beijsterveldt[3], M. Bartels[3], R.R. Althoff[4], X. Xiao[5], P. Scheet[5], E.J. de Geus[3], J.J. Hudziak[4], D.I. Boomsma[3], G.E. Davies[1,2].* 1) Avera Institute for Human Behavioral Genetics, Avera Mckennan Hospital, Sioux Falls, SD, USA; 2) Department of Psychiatry, University of South Dakota, Sanford School of Medicine, Division of Basic Biomedical Sciences, Sioux Falls, SD, USA; 3) Department of Biological Psychology, VU University, Amsterdam, The Netherlands; 4) University of Vermont, College of Medicine, Burlington, VT, USA; 5) Department of Epidemiology, University of Texas M.D. Anderson Cancer Center, Houston, TX, USA.

The purpose of this study was to identify *de novo* copy number variations (CNVs) in monozygotic twin pairs and to examine whether *de novo* and/or inherited CNVs might be related to attention problems (AP) in childhood. Based on longitudinal phenotyping, subjects were selected from the Netherlands Twin Register. We selected fifty monozygotic (MZ) twin pairs (22 concordant affected, 17 concordant unaffected, and 11 discordant pairs). For 36 pairs, their parents could also be included to help detect *de novo* CNVs. Probe intensity data was generated using Affymetrix SNP 6.0 arrays. CNV calls were made using concordance between two algorithms, Birdsuite 1.5.5 and PennCNV. In total 45 complete twin pairs, four separate twins, 26 complete pairs of parents, and 7 separate parents passed quality control thresholds. We are able to detect two different types of *de novo* CNVs: (1) CNVs shared by the MZ twins, but not inherited from the parents (i.e. pre-twinning de novo CNVs), were detected by comparing copy number (CN) calls between parents and twins. (2) The presence of CNVs not shared between MZ twins that may be inherited in one twin, but not in the other (i.e. post-twinning de novo CNVs), was investigated by comparing the CN calls between MZ twins. Genome-wide CNV burden (= all detectable inherited and de novo CNVs) linked to attention problems was tested with permutation tests in Plink for seven groups of CNVs (CN=0 or 1, CN= 1, CN=0, CN=3 or 4, CN=3, CN=4, CN=0, 1, 3 or 4). Eight pre-twinning *de novo* CNV events were identified. We also identified 21 CNV segments that differed in CN between the MZ twins: 9 in the concordant low group, 6 in the discordant group and 6 in the concordant high group. Quantitative PCR is being utilized to confirm the CNVs identified from the microarray data. After corrections for multiple testing, the association tests for genome-wide CNV burden yielded a significant association with AP for the average size of the group of CNVs with any deviation from the expected CN (CN=0, 1, 3 or 4), where the affected individuals had significantly larger CNV events than the unaffected group (p = .0004). Each group of CNVs showed a larger average CNV size in the affected group, except for the CNV group with deletions of 2 copies (CN = 0). This group however was the only group to show a nominally significant result in the amount of CNV events, were the affected group had more events than the unaffected group (p = .036).

Genome-Wide Analysis of Copy Number Variations in Schizophrenia. *N. Feng, G. Todarello, C. Li, B.S. Kolachana, R. Vakkalanka, D.R. Weinberger, R.E. Straub.* CBDB, GCAP, NIMH, National Institutes of Health, Bethesda, MD.

Copy number variants (CNVs) were associated with schizophrenia in several previous genome-wide analyses. However, many specific CNVs reported were unique, with minimal chromosomal overlap between studies and only a few regions have garnered support from multiple studies, and these include 1q21.1, 2p16.3 (NRXN1) and 22q11.2 (VCFS). Moreover, recent studies suggested that rare de novo CNVs 500kb and greater are more likely to be important in the etiology of schizophrenia. Here we report preliminary results from a genome-wide analysis of CNVs in a total of 1851 Caucasian individuals: 570 schizophrenia probands, 213 unaffected siblings, 535 parents, and 533 controls. There were a total of 220 full trios and 213 discordant sibling pairs available for evaluating inheritance. Genomic DNA from lymphoblast cell lines were genotyped on Illumina BeadArray chips (550K, 610K, 660K and 2.5M) and CNVs called by the PennCNV 2010 program. There were no consistently significant differences between schizophrenia probands and controls in the frequency of deletions or duplications at either the >100kb or >500kb size ranges. We examined in greater detail some previously reported regions of interest. At NRXN1, 6 of 570 schizophrenia probands had qPCR confirmed deletions, ranging in size from 25-282kb, whereas none of 533 controls had such deletions called. At 1q21.1, there were 3 schizophrenia probands (2 confirmed as de novo) with >500kb deletions and none of the controls had large deletions. At 22q11.2, 3 VCFS location deletions (2 confirmed as denovo) ranging from 1.5-2.5Mb were called in schizophrenia probands and none in controls. These results support the association of deletions in the 1q21.1, NRXN1 and VCFS regions with schizophrenia. In contrast, regions 15q11.2, 15q13.3, 16p11.2 and 16p13.1 did not show any notable frequency differences, but this may be due to our relatively small sample size. Finally, preliminary analyses indicated a few rare deletions more prevalent in schizophrenia probands in genes of potential biological relevance such as PARK2 and ASTN2 and other genes from neurodevelopmental pathways. qPCR validation and association analysis with cognitive and other phenotypes is ongoing.

586W

Genome-wide Copy Number Variation analysis for Schizophrenia in a large Ashkenazi cohort. *S. Guha[1], J. Rosenfeld[1], A.K. Malhotra[1,2,3], A. Darvasi[4], T. Lencz[1,2,3].* 1) Psychiatry Research, Zucker Hillside Hospital, NSLIJ, New York, NY; 2) Center for Psychiatric Neuroscience, The Feinstein Institute for Medical Research, Manhasset, NY; 3) Department of Psychiatry and Behavioral Science, Albert Einstein College of Medicine of Yeshiva University, NY; 4) Department of Genetics The Institute of Life Sciences, The Hebrew University of Jerusalem, Givat Ram, Jerusalem, Israel.

Copy number variations (CNVs) are recognized to contribute to normal human genomic variability and are also associated with the risk of human disease. Recent genome-wide studies have provided evidence that CNVs may be associated with schizophrenia and other psychiatric disorders. Ethnically homogeneous founder population may increase power for detection of rare and common CNVs associated with human disease. To identify CNVs that increase the risk of schizophrenia, we performed a whole-genome CNV analysis on a cohort of 1233 schizophrenia cases and 2279 controls drawn from the Ashkenazi Jewish (AJ) population from Israel. Ethnically homogeneous samples were selected from a larger AJ cohort and genotyped for 1.4 million probes using Illumina HumanOmni1-Quad arrays. After stringent quality filtering for both samples and markers, we performed PCA with AJ-specific AIMs and MDS correction in PLINK to correct for any population stratification effects. After QC, we analyzed the rare CNVs associated with schizophrenia in 904 schizophrenia cases and 1640 matched controls using three different algorithms: QuantiSNP, PennCNV, and CNVpartition. All the calls were separately assessed using the specific QC threshold recommended by each algorithm. The final CNV calls were made based on common consensus calls from all the algorithms using the following filtration criterion: minimum 20 probes, minimum 500kb in size, at least one gene in the segment and less than 50% overlapping with the common copy number polymorphism at the Database of Genomic Variants (DGV). Our analysis revealed a novel association of a ~ 700 kb deleted segment at chromosome 16, a part of which was previously associated with mental retardation, developmental delay, and associated phenotypes. This CNV successfully replicated in other datasets and the combined analysis identified a significant association (6/9516 cases and 0/10322 controls) p= 0.011, odds ratio = ¥ (1.16-¥) with a common minimum region of ~ 640 kb containing 20 genes. We have also replicated known schizophrenia associated CNVs e.g., 22q11, 3q29. Overall burden analysis showed a significant (p = 0.03) overrepresentation of CNVs in cases compare to controls. Deletions demonstrated a 1.6 fold excess in cases (p = 0.01) compare to controls, but duplications did not differ between cases and controls. Results further contribute to our understanding of the role of CNVs in etiology of schizophrenia and other neurodevelopmental disorders.

A FOXP2 intragenic deletion in a patient with autism. *F. Gurrieri, N. Cannelli, G. Neri.* Genetica Medica, Univ Cattolica, Rome, Italy.

Autistic disorders (ASD) are a group of childhood neurodevelopmental disorders characterized by difficulties in socialization and communication and stereotypic behaviors. Array-CGH has recently allowed the identification of CNVs in 10% of ASD cases, often non randomly. Nevertheless, this high-throughput approach is limited by the resolution and assembly of the array-chip used in which some genes or genomic regions, still involved in ASD, may not be represented. In addition, alterations can be detected in regions not known to be related to ASD and therefore difficult to interpret as meaningful results. With the aim to develop a targeted quantitative genetic test for ASD we built an “in-house” MLPA assay with probes covering 9 candidate genes for ASD and tested it on 120 ASD patients. METHODS: All patients tested negative for Fragile-X syndrome, Rett syndrome and SHANK3 deletions/mutations. Candidate genes included in the MLPA assay were: FOXP2 (7q31), UBE2H (7q32), CALU (7q32.1), GRM8 (7q31), GRM5 (11q14), DOC2B (17p13), HOMER1 (5q14), NLGN3 (Xq13), FHIT (3p14). One or more probes were designed for each gene, according to MRC-Holland online manual and MLPA reactions were performed using EK1 reagent kit (MRC Holland, Amsterdam). Results were analysed by a developed spreadsheet in Microsoft Excel. All test/reference ratio values below 0.7(0.35 for NLGN3 in males) or exceeding 1.3 (0.65 for NLGN3 in males) were considered as CNA. The assay was first validated on 30 controls. RESULTS: We found a CNV in 5 patients (4.1%), all but one in NLGN3. In a single patient we detected a de novo deletion in exon 16 of FOXP2 gene. These probes are not included in the array-chips currently in use in our laboratory (44K and high-definition 105K from Agilent). CONCLUSIONS: Our results indicate that a targeted MLPA assay could allow detection of intragenic CNVs that might have been missed with array-CGH, even at high resolution. This approach needs to be validated in higher cohorts of patients and other combinations of candidate genes might be assembled for a targeted diagnosis in ASD patients. The NLGN3 alterations confirm already known associations of neuroligins to autism; along the same line, the FOXP2 alteration is in agreement with the role of this gene in speech and language disorders but also suggests a role in autism pathogenesis.

588W

Large-scale pathway analysis of copy number variants highlights defective GABAR-A signaling in autism spectrum disorders. *D. Hadley, J. Glessner, F. Mentch, D. Abrams, C. Kim, E. Frackelton, C. Hou, R. Chiavacci, J. Connolly, G. Lyon, H. Hakonarson, Autism Genome Project.* Children's Hospital of Philadelphia, Philadelphia, PA.

The ability to quantify individual's genomic risk for disease can facilitate the development of new interventions and improve medical practice. Many rare Copy Number Variants (CNVs) that harbor small genomic deletions and insertions have been described in the autism spectrum disorders (ASD). To identify these likely functional elements, we combined various large cohorts of autistic patients with a large number of neurologically normal controls to analyze over 3K affected cases and 7K controls. In a two-stage genome-wide association design, we uncovered 266 genome-wide statistically significant (combined P <= 2.76E-08) distinct CNV regions (CNVR). The 38 genes with exons disrupted by these robust CNVRs are most enriched in gene networks impacting neurological disease, behavior and developmental disorder. GABAR-A receptor signaling was found to be the most significant canonical pathways disrupted in ASD because case-enriched defects in GABRA5 ,GABRB3, and GABRG3 genes. Moreover, network analysis of the first-degree gene interactome of the GABAR-A receptor family suggests that ASD cases are significantly enriched for pathway defects (P <= 2.1E-21, OR = 9.9) when compared with neurologically normal controls. Taken together, the CNVRs we have identified impact multiple novel genes and signaling pathways, including genes involved in GABAR-A signaling, that may be important for new therapeutic development.

589W

Copy number aberrations affecting adhesion genes involved in the development of the cerebellar vermis are associated with autism spectrum disorders. *S. Hochreiter[1], D.-A. Clevert[1,2].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Charité University Medicine, Berlin, Germany.

Motivation: We investigated neurodevelopmental dysfunctions in autism spectrum disorders (ASD) by a integrative analysis including the two largest genome-wide studies on associations between copy number aberrations (CNA) and ASD, the BioGPS tissue atlas, the Allen brain atlas, and *in situ* hybridization histochemistry data from the developing mouse brain. In contrast to the original association studies, we considered "ASD candidate genes" each of which is the only CNA-impaired gene in an ASD case, therefore, presumably causing ASD. For extracting ASD candidate genes, we developed an analysis pipeline for rare and small CNAs. Rare CNAs are supposed to be more disease-specific, because CNAs that cause ASD with high probability are assumed to be *de novo* and quickly vanish in the population due to their low reproductive fitness. Small CNAs affect only few genes and, therefore, are very specific concerning the genes they are impairing. **Results:** ASD candidate genes that are indentified independently in both CNA studies include the neurexins *CNTNAP2* and *NRXN1*, the catenin *CTNNA3*, the cadherin *CDH13*, and the contactins *CNTN5* and *CNTN6*. Gene set enrichment analysis of ASD candidate genes showed that significant biological processes are all related to cell and synaptic adhesion the postsynaptic density, membrane and synapse. At data from the BioGPS, the Cancer Genome Anatomy Project, and the Allen brain atlas, ASD candidate genes have significantly different variations in their expression values in cerebellum compared to other genes, where at the Allen brain atlas cerebellar vermis lobes I-II, III, VI, and VIII where most significant. *In situ* hybridization histochemistry data indicate that ASD candidate genes are primarily expressed in the developing mouse cerebellum. **Discussion:** Our results which hint at the cerebellar vermis as the location of ASD's pathogenesis are consistent with pathological studies of ASD cases, where, in over 90% of the examined brains, well-defined cerebellar abnormalities were found. Also studies on children with vermal lesions showed phenotypes like speech disorders and behavioral disturbances similar to autism. The high percentage, 60-80%, of ASD cases showing motoric deficits again hints at the cerebellum. We explain 4:1 male to female ratio in ASD by the regulatory influence of estrogen on the development of the cerebellum. The human estrogen 17) -estradiol enhances in the cerebellum synaptic connectivity.

High coverage of copy number variants (CNVs) in Finnish patients with autism spectrum disorders using Nimblegen 2.1M array. *K. Kantojärvi[1], R. Vanhala[2], T. Lepistö[2], R. Alen[3], I. Järvelä[1], L. Muthuswamy[4].* 1) Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Hospital for Children and Adolescents, University of Helsinki, Finland; 3) Department of Pediatrics, Jyväskylä Central Hospital, Jyväskylä, Finland; 4) The Ontario Institute for Cancer Research, Toronto, Canada.

Autism spectrum disorders (ASD) are neuropsychiatric disorders characterized by restricted repetitive behavior and abnormalities in communication and social interaction. The model of inheritance of ASD seems to be very complex and probably involves multiple interacting genes. Several studies have shown that de novo copy number variants (CNV) contribute to autism risk in 5-15% of cases in families with one affected individual. We performed array comparative genomic hybridization (aCGH) utilizing Nimblegen 2.1M oligonucleotide array on 21 Finnish families with autism spectrum disorders (ASD). The findings were confirmed using quantitative PCR. We detected five copy-number variations that most likely are causative of autism, because they either arose de novo and/or overlapped with known microdeletions. One of the deletions was de novo NRXN1 previously shown in neuropsychiatric conditions.

591W

Familial occurrence of Asperger Syndrome associated with a 1Mb Duplication on Xq including the MCT8-Gene. *P.M. Kroisel[1], K. Wagner[1], M. Mach[1], E. Vallant[1], M. Brunner-Hantsch[2], M.R. Speicher[1], K.M. Roetzer[1].* 1) Human Genetics, Medical University of Graz, Graz, Styria, Austria; 2) Psychiatric consultant, Graz, Austria.

By array CGH using a 60k Agilent oligonucleotide array we were able to identify a maternally inherited microduplication of about 1Mb at Xq12.3-q13.3 that affects at least 5 genes in a patient with Asperger-syndrome. One of the genes involved in this microduplication is the MCT8-(monocarboxylate transporter-8)-gene, already known to cause Allan-Herndon-Dudly-syndrome(AHDS), which follows an X-linked pattern of inheritance and leads to a severe form of mental retardation combined with distinct dysmorphic features in males whereas females show a mild phenotype with no neurologic anomalities. Since different and occasionally reciprocal phenotypic features can be observed in patients with microdeletions versus microduplications of particular genomic regions or loci like the Williams-Beuren- or DiGeorge-syndrome critical region or the PMP22-gene, a different phenotype to AHDS is not unexpected in the patient described here with the identified Xq microduplication. The affected male patient as well as his maternal uncle shows a much milder phenotype compared to AHDS patients with just a few characteristic facial anomalies like smaller ears however a pronounced form of Asperger-syndrome and a general reduction of mental capacity with remarkable strength in fine coordination and spatial orientation is present. Potential additional effects related to an increased gene dosage of the KIAA2022-gene and the ZDHHC15-gene with regard to mental impairment can not be ruled out at the current state of this investigation. Because just a few similar microduplications are currently listed in databases like Decipher a comparison with these patients is difficult. From our findings we would propose that at least in this familial setting a genetic explanation for the development of Asperger-syndrome was found and gain of function mutations of the MCT8-gene might be a more common reason for this syndrome than the identified specific microduplication or mutations of the linked neuroligin-3(NLGN3)-gene.

592W

Genome-wide investigation of rare CNVs in a newly characterized Canadian autism cohort. *A.C. Lionel[1,2], B. Thiruvahindrapuram[1], D. Merico[1], J.L. Howe[1], Z. Wang[1], J. Wei[1], L. Zwaigenbaum[3], B.A. Fernandez[4], W. Roberts[5], P. Szatmari[6], C.R. Marshall[1], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) McLaughlin Centre and Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pediatrics, University of Alberta, Edmonton, Alberta, Canada; 4) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada; 5) Autism Research Unit, The Hospital for Sick Children and Bloorview Kids Rehabilitation, University of Toronto, Toronto, Ontario, Canada; 6) The Offord Centre for Child Studies, Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Ontario, Canada.

Autism spectrum disorder (ASD), a common neurodevelopmental disorder with an estimated prevalence rate of nearly 1% of children, is characterized by impairment in reciprocal social interaction, communication deficits and a repetitive pattern of behavior. In recent years, several studies have highlighted the role of rare copy number variants (CNVs) in the genetic etiology of ASD. The study of these rare deletions and duplications in the genomes of ASD patients has proven to be a powerful tool for the identification of novel candidate genetic loci for further investigation by targeted gene sequencing and functional studies. We conducted, and present here for the first time, a genome-wide CNV scan of more than 700 unrelated, newly characterized Canadian ASD patients using two high resolution SNP genotyping platforms: the Affymetrix SNP 6.0 and the Illumina Omni2.5M-Quad. A multi-algorithm approach incorporating Birdsuite, Affymetrix Genotyping Console and iPattern (for Affymetrix data) and iPattern, PennCNV and CNVPartition (for Illumina data) was utilized for CNV detection. High confidence CNVs detected by this approach in the ASD cases were compared with CNVs found in array data from more than 2,000 ancestry-matched population based controls. We detected and confirmed validated rare exonic CNVs in the ASD cases that were absent in controls and overlapped previously implicated ASD loci (e.g. *NRXN1*, *SHANK3*, *PTCHD1*, 16p11.2), or identified new candidate susceptibility loci for ASD (e.g. *NRXN3*). We are currently collecting samples from the parents and extended family of the ASD cases in order to study the inheritance patterns of the CNVs of interest and their potential segregation with elements of phenotype. We will also test for gene interaction sub-networks enriched for rare CNVs in ASD cases compared to controls. Our results provide support for the role of rare CNVs in risk for ASD and identify new candidate genetic loci for further investigation.

A genome-wide CNV association study on Autism Spectrum Disorder (ASD) in the Japanese population. *X. Liu[1], T. Shimada[2], K. Tokunaga[1], T. Sasaki[3].* 1) Department of Human Genetics, University of Tokyo, Tokyo, Japan; 2) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Office for Mental Health Support and Graduate School of Education, University of Tokyo, Tokyo, Japan.

Introduction: Family and twin studies have strong evidence that autism spectrum disorder has a strong genetic background; however,all know variation only accounts for a small fraction for known patitens. We conducted a genome-wide copy number variation (CNV) association study on ASD in the Japanese population.

Methodology: Participants consisted of 500 ASD trio Japanese CNVs were detected using Genome-Wide Human SNP array 6.0 and determined by PennCNV. CNVs with length <100kb were excluded. CNVs were considered to becolocalized if they overlapped by at least 50%; of their length. They were classified as rare CNVs (found in <1%; of the total sample) or common CNVs (found in ⁄ 5%;).

Results: Identification of the pathogenic CNV variaton is underway.Preliminary results support the association between 15q11.2 with ASD. To identify the pathogenic CNV variation we are focusing on denovo CNVs.

Conclusions: We discuss the Copy Number Variation study in the Japanese population, By comparing our result with the caucasian study we may get new insight into the complex genetic structure of ASD.

Copy number variations reveal novel GABAergic and neural genes potentially involved in autism. *D.Q. Ma[1], A.J. Griswold[1], H.N. Cukier[1], J.M. Jaworski[1], I. Konidari[1], P.L. Whitehead[1], S.M. Williams[2], R. Menon[3], E.R. Martin[1], J.L. Haines[2], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Vanderbilt University, Nashville, TN; 3) Department of Epidemiology and Department of Obstetrics and Gynecology, Rollins School of Public Health, Emory University, Atlanta, GA.

The underlying genetic causes of autism spectrum disorders (ASDs) are complicated given that ASDs are highly heritable yet few associated genetic loci have been identified. Rare copy number variations (CNVs) have been implicated as contributing to autism etiology with each locus explaining less than 1% of the disease population. Due to the extremely heterogeneous nature of ASDs, independent studies are important to evaluate the contribution of ASD related CNVs and discover novel regions containing susceptibility genes and implicated gene networks. In this study, a genome-wide SNP array was utilized for CNV detection. High confidence calls were defined as CNVs identified by two distinct CNV-calling algorithms in a case-control dataset of European ancestry consisting of 813 unrelated ASD cases and 592 pediatric controls. Cases have an overall significantly heavier burden in number and size of deletions, thereby disrupting more annotated genes (size: p=9.90E-06; number: p=2.00E-05). Individual CNVs of interest were validated by real time PCR. Seventeen deletions larger than 1Mb were detected exclusively in cases, implicating CNV regions at 10p15.2, 13q12.12, 13q33.1, 14q23.2-3, and 17p12, which are not reported in DGV or AUTdb. Examination of case-specific CNVs provided additional evidence for pathways previously implicated in ASDs and revealed several novel candidate genes within GABAergic signaling and neural development pathways. The experimentally validated genes include DBI, an allosteric binder of GABRA receptors, the GABRA receptor-associated protein GABARAPL1, and SLC6A11 (GAT-3) a postsynaptic GABA transporter that could affect GABAergic signaling. We also identified CNVs in COBL, deletions of which show severe defects in neuronal cytoskeleton morphogenesis in vertebrates, and DNER, a neuron specific Notch ligand required for cerebellar development. Taken together, these CNVs may be a few of the missing pieces of ASD heritability and lead to discovering novel etiological mechanisms.

Chromosome 15q11.2 is associated with schizophrenia risk in a set of patients. *D. Rudd, M. Axelsen, S. Mugge, E. Epping, N. Andreasen, T. Wassink.* Univ Iowa, Iowa City, IA.

Schizophrenia is characterized by positive and negative symptoms that include hallucinations, delusions and disorganized thought as well as flat affect and decreased speech. Genomic copy number variation (CNV) has been found to underlie and increase risk for a large number of neuropsychiatric disorders including schizophrenia. This project focuses on identification and characterization of pathogenic CNVs in a sample set of 457 schizophrenia patients and 290 psychiatrically healthy controls. To date, 181 probands and 141 controls have been genotyped using the Affymetrix Genome-Wide Human SNP 6.0 Arrays and analyzed for CNVs with Genotyping Console and CNAG. CNVs were compared between cases and controls and cross-referenced with the Database of Genomic Variants. The proximal arm of chromosome 15 contains canonical segmental duplications that predispose the region to CNV formation, but only recently have disease-associated CNVs been reported between the two most proximal breakpoints (BPs), BP1 and BP2. Here we report three case subjects that have a ~1Mb deletion of the BP1-BP2 region at chromosome 15q11.2. The BP1-BP2 deletion encompasses the four genes *CYFIP1, NIPA1, NIPA2* and *GCP5*. The deletion is present in three probands, two were maternally inherited and none were found in controls. All CNVs of interest were validated by qPCR or NimbleGen 385K whole-genome array CGH. The four genes within the deletion have previous association with Prader Willi syndrome, Angleman syndrome, autism and schizophrenia and are often inherited from a mildly or unaffected parent. *CYFIP1*is of primary interest due to its direct interaction with the Fragile X Mental Retardation Protein (FMRP) and its reported role in regulation of neuronal translation during brain development. *NIPA1, NIPA2* and *GCP5* are also expressed in the brain. It is a distinct possibility that in addition to the 15q11.2 deletion in probands, a “second CNV hit” contributes to disease pathology. Thus, the two probands with maternal inheritance of the deletion were further analyzed for sporadic secondary CNVs. For example, a *de novo* duplication of four exons of *ATXN2* as well as a *de novo* deletion of the promoter and the first three exons in *SYN3*, a gene with previous association with schizophrenia, was called in one proband. In the second family the proband had an additional *de novo* duplication of two exons in two synapse-associated genes *CACNA1B* and *DLGAP2* as well as a *de novo* intronic duplication of *SYN3*.

Analysis of copy number variation in Alzheimer's disease: the NIA-LOAD/NCRAD Family Study. *S. Swaminathan[1], L. Shen[1], S. Kim[1], M. Inlow[1, 2], J.D. West[1], T. Foroud[1], K.M. Faber[1], R. Mayeux[3], A.J. Saykin[1], The NIA-LOAD/NCRAD Family Study Group.* 1) Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN; 2) Department of Mathematics, Rose-Hulman Institute of Technology, Terre Haute, IN; 3) The Gertrude H. Sergievsky Center, The Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University College of Physicians and Surgeons, New York, NY.

We previously investigated the role of copy number variants (CNVs) in Alzheimer's disease (AD) and mild cognitive impairment (MCI) using participants in the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort [1]. Case/control association analyses revealed CNVs overlapping the AD candidate gene *CHRFAM7A* as well as *CSMD1*, *HNRNPCL1*, *SLC35F2*, *NRXN1* and *ERBB4* genes in cases (AD and/or MCI), but not controls. Using a similar approach as ADNI, we analyzed the role of CNVs in AD using non-Hispanic Caucasian participants in the NIA-LOAD/NCRAD Family Study. Briefly, CNV calls were generated in PennCNV software for 794 AD cases and 196 neurologically evaluated controls with DNA derived from blood or brain tissue. The controls had no family history of AD and were unrelated to cases. Extensive quality control was performed and 711 cases and 171 controls were retained for a case/control association analyses. We tested for CNVs in the entire genome and also limited our analysis to candidate genes from the AlzGene database. Genes overlapped by CNVs in cases, but not controls were determined. A trend for lower CNV call rate for deletions as well as duplications was observed in cases as compared to controls. The whole genome approach identified CNVs overlapping *IMMP2L* in 13 cases and no controls. As a comparison in the ADNI cohort, CNVs were found overlapping *IMMP2L* in four AD, one MCI and one control. The *ERBB4* and *NRXN1* genes identified in the ADNI CNV study also had CNV calls overlapping them in five and four cases respectively, but no controls. These genes have been previously associated with neuropsychiatric disorders. The candidate gene approach revealed a number of AD candidate genes overlapped by CNVs only in cases. The *CHRFAM7A* AD candidate gene had CNV calls overlapping it in 12 cases and one control. This gene was identified in the ADNI CNV study using a similar candidate gene approach. The present analyses confirm previous findings (*ERBB4*, *NRXN1*, *CHRFAM7A*) and also identified a new gene (*IMMP2L*) that may play a role in susceptibility to AD. Further investigation of these genes in independent cohorts are warranted. Rare variants in the 15q13.3 encoded CHRNA7 gene in autism. *S. Thomson, J. Sutcliffe.* Mol Physiology & Biophysics, Centers for Mol Neuroscience and Human Genetics Research, Vanderbilt Univ, Nashville, TN.

Autism spectrum disorders (ASDs) affect about 1/110 of children and are associated with conditions such as impairments in reciprocal social interaction and communication and presence of restricted and repetitive behaviors. While ASDs seem to be highly heritable, genome-wide association studies thus far have been limited in identifying common risk variants. This suggests a highly complex architecture for the underlying genetic etiology of ASDs. Recent studies showed that ASD individuals carry a higher global burden of rare, genetic copy number variants (CNV) compared to controls. This might also suggests that an increased number of rare variances in probands within a certain gene could be associated with autism, especially since ASD is a clinically heterogeneous genetic disorder. Recurrent deletions in the 15q13-q14 region were first reported in mental retardation, seizures, autism, schizophrenia and bipolor disorder. While the recurrent deletions contain several genes, attention has been focused on CHRNA7 since mutations in ion channel genes have been associated with epilepsy and schizophrenia. CHRNA7 is a member of a superfamily of pentameric ligand-gated ion channels that are distributed throughout the central and peripheral nervous system. Naturally occurring genetic variances in nAChRs can modulate cognition and behavior as well as contribute to the risk for various neurological psychiatric disorders. In an effort to identify rare individuals variances we sequenced all ten exons of CHRNA7 in a large cohort of ASD patients (400) as well as controls (384). We found a number of non-synonymous, synonymous, and intronic variances in probands that were not present in controls indicating that the prevalence of variances are greater in probands compared to controls. To determine if probands contained overall higher number of variances that potentially could alter and/ or interfere with the function or expression of the ion channel, we performed a two-sided Fisher's exact test for non-synonymous and splice side effecting variances. We identified seven non-synonymous and two splicing effecting variances in probands (2.25%) compared to one non-synonymous variance in controls (0.26%), which when combined reached significance (p-value = 0.021). Our study provides further evidence that rare individual variances play an important role in autism and may lead to a better understanding into the genetic complexity of ASD.

Whole genome copy number variation study in an Arab-Israeli sample supports the role of rare large de novo deletions. *F. Torri[1,2], A. Akelai[3], A. Calabria[4,5], D. Amann-Zalcenstein[6], E. Ben-Asher[6], K. Kanyas[3], J.S. Beckmann[7], B. Lerer[3], F. Macciardi[1,2].* 1) Department of Psychiatry and Human Behavior, University of California, Irvine, Irvine, California 92617; 2) Biomedical Informatics Research Network (BIRN), Information Sciences Institute, University of Southern California, Los Angeles, CA 90292; 3) Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 4) Dept. of Medicine, Surgery and Dentistry, San Paolo Hospital, University of Milan; 5) University of Milan - Fondazione Filarete, Genomics and Bioinformatics Unit; 6) Weizmann Institute of Science, Rehovot, Israel; 7) Centre Hospitalier Universitaire Vaudois and University of Lausanne, Switzerland.

We have recently published a fine mapping on an Arab-Israeli sample of schizophrenia with the definitive evidence on the role of the neurodevelopmental gene AHI1 in schizophrenia, shedding light also on new possible candidate genes MAP7 and PDE7B that are expressed in brain and may play a role in neurodevelopment. In line with the rising evidence on the implication of rare copy number variants (CNVs) in schizophrenia, we have carried out a whole-genome CNV analysis in the same familial Arab-Israeli sample, focusing on rare de novo CNVs. With a novel approach for family-based CNVs analysis, we were able to label and filter the events starting from the Penncnv calls. We detected heterozygous deletions and heterozygous duplications previously unreported, of sizes ranging from 7.2 kb to 7 Mb. Genes affected by rare de novo CNVs in our sample show mostly expression in brain. Preliminary pathway and functional analysis revealed a different enrichment profile for genes disrupted by large deletion events (>400 kb), than all the genes disrupted by rare de novo CNVs, independently from the dimension. Genes affected by de novo CNVs detected in our sample are mainly involved in cell metabolism pathways. This evidence may be interesting per se since both genes and metabolites related to energy metabolism (and thus energy-expensive brain functions) are altered in schizophrenia and, at the same time, appear to have changed rapidly during recent human evolution, probably as a result of positive selection. Interestingly, genes disrupted by large de novo deletions in our sample showed a significant enrichment in brain development and function-related pathways and processes like axonal guidance and long term potentiation (LTP). Even if we do not propose a model of interaction between those genes and the most known candidate genes to schizophrenia, there are multiple links between them that can be found by a simple information retrieving. Genes interested by rare large de novo deletion participate also in pathways that show a high level of overlapping to those in which AHI1, PDE7B and MAP7 are involved, with the great majority of the interactors being candidate genes to schizophrenia or involved in other brain pathways and processes. All together, these evidences support the etiologic role of AHI1 as a susceptibility gene for schizophrenia and put it into a potential network of genes that play a role in neurodevelopment and brain processes.

599W

Systematic shRNA-mediated silencing of 100 genes implicated in autism spectrum disorders and schizophrenia in iPSC-derived human neurons. *C. Ernst[1,2], K. Theriault[1], S. Sheridan[1], T. Nieland[2], D. Root[2], S. Haggarty[1,2], J. Gusella[1,2].* 1) Department of Neurology, Harvard Medical School, Boston, MA; 2) RNAi platform, Broad Institue of MIT and Harvard, Cambridge, MA.

Autism spectrum disorders (ASD) and schizophrenia are highly heritable disorders of human cognition and behavior. Advances in sequencing technology have allowed for better refinement of genetic etiology of complex disorders, and numerous genes and microdeletion/microduplication regions have been associated with both disorders, with some overlap. However, it remains challenging to establish a causal role for genetic variants associated with disease risk. One aim of this study is to investigate important implicated genes in these related disorders by identifying aberrant phenotypes in a genetic knock-down system. This is particularly relevant for elucidating the relative contributions of genes encompassed within microdeletion/microduplication syndromes such as 16p11.2 or 22q11.2, where the presumed causative gene(s) has not been found. To complement mutation analysis studies, we developed and characterized a human neural progenitor cell line derived from induced pluripotent stem cells (iPSC-NPs) taken from fibroblasts from a psychiatrically screened healthy male. iPSC-NPs were karyotypically normal, differentiated into all central nervous system cell types assessed, and were capable of synapse formation upon long-term differentiation. We selected over 100 genes associated with ASD and/or schizophrenia and targeted each gene with > four short-hairpin (sh) RNA's/gene, delivered by lentivirus along with a series of control shRNAs not known to target any human gene. In total, over 400 stable cell lines were generated and all cell lines were validated by qPCR in comparison to control shRNAs. A battery of phenotypic assays at both the progenitor and mature neuron stage were developed that assess a range of phenotypes including cell growth, cell extension, and intracellular calcium release. Changes in these cellular phenotypes occur upon knockdown of several of the GWAS-nominated candidate genes suggest that these genes may play a functional role in microdeletion/microduplication syndromes. These results can help the research community prioritize and direct further investigation of the function of genes associated with ASD and schizophrenia.

Dynamic Versus Static Biomarkers of Schizophrenia and Bipolar Disorder: Considering Differential Developmental Courses in Genetic Studies. *M. Maziade[1, 2], T. Paccalet[1], N. Rouleau[1, 3], A. Sasseville[1], E. Gilbert[1], C. Cellard[1, 3], M. Battaglia[4], C. Marino[5], M.A. Roy[1], C. Mérette[1], M. Hébert[1].* 1) Dept Psychiatry, Ctr Rech, Univ Laval R-Giffard, Quebec, QC, Canada; 2) Faculty of Medicine, Laval University, Quebec, QC, Canada; 3) École de psychologie, Laval University, Quebec, Canada; 4) Academic Centre for the Study of Behavioural Plasticity, Vita-Salute San Raffaele University, 20 Via Stamira d'Ancona, 20127, Milan, Italy; 5) Eugenio Medea Institute, Department of Child Psychiatry, Via Don luigi Monza, 2023842 Bosisio Parini (Lecco), Italy.

Objective: Schizophrenia (SZ) and bipolar disorder (BP) are neurodevelopmental diseases and theirphenotype eludes genetic and neurobiological research. SZ and BP patients carry cognitive and physiological intermediate phenotypes (IP) that are precursors of disease in children at risk appearing many years before disease incidence (Maziade et al. *Schizophr Bull* 2009 and 2010; Hébert et al. *Biol Psych* 2010). Few studies have investigated the longitudinal mechanisms underlying intermediate phenotypes in children at risk. Yet, timing and differences in developmental courses need consideration in genetic studies. Our objective was to investigate the developmental courses of cognitive and physiological IP from childhood to young adulthood in terms of stability or fluctuations. **Methods:** We used a step by step sampling approach to narrow-down the early disease mechanisms. Upstream, we started with a 20-year follow-up of 48 densely affected multigenerational kindreds (1500 clinically characterized adult members). We then identified 400 members affected by a DSM-IV SZ or BP. Downstream, we finally focused on the 65 offspring aged 7 to 22, who were administered a neuropsychological battery and electroretinography (ERG) testing. We then constructed cross-sectional trajectories that were compared to those of controls, in order to investigate the developmental courses of IP, cognitive as well as ERG, in these high-risk offspring. **Results:** Three shapes of developmental trajectories were detected. First, some IP (such as lower global IQ and diminished amplitude in rod b-wave, measured by ERG) displayed stability in deficit from childhood until young adulthood. The impairment in visual memory was unstable and exhibited a non-linear two-stage trajectory: a lagging period during childhood followed by a recuperation period from adolescence until adulthood, as supported by a significant Group x Age Periods interaction (p = .035). The working memory impairment was characterized by a late-onset lag, emerging during late adolescence. **Conclusion:** 1. Different cognitive or physiological IP would mark different developmental courses according to three types of trajectories. 2. Timing of intermediate phenotype measurement and targeting dynamic, instead of static, endophenotypes may be crucial when considering how a particular endophenotype relate to genotype or gene expression.

601W

Peripheral blood expression profiles act as biomarkers for postpartum depression in a high risk population. *D. Mehta[1], L. Kraus[1], M. Rex-Haffner[1], J. Newport[2], Z. Stowe[2,3], E. Binder[1,3].* 1) Max Planck Institute for Psychiatry, Munich, Germany; 2) Emory University School of Medicine, Department of Psychiatry and Behavioral Sciences, Atlanta, GA; 3) Emory University School of Medicine, Department of Obstetrics and Gynecology, Atlanta, GA.

Introduction Postpartum depression affects 13% of women and has a strong negative impact on maternal well-being and infant development. Early detection, possibly by using biomarkers, coupled with timely treatment is therefore very important for both mother and child. Aims The aim of this study was to identify biomarkers for postpartum depression by global assessment of peripheral blood expression changes during the peripartum period. Methods Multiple measurements from 67 women (220 samples) were collected longitudinally in the 1st and 3rd trimester and within 7 weeks postpartum. All women had a history of mood or anxiety disorder and included 3 groups: postpartum onset depression (n=16), no depressive symptoms (n= 33) and depressed at all timepoints (n=18). Depression was assessed using the SCID mood module and the Beck Depression Inventory (BDI). Whole blood RNA was extracted from Tempus tubes and hybridized on Illumina HumanHT12-v4 microarrays. Background correction filtering and VSN normalization resulted in 15456 probes. Statistical analysis was performed in R using mixed models. Results Transcriptional profiles of >3000 transcripts were significantly changed across pregnancy and early postpartum after Bonferroni corrections($p<3x10-6$) with significant over-representation of steroid hormone transcription factor binding sites within these transcripts. Comparison of 3rd trimester expression profiles between the post-partum onset and no depressive symptoms groups revealed 116 significant transcripts with significant over-representation of estrogen receptor transcription factor binding sites (ESR1) within these 116 transcripts. Expression levels of these transcripts allowed classifying women with and without postpartum depression with 88% prediction, 82% sensitivity and 93% specificity. Conclusions Third trimester expression profiles of a subset of transcripts allowed high classification accuracy of women who developed postpartum depression, thus serving as potential biomarkers. RT-PCR validation of results and increasing the sample size to add power to the study is currently underway. Over-representation of ESR1 fits to the previous hypothesis that differential sensitivity to changing steroid levels is a vulnerability trait for postpartum depression (Bloch,M.et al.Am J Psychiatry 157,2000). Our results suggest that postpartum depression risk may be biologically detectable in the 3rd trimester, allowing timely prevention and treatment strategies.

Behaviour and learning in children with NF1: Data from a population-based study. *A. Lehtonen[1], S. Garg[3], J. Green[2], D. Trump[1], G. Evans[3], S. Huson[3].* 1) Medical Genetics, University of Manchester, Manchester, United Kingdom; 2) School of Medicine, University of Manchester, Manchester, United Kingdom; 3) Genetic Medicine, Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom.

Research in the last two decades has begun to define the behavioural and cognitive phenotype of neurofibromatosis type 1 in childhood, documenting problems with behaviour and social functioning, academic achievement, attention, executive functioning and coordination (e.g. Hyman et al, 2005; Krab et al., 2008; Ferner et al., 1996). However, there is still a paucity of large-scale, comprehensive studies with representative sampling strategies. Our study aimed to delineate the behavioural and cognitive phenotype of NF1 through a population-based sample of children with NF1. Method Participants: The study took advantage of the large, population-based cohort of NF1-patients followed in Genetic Medicine, St. Mary's Hospital, Manchester, UK. Altogether 220 families with 4-16 year old children were invited to take part. All the families were sent questionnaires about different aspects of behaviour. A hundred children, aged 6-16 years, were also invited to do a cognitive assessment battery. The families invited to the cognitive assessment were randomly selected, stratifying for age and socio-economic status. 108 families returned the questionnaires, and 49 children took part in the cognitive assessment phase. Control participants for the cognitive assessment study included 20 siblings of the children with NF1 and 29 community controls, matched for age and socio-economic status. Measures: The questionnaire measures focussed on attention, social communication and general behaviour. The cognitive assessment included measures of intelligence, attention, memory and learning, academic achievement, visuospatial perception, and facial emotion recognition. Participants were seen either at home or in the hospital. Results Preliminary data analyses demonstrate very high levels of social communication, attention and behavioural problems: 26% of participants were in the `severe' range on the Social Response Questionnaire, indicating almost certain diagnosis of autism, and further 29% were in the moderate range, indicating mild/ moderate autism. 54% of participants scored in the `abnormal' or `borderline' range on the Strengths and Difficulties Questionnaire, and 53% of participants scored beyond the clinical cut-off for ADHD on the Conners' Parent Rating Scale. Results from the cognitive assessment study are pending (data collection has only just finished), but results will be available for the Conference, and we are happy to update this abstract accordingly.

Gene-environment interaction studies in multiple sclerosis: The development of a reliable retrospective survey tool. *A. Hadjixenofontos[1], W.K. Scott[1], L.F. Barcellos[2], J.L. Haines[3], M.A. Pericak-Vance[1], J.L. McCauley[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Division of Epidemiology, School of Public Health, University of California, Berkeley, CA, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Multiple sclerosis (MS) is second only to trauma as the most common cause of neurological disability in young adults. There is increasing appreciation for the existence of a fundamental and complex architecture of gene-environment (GxE) interactions contributing to complex genetic disorders, including MS. While multiple environmental risk factor studies in MS have been undertaken, most have been performed with small numbers and even fewer have incorporated genetic information. Gathering prospective environmental exposure data to study complex genetic diseases is extremely challenging and often prohibitive. We have therefore developed a scripted environmental assessment survey for use in ongoing studies of genetic and environmental risk factors in MS. We utilized the PhenX validated toolkit measures as a primary source in our survey construction, with adaptations to target MS-specific environmental hypotheses. Our survey addresses the roles of latitude, sun exposure, infectious diseases, smoking, alcohol, (environmental, food, and drug) allergies, and gender hormones in the pathogenesis of MS. Our survey is designed to be administered electronically via the use of a tablet computer, supporting both in-person and phone interviews. Before the interview begins, participants are asked to complete a Life Events Calendar which we employ as a recall aid. The phone interviews mimic the in-person design in the use of both the calendar and list cards which are mailed to the participants ahead of the interview. Over-reporting is addressed by the use of questions on infectious diseases that have been shown not to influence MS. The face validity of the resulting survey was assessed by expert epidemiologists. We attempt to minimize interviewer bias by standardized training and a detailed script, which includes scripted clarifications. Our survey has undergone reliability testing via test-retest of 10 subjects. As a result of the reliability testing, we revised and shortened sections on vaccinations and dietary supplements that participants said were overwhelming. Questions that were deemed unreliable due to recall bias (e.g. vaccinations, hours spent in pre-school, time points for contraceptive use) were also removed. The mean time to complete this survey is 31.6 minutes. We are also developing the survey in Spanish, with the reliability to be tested via reverse-translation and additional test-retest assessments.

Genome wide linkage and association analysis of job stress. *K. Min[1], J. Min[2], D. Lee[3], Y. Song[4], K. Lee[5], J. Sung[3,6], S. Cho[3,6].* 1) Ajou University school of Medicine, Suwon, Korea; 2) Institute of Health and Environment, Seoul National University, Seoul, Korea; 3) Department of Epidemiology, School of Public Health and Institute of Health and Environment, Seoul National University, Seoul, Korea; 4) Department of Family Medicine, Samsung Medical Center and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, Seoul, Korea; 5) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Busan, Korea; 6) Corresponding authors.

Objective: Despite evidence for the contribution of genetic makeup to an individual's susceptibility to stress, researchers have largely focused on whether stress acts as a modifier of a genetic predisposition for the occurrence of diseases or symptoms. Mental and physical stress during the occupational activities consists in a substantial part of overall stress. We performed linkage and family-based association tests to identify genetic backgrounds related to job stress using Korean family data. Method: Affymetrix Genome-Wide Human SNP array 6.0 were genotyped in 1269 subjects participating in the Healthy Twin study. After applying extensive quality checks (Exclusion criteria: monomorphic SNPs, Mendelian error > 3 families, MAF < 0.01, HWE < 0.001), a total of 568,121 markers were included for this analysis. Job stress was measured by the short version of Effort-Reward Imbalance Model. We performed nonparametric linkage (NPL) analysis with MERIN and family based association analysis with Golden Helix (Golden Helix, Inc., Bozeman, MT, USA) package. IMPUTE program was utilized to impute the genotypes of all SNPs located in the regions based on Asian HapMap data. Results: The chromosomal region at 1q42.2 (LOD=3.71; NPL Z=4.19) showed strong linkage with job stress. Six suggestive linkage regions are observed at 1q24.3 (LOD=2.15; NPL Z =3.25), 4q35.1 (LOD= 2.79; NPL Z =3.53), 10p11.21 (LOD=2.50; NPL Z =3.59), 12p13.31 (LOD= 2.39; NPL Z =3.17), 14q23.2 (LOD=2.31; NPL Z =3.38), and 21q21.1 (LOD= 2.13; NPL Z =3.20). Moreover, under the linkage peak (LOD>1.9), rs687723 at chromosome 1q42.13 located in the upstream of GALNT2 (UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 2 (GalNAc-T2)) were significantly associated with job stress. As increasing risk alleles of the polymorphisms, ER ratio was significantly increased after age and sex () =0.019, p<0.0001). Conclusion: We identified candidate region 1q42.1-2, harboring the AGT (angiotensinogen (serpin peptidase inhibitor)), DISC1(disrupted in schizophrenia 1), and TRAX (translin-associated factor X) genes, which may explain the control over reactions to stress and neuropsychiatric illnesses. In addition, strong linkage regions for job stress included cardiovascular-related genes, such as GALNT2 and KCNK1(potassium channel).

Challenges in investigating novel SNPs identified from Next Generation Sequencing of the 11p13 locus in a Rolandic Epilepsy family sample. *L. Addis[1], T. Chiang[2], A. Derkach[3], J.J. Russo[4], L.J. Strug[2], D.K. Pal[1].* 1) Institute of Psychiatry, King's College London, London, United Kingdom; 2) Hospital for Sick Children, Toronto, ON, Canada; 3) Department of Statistics, University of Toronto, Toronto, ON, Canada; 4) Center for Genome Technology and Biomolecular Engineering, Columbia University, New York, NY, United States.

Rolandic Epilepsy (RE) is a common childhood epilepsy of complex genetic inheritance, characterized by the abnormal EEG endophenotype of centro-temporal spikes (CTS). CTS is linked to 11p13 (HLOD 4.30), a locus pleiotropic for Speech Sound Disorder (HLOD 7.54) with fine mapping showing association in two independent cohorts to SNPs in *ELP4. EPL4* is a subunit of the Elongator complex involved in transcriptional regulation of many neurodevelopmental genes. As resequencing of *ELP4* coding regions revealed no significant polymorphisms we have used next generation sequencing to interrogate the 650Kb linkage region in 27 RE probands. DNA was amplified by long-range PCR (Roche) before preparation of paired-end multiplexed (9x) Illumina sequencing libraries. Libraries were sequenced using 2x36 cycles on an Illumina GAIIx. Raw sequence data were aligned, sorted, merged and assembled using Mosaik. SamTools was used to call SNPs and InDels with a high quality filter of 45, minimum read depth of 5x and MAF >20%. A validation analysis pipeline incorporating Novoalign and the Broad Institute's Genome Analysis Toolkit is underway. SNPs were called as novel if absent in dbSNP, HapMap and 1000Genomes. Our methodology resulted in read depth averaging 415x, with an average of 1000 SNPs called per sample. We have discovered 252 potential novel SNPs in this region, of which 230 occur in only one individual each. Of the `common' novel SNPs, 18 cases presented with the same SNP in *ELP4* intron 3, and two SNPs within *ELP4* intron 9 were present in 10 cases each. Intron 9 contains *PAX6* enhancer elements, and is an area of alternative *ELP4* splicing. Four high frequency novel SNPs were also found in neighboring *DCDC1*. Reconciling discrepancies between Sanger sequencing for validation and NGS results has been challenging, but 4 of the 7 high frequency SNPs are validated to date. SNP frequency has been compared to control data from Complete Genomics where available, ruling out some variants. Other database releases were not comparable to our data in coverage. After validation, the remaining novel SNPs will be typed in matched controls and family members for comparable sequence data. Almost half of the novel rare variants identified in this study are present in *ELP4*, with half again located in intron 9. We are assessing the probability of this occurrence, and are conducting rare variant analysis using binning statistics and functional analysis to investigate these SNPs further.

Heterogeneous Phenotypes of Idiopathic Occipital Epilepsy, Febrile Convulsion and Hemiplegic Migraine Occurring in a Family with a SCN1A Defect. *G. Annesi[1], L. Mumoli[2], A. Labate[1,2], P. Tarantino[1], G. Palamara[2], E. Ferlazzo[2,3], A. Fratto[1,2], U. Aguglia[2,3], A. Quattrone[2,4], A. Gambardella[1,2].* 1) Institute of Neurological Science, National Research Council, Mangone (CS), Italy; 2) Institute of Neurology, University of Magna Graecia, Catanzaro (CZ), Italy; 3) Regional Epilepsy Centre, Hospital of Reggio Calabria (RC), Italy; 4) Neuroimaging Research Unit, National Research Council, Catanzaro (CZ), Italy.

The voltage-gated Na_channel alfa1 subunit (SCN1A) is the most clinically relevant among all the known epilepsy genes with the largest number of epilepsy related mutations so far characterized. More recently, SCN1A mutations were identified in some families with familial hemiplegic migraine (FHM), further supporting a pathophysiological link between migraine and epilepsy. Here we report a three-generation family, in which affected individuals had heterogeneous phenotypes that included febrile convulsions (FC), focal epilepsy and hemiplegic migraine (HM). We studied a family composed by 13 members spread over three generations. All five affected individuals (5 women, mean age 32.7 years, range: 16-50) underwent a comprehensive clinical evaluation. Peripheral blood samples were obtained for DNA extraction from all members of the family. Mutation analysis was performed by direct sequencing of SCN1A. The neurologic and psychiatric status of all 5 affected subjects was normal, as also brain MRI. The proband (a 16-year-old girl) had developed benign occipital epilepsy (BOE) at the age of 7 years. Her 43-year-old mother had simple febrile seizures (FS) that resolved before the age of five, but she later developed BOE, at the age of 6. The 37-year-old sister also had a similar phenotype of simple FS at the age of 18 months, and BOE that started at the age of 8 years. In all three patients antiepileptic drugs were tapered off, between ages 10 and 12 years, with no seizure relapse. Two additional relatives (50-year-old mother and her 16-year-old daughter) had clear-cut hemiplegic migraine without epilepsy or FS. All affected members and one obliged carrier had the heterozygous T1174S missense mutation of SCN1A. Our findings illustrate that BOE may be part of the clinical spectrum associated with SCN1A mutations. Moreover, the association with FHM further strengthens the molecular links between migraine and epilepsy, two common paroxysmal disorders. Probably, assessing the biophysical and functional consequences of such a mutation will help to better understand the complex genotype-phenotype relationship that underlies SCN1A mutations.

Exploring the genetic complexity of juvenile myoclonic epilepsy. *F. Conte[1], T. Peluzzo[1], F. Oliveira[1], L. Betting[2], D. Holanda[3], L. Gitaí[4], F. Gameleira[4], D. Gitaí[3], F. Cendes[2], I. Lopes-Cendes[1], CInAPCe.* 1) Dept of Medical Genetics; Faculty of Medical Sciences, University of Campinas, Brazil; 2) Dept of Neurology; Faculty of Medical Sciences, University of Campinas, Brazil; 3) Sector of Genetic and Molecular Biology, ICBS; Federal University of Alagoas, Brazil; 4) Neurology Sector, HUPPA; Federal University of Alagoas, Brazil.

Purpose: Mutations in EFHC1 were identified in patients with two forms of idiopathic generalized epilepsy (IGE), juvenile myoclonic epilepsy (JME) and juvenile absence epilepsy. EFHC1 protein has 3 domains of unknown function called DM10 and one calcium binding domain, EF Hand. We aimed to search for mutations in EFHC1 and try to establish correlations between genotype and phenotype. Method: We sequenced all 11 exons of EFHC1 searching for the presence of any variant by the alignment with sequences available in public databases. When a mutation was found, its pathogenic potential was checked by different available algorithms. Of the 184 individuals enrolled in the study, 102 have JME, 32 have other forms of IGEs and 50 are control subjects. Results: We found 5 single nucleotide variants with potential pathogenic effect only in patients with JME. In exon 3, we identified 2 single nucleotide polymorphisms (SNPs) already described previously in patients with JME. The first is a transition from cytosine to thymine at position 475 (475C>T, R159W), present in 12 patients, 10 of whom with a positive family history. The second is a transition from guanine to adenine at position 545 (545G>A, R182H), found in 5 patients, 4 of whom with a positive family history. Interestingly, 1 patient presented both SNPs. In exon 4 we found a SNP in 3 patients (1 with a positive family history); this is a transition from thymine to cytosine at position 685 (685T>C F229L), and it has already being reported previously in a patient with JME. In exon 5 we identified 2 novel mutations. The first, was found in 2 patients with sporadic JME, this is a transition from guanine to adenine at position 887 (887G>A, R296H). The second is a transition from adenine to guanine at position 896 (896A>G, K299R), present in 1 patient with a positive family history. None of these mutations were identified in our control group. Conclusion: We found five nucleotide changes in EFHC1. These changes are located in the coding region of the first and second DM10 domains of EFHC1 protein and in the region between them. Overall the frequency of mutations in EFHC1 was 17% in our IGE group of patients, but if we consider only patients with JME, the frequency raises to 22%. In addition, we found mutations in patients with positive and negative family history; however, we only found mutations in patients with JME. We did not find any phenotypic difference between JME patients with and without EFHC1 mutations.

Protocadherin 19 mutations in sporadic and familial cases of epilepsy and mental retardation in females (EFMR). *L.M. Dibbens[1], R.S. Moller[2], M.A. Bayly[1], S. von Spiczak[3], T. Desai[4], H. Hjalgrim[2,5], G. Wallace[6], S. McKee[7], R.C. Dale[8], I.E. Scheffer[9].* 1) Pharmacy and Medical Sciences, University of South Australia, Adelaide, South Australia, Australia; 2) Danish Epilepsy Centre, Dianalund, Denmark; 3) University Medical Center, Schleswig-Holstein, Kiel, Germany; 4) Epilepsy Research Centre, Department of Medicine, University of Melbourne, Austin Health, Victoria, Australia; 5) University of Southern Denmark, Denmark; 6) Neuroscience Department Royal Children's Hospital and Mater Children's Hospital Brisbane, Australia; 7) 7 Northern Ireland Regional Genetics Service, Belfast City Hospital, Belfast, Northern Ireland, UK; 8) Paediatrics & Child Health, University of Sydney and the Children's Hospital at Westmead, Sydney, Australia; 9) Department of Medicine, Austin Health; Department of Paediatrics, The University of Melbourne; Royal Children's Hospital, Melbourne Australia.

The contribution of mutations in the X-linked protocadherin 19 (PCDH19) gene in epilepsy and intellectual disability was first discovered in six large families in which multiple females over several generations had the disorder Epilepsy limited to Females with Mental Retardation (EFMR) (Dibbens et al 2008). These pedigrees showed an unusual mode of reverse X-linked inheritance where transmitting hemizygous males did not have epilepsy or intellectual disability. Current evidence suggests this is due to the mechanism of cellular interference resulting from a mixture of PCDH19 protein positive and negative cells. PCDH19 encodes a transmembrane protein belonging to the cadherin superfamily and is proposed to function in calcium dependent cell-cell adhesion and /or cell-cell signalling.

The initial gene discovery has been extended to show that de novo PCDH19 mutations cause sporadic cases of EFMR. In this study we set out to further explore the spectrum of clinical phenotypes caused by mutations in PCDH19, to determine if genotype-phenotype correlations can be drawn and to analyse the inheritance of mutations. We report 14 new cases of EFMR due to PCDH19 mutations: 7 familial, 4 de novo and 3 yet to be determined.

To date a total of 66 PCDH19 sequence mutations have been reported in unrelated subjects with seizures with and without intellectual disability: 65 in girls and 1 in a boy mosaic for a PCDH19 deletion. 59 mutations are unique while 3 are recurrent. 60/66 mutations are located in the highly evolutionary conserved extracellular portion of the protein, indicating that amino acid variation in this region is not well tolerated, while 6 mutations are within the cytoplasmic region. 4 PCDH19 gene deletions have been reported, making a total of 70 mutations. 32/70 mutations have been inherited by the proband from a parent, 28/70 are de novo and 10/70 did not have parent material available. We conclude that PCDH19 analysis should be considered in cases of early onset epilepsy in females where mutations can be familial or de novo. Phenotypic analysis of our new PCDH19 mutation positive cases includes later seizure onset than previously reported (6 years) and a catatonic/Parkinsonian-like state.

GENETIC STUDY OF SCN1A-RELATED EPILEPSIES IN SOUTHERN ITALY. *M. Gagliardi[1,2], P. Tarantino[1], E.V. De Marco[1], A. Labate[1,4], G. Tortorella[3], F. Annesi[1], M. Caracciolo[1], F. Cavalcanti[1], A. Quattrone[4,5], A. Gambardella[1,4], G. Annesi[1].* 1) Institute of Neurological Sciences, National Research Council, Mangone (CS), Italy; 2) University of Magna Graecia, Catanzaro (CZ), Italy; 3) Department of Neurosciences, Psychiatry and Anaesthesiology, University of Messina (ME), Italy; 4) Institute of Neurology, University of Magna Graecia, Catanzaro (CZ), Italy; 5) Neuroimaging Research Unit, National Research Council, Catanzaro (CZ), Italy.

Approximately 10% of generalized epilepsy with febrile seizures (GEFS+) families carry mutations in the gene coding for the alpha1 subunit of the neuronal channel (SCN1A). Furthermore, SCN1A mutations occur in more than 70% of patients with severe myoclonic epilepsy of infancy (SMEI) and are usually de novo. Most of the mutations are nonsense or frameshift: missense mutations are also common. Recent studies have already reported that about 12% of mutation-negative SMEI patients have microchromosomal abnormalities involving SCN1A. The aim of this study was to extend the sample number in our population to investigate the frequency of SCN1A mutations in GEFS+ and SMEI patients. Twenty-three GEFS+ probands belonging to unrelated families and 24 SMEI patients were recruited from Southern Italy. Diagnoses were based on the International League against Epilepsy criteria. Mutation analysis was performed by direct sequencing. The genomic anomalies were screened using MLPA and confirmed by real-time PCR. Among the 23 GEFS+ probands (17.4%) had SCN1A variations that we had previously published (Met1841Thr, Tyr779Cys, Ile944Thr); and one novel mutation was found (R604H). Among the 24 SMEI patients, 12 (50%) carried SCN1A mutations. Seven of them were already reported by ourselves. Five novel mutations were found (K1246fsX1268, Phe807Leu, R1636X), p.1502del, Y1492Y) in 5 unrelated SMEI cases. SCN1A is the most clinically relevant epilepsy gene. We found 12 SMEI patients carrying different mutations, thus confirming the high genetic heterogeneity related to these diseases. Moreover in our population we found frequency of GEFS+ mutations that is higher than the one reported by other authors .Our results confirm that SCN1A mutations represent an important cause of GEFS+ and SMEI also in Southern Italy.

Molecular characterization of a new model of generalized epilepsy with absence seizures. *A.H.B. Matos[1], C. Rocha[1], J.F. Vasconcellos[1], V.D.B. Pascoal[1], M.T. Chamma[2], S. Botte[2], C.V. Maurer-Morelli[1], I. Lopes-Cendes[1], A.C. Valle[2].* 1) Department of Medical Genetics, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, BRAZIL; 2) Department of Pathology, School of Medicine, University of São Paulo - USP, São Paulo, SP, BRAZIL.

BACKGROUND: A spontaneous mutant rat was identified presenting generalized epilepsy with absence seizures (GEAS). GEAS rat shows distinct behavioral and electroencephalographic characteristics as compared to previously reported genetic epilepsy rat models. The aim of the present study was to characterize the genetic profile this strain of rat, through gene expression analysis in the hippocampus of these animals. METHODS: We obtained total RNA from the hippocampus (n=3) of GEAS rats and controls Wistar (n=3) with TRIzol (Invitrogen-Life Technologies). Gene expression analysis was performed using the GeneChip® Rat Genome 230 2.0 Array (Affymetrix™), and analyzed using MAS5.0, program R with package Affy and RankProd of Bioconductor for expression measure. The analyses of overrepresented gene ontology categories were performed with DAVID software, and gene interactions and correlation networks were identified with Ingenuity Pathways Analysis software. Statistical analysis was performed by t-test with $p \leq 0.01$ for detecting a significant difference between groups. RESULTS: Forty-five differently expressed genes were identified in GEAS animals compared to controls, among these we found genes related to central nervous system development, activation of MAPK, transcription factors, neuronal migration and apoptosis, such as *Nrsn1, Hspb1, Fos, Twist1* and *Krt18*, respectively. The top enriched gene ontology categories included signal peptide, extracellular region and antigen processing and presentation of peptide antigen. Among the most activated signaling pathways were endocrine system disorders, gastrointestinal disease, cell cycle and neuron system development and function, which include genes such as *Prlr*, *Hspb1*, *Igfpb2*, *CD74* and *Fos*. CONCLUSION: Our results showed a different molecular signature in GEAS rats compared to control animals. The differently expressed genes were related to several essentials cellular functions, in particular, those related to cerebral cortex development, including neuronal migration and apoptosis.

A Bayesian model for splicing QTL mapping with RNA-Seq. *E. Pantaleo[1], M. Stephens[1,2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

An important challenge of the post-genomic era is to make sense of how genome sequences control gene regulation. We developed a Bayesian model that uses RNA-Seq data and SNP data to understand how genetic variation can modify gene expression and splicing pattern.

For a single set of RNA-Seq data (e.g., one individual) the Bayesian model can infer the transcript model, i.e., the set of transcripts that are expressed in the RNA-Seq data (allowing for alternative splicing) and transcript abundances jointly. When applied to a set of RNA-Seq from individuals for which extensive genotype data are available, the Bayesian model can search for splicing QTLs and expression QTLs (where no alternative transcripts are observed) using a transcript model and alternative transcript abundances inferred from the data.

We applied the model to RNA-Seq data of lymphoblastoid cells derived from 69 Nigerian individuals generated as part of the International HapMap project for which we had 1.2 billion reads of either 35 or 46 base pairs. The model has mapped a set of splicing QTLs. An algorithm implementing the method for single-end (short) reads will be made publicly available.

612W

A comprehensive approach to the study of Hearing Loss: identification of new candidate genes and pathways. *G. Girotto[1], M.A Lewis[3], N. Pirastu[1], D. Licastro[2], D. Vozzi[1], K.P Steel[3], P. Gasparini[1].* 1) Med Genet, DMS, UNITS/Burlo, Trieste, IT., Italy; 2) CBM Scrl- Basovizza, Trieste, Italy; 3) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1SA, UK.

Hereditary hearing loss (HHL) is a common disorder accounting for at least 60% of prelingual deafness. Although mutations on GJB2 and GJB6 genes are known to be involved in most of the cases of nonsyndromic HHL (NSHHL) in Caucasian populations, other genes could still be major players in other populations. Moreover, little is known about the molecular bases of normal hearing function and age-related hearing loss (ARHL). Thus, research still needs to identify new genes possibly involved in monogenic forms, study hearing as a complex trait and to understand genetic factors underlying ARHL. To reach this goal we have planned an integrated strategy characterized by: A) a genome-wide association study (GWAS) on hearing quantitative traits. From the meta-analysis of data from 6 isolated populations (more than 3500 samples coming from 2 European countries - G-EAR Consortium) some significant and suggestive loci (p<10-6,10-7) for quantitative traits have been found. Some of them map to known hereditary hearing loss loci whose genes still need to be identified. Data have also been used to construct a highly significant "in silico" pathway for hearing function (Girotto G. et al. JMG 2011). B) a GWAS on qualitative traits focused on ARHL. Preliminary analysis of ARHL in more than 1000 cases (G-EAR Consortium) led to the identification of other suggestive loci/genes including genes known to be involved in auditory development and function but also genes whose function is still unknown. C) a replica phase of the data, which is in progress on additional sample cohorts from Italy, UK and Central Asia. D) Next Generation Sequencing. Whole exome resequencing of selected cases from large pedigrees affected by NSHHL and whole genome sequencing of some ARHL cases belonging to two isolated Italian populations is in progress. In addition, using all the data (from A to D) we were able to define a list of strong candidate genes that have been chosen for in vivo validation. In many cases, little is known about the expression and the possible function of these genes. We are therefore investigating the expression of these candidate genes in the ear by immunocytochemistry using wildtype mice at 5 days old. In conclusion, preliminary results provide new candidate genes for normal hearing function, ARHL and HHL suggesting new targets for hearing impairment treatment and prevention.

Multifactor Dimensionality Reduction 3.0: Open-Source Software for Systems Genetics. *P. Andrews, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Multifactor dimensionality reduction (MDR) was designed as a nonparametric and genetic model-free approach to identifying, characterizing and interpreting gene-gene interactions in genetic and epidemiologic studies of common human diseases. The kernel of the MDR algorithm uses constructive induction to combine two or more polymorphisms into a single predictor that captures interaction effects. This general approach has been validated in numerous simulation studies and has been applied to a wide-range of different human diseases. We describe here version 3.0 of the open-source MDR software package that has been made freely available to the genetic epidemiology and bioinformatics communities since February of 2005. Over this time period MDR has been downloaded more than 30,000 times. This new version of MDR has been significantly updated to allow users carry out a systems genetics analysis by inferring and characterizing large networks of gene-gene interactions. Here, the vertices of the network represent the single-nucleotide polymorphisms in the data while the edges or connections among vertices represent the synergistic gene-gene interactions that exceed some predefined threshold. We report the degree distribution, subgraph motifs, centrality, modularity and other measures of network complexity. We also allow users to filter their list of SNPs according to the structure of the network as a way to refine and focus their MDR analysis. These new features in the MDR software move beyond models of several SNPs to the inference of large interacting networks of SNPs enabling a systems genetics approach to complex diseases association studies.

Accelerated skeletal muscle ageing is a molecular signature in OPMD. *S.Y. Anvar, P.A.C. `t Hoen, S.M. van der Maarel, V. Raz.* Center for Human and Clinical , Leiden University Medical Center, Leiden, Netherlands.

Reduced physical ability and progressive loss of skeletal muscle mass and strength are major contributors to health problems at late age. The molecular pathogenesis of muscle weakness onset and progression is poorly studied. In a longitudinal ageing study of genome-wide expression profiles in quadriceps of control individuals (17-89 years), we revealed that the major transcriptional changes occur around the age of 42. A genome-wide transcriptome comparison between muscle-ageing and muscles of patients with oculopharyngeal muscular dystrophy (OPMD) revealed significant similarities. OPMD is an autosomal dominant and late-onset muscle weakness. It is caused by a poly-alanine expansion in PABPN1 protein, leading to higher aggregation potency. Here, we found substantial similarities between OPMD and ageing on gene and pathway levels. Commonly, major transcriptional changes begin at midlife. This suggests that the onset of OPMD is triggered by ageing-associated factors. In addition, as the progression of transcriptional changes in ageing was found to be accelerated in OPMD, we suggest that progressive muscle weakness is faster in OPMD patients. From the ageing and OPMD deregulated processes, the highest association was found for genes in muscle contraction, mitochondria and ubiquitin-proteasome system. Evidently, genes encoding for aggregation-prone proteins were highly enriched in OPMD and muscle ageing. We suggest that changes in expression levels can portray the onset and progression of muscle weakness.

A Comparison of Cataloged Variation between International Haplotype Map Consortium and 1000 Genomes Project. *C. Buchanan, E. Torstenson, W. Bush, M. Ritchie.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Since the publication of the relatively complete human genome in 2003, geneticists have been increasingly interested in risk variant associations to resolve the etiology of traits and complex diseases. The International Haplotype Map Consortium (HapMap) undertook the task of cataloging all of the common variation across the genome (variants with a frequency of at least 5%). It was the HapMap along with high-throughput genotyping technological advances that led to the era of genome-wide association studies (GWAS). GWAS have been a successful endeavor to identify common variants associated with many traits and diseases. Subsequently, another effort began in 2008 with the 1000 Genomes Project, which aims to sequence 2,500 individuals and identify rare variation across the genome. They intend to identify 99% of variants with a minor allele frequency of at least 1%. One might conclude, given the goals of both consortia that 1000 Genomes Project would include all of the variants originally discovered (or validated) in the HapMap project. Using merged Phase I/II/III HapMap data and low coverage pilot data from 1000 Genomes Project, we compared the overlap between the two resources. In a comparison of the two raw data sets, only approximately 84% of HapMap SNPs were found in 1000 Genomes data. After filtering out HapMap variants for allele frequencies greater that 95% or less than 5%, 99% of HapMap SNPs were found in 1000 Genomes Project data. Therefore, if one is interested in both common and rare variation, it is essential to note that not all of the variants cataloged in the HapMap are also cataloged in the 1000 Genomes Data. This could potentially impact decisions about which resource to use for SNPs queries, rare variant validation, or imputation. Both the HapMap and 1000genomes are useful resources for human genetics; it is important to understand the assumptions made and filtering strategies implemented to deposit into these resources.

Comparison of different methods for detecting gene-gene interactions in case-control data. *T. Cattaert[1], J.A. Rial Garcia[2], E. Gusareva[1], K. Van Steen[1].* 1) Montefiore Inst and GIGA-R, Univ Liège, Liège, Belgium; 2) Universidade da Coruña, Spain.

It is generally believed that epistasis makes an important contribution to the genetic architecture of complex disease, and numerous statistical and bioinformatics methods have been developed to detect it.

We compare several state-of-the-art epistasis detection methods in terms of empirical power, type-I error control, and CPU time. The methods compared include Model-Based Multifactor Dimensionality Reduction (MB-MDR) [1, 2], BOolean Operation-based Screening and Testing (BOOST) [3], EPIBLASTER [4], Random Jungle (RJ) [5], Logistic Regression and PLINK.

Our comparative study is based on an extensive simulation study using different two-locus models, exhibiting both main effects and epistasis [3]. In these simulations, 100 SNPs are generated, no LD between them. All genotypes are assumed to be in Hardy-Weinberg equilibrium. Furthermore, 2 disease-associated SNPs are selected, with MAFs set to 0.1, 0.2 and 0.4. The MAFs of the non-disease associated SNPs are uniformly distributed on [0.05, 0.5]. In order to achieve high accuracy in empirical power estimation, all simulation settings involve 1000 replicates. All methods are applied to WTCCC Rheumatoid Arthritis data.

The OBiBa project: An international collaboration for open source software for biobanks. *V. Ferretti[1], P. Laflamme[1], P. White[2], P. Burton[4], I. Fortier[3].* 1) Ontario Institute for Cancer Research; 2) University of Western Australia; 3) Research Institute of the McGill University Health Center; 4) University of Leicester.

OBiBa is an international collaborative initiative whose mission is to develop high quality open source software for large-scale population-based biobanks and clinical studies. It is comprised of independent and self-funded teams in Canada and Australia, each of which is producing stand-alone applications that support particular biobank activities. In this presentation, we will describe briefly the OBiBa software modules:

- ETA: a participant management and recruitment application used to track communication with participants, store and manage consent as well as contact information.
- DataSHIELD: An innovative statistical analysis tools enabling pooled data analysis without sharing any individual-level data among studies.
- GenoByte: a high-performance database engine for storing and querying genomic variations and data produced by high-throughput sequencing and genotyping technologies.
- Mica: a web-based application for creating web portals used by epidemiology study consortia to disseminate various information, such as studies design, data dictionaries, and data content.
- Onyx: A comprehensive software suite used for managing participant baseline interviews and collecting data in clinics. Onyx combines web-based data collection modules for questionnaire administration, consent electronic signature and physical measurements.
- Opal: A web-based data integration platform used to manage, store, query and transform phenotypic data from multiple heterogeneous sources. Opal architecture and tools are designed to ensure and enforce participant privacy and confidentiality.

OBiBa is a core project of the Population Project in Genomics Consortium (P3G), a consortium including some of the world's largest population-based biobanks. OBiBa modules are developed in collaboration with many partners including the Dunes Environment which aims to offer methods and IT solutions to support data harmonization and synthesis.

Current main OBiBa software users include the Canadian Partnership for Tomorrow (300,000 participants), the Canadian Longitudinal Study for Aging (50,000 participants), the Leicester Cardiovascular Biomedical Research Unit (UK), the Ontario Institute for Cancer Research and the McGill University and Genome Quebec Innovation Center. OBiBa is also partner of the recently granted EU FP7 BioSHaReEU project. OBiBa software are freely available at www.obiba.org.

GAMETES: A Fast, Direct Algorithm for Generating Pure, Strict, Epistatic Models with Random Architectures. *J. Fisher, R. Urbanowicz, J. Kiralis, N. Sinnott-Armstrong, T. Heberling, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Statistical epistasis can be defined as deviation from additivity in a linear mathematical model summarizing the relationship between multi-locus genotypes and phenotypic variation in a population. The detection and modeling of statistical epistasis is a bioinformatics challenge. Thorough evaluation of newly developed epistasis analysis algorithms calls for simulation studies in which a priori disease models are used to provide test data where the true underlying genetic architecture is known. However, few user-friendly software packages are available for developing epistasis models and simulating data. Here, we introduce Genetic Architecture Model Emulator for Testing and Evaluating Software (GAMETES), an algorithm and software package for the generation of complex single nucleotide polymorphism (SNP) disease models. GAMETES has the flexibility to efficiently generate n-locus strict and pure epistatic models of “random” architecture. N-locus models are purely and strictly epistatic if all n loci, but no fewer, are predictive of disease status. All models are generated to fit specified model constraints including heritability, SNP minor allele frequencies, and population prevalence. For every valid combination of these model constraints, a population of model architectures can be generated rapidly. We use the term architecture to reference the unique composition of a model (i.e. the penetrance values and arrangement of those values within a penetrance function). We tested GAMETES by simulating pure, strict, epistatic models with respective datasets, having 2-6 loci, and variable heritabilities, minor allele frequencies, and sample sizes. We evaluate GAMETES by searching for these simulated models using multifactor dimensionality reduction (MDR), an established machine learning methods for detecting epistasis. Our results indicate that GAMETES is a fast, reliable, and flexible method for generating complex genetic models of “random” architecture. Beyond data simulation, this strategy also offers a framework for the theoretical investigation of genetic models. The GAMETES software is open source, and implemented in a user-friendly manner.

A SYSTEMATIC COMPARISON OF GWAS PATHWAY ANALYSIS METHODS. *H. Gui, M. Li, P. Sham, S. Cherny.* The University of Hong Kong, Hong Kong, Hong Kong.

Though rooted in genomic expression studies, pathway analysis for genome-wide association studies (GWAS) has gained increasing popularity, since it provides a way of discovering hidden disease causal mechanisms by combining statistical methods with biological knowledge. Algorithms or programs currently available can be categorized by different types of input data, null hypothesis or number of analysis stages. Due to complexity caused by SNP, gene and pathway relationships, re-sampling strategies like permutation are always utilized to derive empirical distributions for test statistics, and then evaluate the significance of candidate pathways. However, thorough performance evaluation of these algorithms on real GWAS datasets and real biological pathway databases needs to be done before these methods should become common practice in GWAS. Seven algorithms were selected to conduct pathway analysis on SNP genotypes together with simulated and real phenotypes from the WTCCC Crohn's disease study. All 7 methods control type I error rate (at 0.05) well, and are mostly slightly conservative. However, the methods varied greatly in terms of power and running time. In real data analysis, raw data-based algorithms turn out to be best, provided sufficient computation capacity is available. Given the variability in performance, in general, particularly when underlying disease causal mechanism is ambiguous, it is worthwhile to apply two or more pathway analysis algorithms on the same GWAS dataset.

Integration and Visualization of Genetic and Genomic Data Using a 3-D Video Game Engine. *D. Hill, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

This is an exciting time in biomedical research due to the availability of technology that allows us to measure tremendous amounts of information about genes, proteins and other biomolecules that play an important role in the molecular pathology of disease. However, it is also a challenging time due to the bioinformatics needs associated with storing, managing, analyzing and interpreting `omics' data. While we have made great progress in developing the databases and data analysis tools for measuring statistical relationships in high-dimensional datasets, the bioinformatics methods for knowledge discovery in the large volumes of statistical results generated from `omics' analyses are in their infancy. To address this interpretation challenge, we have developed an innovative three-dimensional (3-D) visualization approach to the exploration of statistical analysis results from genome-wide association studies (GWAS) that capitalizes on the power of human visual perception and our evolved ability to recognize complex patterns. The overall goal of this study is to replace the traditional approach of sifting through thousands of rows of p-values in an Excel spreadsheet with an innovative and unconventional visual approach that presents the results in an interactive 3-D graphical format that makes important local and global patterns much easier to identify by the user. To implement this we have harnessed the power of cutting-edge computer graphics technology in the form of fast Graphical Processing Unit (GPU) video card hardware and sophisticated 3-D video game engine software (Unity3D) that is designed for real time rendering of 3-D visual environments and animation. Here, we introduce a 3-D heatmap software package that is able to visualize more than five dimensions of genetic and genomic research results thus permitting the integration of SNPs, gene expression and clinical data, for example. Our 3-D heatmap software is open-source and freely available.

Systems Genetics Analysis of Bladder Cancer Susceptibility using Statistical Epistasis Networks. *T. Hu, N. Sinnott-Armstrong, J. Kiralis, A. Andrew, M. Karagas, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Epistasis is ubiquitous in the genetic architecture of complex traits such as disease susceptibility. Experimental studies in model organisms have revealed extensive evidence of biological interactions among genes, and statistical and computational studies in human populations have revealed evidence for nonadditive effects of genetic variation on complex traits. The goal of this study was to use network science to determine the extent to which nonadditive interactions exist beyond small subsets of genetic variants. We inferred statistical epistasis networks to characterize the space of pairwise interactions among approximately 1500 single nucleotide polymorphisms (SNPs) spanning nearly 500 cancer susceptibility genes in a large population-based study of bladder cancer. Networks were built by incrementally adding edges between SNPs if the strength of their pairwise interactions was greater than a given threshold. By changing the value of the threshold, we obtained a series of such networks. We then statistically compared them to series of networks derived from permuted data to determine whether the topological properties were consistent with those expected under the null hypothesis of no association between genotype and phenotype. We observed that once a specific value of the threshold was reached, the real-data network clearly differentiated itself both from the other real-data networks and from the permuted-data networks. In particular, at that point, it comprised a significantly higher number of hub SNPs and a large sizeable connected component became detectable. We determined that the vertex degree distribution of this largest network was distinctively different from all others and its topology was approximately scale-free. In contrast to many existing techniques proposing a classification model of a subset of susceptibility SNPs, this network approach characterizes a global picture of genetic interactions in a populated-based genetic data.

Optimized Rsq thresholds for quality control of MACH/minimac imputed genotypes. *T.A. Johnson[1], H. Fujita[2], K. Hara[2], T. Tsunoda[1].* 1) Laboratory for Medical Informatics, Center for Genomic Medicine, RIKEN Yokohama Institute, Yohohama, Kanagawa, JAPAN; 2) Department of Diabetes and Metabolic Diseases, Graduate School of Medicine, University of Tokyo, Bunkyo-ku, Tokyo, JAPAN.

Quality control of imputed genotypes for genome-wide association analysis is even more essential than for real genotype data. To evaluate the efficiency of suggested Rsq QC cutoffs for the MACH/minimac imputation program, we compared Rsq with genotype concordance for a subset of samples that had additional real genotype data. We selected 423658 autosomal SNPs for 7541 Japanese samples with Illumina 550k or 610k data, estimated haplotype phase using MACH, and imputed genotypes using minimac with 1000 Genomes ASN reference haplotypes (_$8.7x10^6$ loci after filters). Illumina 610k data for 4470 samples overlapped 52335 imputed non-550k loci, for which overall percent concordance between real/imputed genotypes was quite good (94.2±12.5%; mean±SD), although a sizable fraction of imputed loci were of lower quality (<90% concord.=14.7%, <80% concord.=9%). Concordance decreased with respect to the number of major alleles in a genotype class (major homozygotes:93.9±20.2%, heterozygotes: 90.9±22.9%, minor homozygotes: 81.0±33.6%). Since low MAF loci could exhibit high total concordance despite less accurate imputation of heterozygote and minor homozygote genotypes, we calculated concordance for GWAS purposes as the worst performing genotype class for a particular locus. For each locus, we extracted minimum concordance values across the three genotype classes ($min_{gt.concord}$) and plotted them against minimac's Rsq values for five MAF bins (MAF bin ranges: 0.0-0.1, 0.1-0.2, 0.2-0.3, 0.3-0.4, 0.4-05), which indicated that Rsq filtering efficiency varied with MAF. We then categorized loci as well-imputed ($min_{gt.concord}$ ⁄ 80%, n=40217) or poorly-imputed ($min_{gt.concord}$ <50%, n=8310). We observed using the lower suggested Rsq cutoff of 0.3 that almost 100.0% of well-imputed genotypes were included ($Prop_{w.i.inc}$) and 71.2% of poorly-imputed genotypes excluded ($Prop_{p.i.exc}$), while the higher Rsq cutoff of 0.5 had $Prop_{w.i.inc}$ and $Prop_{p.i.exc}$ of 99.8% and 87.1%, respectively. While $Prop_{w.i.inc}$ was satisfactory, the high proportion of poorly-imputed loci not excluded could lead to increased false-positive associations during analyses. We therefore attempted to determine an optimized Rsq cutoff for each MAF bin by finding Rsq that maximized the product $Prop_{w.i.inc}$* $Prop_{p.i.exc}$. The optimized Rsq thresholds of 0.75, 0.70, 0.66, 0.60, and 0.55 for the five MAF bins from 0 to 1.0 allowed retention of 98.1% of well-imputed loci while removing 96.4% of those that were poorly-imputed.

Gene Ontology Analysis of Genome-Wide Epistatic Interactions Supports a Role for Actin Cytoskeletal Genes in Sporadic ALS. *N. Kim[1], J. Fisher[1], P. Andrews[1], C. Read[2], K. Askland[2], B. Harris[3], J.H. Moore[1].* 1) Dartmouth Medical School, Lebanon, NH, USA; 2) Brown University, Providence, RI, USA; 3) Georgetown University, Washington D.C., USA.

Sporadic amyotrophic lateral sclerosis (ALS) has a complex and unknown multifactorial etiology that is likely influenced by multiple gene-gene and gene-environment interactions. We conducted a genome-wide interaction analysis in two publically available data sets each with approximately 500,000 single-nucleotide polymorphisms from the Illumina HumanHap 550k chip. The detection set consisted of 276 cases and 271 controls from the USA (Schymick et al. 2007) while the replication set consisted of 221 cases and 211 controls from Ireland (Cronin et al. 2008). Genome-wide interaction analysis was previously carried out using the multifactor dimensionality reduction (MDR) method implemented on graphical processing units for high-performance computing (Greene et al. 2010). All pairwise interactions were analyzed and assessed for statistical significance using a 1000-fold permutation test that corrects for multiple testing. In the present study, we carried out a Gene Ontology (GO) analysis of the interaction results in the following manner. First, we assigned each SNP an accuracy value corresponding to the model with the strongest interaction involving that SNP among all pairs. Second, we assigned each SNP a p-value from the permutation test. Third, we assigned each gene a p-value based on whether there was an overabundance of SNPs with p-values less than or equal to 0.05. For this analysis we used the Exploratory Visual Analysis (EVA) software that performs a spatial permutation test that corrects for gene size. Fourth, we assigned each GO category a p-value using EVA based on the overabundance of genes with p-values less than or equal to 0.05. This was repeated in both data sets and any GO category that was significant at the 0.05 level in both studies was considered statistically significant with replication. This analysis identified the actin cytoskeleton cellular component as the only GO category that met the replication criteria. These genetic association results are consistent with previous biochemical and cellular studies documenting cytoskeletal changes in ALS motor neurons that require structural integrity for proper function. This study highlights the power of combining epistasis analysis using MDR with GO analysis of biological annotation.

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Genotyping Informatics and Quality Control for 100,000 Subjects Genotyped on the Affymetrix Axiom System. *M.N. Kvale[1], S. Hesselson[1], T. Hoffmann[1], J. Gollub[3], T. Webster[3], Y. Zhan[3], Y. Lu[3], G. Mei[3], L. Walter[2], D. Ludwig[2], B. Dispensa[1], C. Schaefer[2], P.Y. Kwok[1], N. Risch[1].* 1) Human Gen, Univ California, San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Affymetrix Inc., Santa Clara, CA.

A goal of Kaiser Permanente/UCSF Research Study on Adult Health and Aging is to assay genotypes on 675,000+ SNPs for each of 100,000 subjects in a highly accurate and consistent fashion. The unprecedented number of subjects and the 14-month duration created unique opportunities and challenges for ensuring the highest possible quality of genotype calling across the entire dataset. One such challenge was the design and use of four different arrays, based on European, Asian, African and Latino ancestry, respectively, with the latter two using different chemistries than the first two. The improved chemistry also allowed for the tiling of up to 50% of SNPs with single (versus double) probe set representation for the latter two arrays (and hence more SNPs overall), but presented additional issues regarding genotype calling. For all arrays, we created algorithms for assaying genotype reproducibility, measuring and classifying genotype call quality, and for change-point detection of non-stationarities in the stream of data as the experiment progressed. We created methods for increasing sample call rate, optimizing genotype reproducibility across samples and reducing biases wrought by changing experimental conditions over the course of the experiment. In particular, we generated call rate statistics across all probes on each of the four arrays and demonstrated that the dQC composite metric can be used to predict sample call rates and diagnose performance problems. The use of a Fisher Linear Discriminant metric proved useful in comparing the performance of SNPs. By design, we included a single duplicate sample on each plate to measure sample reproducibility and to detect changes due to assay chemistry and performance. Axiom genotype calling is based on the BRLMM Bayesian clustering algorithm. For some arrays, we found sensitivity to characteristics of cluster location priors, and as a result devised methods to create good Bayesian priors to enhance genotyping performance and reproducibility. We also created a support vector machine classification algorithm for classifying SNP call quality and for detecting poorly performing SNPs that could be rescued through the use of alternative BRLMM algorithm parameters. Across all probes placed on the arrays and over 100,000 saliva-derived DNA samples, we achieved a SNP probe success rate (SNP call rate > 97%) ranging from 94.4% to 96.8% for the four different arrays.

A Genome wide association identifies six loci associated with Chiari-like malformation in the Griffon Bruxellois breed. *P. Lemay[1], Q-H. Trinh[1], P. Knowler[2], M-P. Dubé[3], S. Blott[4], G.A. Rouleau[5], C. Rusbridge[2], Z. Kibar[1].* 1) Obstétrique et gynécologique, CHU Ste-Justine, Montreal, Quebec, Canada; 2) Stone Lion Veterinary Hospital, Wimbledon Village, United-Kingdom; 3) Institut de cardiologie de Montréal, Université de Montréal, Canada; 4) Centre for Preventive Medicine, Department of genetics, Animal Health Trust, United-Kingdom; 5) Centre de recherche du CHUM, Université de Montréal, Canada.

Chiari malformation type 1 (CMI) is a very common congenital abnormality of the craniovertebral junction affecting 1 in 1280 humans. It is characterized by a descent of the cerebellar tonsils through the foramen magnum and is frequently associated with syringomyelia. The etiology of CMI is thought to be multifactorial involving genetic factors. Human CMI is very similar to the canine condition referred to Chiari-like Malformation (CM) characterized by disproportionally small volume caudal cranial fossa and large brain. CM occurs in a variety of Toy breed dogs in particular the Griffon Bruxellois (GB). The strong genetic homogeneity of the canine population made this animal model a powerful tool for genetic mapping of complex human diseases. The high incidence of CM in the GB as well as the increased genetic homogeneity in the dog population will help us achieve our main objective of identifying genes predisposing to CM in the GB.

A GWAS was conducted using 56 GB dogs and the Canine SNP20 BeadChip array developed by Illumina. CM affectedness was determined by magnetic resonance imaging. Basic case-control association analysis of the genotyping data with PLINK v1.07 generated highly significant association scores over the Bonferroni threshold at six different genomic loci on chromosomes 2, 8, 12, 16, 38. P values for CM association at these regions ranged between 1.439×10^{-6} and 1.63×10^{-10}. After adjustment for population stratification with EIGENSOFT v.3.0, one SNP rs22804546 on chromosome 2 remained strongly associated to CM with an adjusted empirical P value of 1.9×10^{-5}.

Fine mapping of the candidate locus is currently underway. Once this locus is reduced to the minimum possible, a positional candidate gene approach will be used to identify the mutation associated with CM in the GB breed. To this day, no genes have been associated to the human and canine versions of CM. This study will give insight in the pathophysiological mechanisms of this disease, which could lead to the development of better diagnostics and prognostic tests.

MaCH-Admix: Genotype Imputation for Admixed Populations. *Y. Li[1], Y. Liu[2], M. Li[3], W. Wang[2].* 1) Dept Genetics, Univ North Carolina, Chapel Hill, NC; 2) Dept Computer Science, Univ North Carolina, Chapel Hill, NC; 3) Dept Biostatistics and Epidemiology, Univ Pennsylvania School of Medicine, Philadelphia, PA 19104.

Genotype imputation has become a standard practice and a powerful tool for genome-wide association studies (GWAS) and meta-analysis, particularly when studying individuals of European or East Asian ancestry due to their higher level of LD and the existence of closely matched reference populations. However, little methodological work exists for genotype imputation in admixed populations, which comprise >20% of the U.S. population. Here, we extend our previously described MaCH hidden Markov model to incorporate two classes of approaches for imputation in admixed populations: (1) ancestry-weighted approach, where haplotypes from different reference populations are weighted according to inferred ancestry of the to-be-imputed individuals; and (2) Identity by State (IBS) based methods where a different set of reference haplotypes is selected for each to-be-imputed individual based on genetic similarity. Using HapMapIII African Americans (ASW) and Hispanics (MEX), we compared with other approaches including a baseline where all reference haplotypes are selected, random selection of reference haplotypes (from only the reference or from the reference plus constructed haplotypes of to-be-imputed individuals), and IMPUTE which uses one special case of IBS-based approaches. Based on our results, we recommend simple ancestry-weighted approach when 20-50% of the entire reference pool is selected at each Markov iteration and IBS-based approaches when a small proportion (<20%) of the reference pool is utilized at each iteration. Our IBS-based approaches resulted in 1.13% and 1.96% increased dosage r2 than the IBS-based approach implemented in IMPUTE, for ASW and MEX respectively. Our new methods, together with the functionality to infer ancestry, are implemented in MaCH-Admix, freely available at http://www.sph.umich.edu/csg/yli/MaCH-Admix/.

A Graphical Representation of Quality Control Metrics for Next Generation Sequencing. *S. McGee, J. Smith, J. Furlong, I. Stanaway, I. Robertson, M.J. Rieder, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

With the wide acceptance of second-generation, massively parallel DNA sequencing methods and increases in sample throughput, it is necessary to automate the accurate and efficient determination of data quality at numerous points along the data processing pipeline to locate possible errors. These QC data need to be presented in a concise, informative, and data rich format to facilitate rapid decision-making about whether to proceed, remove, or hold a sample. To facilitate this process we have developed a "QC Dashboard" that presents an overview of quality metrics and is currently in use for exome sequencing at the Northwest Genome Center (NWGC). The QC Dashboard is a graphical and textual display of statistical information parsed from the flatfiles of sequence assembler routines (multiple assembler formats are accepted). Plots include overall number of reads, reads mapped to target and number of unique reads; allele distributions at each cycle in the analysis; plots for sample complexity and read depth coverage and uniformity. Per cycle error rates and read qualities are also plotted and summarized. In addition, a predictor is displayed detailing the number of lanes required until the depth-of-coverage goal (i.e., 90% of the sequence target with greater than 8x coverage). Each dashboard is adaptable to individual- or merged-lane data and is generated automatically to be displayed for human review.

Combining gene flow with exome sequencing in large family studies of complex disease. *J.A. Morris, J.C. Barrett.* Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom.

In contrast to Mendelian diseases, linkage studies of large families with multiple affected individuals of complex diseases such as autism and diabetes have identified very few linked loci replicated across multiple families. Genome-wide association studies have subsequently identified dozens of common alleles of modest affect associated with such diseases, but these results do not explain either the extreme disease load, or the within-family linkage peaks of some large pedigrees. Next generation sequencing has enabled the molecular diagnosis of previously intractable Mendelian diseases and will soon be applied on a population scale to the study of complex disease. One intermediate study design between these two extremes is to sequence the exomes or genomes of individuals from large complex disease pedigrees in order to identify family-specific high-penetrance mutations. For example, the UK10K project is sequencing individuals from a number of large Finnish pedigrees with >4 cases of autism spectrum disorder. To enable this and similar studies, we have developed a tool which integrates gene flow within a family (single family linkage) and next generation sequencing data. Users can interactively filter and prioritize variants based on haplotype sharing across different sets of selected individuals, allele frequency in reference datasets, and functional annotation. The application requires a compressed and indexed VCF file containing sequence data (exome or whole genome) from one or more family members and genotypes across all family members used by the MERLIN software package to reconstruct haplotype flow within the family. Users can then interactively filter variants based on sharing among different individuals, or parametrically specify penetrance and phenocopy rates. The variants that remain after the haplotype based filtering are displayed in an interactive, annotated table view. Using this view the user can further sort and filter the variants using any metadata in the original VCF file or direct online connection to public databases, such as ENSEMBL. Once the user is happy with their list of variants it can be output in text format using a fully customizable export tool. Our application effectively harnesses the power provided by sequencing related individuals in multiply affected families for identifying disease-causing variants.

Dyadic and Heterophilic Properties of SNPs with Marginal Effects Across Statistical Epistasis Networks. *D. Ng, T. Hu, A. Andrew, M. Karagas, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Susceptibility to common human diseases is determined partly by the complex interplay between multiple genetic and environmental factors. A central goal of computational genetics is to develop and apply analytical methods that are able to embrace, rather than ignore, the complexity of the genotype-phenotype relationship. The goal of this study was to use network science to determine the extent to which nonadditive interactions exist beyond small subsets of genetic variants. We previously inferred statistical epistasis networks to characterize the space of pairwise interactions among approximately 1500 single nucleotide polymorphisms (SNPs) spanning nearly 500 cancer susceptibility genes in a large population-based study of bladder cancer. Here, vertices are SNPs and edges or connections represent epistatic relationships. We discovered that statistical epistasis networks associated with bladder cancer are much larger than expected under the null hypothesis of no association. The goal of the present study was characterize the distribution of SNPs with marginal effects across these epistasis networks. First, we measured the dyadic properties of SNP-SNP pairs with states (1-1), (1-0) and (0-0) for SNPs with significant marginal effects (1) and those without (0). A network is considered dyadic if SNPs with marginal effects tend to interact with themselves and heterophilic if not. We found significant evidence for networks with heterophilic properties suggesting that SNPs with significant marginal effects are more to interact with SNPs that do not exhibit marginal effects than with each other. We then repeated the analysis labeling SNPs as included (1) or excluded (0) from different Gene Ontology (GO) categories and repeated the vertex distribution analysis. We found a diversity of dyadic and heterophilic properties across different GO categories. This study brings us a step closer to a systems genetics approach to complex disease that embraces the complexity of the genotype-phenotype mapping relationship by explicitly modeling the connections and properties among many SNPs.

Phenotype-Genotype Integrator (PheGenI): Synthesizing Genome-Wide Association Study Data with Existing Genomic Resources. *E.M. Ramos[1], D.J. Hoffman[2], H.A. Junkins[1], D.R. Maglott[2], J. Paschall[2], L. Phan[2], S.T. Sherry[2], M. Feolo[2], L.A. Hindorff[1].* 1) Office of Population Genomics, National Human Genome Research Institute, NIH, Bethesda, MD; 2) National Center for Biotechnology Information, National Library of Medicine, NIH, Bethesda, MD.

Objective: Rapidly accumulating data from genome-wide association studies (GWAS) and other large-scale studies will be most useful when synthesized with existing databases. To address this, we developed the Phenotype-Genotype Integrator (PheGenI), a user-friendly web interface that integrates various National Center for Biotechnology Information (NCBI) genomic databases with association data from the NHGRI GWAS Catalog and supports downloads of search results. **Background:** The GWAS design has identified over 4,400 genetic variants associated with over 200 human traits and diseases. Rarely are the functional consequences of these variants understood, and replication, functional and follow up studies are crucial next steps. Integration of GWAS data with existing complementary databases can facilitate prioritization of variants to follow up, study design considerations, and generation of biological hypotheses. **Methods:** A number of existing genomic resources are housed at the NCBI, including dbSNP, Gene, and the Genotype-Tissue Expression (GTEx) program. GWAS association data are available through two other NIH resources, the Database of Genotypes and Phenotypes (dbGaP) and the NHGRI GWAS catalog. The availability of these centralized resources made possible the development of PheGenI (http://www.ncbi.nlm.nih.gov/gap/PheGenI), an online portal for scientists and clinicians who use or produce GWAS data, to browse, search, integrate and download results. **Results:** 7,614 association records have been integrated with approximately 38,000 records from dbSNP, 46,000 records from Gene, and 61,000 expression QTL records from GTEx. After weighting for associations that belong to multiple trait categories, 78% of these association records are distributed among a few categories: Chemicals and Drugs, Digestive System Diseases, Eye Diseases, Immune System Diseases, Mental Disorders, Neoplasms, Nervous System Diseases, Skin and Connective Tissue Diseases, and Other. PheGenI features include the ability to search by phenotype, gene, SNP, or chromosomal range. In addition, users can filter search results by association p-value or SNP functional class; display results locally on DNA sequence tracks or globally across the genome; and download data tables. **Conclusions:** PheGenI will facilitate follow up of results from GWAS, enabling scientists to investigate functionality of identified SNPs and interrogate relationships between SNPs and human disease.

A software package for examining bisulfite conversion rates in methylation sequencing data. *S. Sun[1,2], X. Yu[2].* 1) Case Comprehensive Cancer Center, Case Western Reserve Univ, Cleveland, OH; 2) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH.

DNA methylation is adding a methyl-group to the 5's cytosine. It is a very important epigenetic phenomena that can affect gene expression significantly in both normal and disease cells. Therefore, it is very important to study methylation patterns in the whole genome. With the aid of the next generation sequencing technology and the bisulfite conversion technique, it is now possible to identify methylation signals at single CG site level in a genome. However, sometimes bisulfite conversions may not be complete, and this will dramatically affect the methylation signal at cytosine sites. Therefore, it is crucial to examine the bisulfite conversion rate before any down-stream analysis. In order to meet this need, we have developed a software package that takes the ACGT-count output from BRAT (Bisulfite-treated Reads Analysis Tool) alignment (Harris et al. 2009) to access bisulfite conversion rates. Our software package has the following feature: generating summary statistics and figures for the structures of genome sequences and bisulfite conversion rates of either partial or all nonCGc sites (i.e., cytosine sites that are not followed by guanines) from (1) any specific region in the whole genome with a chromosome name, start and end positions; (2) a list of target regions with different chromosome names, start and end positions; and (3) a specific chromosome. Our software package is suitable for sequencing data from human adult samples and can help the user quickly diagnose whether a methylation sequencing data set has successful bisulfite treatments.

632W

A simulation-based comparison of statistical tests for incorporating biological information into analyses of genome-wide data. *J.L. Taylor[1], F.S. Goes[2], J.T. Leek[3], M. Pirooznia[2], F. Seifuddin[2], P.P. Zandi[4].* 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Biostatistics, Johns Hopkins University School of Public Health, Baltimore, MD; 4) Department of Mental Health, Johns Hopkins University School of Public Health, Baltimore, MD.

In genome-wide association and expression studies, it is often a goal to identify biologically-defined groups of genes which collectively are more associated with a phenotype of interest than other genes. One approach, referred to here as the “over representation approach”, asks whether there are more in-group genes that meet an arbitrary threshold for significance than expected by chance. Another approach uses information from all genes in the genome-wide experiment, rather than just those that meet some threshold, and asks whether in-group genes are enriched among the most significant. A popular example of the latter approach is gene-set enrichment analysis (GSEA). GSEA typically uses the Kolmogorov-Smirinov (KS) statistic or a weighted version of it (wKS) in order to test for enrichment. However, it has been proposed that a simple t-test between in-group and out-of-group genes may alternatively be used to test for enrichment. We propose another test which borrows from the “over-representation” approach but does not rely on arbitrary thresholds. In this test, referred to here as the “modified over-representation” (MOR) test, the minimum p-value for a binomial test of over-representation at every possible threshold is taken as the test statistic and permutation is used to determine its significance. We use simulations to compare the power of the KS statistic, the wKS statistic, the t-test and the MOR test for detecting enrichment of a group of genes under different scenarios. Simulations under the null hypothesis show that all tests provide appropriate control of Type I errors. When there is true enrichment, the t-test has equal or better power than the wKS test under all conditions examined. When there are no true associations among out-of-group genes, these two tests outperform the KS test. However, when there are also true associations among out-of-group genes , the KS test outperforms the t-test and wKS test. Under all conditions examined, the novel MOR test performs as well or close to the best performing test. This simulation suggests a simple t test is more powerful for detecting enrichment than the most popular method for GSEA currently in use. However, it does not perform as well when there is genetic heterogeneity and genes outside the group of interest are also associated with the phenotype. The novel MOR test does as well as the best performing test under all conditions examined, whether there is genetic heterogeneity or not.

Quantifying Genome-Wide Pleiotropy. *A. Tyler, J. Payne, A. Erives, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Pleiotropy is a widely documented phenomenon in which a single gene has the potential to affect more than one phenotype, and is identified as a single mutation that alters these phenotypes relative to a wildtype baseline. Despite there being many known examples of pleiotropy, it remains poorly understood as a genetic principle. In recent years advances in high-throughput technologies have allowed researchers to begin to quantify instances of pleiotropy at the genome-wide scale in organisms such as Baker's yeast (Saccharomyces cerevisiae) and nematodes (Caenorhabditis elegans). The vast majority of these large scale efforts to quantify pleiotropy have used one of two methods: gene deletion or quantitative trait locus (QTL) analysis. These two methods rely on different types of mutation to identify pleiotropic genes, and may therefore identify different genes as pleiotropic. Here we use computational models of gene regulatory networks to simulate both gene deletion studies and QTL analyses. We find that in simulated gene deletion studies there is a positive correlation between gene degree and pleiotropic impact; deletion of highly connected genes (hubs) results in the largest change in phenotype. In QTL analyses, on the other hand, we find that hubs are minimally pleiotropic. We show that this difference is due to the nature of the mutations used in each type of analysis. Using data from a gene deletion study and a QTL analysis in S. cerevisiae, we show that these correlations between gene degree and pleiotropic impact arise in biological systems as well. We further show that these two types of analysis identify functionally distinct sets of genes as pleiotropic. We discuss the implications of these results in light of interpreting future analyses of genome-wide pleiotropy.

Genetic Heterogeneity Detection Using a Learning Classifier System. *R. Urbanowicz, A. Granizo-Mackenzie, J.H. Moore.* Dartmouth Medical School, Lebanon, NH, USA.

Machine learning algorithms within complex problem domains have been described as ``black boxes'' when it comes to data mining and interpretation. Learning classifier system (LCS) algorithms are characteristic of this description, evolving an entire population of rules or “classifiers” which collectively comprise the evolved solution. While flexible, adaptive, and adept at classification, LCSs are notoriously problematic when knowledge extraction is the goal. In the present study we combine a number of processing heuristics with a re-tasked visualization strategy to form an interpretation pipeline seeking to detect heterogeneity within single nucleotide polymorphism (SNP) association studies. Processing includes the following steps; (1) rule compaction, to remove useless rules, and condense the population to a much smaller set of non-redundant, maximally general classifiers, (2) binary re-encoding of all classifiers, to simply discriminate whether a given SNP within a classifier was specified in a rule or not, and (3) hierarchical clustering across all remaining classifiers as well as across all SNPs. Previous work had introduced a 3-D heat map for bioinformatics visualization. We apply this software to examine the processed population of LCS classifiers. The dimensional flexibility of the 3-D heat map software allows users to simultaneously visualize all classifiers, the SNPs they specify, and their numerosity and fitness. We also incorporate a weighting scheme to draw attention to SNPs which are most frequently specified within the classifier population. When an LCS is correctly learning underlying associations within the training data, it is expected that the SNPs predictive of disease classification will be more frequently specified in rules while those SNPs that are just noise, will tend to be assigned a “don't care” symbol. We demonstrate the usefulness of this methodology on datasets which simulate a complex and heterogeneous association. All datasets have two independent 2-locus epistatic interactions, representing genetic heterogeneity. We found that the implementation of this approach facilitates the identification of predictive SNPs as well the heterogeneous relationship between independent pairs of SNPs and disease status. This strategy offers an intuitive pathway to guide the identification of potential heterogeneous subgroups within a case/control disease study.

TRANS-EQTL MAPPING USING 55,000 SAMPLES ALLOWS FOR DISSECTING DISEASE MECHANISMS. *H. Westra[1], J. Karjalainen[1], G.J. te Meerman[1], R.C. Jansen[2], R.S.N. Fehrmann[1], C. Wijmenga[1], L. Franke[1,3].* 1) Department of Genetics, University Medical Center Groningen, University of Groningen, 9700RB, Groningen, The Netherlands; 2) Groningen Bioinformatics Center, Groningen Biomolecular Sciences and Biotechnology Institute, University of Groningen, 9700AB, Groningen, The Netherlands; 3) Blizard Institute of Cell and Molecular Science, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London E1 2AT, UK.

In recent years, multiple genome-wide association studies (GWAS) have been performed in order to elucidate the genetic basis of complex diseases, such as Type 1 diabetes (T1D). While successful in identifying associated loci for a multitude of diseases, the challenge is now to understand the downstream effects of these associated variants. One strategy to gain such insight is by investigating whether these variants affect gene expression (i.e. expression quantitative trait locus (eQTL) mapping). A few recent eQTL studies for these traits have identified *trans*-eQTL genes that are both biologically plausible and which often contain additional SNPs that also confer susceptibility to the trait. While these results are encouraging, these studies are currently still faced with two main problems: sample sizes are often too small to detect many small-effect size *trans*-eQTLs and usually eQTL data is available for only one single tissue. As such it is impossible to make inferences on the effects of the variant in multiple tissues. To resolve both of these problems, we generated a dataset of 55,000 human Affymetrix gene expression array samples from the Gene Expression Omnibus. These samples reflect many different tissues and cell-types, such as the HapMap phase II samples, although genotype data is lacking for most of these samples. By employing principal component analysis we identified ~400 principal components (PC) that generally reflect differences between cell-types, physiological and metabolic state. We argued that the accuracy for observing the effect of genetic variation on gene expression should increase by removing the PCs from the data. As expected, we observed a considerable increase in the number of detectable eQTLs after removal of PCs from 246 HapMap samples, for which genotype data was also available. Owing to their large effect size, some of these eQTLs allowed us to use residual gene expression as perfect proxies for SNP genotypes. This allowed us to predict SNP genotypes for each of the 55,000 samples, and subsequently permitted us to perform *cis*- and *trans*-eQTL mapping. We present results using all samples, and show how these results compare to cell-type and tissue-specific eQTL analyses. Particular attention will be devoted to an important type 1 diabetes SNP, and we will show how the detected downstream effects compare to our conventional eQTL analysis in 1,469 peripheral blood samples, for which genome-wide genotype data is available.

Genetic association of the Dickkopf 1 gene with Paget's disease of bone. *M. Beauregard[1,2], E. Gagnon[2], J. Morissette[2], J.P. Brown[1,2,3], L. Michou[1,2,3].* 1) Laval University, Quebec, Quebec, Canada; 2) CHUQ (CHUL) Research Centre, Quebec (Quebec) Canada; 3) Rheumatology Department, CHUQ (CHUL), Quebec (Quebec) Canada.

Introduction: Paget's disease of bone (PDB) has an autosomal-dominant mode of inheritance with incomplete penetrance. Mutations of the Sequestosome-1 gene have been identified, but account for only 37% of familial and 10% of sporadic forms of PDB. The Dickkopf 1 gene, expressed by osteoblasts and osteocytes, encodes a protein that inhibits Wnt signaling and downregulates bone remodeling. Expression of DKK1 is increased in pagetic osteoblasts and stromal cells and DKK1 serum levels are elevated in pagetic patients. The objectives of this study were to identify rare variants of DKK1 and to test for genetic association with PDB. Materials and methods: DKK1 exons, promoter and exon-intron junctions from 30 French-Canadian patients with familial PDB and four unrelated healthy individuals were amplified and sequenced. All variants identified in at least one individual and absent from NCBI's SNP database were considered as potential rare variants. An association study was also conducted by genotyping three common variants of DKK1 in unrelated French-Canadian PDB patients (N=183) and healthy individuals (N=295). The association study compared minor allele frequencies between cases and controls. Haplotypes composed of the two mostly-associated Tag SNPs were inferred by the use of SIMWALK 2.89 and PHASE. Results: Three rare variants of DKK1 were identified. The first rare variant was located in exon 2 and alters an amino acid highly conserved in evolution (Arg120Leu) and predicted in silico to be damaging, the second found in the 3'UTR, and the third found in intron 1 (IVS1 184 T/C) on a splice site. The G allele of the TagSNP rs1569198 was significantly lower in patients compared with controls (42% versus 49%, p=0.03, RR=0.77, 95% confidence interval: 0.61, 0.98), and a trend toward an association was found with the A allele of the rs2241529 (p=0.08). The haplotype GG was significantly less frequent in patients when compared to controls (41% versus 47%, p=0.047, RR=0.79, 0.62, 1.00). Conclusion: This study identified three rare genetic variants in DKK1 in patients with familial PDB. These variants are all located in regions important for the DKK1 function, especially exon 2 which encodes a cysteine-rich domain interacting with LRP5/6 co-receptors. In addition, a genetic association was found between an haplotype and a common variant of DKK1 in unrelated PDB patients. Further studies are required to investigate the functional consequences of this association.

The Interaction between Killer-cell Immunoglobulin-like Receptor Genes and HLA Alleles in Susceptibility to Psoriatic Arthritis. *V. Chandran[1], F.J. Pellett[2], R. Ayearst[2], R.A. Pollock[2], D.D. Gladman[1].* 1) Medicine/Rheumatology, Unversity of Toronto, Toronto, Ontario, Canada; 2) Toronto Western Research Institute, Toronto, Ontario, Canada.

Introduction: HLA Class I genes are strongly associated with PsA. HLA Class I alleles interact with KIRs on NK cells and this interaction may play a role in PsA susceptibility. We therefore conducted a case-control study to determine the association between KIR2D & KIR3D genes and their interactions with HLA alleles in PsA. Methods: 678 PsA cases satisfying CASPAR classification criteria and 688 healthy ethnically matched controls were selected. KIR typing was performed by PCR-SSP and HLA typing by PCR-SSO with appropriate quality controls. The difference in the frequency of individual KIR genes in cases and controls was tested for significance using $\chi 2$ test and Fisher's exact test. Trends for increasing susceptibility to PsA from combined genotypes (HLA-KIR and HLA) were evaluated by the Cochran-Armitage trend test. Multivariate analyses were conducted using logistic regression. Results: In univariate analyses, KIR2DL2 and KIR2DS2 genes were significantly associated with an increased risk of PsA. Multivariate analysis revealed that only KIR2DS2 was independently associated with PsA (OR 1.258, 95% CI 1.017, 1.556, p= 0.03). The presence of HLA-C group 2 was associated with an increased risk of PsA (trend test p=0.006). The risk of PsA is increased when KIR2DS2 is present in the presence of HLA-C ligands (C group 1) for the corresponding inhibitory KIRs, and is highest when KIR2DS2 is present in the absence of HLA-C ligands for homologous inhibitor KIRs, compared to the state when KIR2DS2 is absent (trend test p=0.03). The presence of HLA-C alleles that have high cell surface expression was also associated with increased risk of PsA (trend test p<0.0001). Although association between HLA-B, Bw4 and HLA-Bw4 80isoleucine was associated with increased PsA risk (trend test p<0.0001 for both analyses), no statistical interaction between HLA-Bw4 80ile and KIR3DS1 could be demonstrated. Conclusion: This study confirms the association between the KIR2DS gene, especially KIR2DS2, with PsA. The increased risk conferred by HLA-C alleles that have high cell surface expression and HLA-B Bw4 alleles was demonstrated. These results indicate a potential role for NK cells in PsA pathogenesis since KIRs interact with these alleles to enhance the inflammatory response.

Linkage Analysis in an Australian Population Identifies a Region Affecting Femoral Neck BMD. *S.C. Nguyen, J.R. Center, J.A. Eisman, T.V. Nguyen.* Osteoporosis and Bone Biology, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia.

Genome-wide association studies, with their large cohorts and dense sequencing coverage, have been extremely successful at identifying the gene regions which influence many different traits, including bone mineral density (BMD). Whilst they continue to be useful, the numbers needed to detect and replicate signals is at times prohibitively large. Given the high heritability of BMD traits, linkage studies using related individuals represent a cost-effective alternative for detecting regions associated with variation in BMD. A moderately-sized linkage study using related individuals can have the same power to detect gene regions as a much larger association study using unrelated individuals. Here we perform a linkage analysis for BMD at the femoral neck, lumbar spine and total body using 500 people across 90 extended pedigrees from the Dubbo Osteoporosis Genetics Study (DOGS). This study was designed as an off-shoot of the Dubbo Osteoporosis Epidemiology Study (DOES), and is a multi-generational family study with ongoing recruitment and follow-up. Using a multipoint linkage scan, we find evidence for linkage at chromosome 3q25 with respect to variation in femoral neck BMD (but not lumbar spine or total body BMD). Furthermore we find evidence for suggestive linkage at regions previously identified in other linkage and association studies looking at BMD. Overall there is reason to once again pursue linkage as a study design for identifying gene regions associated with BMD traits.

Pathway-based analysis of bladder cancer genome-wide association study highlights metabolic detoxification, mitotic, and clathrin-mediated pathways. *I. Menashe[1*], J. Figueroa[1*], M. Garcia-Closas[1], Q. Yang[1], D. Maeder[1], W. Wheeler[2], T. Picornell[3], M. Malatas[3], F. Real[3], N. Chatterjee[1], S.J. Chanock[1], D.T. Silverman[1], N. Rothman[1].* 1) DCEG, NCI, Rockville, MD; 2) IMS Inc., Rockville, MD; 3) CNIO, Madrid, Spain.

Genetic association studies have conclusively identified ten variants associated with bladder cancer risk; however, estimates suggest additional susceptibility loci for this disease. To identify new candidate susceptibility loci, we applied a pathway analysis to a bladder cancer genome-wide association study containing data from 3,532 cases and 5,120 controls of European background (n=5 studies). 1,399 pathways were drawn from five publically available resources (Biocarta, Kegg, NCI-PID, HumanCyc, and Reactome), and we constructed 23 additional candidate pathways related to bladder cancer. In total, 1422 pathways, 5647 genes and ~90,000 SNPs were included in our study. Logistic regression models adjusting for age, sex, study, DNA source, and smoking status was used to assess the marginal trend effect of SNPs on bladder cancer risk. Two complementary pathway-based methods (gene-set enrichment analysis [GSEA], and adapted rank-truncated product [ARTP]) were used to assess the enrichment of association signals within each pathway. Eighteen pathways were detected by either GSEA or ARTP at $P < 0.01$. To minimize false positives, we used the I^2 statistic to identify SNPs displaying heterogeneous effects across the five studies. After removing these SNPs, seven pathways (`Aromatic amine metabolism', `NAD biosynthesis', `NAD salvage', `Clathrin derived vesicle budding', `Lysosome vesicle biogenesis', 'Retrograde neurotrophin signaling', and `Mitotic metaphase/anaphase transition') remained. These pathways seem to belong to three fundamental cellular processes (metabolic detoxification, mitosis, and clathrin-mediated vesicles). Identification of the aromatic amine metabolism pathway supports the ability of this approach to identify pathways with established relevance to bladder carcinogenesis and suggest additional candidate susceptibility loci.

Genetic Analysis of Prostate Cancer Using Automatic Computer Programming. *J.H. Moore[1], D. Hill[1], J. Fisher[1], N. Lavender[2], L. Kidd[2].* 1) Dartmouth Medical School, Lebanon, NH, USA; 2) University of Louisville, Louisville, KY, USA.

The paradigm of identifying genetic risk factors for common human diseases by analyzing one DNA sequence variation at a time is quickly being replaced by research strategies that embrace the multivariate complexity of the genotype to phenotype mapping relationship that is likely due, in part, to nonlinear interactions among many genetic and environmental factors. Embracing the complexity of common diseases such as cancer requires powerful computational methods that are able to model nonlinear interactions in high-dimensional genetic data. Previously, we have addressed this challenge with the development of a computational evolution system (CES) that employs an automatic computer programming approach called genetic programming (GP). Our CES approach is different from most other GP-based methods in that it can learn how to solve a genetic analysis problem in addition to finding a good model. Our results have demonstrated that CES is capable of efficiently navigating these large and rugged fitness landscapes toward the discovery of biologically meaningful genetic models of disease predisposition. Further, we have shown that the efficacy of CES is improved dramatically when the system is provided with statistical expert knowledge, derived from a family of machine learning techniques known as Relief, or biological expert knowledge, derived from sources such as protein-protein interaction databases. The goal of the present study was to apply CES to the genetic analysis of prostate cancer aggressiveness in a large sample of European Americans. We introduce here the use of 3-D visualization methods to identify interesting patterns in CES results. Information extracted from the visualization through human-computer interaction (HCI) are then provide as expert knowledge to new CES runs in a cascading framework. We present a CES-derived multivariate classifier and provide a statistical and biological interpretation in the context of prostate cancer prediction. The incorporation of HCI into CES provides a first step towards an interactive discovery system where the experts can be embedded in the computational discovery process. Our working hypothesis is that this type of HCI will provide more useful results for complex problem solving than the traditional black box machine learning approach.

Gastric cancer is associated with Native American ancestry in the Latin American (Peruvian) population. *L. Pereira[1], R. Zamudio[1], G. Soares-Souza[1], R. Gilman[2, 3], E. Tarazona-Santos[1].* 1) Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil; 2) Johns Hopkins School of Public Health; 3) Asociación Benéfica PRISMA.

Gastric cancer (GC) is one of the most important causes of cancer deaths worldwide. In the Peruvian population, the gastric cancer ranks second in incidence among men and third among women, and is the most lethal type of cancer. We performed an association study to test the hypothesis that ethnicity is associated with gastric cancer in the Peruvian population from the city of Lima, controlling the effect of potential confounding variables. We collected biological samples (biopsies and blood for DNA extraction) as well as clinical, socioeconomic and dietary data from 200 GC cases and 297 controls from three hospitals from Lima. To estimate admixture, we genotyped 106 ancestry informative SNPs in these samples and used published data from the following ancestral populations: HapMap Yoruba (176 individuals), HapMap Europeans (174 individuals), and Native American (296 indigenous individuals groups from Peru collected by our group). We estimated admixture using the Bayesian method implemented in the software Structure 2.3.3. Our samples from Lima, even if mostly categorized phenotipically as “mestizos”, showed a high level of Native American ancestry (78.4% for the cases and 74.6% for the controls) and very low level of African ancestry (<5%). Using a logistic regression model we found association between gastric cancer and Native Ancestry (ORs 4.02, p<0.01). Considering other variables, we observed association of gastric cancer with fruit/vegetables intake (ORs 0.58-0.63, p<0.03) and burning symptom (ORs 1.69, p=0.03). The association with Native American ancestry persists when these covariates were controlled for. Our study provides the first evidence of association of GC and ethnicity in Latin America. We are currently genotyping common variants in candidate genes (selected from immune pathways and from results of genome-wide association studies) to test the association between these genetic variants and GC, controlling the effect of admixture and other environmental covariates. Support: NCI-Fogarty, CNPq-Brazil, CAPES-Brazil, FAPEMIG-Brazil.

643W

GSTM1 and GSTT1 copy numbers and mRNA expression in lung cancer. *M. Rotunno[1], T.K. Lam[1], J. Lubin[1], A. Vogt[1], P.A. Bertazzi[2], N.E. Caporaso[1], M.T. Landi[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland; 2) Unit of Epidemiology, Fondazione IRCCS Ospedale Maggiore Policlinico and Department of Occupational and Environmental Health, Università degli Studi di Milano, Milan, Italy.

Deletions in Glutathione S-transferase M1 and T1 (GSTM1/T1) are common in the general population and can affect xenobiotic metabolism. Numerous studies evaluated the effect of GSTM1/T1 deletions on lung cancer risk using a null/present model, but only two small studies estimated the contribution of the heterozygous deletion with mixed results. We measured GSTM1/T1 copy numbers in 2120 controls and 2100 cases from the Environment And Genetics in Lung cancer Etiology population (EAGLE) study. We evaluated their effect on mRNA expression from tissue and blood samples and their association with lung cancer risk overall and for different histology types. We tested the null/present, dominant and additive models using logistic regression. Cigarette smoking, sex, cruciferous-based diet, and hormone-related information for women were studied as possible modifiers of the tested associations. Gene expression from blood and lung tissue cells was strongly down-regulated in subjects carrying GSTM1/T1 deletions by both trend and dominant models ($p<0.001$). No significant associations between lung cancer and GSTM1/T1 were detectable using the null/present model. In contrast, analyses distinguishing subjects with 1 and 0 deletions of GSTM1/T1 revealed several significant associations. There was a decreased risk of lung cancer in never smokers (OR=0.44, 95%CI=0.23-0.82, p=0.01) and women (OR=0.50, 95%CI=0.28-0.90, p=0.02) carrying 1 or 2 GSTM1 deletions. Analogously, male smokers had an increased risk (OR=1.13, 95%CI=1.0-1.28, p=0.05) and women a decreased risk (OR= 0.78, 95%CI=0.63-0.97, p=0.02) of lung cancer for increasing number of GSTT1 deletions. The corresponding gene-smoking and gene-gender interactions were significant ($p<0.05$). In summary, by distinguishing individuals carrying 0 and 1 deletion of GSTM1/T1 for the first time in a large population of lung cancer, we have found a clear relationship between deletions and gene expression in blood and lung tissue cells and showed opposite effects of GSTM1/T1 deletions on lung cancer susceptibility for male smokers and for never smokers and women. Our results suggest that a decreased activity of GSTM1/T1 enzymes is 1) a risk factor for lung cancer in smokers, likely due to mechanism of impaired ability to detoxify carcinogens, 2) a protective factor in nonsmokers, possibly because of enhanced activity of protective dietary constituents, and 3) a protective factor in women, possibly due to hormonal-related mechanisms.

Prevalence of beta Thalassaemia. *K. Sanwaria[1], M. Vashist[1], P. Abrol[2].* 1) Department of Genetics, M.D.University, Rohtak, Haryana, India; 2) Depart of Paediatrics,Pandit Bhagwat Dayal University of Health Sciences, Rohtak ,Haryana,India.

INTRODUCTION: India is an ethnically diverse country with an approximate population of 1.2 billion.) -thalassemia is the commonest single-gene disorder in the Indian population The frequency of) -thalassemia trait () TT) has been reported from <1% to 17% and an average of 3.3. It is characterized by reduced synthesis of Hb subunit that results in microcytic hypochromic anemia, an abnormal peripheral blood smear with nucleated red blood cells and reduced amounts of Hb A. Without treatment, affected children have severe failure to thrive and shortened life expectancy. OBJECTIVE: To investigate the) thalassemia profile. METHODS: All subjects were interviewed using a standarized proforma .Various hematological analysis and hemoglobin electrophoresis was done after the informed consent of parents/ guardian . RESULTS: Two hundred thirty patients of) thalassemia major were analysed from year 2009 to Jan 2011. Thalassaemia incidence rates varied significantly among age groups and gender. The occurance of) -thalassaemia was inversely propotional with age.Retrospective study revealed that 51%) thalassemic major patients were diagnosed before 8 months of age and 38% of cases between 8 months & 5 years.Twelve percent patients came to light after 5 years of age Sex ratio revealed prevelance of) thalassemic males(males-71.6%& females- 28.4%). Patients belonged to nine communities i.e Punjabi, Sunar, Jaat, Brahmin, Ahir, Khaati, Baniya, Chauhan and Sikh. Punjabis were found to have the highest frequency (31%) of) thalassemia followed by Jaat (11.6%), Brahman (8.3%) and Sunar (8%). As a corollary, the projected incidence of) -thalassaemia major in newborn babies greatly varied by the subcastes of the parents.Two third (75%)patients were from Urban region and 25% belonged to rural area. Highest frequency of) thalassemia was found in B+ blood group, whereas no case was reported in A- and AB- blood group. The frequency of ABO blood group in) thalassemic patients varied in the descending order of B, O, A, AB, Rh+, Rh- and O, B, A, AB, Rh+, Rh- in thalassemics and control group respectively. CONCLUSION: Specific genes were proliferated along with the extension of time. Ethnic subgroups within populations known to commonly carry the) -thalassaemia gene will provide useful information in genetic research,epidemiological and public health perspectives.

Efficient Detection of Tumor Somatic Mutations using Next-Generation Sequencing Data. *Z. Song[1], J. Long[2], J. He[3], W. Zheng[2], C. Li[1,3].* 1) Center for Human Genetics Research, Vanderbilt Medical Center, Nashville, TN; 2) Vanderbilt Epidemiology Center, Nashville, TN; 3) Department of Biostatistics, Vanderbilt University School of Medicine, Nashville, TN.

Direct comparisons between normal and tumor samples allow us to identify somatic mutations that either trigger tumorigenesis or arise as a result of it. However, a tumor sample may be a mixture of tumor and non-tumor cells, and a somatic mutation may not be present in all tumor cells. As a result, a somatic mutation may exist only in a fraction of cells of a tumor sample, and thus may not be detectable through genotype calls. We develop a novel algorithm SMUG (Somatic MUtation Gleaner) for detecting two types of somatic mutations, base substitution and loss of heterozygosity (LOH), by examining the sequence reads of tumor samples. We applied our method to whole exome sequencing data of 8 breast cancer patients, and detected many somatic mutations that were missed by the traditional approach of comparing genotype calls between normal and tumor samples (denoted CALL). To detection base substitutions, we walk through the tumor data to identify potential sites, force genotype calls in blood samples, and keep the sites that are homozygous in blood. To distinguish sites that have the same mutation rate but different depth, we employ an empirical Bayes (EB) approach to adjust mutation rate. High depth sites will receive less adjustment than low depth sites. To detect LOH regions, we focus on sites that are heterozygous in the normal sample. If there is no LOH at a site, the tumor sample allele counts should follow a binomial distribution with equal probability for the two alleles in the normal sample. For each site, we define an LOH score to reflect the level of departure from the expected distribution. LOH regions and their boundaries can be determined by applying a threshold to LOH scores. For our 8 breast cancer patients, we compared the results of SMUG and CALL to the COSMIC (catalogue of somatic mutations in cancer) database and published LOH regions in breast cancer. With the same QC criteria, SMUG identified 8,207 base substitutions, while CALL found 784, in which only 6 were not reported by SMUG. At gene level, nonsynonymous substitutions found by SMUG hit 342 COSMIC genes (43 breast cancer genes), while those found by CALL hit 61 COSMIC genes (9 breast cancer genes). For LOH detection, SMUG identified an average of 265 LOH regions per subject, while CALL reported 40. Among 19 published LOH regions related to breast cancer, SMUG found 126 LOH intervals in 13 of them, while CALL found 22 intervals in 7 of them.

High-resolution array-CGH analysis of germline DNA in a melanoma-prone family linked to chromosome 9p21. *R. Yang[1], J. Struewing[2], S. Chanock[1], M. Tucker[1], A. Goldstein[1], NCI Core Genotyping Facility.* 1) Dept DCEG, NCI, Bethesda, MD; 2) NHGRI, NIH, Bethesda, MD.

Germline copy number variations (CNVs) have recently been recognized as a significant source of genetic variation and have been associated with disease susceptibility. Chromosome 9p21 has been implicated in the pathogenesis of cutaneous malignant melanoma (CMM) because it contains CDKN2A, the major known high-risk CMM susceptibility gene. However, a subset of CMM families linked to 9p21 has no CDKN2A mutations. The goal of this study was to determine whether CNVs, particularly 9p21 CNVs, were related to CMM risk in a 9p21-linked melanoma-prone family without a CDKN2A mutation. The family has 13 CMM members and 6/7 genotyped CMM cases shared a common 9p21 haplotype. An extensive mutation analysis did not detect any mutations in coding or non-coding regions of CDKN2A. We therefore conducted a genome-wide search for CNVs using the Nimblegen 385K whole-genome array-CGH. We analyzed genomic DNA from 4 CMM cases and 1 spouse. We used the Nexus Copy Number™ built-in Rank Segmentation algorithm to identify significant CNVs (significant threshold=0.000001; minimal number of probes per segment=5; log2 ratio>0.2 for gains and -0.3 for losses). No CNVs were consistently shared by multiple CMM cases. However, there were some small CNVs in the 9p21 linked region that occurred in some but not all CMM cases. Given the importance of 9p21 in melanoma susceptibility and the observed linkage to this region in this family, we further evaluated CNVs in this region using two independent approaches: 1) a custom-made array-CGH design to focus on the linked region (average probe spacing, 13 bp) [analyzing 3 cases]; and 2) quantitative PCR (qPCR) targeting 4 genes (SH3GL2, CDKN2A, KIAA1797, and SLC24A2) in this region [analyzing all 26 individuals with available DNA]. No CNVs that were shared by multiple cases were identified suggesting that CNVs in the 9p21 region do not cause melanoma predisposition in this family. We are currently using next-generation sequencing technology to examine all exons in the 9p21 linkage region as well as exomic and complete genomic sequencing to identify disease-related variant(s) in the entire exome/genome in this family.

Genetics factors involved in MLIA susceptibility: an association study in a Portuguese sample. *M. Alves-Ferreira[1,2], T. Pinho[3], A. Sousa[1,4], J. Sequeiros[1,2,4], C. Lemos[1,2,4], I. Alonso[1,2,4].* 1) UnIGENe, IBMC, Porto, Portugal; 2) CGPP, IBMC, University of Porto, Portugal; 3) CICS, ISCS-N/CESPU, Portugal; 4) Department of Population Studies, ICBAS, University of Porto, Portugal.

Tooth agenesis affects 20% of the world population and agenesis of maxillary lateral incisors (MLIA) is one of the most frequent subtypes, characterized by the absence of formation of deciduous or permanent lateral incisors. In the Portuguese population, we found a prevalence of 1.3% for MLIA. In a previous study, we also found evidence of a strong genetic component for this trait. Several genes such as MSX1, PAX9 and AXIN2 have been identified as being expressed during odontogenesis. Mutations in these genes can lead to abnormalities in odontogenesis, which is a complex mechanism regulated by sequential and reciprocal epithelial-mesenchymal interactions, resulting in tooth agenesis. Therefore, our aim was to study the association of polymorphisms in these genes and in other genes related with odontogenesis and MLIA susceptibility. Association studies are an essential approach in the research of candidate genes involved in MLIA susceptibility in our subjects, allowing the identification of common variants associated with this trait. A case-control study, in a total of 300 individuals, is underway; a 1:2 ratio was achieved in order to increase the study statistical power. We selected 44 tagging single nucleotide polymorphisms (SNPs), which were genotyped by SNaPshot, using a multiplex approach. After genotyping, statistical analysis was performed by logistic regression. Regarding allelic frequencies, a significant high risk was found for the A allele of rs7149262 in PAX9. The results of the logistic regression analysis show that the AA genotype of rs8004560 in PAX9 confers a significant increased risk for individuals with MLIA (OR= 7.06, 95% CI: 1.54-32.34). These results, although preliminary, allow us to hypothesize that PAX9 may have a role in MLIA susceptibility. In the end of this study, we expect to find or exclude the role of the selected candidate genes in MLIA susceptibility. Furthermore, epistasis analysis also will be performed in order to identify possible gene-gene interactions, which are important in the etiology of complex traits. This study has identified some polymorphisms potentially involved in MLIA susceptibility and may contribute to better understand the genetic basis of dental agenesis.

The Genetic Underpinnings of Exercise Adherence. *M.S. Bray[1], J.R. Fernandez[2].* 1) Epidemiology/Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) Nutrition, University of Alabama at Birmingha, Birmingham, AL.

The increasing prevalence of obesity is one of the most important public health issues today, with more than two thirds of the U.S. population being overweight or obese. Though physical activity is recommended to improve health and facilitate weight loss and weight maintenance, the ability of individuals to respond and/or adhere to an exercise program varies widely. Preliminary studies in our group point to a genetic basis for exercise adherence that is neural in origin. Thus, we examined a dense array of markers in genes residing in neural pathways related to satiety signaling and pleasure/reward systems in a large cohort of young adults (18-35 y) from the Training Interventions and Genetics of Exercise Response (TIGER) study. Subjects in the study underwent a 30-week exercise intervention, which involved 30 minutes of aerobic exercise at 65-85% of maximum heart rate reserve three days per week. Exercise adherence was defined by more than 42,000 computerized exercise sessions in which exercise duration, frequency, and intensity were documented. Of 12 tag SNPs located across the fat mass and obesity associated (FTO) gene, five loci (rs13334933, rs9924072, rs1125392, rs7205987, and rs10492872) significantly raised risk of exercise dropout ($p<0.02$). Combinations of any three risk raising alleles in these loci more than doubled exercise dropout risk (OR=2.22; 95%CI: 1.45-3.40). A linear decrease in exercise intensity/duration was observed with increasing number of risk alleles, suggesting a putative functional role for the combined variants in limiting the capacity for high endurance exercise. The fat mass and obesity associated (FTO) gene is the most highly replicated GWAS finding for obesity to date, and several studies have demonstrated that the risk-raising effects of the FTO locus may be ameliorated by physical activity. The results presented here are the first to document a role for the FTO gene in influencing both exercise adherence and duration.

Association analysis of rare variants and alcohol level of response in the San Diego Sibling cohort. *H. Choquet[1], G. Brush[1], J. Kasberger[1], M. Robertson[1], M. Schuckit[2], R. White[1], E. Jorgenson[1].* 1) Ernest Gallo Clinic and Research Center, University of California, San Francisco, Emeryville, California; 2) Department of Psychiatry, University of California, San Diego, and the Veterans Affairs San Diego Healthcare System, San Diego California.

BACKGROUND: Evidence suggests that rare genetic variants may play an important role in complex disease etiology. Genome-wide association studies, however, have limited power to examine the effect of rare variants; for this reason, understanding of the effects of rare variants on complex diseases remains limited. Recently, a number of statistical "collapsing" methods have been proposed to examine rare variants from sequence data by testing the aggregate effect of the variants in a gene on disease susceptibility. The aims of the present study are to apply collapsing methods to investigate the effect of variants identified through sequencing of alcohol use disorder candidate genes in subjects with a familial background of alcohol dependence to identify genes that influence level of response to an alcohol challenge. METHODS: The coding regions and exon-intron boundaries of 240 candidate genes were sequenced in 295 Caucasian subjects with a familial background of alcohol dependence from the San Diego Sibling cohort who had been tested for level of response to an alcohol challenge. To classify the variants detected either as pathogenic mutations or as neutral, we used functional in silico analyses. To assess the association between rare genetic variants and level of response to an alcohol challenge, we used the "step-up" statistical approach to combine multiple rare variants in each gene and analyze them as a single group. RESULTS: Genetic screening of 240 genes in 295 subjects has led to the identification of 4,207 genetic variants (8.8% of them are novel or rare (MAF<5%)). Out of these variants detected, 29.7% were non-coding variants, 30.8% silent variants and 39.5% missense variants. Approximately 65.5% of these missense variants have been considered as deleterious mutations using in silico functional predictions. Finally, using the "step-up" statistical method, a number of novel associations with a level of response to alcohol were identified. CONCLUSIONS/PROSPECTS: This study demonstrates that the evaluation of rare variants using sequence data is possible. Furthermore, the "step-up" approach that groups rare variants allowed the identification of response to alcohol traits-associated genes. To confirm our findings, identified rare missense variants will be investigated for cosegregation with response to alcohol in families. Furthermore, replication studies using large sample sizes will need to be carried out.

650W

No genetic association with *CCR5, CD226* or *RFX* polymorphisms in Norwegian Addison's disease patients. *M.C. Eike[1], B. Skinningsrud[1], A. Stormyr[1], B.A. Lie[1], E.S. Husebye[2, 3], D.E. Undlien[1].* 1) Department of Medical Genetics, Oslo University Hospital, University of Oslo, Oslo, Norway; 2) Section of Endocrinology, Institute of Medicine, University of Bergen, Bergen, Norway; 3) Department of Medicine, Haukeland University Hospital, Bergen, Norway.

Autoimmune Addison's disease (AAD) is a rare disease characterised by autoimmune destruction of the adrenal cortex. As AAD patients frequently suffer from concomitant autoimmune diseases of other organs, AAD is an interesting model disease for susceptibility factors common to autoimmunity. Accordingly, many of the genes involved in other autoimmune diseases have also been associated with AAD. In this study, we investigated two candidate polymorphisms strongly associated with other autoimmune diseases, a 32 bp deletion (Δ32) in the *chemokine C-C motif receptor 5 gene* (*CCR5*) and the rs763361 C>T Gly307Ser SNP in the *CD226* gene. In addition, SNPs in the *class II MHC transactivator* (*CIITA*) gene has previously been associated with disease in our AAD patients and a number of other autoimmune diseases. We therefore investigated the possibility for presence of susceptibility factors in the genes of the three coregulatory factors of CIITA, the *regulatory factor X* genes (*RFXANK*, *RFX5* and *RFXAP*), with a total of eight tagging SNPs. 416 patients with Addison's disease (321 for rs763361) and 1029 healthy blood donors were genotyped, all of Norwegian origin. *A priori*, we had ⁄ 80% power to detect an OR above 1.41-1.85 or below 0.70-0.45, depending on minor allele frequency. Two of the tagging SNPs, in *RFX5* and *RFXAP* respectively, were not in Hardy-Weinberg equilibrium in the control population ($p<0.05$), and were therefore excluded. No significant associations were found between Addison's disease and either polymorphism, nor with haplotypes of any of the *RFX* SNPs ($p>0.05$). However, a tendency for a protective effect was observed for patients homozygous for *CCR5*Δ32 (recessive OR 0.39, 95% CI 0.11 to 1.31, $p=0.11$), similar to what has been reported earlier for patients with type 1 diabetes. In conclusion, no significant disease association was found in this study, possibly due to limited power. However, a tendency was observed for the 32 bp deletion polymorphism in the *CCR5* gene, which could merit follow-up studies in other AAD cohorts.

651W

Genetic Analysis of *CAPN10* gene: a candidate region for the susceptibility to Polycystic Ovary Syndrome. *F.R. Faucz[1,2], I.R. Hauer[1,3], R.I. Werneck[1], M. Olandoski[1], R.B. Alexandre[1,2].* 1) Laboratory of Human Molecular Genetics, Group for Advanced Molecular Investigation (NIMA), PPGCS/CCBS, Pontifícia Universidade Católica do Parana, 80215, Curitiba, PR, Brazil; 2) Section of Endocrinology and Genetics, Program on Developmental Endocrinology Genetics, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, 20892, Bethesda, Maryland, USA; 3) Laboratory of In Vitro Fertilization of Fertway Clinic, 80250, Curitiba, PR, Brazil.

The Polycystic Ovary Syndrome (PCOS) is a heterogeneous endocrinological disease, usually characterized by enlarged and containing numerous small cysts ovary (polycystic appearance) and excessive hormone production. PCOS affects between 4 and 12% of women in reproductive age, and while the exact cause is undetermined, a genetic component is suggested by several association studies. Recent evaluation of the *CAPN10* gene in PCOS patients has suggested that different alleles may play a role in PCOS susceptibility. We searched for possible association between four single nucleotide polymorphisms in the CAPN10 gene (SNP-19 rs3842570, -43 rs3792267, -44 rs2975760 and -56 rs2975762) and Brazilian women with PCOS. Fifty women with PCOS (34,9 +/- 5,27y) and 150 healthy women (35,6 +/- 5,79y) were genotyped, and uni-and multi-variate analysis were conducted. Applying Fischer Exact Test and logistic regression model, we observed strong association between markers SNP-43 (p=0,026; OR=2.25, IC 1.1 - 4.6) and SNP-56 (p=0,005; OR=3.05, IC 1.4 - 6.63). Allele A of SNP-56 showed highest disease association (p=0.031). Stronger association with the PCOS disease status was observed after construction of haplotypes, which was in line with previous studies. The construction of haplotypes was performed by the Thesias software package. As reported before, haplotype TGG3 showed protective effect against the development of PCOS (OR= 0.25; CI=0.143-0.445; p=0.000431). While haplotypes TGA2 (OR=3.73778; CI=1.759-7.941; p=0.00065) and TAG3 (OR=3.01389; CI=1.425-6.376; p= 0.003902) showed high probability to increase the predisposition for the disease. Further studies on greater sets of samples are needed to confirm this observation.

Genetic and serologic evidence implicate *IL6* as a susceptibility gene for leprosy type 2 reaction. *V.M. Fava[1], A.L.M. Sousa[2], L.H.F Sampaio[2], C.M.T Martelli[2], M.B. Costa[2], M.T. Mira[1], M.M.A. Stefani[2].* 1) Pontifical Catholic University of Paraná, Curitiba, Brazil; 2) Federal University of Goiás, Goiânia, Brazil.

Type 1 (T1R) and Type 2 (T2R) leprosy reactions (LR) are aggressive inflammatory episodes of sudden onset that occur in 30% of leprosy affected individuals, often several months after successful completion of treatment. Today, these unpredictable episodes are the major cause of permanent disabilities associated with leprosy. In this scenario, the description of innate predictive factors for LR will have a major impact over preventive strategies against the effects of such a stigmatizing event, which only recently has come under leprosy research focus. In a previous comparative screening of a large panel of cytokines in the serum of individuals affected by T1R and T2R, our group identified *IL6* as a strong candidate for genetic analysis. Here, we present the results of a prospective follow-up study involving 409 leprosy-affected individuals monitored for at least one year for the occurrence of LR. By the end of the follow-up, 154 individuals had developed T1R, 39 had developed T2R and the remaining 216 were considered as controls. Fluorescence-based TaqMan technology was applied to produce genotypes of all individuals for three tag SNPs capturing the entire information of the *IL6* locus. Allele frequencies were compared between cases and controls matched by leprosy clinical form. No association was observed between IL6 variants and occurrence of T1R. However, we found independent, positive evidence for association between T2R and all three tag SNPs: rs2069832 (p=0.002), rs2069840 (p=0.03) and rs2069845 (p=0.04); Interestingly, SNP rs2069832 is in the same bin as rs1800795, a known functional *IL6* regulatory variant. Genotyping of rs1800795 confirmed association with T2R (p=0.005). Finally, we produced functional data showing statistically significant correlation between risk genotypes of rs2069832 (p=0.04), rs2069840 (p=0.02) and rs1800795 (p=0.04) and serum levels of IL6 in a sample of 49 selected individuals. Taken together, these results strongly implicate *IL6* polymorphisms in the control of susceptibility to leprosy T2R.

A combination of variations near NMU and NMUR2 coding regions identifies young women with significant lower bone mineral density at femoral neck. *S. Giroux[1], V. Clément[1], A. Bureau[2,3], D.E.C. Cole[4,5], F. Rousseau[1,2,6].* 1) Centre de Recherche de l'Hôpital St-François d'Assise du Centre hospitalier universitaire de Québec, Québec, Canada; 2) Faculté de Médecine, Université Laval, Québec, Canada; 3) Centre de recherche Université Laval Robert-Giffard, Québec, Canada; 4) Department of Clinical Pathology, Sunnybrook Health Sciences Centre, Toronto, Ontario, Canada; 5) Department of Laboratory Medicine & Pathobiology, University of Toronto,Toronto, Ontario, Canada; 6) Centre for the Development, Evaluation and Rational Implementation of New Diagnostic Tools in Medicine (CEDERINDT) Québec, Canada.

Bone mass is highly variable among healthy individuals and genetic variations are thought to be an important factor explaining this diversity. In addition, pathway specific gene-gene interactions are likely to affect the determination of complex traits such as bone mineral density (BMD). Recently, bone remodeling was shown to be under neuronal control mediated by neuropeptides such as leptin and neuromedin. We analyzed selected candidate genes involved in these pathways (LEP, LEPR, ADRB2, NMU, NMUR2, NPY, NPY2R and CART) with HapMap data tools to select a set of Tag SNPs. 79 Tag SNPs were analyzed in a group of women from Québec city (709 women) using the Sequenom technology. SNPs were analyzed for association with BMD measured at lumbar spine (LS) and femoral neck (FN). 14 significant associations ($p < 0.05$) were tested in a second group of women from Toronto (673 women) using the same technology. Genetic variants remaining associated with BMD in the combined samples of women were tested against all others for interactions. We found a significant association between LS BMD and one SNP in the NMU gene in the Quebec sample ($p = 0.017$) and the same SNP was associated with FN BMD in the Toronto sample ($p = 0.025$). After samples were combined, the same SNP showed a significant association with FN BMD ($p = 0.011$) and a trend with LS BMD ($p= 0.077$). We also found a significant interaction between that SNP and one SNP in the NMUR2 gene ($p = 0.035$). After stratification, we identified a subgroup of women with significantly lower FN BMD (gene effect size = 0.53SD) representing 3.1% of the population. The same group also exhibited a significantly lower LS BMD (0.32SD) when compared to all other women combined. Interestingly, the SNP in NMUR2 was correlated ($r = 0.33$) with a deletion located 200kb downstream from NMUR2 gene. Two individuals identified as deleted with a TaqMan assay were sequenced to determine the deletion boundaries. The sequence revealed a complex organization with a loss of 4kb and an addition of a 250bp originating from a region some 4kb downstream from the deletion. A PCR assay was designed to genotype the entire sample. The deleted allele was also associated with a lower BMD in interaction with NMU. Although the potential for a CNV to be functional is greater than that of a SNP, functional assays will be needed to prove that the CNV is causal. Replication in different samples of women will also be required to validate this association.

654W

Testing GWAS SNPs for COPD and lung function in a Polish cohort with severe COPD. *M. Hardin[1], J. Zielinski[2], E. Wan[3], C.P. Hersh[3], P.J. Castaldi[3], E. Schwinder[3], P. Sliwinski[2], I. Hawrylkiewicz[2], M. Cho[3], E.K. Silverman[3].* 1) Pulmonary Critical Care, Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) National Tuberculosis and Lung Diseases Research Institute, Warsaw, Poland; 3) The Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Rationale: Previous genome-wide association studies (GWAS) have demonstrated genetic loci associated with COPD. More recently, in the CHARGE and SpiroMeta consortiums, additional loci associated with lung function (FEV1 and FEV1/FVC) have been identified. In order to confirm previously identified COPD loci and to assess pulmonary function loci as COPD genetic determinants, we performed candidate gene analyses of loci previously associated with COPD and lung function in a novel cohort with severe to very severe COPD. **Methods:** All subjects were Caucasian smokers from Poland. 315 COPD cases and 338 controls were enrolled. All subjects completed a respiratory questionnaire, performed standardized spirometry, and provided blood samples for testing. From previous GWAS studies, we included four single nucleotide polymorphisms (SNPs) that had been associated with COPD: FAM13A(rs7671167), HHIP(rs13118928), IREB2(rs13180), and CHRNA3/5(rs8034191), as well as four SNPs that have been associated with lung function in general population samples: AGER(rs2070600), ADCY2(rs11134242), THSD4(rs4316710), and INTS12(rs17096090). We tested for association with COPD using logistic regression, controlling for age, gender and pack-years. **Results:** Subjects with COPD were older (62 vs 58 years, p<0.01) with greater pack-years (45 vs 34 pack-years, p<0.01). There were more males than females but gender was equally distributed among cases and controls. Cases had significantly worse lung function (FEV1 31% predicted vs 103% predicted, p<0.01; FEV1/FVC 36% vs 76%, p<0.01). Among SNPs previously associated with COPD, CHRNA3/5 (OR 1.8 [1.4,2.4], p = 1x10-8), IREB2 (OR 0.7[0.5, 0.9], p = 0.003), and HHIP (OR 0.7 [0.5,0.9], p= 0.001) demonstrated significant association with COPD. FAM13A (OR 0.8 [0.7,1.1], p=0.06) approached statistical significance. The CHRNA3/5 locus was no longer significant when adjusting for the presence of the IREB2 locus. Among the SNPs associated with lung function, ADCY2 demonstrated a significant association with severe COPD (OR 1.3 [1.1,1.7], p=0.007); however, SNPs near AGER (p= 0.25), THSD4 (p=0.18) and INTS12 (p=0.3) did not demonstrate association. **Conclusion:** In a population of Polish subjects with severe to very severe COPD, we demonstrate replication of association between three SNPs and COPD (CHRNA3/5, IREB2 and HHIP) as well as association with COPD of two loci that have been associated with lung function (HHIP and ADCY2).

Imputation-based association analysis within the ITGAM-ITGAX region identifies multiple common variants associated with SLE susceptibility in multiple ethnic populations. *X. Kim-Howard[1], C. Sun[1], K. Kaufman[1], J. Kelly[1], J. James[1], P. Gaffney[1], K. Moser[1], G. Gilkeson[2], C. Langfeld[3], R. Kimberly[4], T. Vyse[5], M. Alarcón-Riquelme[1], A. Adler[1], G. Wiley[1], J. Harley[6], S.K. Nath[1], SLEGEN, PROFILE.* 1) Oklahoma Med Res Foundation, Oklahoma City, OK; 2) Medical University of South Carolina, Charleston, South Carolina; 3) Wake Forest University Health Sciences, Winston-Salem, North Carolina, USA; 4) University of Alabama at Birmingham, Birmingham, Alabama; 5) King's College London, Guy's Hospital, London, UK; 6) Cincinnati Children's Hospital Medical Center and the US Department of Veterans Affairs Medical Center, Cincinnati, Ohio.

Introduction: We identified a novel non-synonymous ITGAM variant, rs1143679, associated with systemic lupus erythematosus (SLE). Subsequent GWAS confirmed association with ITGAM and expanded susceptibility to the ITGAM-ITGAX region. We hypothesize that there are multiple independent, possibly ethnic-specific, SLE-predisposing variants within the ITGAM-ITGAX region. Objective: We performed a comprehensive analysis to assess whether single or multiple causal variants from ITGAM-ITGAX are involved in SLE susceptibility for independent data sets (N=13,064), including European-American (EA) (3980 cases/3491 controls), African-American (AA) (1527/1811), Hispanic (HS) (961/336), and Native-Americans (NA) (531/471). Methods: We genotyped 79 SNPs from ITGAM-ITGAX and imputed SNPs using sequence data as a reference panel for EA, AA, and HS. For EA and AA we used dense fine-mapping data from the ImmunoChip SNP array and 1000Genomes as reference panels for a confirmation set. This allowed single- and multiple-SNP association analysis of nearly all common SNPs within this region. LD patterns and conditional logistic regression analysis were used to assess independence between SNPs. Results: After imputation and quality control we analyzed 164-304 SNPs. We found multiple significantly associated SNPs, many of which were in strong LD. Using differences in LD structure between populations and conditional analysis we identified 2 SNPs independently associated in at least 3 populations. As expected, rs1143679 was significantly, independently associated (EA p=1.9E-29, AA p=1.4E-8, HS p=0.001, NA p=2.6E-8). ITGAM intronic SNP rs35472514 was independently associated in AA (p=7.3E-5) and HS (p= 0.003). Though rs35472514 is significant in EA (p=6.9E-30) we could not assess independence due to strong LD. These results were confirmed. Interestingly, 2 SNPs (1910 bp) were independently associated in HS (rs62051471 p=0.001) and NA (rs12928810 p=9.7E-11). While we could not confirm that these SNPs are independently associated, they may represent a population-specific association in HS and NA. There is also a population-specific independent association for HS in ITGAX (rs13332545 p=0.0007). Conclusion: Using recently available unpublished sequence data we confirmed that ITGAM SNP rs1143679 is highly associated with SLE. We identified an independent, SLE-predisposing ITGAM SNP rs35472514, ITGAX SNP rs13332545 in HS, and potential population specific SNPs rs62051471 and rs12928810.

Replication in Korean women of an association between a common variant in the breast cancer susceptibility gene, ZNF365, and a mammographic density measure that predicts breast cancer: The Healthy Twin Study. *M. Lee[1], J. Lee[1], D.H Lee[1], Y.M Song[2], K. Lee[3], J. Stone[4], J. Hopper[4], J. Sung[1].* 1) Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology and Institute of Environment and Health, School of Public Helath Seoul National University, Seoul Korea; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, Seoul Korea; 3) Department of Family Medicine, Busan Paik Hospital, Inje University College of Medicine, Busan Korea; 4) Centre for Molecular, Environmental, Genetic and Analytic Epidemiology, University of Melbourne, Australia.

Mammographic density (MD) for age and BMI is a major risk factor for breast cancer (BC), the most frequent cancer in women worldwide. BC is one of the most rapidly increasing cancers in Asian women; age at onset of BC in East Asian women tends to be younger and mammographically `dense' breasts more common than in Western women. Although an association between MD and BC risk has yet to be formally established in Asian women, the authors have shown that MD has similar genetic variance in Korean and Caucasian women (heritability of 0.6~0.7) despite the differences in their BC and MD epidemiology. We attempted to further dissect the genetic etiology of MD by identifying candidate genetic variants and comparing them with the recent findings from genome-wide association (GWA) studies on MD and BC. The Healthy Twin study recruited twin-families from 2005 to 2011 in Korea. Clinical information, epidemiological data and MD values were collected. A total of 583 women with MD values from 314 families were included in the genetic analysis. Family-based GWA method was adopted to investigate causative variants for MD variation (FBAT and QTDT). The common variant rs10995205 in the gene ZNF365, a known susceptibility variant for BC in Caucasian women, was replicated as being associated with MD adjusted for age in Korean women ($p = 0.008$). The C allele (frequency = 80 %) was associated with an increase in MD by 32% and 42% for having one or two more C alleles, respectively. Significantly associated SNPs were also found in 13q14.11 and 13q31.1 as well as in 1p13.3 ($p< 10-6$). Additive effects of specific allele in several SNPs on MD values were investigated. Additionally possible candidate variants with p-value less than 10-5 were identified in chromosomes 2, 3, 6, and 8. This study replicated in Korean women the association between ZNF365 which has been associated with MD and BC in studies with Caucasian women. We also found variants in several regions responsible for variation in MD. These findings suggest that at least some of the genetic causes of the association between MD measures and BC risk are common to Asian and Caucasian women.

Searching for modifiers of age-at-onset in familial amyloid polyneuropathy (FAP) ATTRV30M : a candidate gene approach. *D. Santos[1], T. Coelho[2], J.L. Neto[1], J. Pinto-Basto[1,3], J. Sequeiros[1,3], I. Alonso[1,3], C. Lemos[1,3], A. Sousa[1,3].* 1) UnIGENe, IBMC, Porto, Porto, Portugal; 2) Unidade Clínica de Paramiloidose, Centro Hospitalar do Porto (CHP), Porto, Portugal; 3) ICBAS, Instituto Ciências Biomédicas Abel Salazar, Univ. Porto, Portugal.

Familial amyloid polyneuropathy (FAP) is a monogenic disease caused by mutations in the transthyretin (TTR) gene (chr18q12.1). This disease is an autosomal dominant type of systemic amyloidosis and is characterized by amyloid deposition of mutated fibrillar TTR. The main clinical expression is a progressive peripheral sensori-motor and autonomic neuropathy. Of all FAP-related mutations described in the TTR gene, the most frequent is V30M which is associated with clusters in Portugal, Japan, Sweden, Majorca and Brazil, known for their remarkable differences in age-at-onset (AO). However, and most importantly, among Portuguese families although the same mutation is present, FAP shows a wide variation in AO (17-80 yrs) and even with asymptomatic carriers aged 93. This variability is also evident between generations. Also, significant differences in AO regarding gender are known in Portuguese serie, suggesting that sex hormones may have a modifier role in the disease onset, affecting the expression levels of TTR. In mice, 5-alpha-dihydrotestosterone has a stronger inducer effect in TTR expression than 17-beta-estradiol, which may explain a significantly earlier onset in men, in most populations. Genes found to be upregulated in FAP may also act as modifiers. Our aim was to study 11 candidate-genes as genetic modifiers of AO in FAP ATTR V30M. We analysed a sample of 100 FAP families with at least 2 generations affected. Through the degree of linkage disequilibrium (LD) existing between SNPs, 73 tagging SNPs were selected (with a minor allele frequency of 0.1%). The SNPs frequencies in the European population were obtained resorting to the Hapmap (http://www.hapmap.org/), using Haploview v.4.1 to plot LD patterns and to select the tagging SNPs. The SNPs in study were divided in four sets, and genotypes are being analysed in three 19-plex and one 16-plex multiplex SNaPshot® (Applied Biosystems) assays. SNaPshot® is an efficient and sensitive multiplexing SNP typing method. Results are being analyzed with the GeneMapper™ v4.0 software. The samples' genotyping for 73 SNPs is currently in an optimization stage, and a preliminary analysis is underway. Allelic or haplotypic frequencies will be compared in classic- (early-) and late-onset patients groups. We expect to find or exclude the potential role of a selected number of candidate genes as modifiers of FAP ATTR V30M, in order to better understand the mechanisms involved in AO variability.

***In silico* candidate gene study for childhood tooth decay.** *J.R. Shaffer[1], Z. Zeng[1], X. Wang[2], M. Lee[2], K. T.Cuenco[2], M.M. Barmada[1], D.E. Polk[3], R.J. Weyant[3], R. Crout[4], D.W. McNeil[5], D.E. Weeks[1], E. Feingold[1], M.L. Marazita[1,2].* 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Center for Craniofacial & Dental Genetics, Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 3) Department of Dental Public Health and Information Management, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Department of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 5) Dental Practice and Rural Health, West Virginia University, Morgantown, WV.

Dental caries (*i.e.*, tooth decay) is one of the most common chronic diseases in children and leads to several associated health and social problems including chronic pain, tooth loss, difficulty hearing, eating, and sleeping, failure to thrive, poor school performance, poor social relationships, and decreased success later in life. As a multi-factorial disease, it is the result of a complex interplay of genetic and environmental factors. Despite the high heritability (30-60%), few specific risk genes have been identified. We generated a list of 140 candidate genes on the basis of a variety of lines of evidence supporting possible roles in cariogenesis including known enamel, saliva, and taste preference genes, MMP genes, FGF genes, and WNT signaling pathway genes (all regulators of odonogenesis), and other genes implicated in linkage or association studies and/or animal models. As a complementary analysis to our genome-wide association scan (GWAS), we performed an *in silico* candidate gene study by testing 1440 SNPs in these *a priori* candidate genes for association with childhood dental caries. Two phenotypes were considered: the number of carious pit and fissure tooth surfaces (PF, *i.e.*, molar surfaces where the enamel folds inward) and smooth tooth surfaces (SM, *i.e.*, all non-PF surfaces). 596 samples of European ancestry were included for analysis of SM caries (ages 3 to 12 years); 572 samples were included for PF caries (age 4 to 14 years). All analyses were adjusted for the effects of age and age^2. Bonferroni adjustment was used to correct for multiple comparisons at the gene-level (*i.e.*, 140 genes, (= 0.00036). After correcting for multiple comparisons, the known cariogenic gene CD14 was associated with both SM caries and PF caries (rs702399, p = 0.0001 for both). The osteogenesis gene BMP6 (rs11760020, p = 0.0003) and the SHH pathway gene GLI1 (rs=3741414, p = 0.00002) were associated with SM caries only. Taken together, SNPs in *a priori* candidate genes exhibited a modest excess of association with SM caries than expected by chance alone (*i.e.*, 8.3% yielded p-values < 0.05). This finding suggests that our list may include other potential caries genes. Additional work is needed to determine the effects of these genes, if any, on dental caries. Goldilocks variants: prevalence and significance in association studies. *D. Waterworth[1], L. Warren[2], M. Ehm[2], M. Nelson[2], V. Mooser[1].* 1) Genetics, GlaxoSmithKline, King of Prussia, PA; 2) Genetics, GlaxoSmithKline, Research Triangle Park, NC.

As the GWAS era wanes and sequencing approaches come to the fore, questions around the utility of rare or low frequency variation arise. A few tantalizing functional “goldilocks” variants, here defined as ~0.5-2% MAF and putatively functional, have been discovered in early sequencing experiments, such as in the example of PCSK9, which proved to be informative for understanding this gene, its role in disease and the potential for pharmacotherapy. How often will goldilocks variants be present? 202 drug target genes were sequenced in 14,002 mostly Caucasian individuals with a variety of diseases and medically relevant traits. Variants were considered putatively functional if they met the criteria for any of the 3 in silico methods (SIFT, PolyPhen and PhyloP). Out of a total number of 38535 variants detected in Caucasians, 53 were goldilocks (0.14%). On a per gene basis, these 53 goldilocks variants were found in 41 genes, representing 20% of the genes sequenced. A higher percentage of non-synonymous variants were putatively functional within the goldilocks frequency range (53/105-50%) as compared to variants with greater than 2% frequency (45/154-29%). Two deeply phenotyped studies, GEMS (dyslipidemia case-control, n=1583) and Lausanne (population-based, n=2086) were analyzed for association over a range of cardiovascular and inflammatory phenotypes. Variants with MAF>0.2% were analyzed individually whilst putative functional variants including non-synonymous, nonsense, splice and readthrough variants with MAF < 0.2% were aggregated (104157 tests - 42 traits and 108329 tests - 45 traits, respectively). We evaluated how many of our top association results were with goldilocks variants. In both the GEMS and Lausanne analysis, 5 out of 11 significant associations (p<3.6e-5) were with goldilocks-type variants, whereas 0 would be expected by chance. These included ADIPOQ with adiponectin (MAF=0.015; P = 2.2E-17), EDNRA and IL-18 (MAF= 0.004; P=8.8E-8), and TACR2 and waist (MAF=0.004; P=1.5E-5). These variants exhibited particularly large effect sizes, from 0.7-2SD difference between carriers and non-carriers. In summary, goldilocks are particularly informative variants, however only ~20% of genes were found to contain putative goldilocks variants and they represent only 0.14% of the total variants generated by sequencing. Additionally, only about one third of them are imputable (r2 > 0.7), thus resequencing is often required to detect these variants.

Common genetic variants underlie endometriosis and obesity-related traits. *N. Rahmioglu[1], H.R. Harris[2], S. Macgregor[3], A. Morris[1], G.W. Montgomery[3], S.A. Missmer[2], C.M. Lindgren[1], K.T. Zondervan[1], The International EndoGene Consortium, The GIANT Consortium.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Brigham and Women's Hospital and Harvard Schools of Medicine and Public Health, Boston, MA, USA; 3) Queensland Institute for Medical Research, Herston, Queensland, Australia.

Lower body mass index (BMI) and waist-hip ratio (WHR) have previously been associated with an increased risk of endometriosis in epidemiological studies. As both endometriosis and obesity-related traits are heritable, we aimed to investigate the potential commonality (pleiotropy) in genetic variants underlying their aetiology and identify common pathogenic pathways, using data from three large-scale genome-wide association studies (GWAS). The IEC GWAS included data for ~500,000 genotyped SNPs on 3,194 endometriosis cases (42.7% rAFS III/IV) and 7,060 controls from the UK and Australia; the GIANT Consortium BMI GWAS included data on ~2,400,000 genotyped and imputed SNPs for 32,387 individuals; the GIANT WHR-adjusted for BMI (WHR-adjBMI) dataset on ~2,850,000 genotyped and imputed SNPs for 190,803 individuals. All individuals in the three datasets were of European ancestry. Overlap between endometriosis signals (all cases and rAFS III/IV only) vs. BMI and WHR-adjBMI signals, effectively ~500,000 SNPs, were investigated systematically through genetic enrichment analyses using binomial exact tests and polygenic prediction modelling. The top SNP previously found to be significantly associated with increased risk of endometriosis, rs12700667 on chromosome 7 (all endo: p=2.6x10-7; rAFS III/IV: p=1.5x10-9), had a p-value of 4.4x10-5 in the WHRadjBMI GWAS and marked one of 13 reported genome-wide significant loci associated with lower WHRadjBMI. Further comparison of results showed significant enrichment for 5 SNPs (binomial p≤0.009) and similarly opposite directions of effect between the traits, including rs10919299 in close proximity to the selectin gene family, rs7521902 upstream of WNT4 (wingless-type MMTV integration site family), rs1250248 in FN1 (fibronectin1), and rs6556301 in FGFR4 (fibroblast growth factor receptor). Enrichment between genetic variants involved in endometriosis and BMI was less pronounced (3 SNPs with binomial p≤0.01). Here we identify support for pleiotropy in genetic variants underlying endometriosis and obesity-related traits, and pinpoint several novel genetic loci with plausible biological candidacy. Ongoing work, involves replication and regression modeling of these pleiotropic loci in the Nurses Health Study on both endometriosis and obesity-related traits to investigate their correlation and the potential influence of covariates further.

Genes associated with cephalometric variation in the Tricho-Dento-Osseous syndrome. *M.E. Cooper[1], M. Govil[1], M.A. Torain[2], T.C. Hart[3], M.L. Marazita[1], J.T. Wright[2].* 1) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 2) Dept. of Pediatric Dentistry, University of North Carolina, Chapel Hill, NC; 3) Department of Periodontics, University of Illinois at Chicago, Chicago, IL.

Individuals with the extremely rare tricho-dento-osseous syndrome (TDO) exhibit marked variation in their hair, tooth enamel thickness and progressive bone density. TDO syndrome results from a 4G deletion in the DLX3 gene on 17q21, a transcription factor that is important in the development of many different tissues. The objective of this study is to evaluate genotypes contributing to observed variations in the TDO bone density phenotype in TDO affected individuals. **Methods**: Twenty-two Cephalometric measures were evaluated from radiographs. These measures were then normalized using age-by-gender published standards if available, otherwise the individual's age and gender. Thirty-seven TDO individuals with 2-22 Cephalometric measures were successfully genotyped using 10K SNP Chips (Affymetrix USA). Simple linear regression, as implemented in PLINK, was used to test for association. The analysis was repeated with a subset of 18 unrelated or very distantly related TDO individuals. **Results**: The full sample had 73 SNPS from 22 chromosomes for 18 phenotypes with p-values <E-04. Six SNPs achieved p=E-06. Three SNPS with p=3.55E-06 were associated with the ANS_Me (Anterior vertical mandibular height) (chr1_rs953653, chr3_rs1398735, chr14_ rs728497 in RGS6 gene). Six SNPS were associated with multiple cranial measures at the p<E-05 level; four SNP pairs involve the Go landmark (gonion- posterior mandible) extending to S (sella) or to Ar (articulare-point at the mandible ramus) ï¿½ essentially posterior mandibular heights. SNP chr2-rs699662 is associated with S-GO(Posterior mandibular vertical position) as well as Co-Gn (total mandibular length). SNP chr3-rs1391962 is associated with 2 facial depth measures: (S-N or anterior cranial base)and N-Ba. The cranial measure Glabella had 3 SNPs associated at the p=E-06 level and another 5 SNPS at the p=E-05 level. The 18-person subset had 28 SNPs associated with the N_S_Ar angle (p=4E-05, 9 individuals); but this is very possibly an inflated result as the regression had to be adjusted using the subjects age and sex as no published data for children less than 18 years existed. **Conclusions**: Despite the small sample size, several associations approached Bonferroni significance levels of p ≤ 5E-06, providing evidence for a relationship between TDO cranial densities and particular SNPs and potentially several genes of interest that may be important in bone formation. Clinical and Genetic Epidemiology of Bardet-Biedl syndrome in Tunisia. *O. MHAMDI[1], I. Ouertani[1,2], H. CHAABOUNI BOUHAMED[1,2].* 1) Department of Human Genetics, Faculty of Medicine Tunis, Tunis, Tunisia; 2) Department of congenital and Hereditary diseases, Charles Nicolle hospital Tunis. Tunisia.

Abstract Bardet-Biedl syndrome is a ciliopathy causing multivisceral abnormalities. This disease is defined by a combination of cardinal features: obesity, post axial polydactyly, hypogonadism, intellectual disabilities, pigmentary retinopathy and renal deficiency. The prevalence of BBS in Europe ranges from 1/125000 to 1/160000. In some isolated populations over the world, it was estimated 1 in 17000 in Bedouins of Kuwait and 1 in 18000 in Newfoundland. We report in the present study the first epidemiological study of BBS in North Africa. Aim: The aim of this study was to evaluate the epidemiological criteria and estimating the current prevalence of BBS in Tunisia. Methods: A three pages of clinical analysis index card requesting details of the patient's birth and delivery, age at diagnosis. Information's was sought including consanguinity, geographic origin, height, weight, presence or absence of limb abnormalities, presence of rod/cone dystrophy, renal abnormalities, development delay, hypogonadism in males and other minor criteria including learning disabilities, disorders of speech language, ataxia and other medicals problems. Results: From 1984 to 2009, 46 Tunisian families including 67 affected members were diagnosed as BBS. Consanguinity was highly in our group 93.47 %. The overall minimum prevalence of BBS in Tunisia was found to be approximately 1 in 156 000. This frequency increases in the north, 1 in 87000, which is about 2 times higher than the figure from the overall country. In spite of limited study, our report showed that BBS was an uncommon disease in Tunisia and this result may be reflecting the actual frequency of BBS in North Africa where the disease seems uncommon.

A Comprehensive Evaluation of SNP Weighting Schemes for the Analysis of Uncommon Genetic Variants. *A. Byrnes[1], Y. Li[1, 2], M. Li[3].* 1) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 2) Department of Genetics, University of North Carolina, Chapel Hill, NC; 3) Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, PA.

Genome Wide Association Studies (GWAS) have, and continue to, generate a wealth of genomic data on millions of individuals. As this technology becomes less costly, larger studies become possible thus increasing the power to detect even variants of low frequency or small effect size. Simultaneously, massively parallel sequencing is generating an unprecedented amount of data, including direct measurements of uncommon genetic variants. These data provide an opportunity to more systematically examine the effects uncommon variants exert on complex human diseases and traits. Several methods currently exist to aggregate information across SNPs to implicate regions in which uncommon variants contribute to phenotypic variation. However, there is little consensus on which method is most effective. Two of the most important determinants are the weighting scheme adopted when aggregating information across SNPs and whether a method is robust when both risk and protective variants are present. Here we present a comprehensive evaluation of multiple weighting schemes through a series of simulations intended to mimic large case-control studies genotyped with a current-era GWAS chip (e.g. the Affymetrix Axiom and Illumina HumanOmni chips). We evaluate data-independent and data-dependent methods, as well as a novel method that constructs weights by combining information from regression coefficients, minor allele frequency, and functional annotation. We examine the performance of each of these methods in simulations where there are both single and multiple contributing uncommon variants. In addition, we investigate situations in which variants contribute in the same direction and those in which variants contribute in different directions. The results provide practical guidelines regarding the choice of weighting scheme under a wide range of scenarios so that current era association data can be utilized to implicate regions where uncommon variants may play an important role.

Association Testing Combining Family-Based and Case-Control Designs. *J.E. Cerise, W.C.L. Stewart.* Div. Stat. Genetics, Biostat, Sch. Pub. Health, & Psychiatry Dept., Columbia U., New York, NY.

Many genetic studies use case-control data as well as overlapping family data. Each contains information about association that the other lacks but, because these designs share an overlapping set of patients, the family-based and case-control association tests are correlated. Researchers often ignore the correlation, reporting each p-value separately. But this approach is inefficient and the overall evidence for association is often unclear. We present an efficient test that summarizes all the evidence for association by scaling the weighted average of the family-based and case-control test statistics; the weights vary in proportion to the corresponding sample size. In the simplest setting, our test is the standardized weighted average of the transmission disequilibrium test and the two-sample test of proportions (i.e. allele frequencies). The scaling factor, estimated from the parametric bootstrap, depends on the covariance between the family-based and case-control test statistics. Due to its increased efficiency, our combined test has notably more power to detect association than either test alone. Another attractive feature is that the same bootstrap procedure can provide estimates of the critical value for testing. This is useful if either the family-based or case-control test is non-normal (e.g. chi-squared). Also, if controls are unavailable, an appropriate reference data set may be used. To assess the power of our combined test, we generated data at a single SNP using different genetic models, minor allele frequencies (MAFs), and levels of linkage disequilibrium (LD) between the SNP and a simulated disease locus. The phenotypes and family structures were taken from a real type 1 diabetes study. There were 325 controls, 323 disjoint cases, and 108 overlapping cases shared between the family-based and case-control designs. When the MAF, LD, gene frequency, and penetrance were 0.4, 0.3, 0.1, and 0.1, respectively, the family-based test had 33% power; the case-control test had 25% power; and our combined test had 58% power to detect an association. Other scenarios showed similar gains in power. In summary, we've developed a general framework for detecting association that integrates case-control and family data to increase power. Our test is implemented in the software package EAGLET, and is freely available for download from the web. This research was supported in part by the National Institutes of Health grants MH48858, MH65213, and NS27941.

Evaluating type 1 error in large pedigree analyses. *L.N. D'Aoust[1], A.C. Cummings[1], E. Torstenson[1], M.F. Davis[1], W.K. Scott[2], M.A. Pericak-Vance[2], M.D. Ritchie[1], W.S. Bush[1], J.L. Haines[1].* 1) CHGR, Vanderbilt University, Nashville, TN; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL.

Studying population isolates with large, complex pedigrees has many advantages for discovering genetic susceptibility loci; however, analyses can be quite complicated. Association tests need to be corrected for relatedness, and linkage analysis requires subdividing and simplifying the pedigree structure. The Modified Quasi-Likelihood Score (MQLS) test developed by Thornton and McPeek corrects for all pedigree relationships while testing for association with a binary trait, but simulations to evaluate type 1 error rates using pedigree structures as large and as complex as pedigrees in the Amish population have not been published. Additionally, the effect of pedigree splitting on linkage type 1 error rates also has not been evaluated extensively. We have extended GenomeSIMLA to simulate SNP data in complex pedigree structures based on template pedigrees to generate the same structure and distribution of sampled individuals. Using 1000 simulated pedigrees (124 null SNPs each) with the same structure as an Amish pedigree, we have evaluated type 1 error rates for MQLS and for 2-point and multipoint analyses using PedCut for pedigree splitting and Merlin for linkage analyses. We see no inflated type 1 error rate (5.06% for p-values ≤ 0.05 and 0.13% for a p-values ≤0.001) when using MQLS. Using PedCut-derived sub-pedigrees for linkage analysis, we see low type 1 error rates of 0.01% and 0.02% under dominant and recessive two-point models using an HLOD threshold of 3.0. Under dominant and recessive multipoint linkage models, we see type 1 error rates of 2.50% for both models using an HLOD threshold of 3.0. The average peak HLOD scores under the dominant and recessive multipoint models were 0.66 and 0.57, respectively. We also ran MQLS on the sub-pedigrees, and we see no change in type 1 error compared to running MQLS on the entire pedigree. Therefore, pedigree splitting does not seem to inflate type 1 error in large complex pedigrees such as those seen in the Amish population.

A fast algorithm to optimize SNP prioritization for gene-gene and gene-environment interactions. *W.Q Deng, G. Paré*. Department of Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, Ontario, Canada.

Detection of gene-environment interactions using exhaustive search necessarily raises the multiple hypothesis problem. While frequently used to control for experiment-wise type I error, Bonferroni correction is overly conservative and results in reduced statistical power. We have previously shown that prioritizing SNPs on the basis of heterogeneity in quantitative trait variance per genotype leads to increased power to detect genetic interactions. Our proposed method, Variance Prioritization (VP), selects SNPs having significant heterogeneity in variance per genotype using a pre-determined P-value threshold. We now suggest prioritizing SNPs individually such that the optimal heterogeneity of variance P-value is determined for each SNP. The large number of SNPs in genome-wide studies calls for a fast algorithm to output the optimal prioritization threshold for each SNP. In this report, we present such an algorithm, the Gene Environment Wide Interaction Search Threshold (GEWIST), and show that the use of GEWIST will increase power under a variety of interaction scenarios. Furthermore, by integrating over possible interaction effect sizes, we provide a framework to optimize prioritization in situations where interactions are *a priori* unknown.

Interpreting Meta-Analyses of Genome-Wide Association Studies. *B. Han[1], E. Eskin[1,2].* 1) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

Meta-analysis is an increasingly popular tool for combining multiple genome-wide association studies in a single analysis to identify associations with small effect sizes. The effect sizes between studies in a meta-analysis may differ and this difference, or heterogeneity, can be caused by many factors. If heterogeneity is observed in the results of a meta-analysis, interpreting the cause of heterogeneity is important because correct interpretation can lead us to a better understanding of the disease and an effective design of a replication study. However, interpreting heterogeneous results is difficult. The traditional approach examining the association p-values of the studies does not effectively predict if the effect exists in each study and utilizes only within-study information. In this paper, we propose a framework facilitating the interpretation of the results of a meta-analysis. Our framework is based on a new statistic representing the posterior probability that the effect exists in each study, which is estimated utilizing cross-study information. Simulations and application to the real data show that our framework effectively segregates the studies predicted to have an effect, the studies predicted to not have an effect, and the ambiguous studies that are underpowered. In addition to helping interpretation, the new framework also allows us to develop a new association testing procedure taking into account the existence of effect, which is shown to improve p-values at all six associated loci showing high heterogeneity in the Crohns disease data.

668W

Novel susceptibility loci for Crohn's disease, rheumatoid arthritis and type 1 diabetes identified using a data mining approach designed to detect weak associations. *G.E. Hoffman[1], B.A. Logsdon[1,2], J.G. Mezey[1,3].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Department of Genetic Medicine, Weill Cornell Medical College, NY, NY.

There has been mounting interest in identifying weak associations in genome-wide association studies (GWAS) using multiple-locus methods that incorporate tens to hundreds of thousands of genetic markers in a single statistical model using the widely applied framework of regularized regression. Yet high computational costs and concerns about performance have prevented widespread adoption by the GWAS community.

We applied a class of highly scalable regularized multiple-locus methods to mine datasets from the original Wellcome Trust Case Control Consortium (WTCCC) to identify new disease susceptibility loci. Our likelihood methods incorporated four penalties suggested to date for regularized regression analysis of GWAS data and we additionally implemented a variational Bayes algorithm that incorporates a statistically justified mixture penalty. Our algorithmic and implementation improvements allow us to simultaneously analyze hundreds of thousands of genetic markers and overcome the previous computational limitations that have prevented wider adoption of regularized multiple-locus methods. We also provide a novel method for assessing significance and the data-adaptive tuning of the strength of the penalties to facilitate substantial gains in the statistical power. We have made these implementations available in a user-friendly software package.

Our re-analysis of the WTCCC identified associations for Crohn's disease, rheumatoid arthritis and type 1 diabetes. These associations re-capitulated all of the non-marginal associations discovered in the original WTCCC analysis and also identified additional susceptibility loci that were too weak to be significant in the original analysis. Of these latter associations, over 25 were identified in an independent GWAS of the same or etiologically similar phenotype. Another 20 novel associations were too weak to be detected by standard single marker methods, yet they implicate loci known to play a role in disease etiology or are known to function in a relevant biological pathway. We also identified additional novel loci with no previously reported link to these autoimmune diseases. These results establish the power of multiple-locus methods to extract additional biologically relevant information from existing GWAS datasets as well as emerging next-generation sequencing datasets.

669W

A combined functional annotation score for non-synonymous variants. *M.C. Lopes[1,2], C. Joyce[1], F. Cunningham[3], S.L. John[4], J. Asimit[1], E. Zeggini[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) European Bioinformatics Institute, Hinxton, Cambridge, United Kingdom; 4) Pfizer, Groton, Connecticut, United States.

Next generation sequencing has opened the possibility of large-scale sequence-based disease association studies. A major challenge in interpreting whole-exome data is predicting which of the discovered variants are deleterious or neutral. To address this question, in the absence of further experimental research, several functional-annotation tools focusing on the analysis of non-synonymous coding variants (ns variants) have been implemented. We have developed a score called **C**ombined **A**nnotation sco**R**ing to**OL** (CAROL), which combines information from two bioinformatics tools: PolyPhen-2 and SIFT, in order to improve the prediction of the effect of ns variants. We used a weighted-*Z* method, which combines the ratio of the probability of the variant amino acid ($P_{(v,i)}$) to the probability of the wild-type amino acid ($P_{(w,i)}$) occurring at each position (*i*) from protein alignments. The algorithm used for the weighting method equals the inverse of the log-likelihood probability of substituting wild-type amino acid (*w*) for the variant amino acid (*v*). We defined two dataset pairs to train and test CAROL using information from the dbSNP, `HGMD-PUBLIC' and 1000 Genomes Project databases. The training pair comprises a total of 1000 positive control (disease-causing) and 5,100 negative control (non-disease-causing) variants. The test pair consists of 1,944 positive and 10,206 negative controls. CAROL was found to have good predictive power for the effect of non synonymous variants, and had a higher predictive accuracy than each individual annotation tool (Polyphen-2 and SIFT). In addition to this, CAROL had the distinct advantage of higher coverage. The combination of annotation tools can help improve automated prediction of whole-genome/exome non-synonymous variant functional consequences.

Comparison of genome-wide association genotyping products for imputation of low-frequency and rare variants. *A. Mahajan[1], B. Howie[2], C. Fuchsberger[3], R.D. Pearson[1], K.J. Gaulton[1], N. Robertson[1], N.W. Rayner[1,4], Y. Chen[1], I. Prokopenko[1,4], M.I. McCarthy[1,4], A.P. Morris[1] on behalf of the GoT2D Consortium.* 1) WTCHG, University of Oxford, Oxford, United Kingdom; 2) Department of Human Genetics, University of Chicago, Chicago, USA; 3) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 4) OCDEM, University of Oxford, Oxford, UK.

Imputation methods are widely used in the analysis of genome-wide association studies (GWAS). These methods predict genotypes at untyped variants present on high-density reference panels, like those made available through the 1000 Genomes project. For any reference panel, the success of genotype imputation at an untyped variant depends crucially on: (i) the "scaffold" of variants typed in the GWAS samples; and (ii) the minor allele frequency (MAF) of the variant. We undertook imputation in 314 type 2 diabetes (T2D) cases genotyped using two GWAS scaffolds: (i) the Affymetrix GeneChip 500K Mapping Array Set (A500K); and (ii) the Illumina Omni2.5 BeadChip (O2.5M). Imputation was performed using IMPUTEv2 and the 1000 Genomes European (EUR) reference panel (August 2010 release) across 27 established T2D susceptibility loci (6.2Mb of the genome). For each scaffold, we evaluated the proportion of variants, $\hat{\beta}$, not genotyped on either chip, that were "well" imputed (info $\geq$ 0.4). There was little difference in imputation quality between scaffolds for common variants (MAF $\geq$ 5%; A500K $\hat{\beta}$=0.912, O2.5M $\hat{\beta}$=0.941). However, there were substantial improvements in quality using the O2.5M scaffold for low-frequency variants (1%$\leq$MAF<5%; A500K $\hat{\beta}$=0.686, O2.5M $\hat{\beta}$=0.879; 28% improvement) and rare variants (MAF<1%; A500K $\hat{\beta}$=0.150, O2.5M $\hat{\beta}$=0.245, 63% improvement). We assessed concordance between "predicted" genotypes (posterior probability $\geq$ 90%) at well imputed variants with "truth" genotypes in 108 overlapping samples sequenced by the UK component of the GoT2D Consortium. However, our analysis showed no clear difference in concordance rates between scaffolds. Our empirical observations were confirmed through simulations using the EUR reference panel for chromosome 22. Our simulations demonstrated that imputation from the O2.5M scaffold substantially increased the posterior probability of the correct genotype call for common variants (A500K 91.6%, O2.5M 96.2%). This increase was most noticeable when the correct genotype was heterozygous (A500K 86.3%, O2.5M 93.3%) or homozygous for the minor allele (A500K 67.9%, O2.5M 75.0%). The results of our study highlight that a dense GWAS scaffold, such as O2.5M, provides improved quality of imputation for low-frequency variants, and increased accuracy in genotype prediction at well imputed common variants. However, more costly re-sequencing experiments will be required to recover high-quality genotype calls at rare variants.

ParaHaplo 3.0: A program package for imputation and a haplotype-based whole-genome association study using hybrid parallel computing. *K. Misawa[1], N. Kamatani[2].* 1) Research Program for Computational Sciences, Riken, Yokohama, Kanagawa, Japan; 2) Center for Genomic Medicine, RIken, Yokohama, Kanagawa, Japan.

Background: Use of missing genotype imputations and haplotype reconstructions are valuable in genome-wide association studies (GWASs). By modeling the patterns of linkage disequilibrium in a reference panel, genotypes not directly measured in the study samples can be imputed and used for GWASs. Since millions of single nucleotide polymorphisms need to be imputed in a GWAS, faster methods for genotype imputation and haplotype reconstruction are required.

Results: We developed a program package for parallel computation of genotype imputation and haplotype reconstruction. Our program package, ParaHaplo 3.0, is intended for use in workstation clusters using the Intel Message Passing Interface. We compared the performance of ParaHaplo 3.0 on the Japanese in Tokyo, Japan and Han Chinese in Beijing, and Chinese in the HapMap dataset. A parallel version of ParaHaplo 3.0 can conduct genotype imputation 20 times faster than a non-parallel version of ParaHaplo.

Conclusions: ParaHaplo 3.0 is an invaluable tool for conducting haplotype-based GWASs. The need for faster genotype imputation and haplotype reconstruction using parallel computing will become increasingly important as the data sizes of such projects continue to increase. ParaHaplo executable binaries and program sources are available at http://en.sourceforge.jp/projects/parallelgwas/releases/.

Privacy preserving meta-analysis of sequencing-based association studies. *I. Pe'er, R. Banerjee, S. Zafer.* Dept Comp. Sci, Columbia Univ, New York, NY.

Human genetics recently transitioned from GWAS to studies based on NGS data. For GWAS, small effects dictated large sample sizes, typically made possible through meta-analysis by exchanging summary statistics across consortia. NGS studies groupwise-test for association of multiple potentially-causal alleles along each gene. They are subject to similar power constraints and therefore likely to resort to meta-analysis as well. The problem arises when considering privacy of the genetic information during the data-exchange process. Many scoring schemes for NGS association rely on the frequency of each variant, and therefore standard meta-analysis would require exchanging the identity of the sequenced variant. As such variants are often rare, potentially revealing the identity of their carriers, such disclosure jeopardizes privacy. We tackle the challenge of tallying frequency counts of rare, sequenced alleles between consortium members, for meta-analysis of sequencing data without disclosing the allele identity and counts, thereby protecting sample identity. This apparent paradoxical exchange of information is achieved through cryptographic means. The key idea is that parties encrypt identity of genes and variants. When they transfer information about frequency counts in cases and controls, the exchanged data does not convey the identity of a mutation, therefore does not expose carrier identity. The parties use identical encryption key, thus identical variants will be encrypted identically. One could therefore sum up the counts for identical variants, without knowing the identity of the alleles whose counts are being tallied. We have developed a protocol for such meta-analysis of genomewide sequencing data, scoring association for rare variants pooled per gene. The exchange relies on a 3rd party, trusted to follow the protocol although not trusted to learn about the raw data. The 3rd party only sums up counts of encrypted variants within encrypted-name genes and computes the per-gene score without learning about the sequenced variants. For some groupwise testing methods, the counts may also be encrypted, with the 3rd party tallying counts through partially homeomorphic encryption, without knowing the counts themselves. We show applicability of this method to publicly available exome-sequencing data from multiple studies, simulating phenpotypic information for meta-analysis. The protocol is publicly available as open source.

Hardy-Weinberg Equlibrium in Triad Designs. *M. Rao[1], S. Venkatesan[2], S. Kasala[3].* 1) Environmental Hlth, Univ Cincinnati, Cincinnati, OH; 2) Department of Biomedical Engineering, Univ Cincinnati, OH; 3) Department of Mathematics and Statistics, Univ North Carolina, Wilmington, NC.

The focus of a triad design is identifying a bi-allelic SNP associated with a disease of interest. The case is one with the disease. The parents of the case are inducted into the study thus constituting a triad. All three members of the triad are genotyped at the SNP. The data consist of a random sample of such triads. The goal of this research is to test Hardy-Weinberg Equilibrium of the population at the SNP. A large sample chi-squared test can be used to test the validity of Hardy-Weinberg Equilibrium. There is no direct exact test a la Fisher available. We develop an exact test in a novel way using algebraic statistics methodology and invoking Markov Chain Monte Carlo algorithm. The key idea is to enumerate all possible triad data sets (fiber) with exactly the same allele frequencies provided by the given triad data set. Algebraic statistics methodology provides a way to get a handle on the fiber and a minimal markov basis provides a deep insight into the fiber.

KELVIZ: A Graphing and Annotating Tool for Statistical Evidence in Human Genetics. *S. Seok, B. Nouanesengsy, V. Vieland.* BCMM, Nationwide Children's Hospital, Columbus, OH.

KELVIZ is a custom built graphing application designed to plot output from KELVIN, a software package implementing the PPL statistical framework for linkage and/or association analysis. The program can also be used to graph other statistics, such as p-values, LODs, etc. Current options in KELVIZ include plots over the genome, groups of chromosomes, or specified regions, while allowing for overlap of multiple sets of results. Additional features include a flexible set of options for custom annotations, either input from files or manually edited, zooming, adding comments, and overlaying marker maps. A variety of options for displaying and saving graphs are provided. Graphs can also be saved in a custom file format, for reuse and further editing at a later data. This feature, similar to the “FIG” file used in MATLAB, efficiently facilitates collaboration efforts for graph creation. KELVIZ also provides a non-GUI command-line interface to expedite and automate the generation of graphs. KELVIZ is a graphical user interface (GUI) program written in Python and it uses the Matplotlib graphing library. It is a cross-platform application that has been shown to work on Windows, Mac, and Linux.

A tool to test for functional enrichment of GWAS hits. *C. Tang, M. Ferreira.* Genetic Epidemiology, Queensland Inst Med Research, Brisbane, Australia.

To facilitate the interpretation of GWAS results, we developed a tool that integrates and annotates the genomic, transcriptional and epigenetic properties of genetic variants (e.g. protein-coding, conservation, CpG islands, eQTL and transcriptional factor binding site) from various biological databases. Our software allows users to upload summary statistics from a GWAS and not only pinpoint the functionally important variants amongst GWAS hits but also to directly test various biological hypotheses by performing functional enrichment analysis. It also incorporates findings from recent, large published GWAS to test for shared genetic components across different phenotypes. We illustrate the applicability of this approach through the analysis of several published GWAS results.

676W

Sex specific prediction of genomic segments shared IBD by family members, with applications in disease mapping by family based sequencing. *M. Vigeland.* Department of Medical Genetics, Oslo University Hospital, Oslo, Norway.

We present an R package - IBDsim - for simulation and statistical processing of segments shared identically by descent (IBD) by pedigree members. The package provides flexible IBD simulation imposing few restrictions on the user, as well as offering specialized functionality for family based disease mapping. The recent advances in sequencing technology have made possible mapping of disease-causing mutations in families too small for traditional linkage analysis. By comparing sequence data from several family members, genomic regions not compatible with the observed segregation pattern are excluded to reduce the number of false positive variants. A well known example of this approach is autozygosity mapping, in which non-homozygous regions of inbred patients are excluded in search for recessive disease loci. Power assessment in exclusion mapping involves predicting how much of the genome that can be excluded. While expected values are easy to compute from Mendel's laws, one can go much further using simulations. In particular the distributions of the number and size of random IBD segments, and the size of the disease segment, are important tools both for power computations and in evaluating identified segments. Compared with existing IBD predicting software, IBDsim has several advantages. Building on an inhomogeneous χ^2 model for recombination, it incorporates up-to-date sex specific recombination maps of the human genome (Decode, 2010). The sizes of IBD regions are reported in physical length rather than genetic, giving researchers a direct indication of how much sequence will remain after the exclusion process. The use of male/female specific maps instead of averaged maps has a large impact on the distribution of IBD segments. For example, in a family with one parent and three offspring affected by an autosomal dominant disease, the expected length of the shared disease-containing haplotype is 65 Mb if the father is the affected parent, but only 37 Mb if the mother is affected. By taking advantage of the R environment, users of IBDsim can investigate the simulated IBD distributions in great detail. As an example we take a modern look at some classical results concerning relatedness, like the probability that two related individuals have no segments in common IBD. While the theoretical results agree well with the simulations for average pedigrees, the probabilities are shown to be highly dependent on the gender distributions within the pedigree.

677W

An algorithm for splitting and trimming large pedigrees. *Q. Yang[1,2], M. Chen[1,2,3].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 2) The NHLBI's Framingham Heart Study, Framingham, MA, USA; 3) Department of Neurology, Boston University School of Medicine, Boston, MA, USA.

In genome-wide association studies (GWAS) with family data, it is possible to impute missing genotypes for un-genotyped individuals who have genotyped relatives. Including these additional samples with phenotypes and imputed genotypes in GWAS can substantially increase the power to detect an association. Large pedigrees however pose particular difficulty because the computation load in imputation increases exponentially with family size. To enable using as much familial genotype information as possible in imputing genotypes for each un-genotyped individual given computational limitations, we propose an algorithm for splitting and trimming large pedigrees into smaller pedigrees that maximize the genotyped relatives for each un-genotyped individual while keeping the new pedigree size within user-specified limit. The algorithm is described as follows: First we form clusters of related un-genotyped individuals within a pedigree. We then include genotyped blood relatives of each cluster member to construct a sub-pedigree for each cluster. If the bit size of the sub-pedigree is not close to the user-specified limit, we further include genotyped blood relatives of spouse and genotyped offspring of each cluster member. If the bit size of a sub-pedigree is greater than the user specified limit, we compute the numbers of closest, 2nd, 3rd, 4th, and 5th closest cluster members as scores for each genotyped person. From the bottom level of the sub-pedigree, we remove persons by the rank of the scores and if the bit size is still greater than the limit, we move up to the next level. The procedure repeats until the bit size is less than the limit. If the bit size is not close to the limit, we add back genotyped persons so that the bit size is as close to the limit as possible. We apply our algorithm to the Framingham Heart Study sample. Among about 1,200 selected un- or ill- genotyped persons, the products of our algorithm, the split sub-pedigrees keep 99.7% and 82% of their genotyped 1st and 2nd degree relatives, respectively. These split sub-pedigrees are used to impute the genotypes of the 1,200 persons which increases the sample size and thus the statistical power to identify genetic variants. We will use a GWAS to compare the results with and without using the imputed sample.

678W

Copy number variations detection using family data. *J. Chu[1], I. Ionita-Laza[2], A. Rogers[1], K. Darvishi[1], R. Mills[1], G. Maier[1], B. Klanderman[1], C. Lee[1], B. Raby[1].* 1) Brigham & Women's Hosp, Boston, MA; 2) Columbia University, New York, NY.

In recent years there has been a growing interest in the role of copy number variations (CNV) in genetic diseases, which leads to the rapid development in technologies and statistical methods devoted to detection in CNVs from array data. To establish association between CNVs and diseases one would still have to overcome the noisy nature of the data, which remains a challenging problem. To help address the data quality issue we introduce a statistical framework for the intensity-based array data that takes into account the family information in detection of the CNVs. The method is based on the traditional methods for SNP genotyping in which the distribution of intensity data is modeled with a Gaussian mixture model and the samples are clustered into different copy number groups. In our method we perform the CNV calling for the whole family simultaneously, incorporating family information to reduce CNVs that are incompatible with Mendelian inheritance while still allowing de-novo CNVs. We applied this method to 403 asthmatic trios who were genotyped using a 180K Agilent CNV array. We found that our method substantially reduced Mendelian inconsistency in this dataset. In particular, in 50 CNV regions near or overlapped with an asthma candidate gene our method eliminated 68% of the CNVs calls with Mendelian inconsistencies, which are likely false positive. In conclusion, we have demonstrated that the use of family information can improve the quality of CNV calling and hopefully give more powerful association test of CNVs.

Cheek swabs, SNP chips, and CNVs: Assessing the quality of copy number variant calls generated with subject-collected mail-in buccal brush DNA samples on a high-density genotyping microarray. *S.W. Erickson, S.L. MacLeod, C.A. Hobbs.* Pediatrics, Univ Ark Med Sci, Little Rock, AR.

Multiple investigators have established the feasibility of using buccal cytobrush samples to genotype single nucleotide polymorphisms (SNPs) with high-density genome-wide microarrays, but there is currently no consensus on the accuracy of copy number variants (CNVs) inferred from these data. To demonstrate the quality of CNVs generated from these samples and instruments, we evaluated the concordance of CNV calls from DNA extracted from blood to DNA extracted from subject-collected mail-in buccal cytobrushes (i.e. cheek swabs). The Illumina Human660W-Quad BeadChip was used to determine CNVs of 39 Arkansas participants in the National Birth Defects Prevention Study (NBDPS) who provided both whole blood and buccal brush DNA samples. Analysis of these genotypes revealed a 99.9% concordance rate of SNP calls in the 39 blood-buccal pairs. From the same dataset, we performed a similar analysis of CNVs. Each of the 78 samples was independently segmented into regions of like copy number using the Optimal Segmentation algorithm of Golden Helix SNP & Variation Suite 7. Across 640,663 loci on 22 autosomal chromosomes, segment-mean Log R ratios had an average correlation of 0.90 between blood-buccal pairs, while the correlation between unrelated pairs averaged 0.32. An independent analysis using the QuantiSNP algorithm produced average correlations of 0.94 between blood-buccal pairs versus 0.33 between unrelated pairs. These results show that DNA derived from subject-collected mail-in buccal-brush samples can be used for genome-wide scans of both SNPs and CNVs, and that high rates of CNV concordance were achieved whether using a change-point-based algorithm or one based on a hidden Markov model (HMM).

A Likelihood-Based Framework for Association Analysis of Allele-Specific Copy Numbers. *Y.J. Hu[1], W. Sun[2], D.Y. Lin[2].* 1) Biostatistics, Emory University, Atlanta, GA; 2) Biostatistics, University of North Carolina, Chapel Hill, NC.

Copy number variants (CNVs) and single nucleotide polymorphisms (SNPs) co-exist throughout the human genome and jointly contribute to phenotypic variations. Thus, it is desirable to consider both types of variations, as characterized by allele-specific copy numbers (ASCNs), in association studies of complex human diseases. Current SNP genotyping technologies can simultaneously capture the CNV and SNP information. The common practice of first calling ASCNs from the SNP array data and then using the ASCN calls in downstream association analysis has important limitations. First, the association analysis may not be robust to the differential errors between cases and controls caused by the differences in DNA quality or handling. Second, the phenotypic information is not used in the calling process and the uncertainties in the ASCN calls are ignored. We present a general framework for the integrated analysis of CNVs and SNPs in association studies, including analysis of total copy numbers as a special case. Our approach combines the ASCN calling and association analysis into a single step while allowing for differential errors. We construct likelihood functions that properly account for case-control sampling and measurement errors. We establish the asymptotic properties of the maximum likelihood estimators and develop EM algorithms to implement the proposed inference procedures. The advantages of the proposed methods over the existing ones are demonstrated through realistic simulation studies and an application to a genome-wide association study of schizophrenia. Extensions to next-generation sequencing data are discussed.

Detection of Copy Number Variation in Whole Exome Sequencing Data Using Read-Depth of Coverage. *J. Lihm[1,2,7], V. Makarov[1,2], T. O'Grady[6], G. Cai[1,2], N. Takahashi[2], E. Parkhomenko[1,2], M. Gazdoiu[2], J. Buxbaum[1,2,3,4,5], S. Yoon[1,2].* 1) The Seaver Autism Center for Research and Treatment, Mount Sinai School of Medicine, New York, NY; 2) Department of Psychiatry, Mount Sinai School of Medicine, New York, NY; 3) Department of Neuroscience, Mount Sinai School of Medicine, New York, NY; 4) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 5) The Friedman Brain Institute, Mount Sinai School of Medicine, New York, NY; 6) Gustave L. and Janet W. Levy Library, Mount Sinai School of Medicine, New York, NY; 7) Stony Brook University, Stony Brook, NY.

In order to elucidate genetic mechanisms of disease in a cost effective way, a large number of individuals are being sequenced in various studies using whole-exome sequencing (WES) technology, which enables researchers to perform a survey of the coding regions in a thorough and exhaustive search. To detect copy number variation (CNV) in WES data, we developed a robust and scalable method based on read-depth of coverage. Our method relies on read-depth calculation using 10bp-non-overlapping windows with separation of uniquely and multiply mapped reads, GC-correction, normalization and segmentation of the log-ratio of read-depths of a sample to read-depths of the selected reference. For a data-driven approach to optimizing the callset, we used as comparison validated CNV calls from individuals who were whole genome-sequenced in high coverage in the 1000 Genomes Project. Our analyses, and validation studies, show that both common and rare CNV can be captured by calls derived from our algorithm. More generally, calls based on read-depth can complement and/or confirm calls from other methods based on such information as paired-end and split-read data, for the comprehensive analysis of WES data. In a disease association study, the CNV calls as well as the log-ratio itself can be used for comparing cases to controls regardless of the size of samples used in the study. The application code “exome-cnv” is freely available for academic use from http://exome-cnv.sourceforge.net/.

Detecting chromosomal inversion polymorphisms using principal components analysis. *J. Ma, C. Amos.* University of Texas, M.D. Anderson Cancer Center, Houston, TX.

An inversion is a chromosome rearrangement in which a segment of a chromosome is reversed. In contrast to other types of structural variations, fewer inversion polymorphisms have been detected and characterized, because, unlike copy number variants, the allele intensity is unaltered and the alleles are mapped to their location on the reference genome. Inversions are usually detected using sequence-based and cytogenetic approaches, or unusual linkage disequilibrium (LD) patterns from high-density SNP data. Here, we propose to use principal components analysis (PCA) to detect inversion using genotype data. Because inversions suppress recombination when heterozygous, chromosomes with the inverted segment in different orientations represent two distinct lineages that have been diverging for many generations. Using genotype data in the inversion region, individuals can be classified as different "populations" according to their inversion genotypes, and this population structure can be readily detected using PCA. The pattern of the principal components scatter plot for an inversion region can be explained as a special admixture of "populations". Using the results of PCA, we can assign inversion genotypes to each individual in the sample. We used simulated data generated using the invertFREGENE software to demonstrate our method. We also applied our method to some real data sets and confirmed some of known inversion regions, such as the 8p23.1 and 17q21.31 inversions. Our method provides not only simple way to test association between disease and inversion polymorphisms, but also tool for correcting inversion-induced stratifications for association scan in an inversion region.

683W

Performances of copy number variant detection algorithms applied to SNP-array and impact on GWAS results. *G. Marennne[1,2], SJ. Chanock[3], L. Pérez-Jurado[4], N. Rothman[3], B. Rodríguez[4], M. Kogevinas[5], M. García-Closas[3], DT. Silverman[3], FX. Real[2], N. Malats[2], E. Génin[1].* 1) Inserm UMR-S946, Univ. Paris Diderot, Institut Universitaire d'Hématologie, Paris, France; 2) Centro Nacional de Investigaciones Oncológicas (CNIO) Madrid, Spain; 3) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Department of Health and Human Services, Bethesda, MD, USA; 4) Departament de Ciències Experimentals i de la Salut, Universitat Pompeu Fabra, Barcelona, Spain; 5) Institut Municipal d'Investigació Mèdica (IMIM-Hospital del Mar), Barcelona, Spain.

SNP-arrays developed to perform genome-wide association studies are also applied to detect copy-number variants (CNV) and, to this end, several CNV calling algorithms have been proposed. However, previous studies have highlighted their low sensitivity [Dellinger, Nucleic Acids Research 2010; Marenne, Human Mutation 2011]. Results from CNV-association studies strongly depend on the accuracy of CNV assessment mainly if they are affected by differences between cases and controls. It is thus important to identify characteristics influencing sensitivity and false positive rate (FPR) of CNV detection algorithms. In this study, we used data on 21 HapMap samples genotyped on Illumina Human 1M array as part of the Spanish Bladder Cancer / EPICURO Study [Rothman, Nature Genetics 2010] to evaluate the performance of four CNV detection algorithms: cnvPartition, PennCNV [Wang, Genome Res 2007], QuantiSNP [Collela, Nucleic Acids Res 2007] and cnvHap [Coin, Nat Methods 2010]. The callings obtained with these algorithms in 3109 autosomal CNV regions were compared to those reported in the Sanger public database [Conrad, Nature 2010]. The overall sensitivities for the four algorithms were 0.05, 0.09, 0.07 and 0.21 and the FPR were 0.28, 0.33, 0.37 and 0.31, respectively. These figures varied depending on the CNV regions (length, number or density of probes). To assess the impact on association tests of differences in the accuracy of CNV detection in cases and controls, we performed some simulations of CNVs in cases and controls under different models of correlation between calling performance and disease status. We evaluated type one error and power rates and studied whether accounting for CNV region characteristics related to sensitivity and FPR reduces false positive association signals.

Genome-wide analysis shows enrichment of copy-number variations in preeclampsia patients. *L. Zhao[1], E. Triche[2], A. Saftlas[3], J. Hoh[1], A. DeWan[1].* 1) Yale University, New Haven, CT; 2) Brown University, Providence, RI; 3) University of Iowa, Iowa City, IA.

Background: Preeclampsia (PE) is a life-threatening, multi-system disorder of pregnancy characterized by hypertension and proteinuria. Specific genetic contributions for PE, particularly copy-number variations (CNVs), are currently unknown. This study aims to identify distinct maternal CNVs involved in the etiology of PE. **Methods:** A genome-wide CNV scan using SNP arrays was performed on 177 PE case and 117 normotensive control subjects. All subjects were of Caucasian ethnicity and genotyped on Affymetrix SNP 6.0 arrays with some 906,600 SNP and 946,000 copy number probes. CNV calls were made using a combination of Birdsuite, PennCNV, and QuantiSNP detection algorithms and merged using Combined_CNV. Merged regions were screened based on either the effect size of association between PE cases and controls or calls present in ⁄ 5 cases and absent in controls. Further, the same criteria was applied to the shortlisted regions comparing PE cases and an independent set of population-based controls (n=774). Regions were selected to be assayed on the entire case-control dataset using RT-qPCR based on the presence of genes at or near (≤100kb) site, the availability of DNA for samples displaying the CNV, and having the majority of samples without the CNV type to be copy normal. Finally, $\log_2$ratio and B allele frequency plots were visually inspected for a clear change in probe hybridization intensity and zygosity, respectively, to ensure patterns consistent with calls. **Results:** Putative CNVs across ⁄ 10 contiguous probes were merged into 4271 and 25,408 regions of deletion and duplication, respectively, as defined by minimum region of overlap for sample calls. Among these, 11 deletions and 41 duplications met the pre-specified screening criteria. Several merged regions of recurrent rare CNVs were detected in multiple cases, but were singular or undetected in controls. Loci of particular interest include enrichment of case deletions among regions within 14q21.1 (5 case, 1 control, and 6 population-based control deletions) and 19q13.31 (5 case, 1 control, and 2 population-based control deletions). **Conclusions:** These results suggest that several CNVs confer risk for pathogenicity in patients with PE. Rare CNVs, particularly deletions which disrupt genes, enriched in patients represent potentially interesting regions for PE that warrant further investigation.

Admixture Analyses of Lipoprotein (a) Levels. *M. de Andrade[1], M. Matsumoto[1], T. Lesnick[1], E. Boerwinkle[2], S. Kardia[3], I. Kullo[4].* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Health Sciences Center, University of Texas, Houston, TX; 3) Epidemiology, University of Michigan, Ann Arbor, MI; 4) Cardiovascular Diseases, Mayo Clinic, Rochester, MN.

Background: Levels of lipoprotein(a) (Lp(a)), a circulating lipoprotein that resembles low-density lipoprotein cholesterol, are higher in African Americans than European Americans. To better understand the basis of ethnic differences in Lp(a) levels, we conducted admixture analyses of Lp(a) levels in the Genetic Epidemiology Network of Arteriopathy (GENOA) cohorts. Methods: The GENOA cohorts comprise of sibships with least two individuals with essential hypertension diagnosed before age 60 years, enrolled in Jackson MS (African Americans, n =xxx) and in Rochester MN (European-Americans, n =xxx). Genome-wide admixture analysis was performed to test whether local ancestry at each site was associated with log transformed Lp(a) levels using a linear mixed model adjusted for age and sex and taking into account relatedness in the two cohorts. Results: Admixture analysis was performed using HapMix and LAMP. HapMix bases its local ancestry estimates on haplotypes. It returns a local ancestry estimate for any locus in the reference population. We used HapMap Phase 3 CEU and YRI samples as the reference with HapMix. LAMP bases its local ancestry estimates on allele frequency. It only estimates local ancestry at loci genotyped in both the study sample and the reference population. We used the HapMap Phase 2 CEU and YRI founder samples to calculate the reference population allele frequencies for LAMP. We observed average local ancestry to be ~0.87 (the average STRUCTURE-estimated global ancestry) across the genome with an estimated 6 admixture generations. Results were consistent for the estimates from HapMix and LAMP. There was a peak on Chrm 6, between LPA and PLG for both sets of estimates. We observed that the average percent European Ancestry across the LPA/PLG locus and a 500 kb flanking region was associated with Lp(a) levels, and the average local ancestry estimates within these regions were significantly associated with Lp(a) more than the global ancestry estimates. Furthermore, subjects with lower and higher Lp(a) levels (1st and 4th quartiles) had, on average, lower and higher African ancestry across the LPA/PLG locus , respectively. Conclusions: Greater African ancestry across the LPA/PLG locus was associated with higher Lp(a) levels, suggesting that increased transcription of LPA might be the basis of increased Lp(a) levels in African Americans.

686W

The associasion between genetic polymorphism of TGF-) 1 and obesity in Nan-tou County in Taiwan. *P. Lin[1], Y. Hsiao[1], R. Wang[1], F. Wu[1], C. Chen[1], T. Wu[1,2].* 1) Department of Public Health, China medical University, PhD; 2) Graduate Institute of Biostatistics, China Medical University, PhD.

Dietary, social economic and lifestyles change in recent years have lead to an increasing prevalence of obesity worldwide. In developed countries, obesity is a growing public health concern and also is a major risk factor for chronic diseases such as cardiovascular disease, diabetes, hyperlipidemia, metabolic syndrome and cancer. Transforming growth factor - beta 1 (TGF-) 1) is a candidate gene for the development of obesity. TGF-) 1 expression is associated with body mass index (BMI) and abdominal adipose tissue in morbid obesity. Obesity is not only affected by environmental factors but also caused by TGF-) 1 gene mutation. The purpose of this study was to evaluate the role of TGF-) 1 C-509T genotypes as genetic indicator of susceptibility to obesity. In this cross-sectional study 300 subjects was collected from adult health examination at Nan-tou County in Taiwan. BMI as a standard, the subjects separated into obese (n=131, BM⁄ 27 kg/m^2) and non-obese (n=169) two groups. Each subject completed the demographic and lifestyle questionnaire. Blood samples were collected for DNA extraction to analyze TGF-) 1 genotype by Polymerase Chain Reaction-Restriction Fragment Length Polymorphism (PCR-RFLP). The chi-square analysis was used to assess differences in genotypes and allele frequencies. Logistic and linear regression were performed to examine whether TGF-) 1 genetic polymorphism associated with obesity. Data analysis showed that TGF-) 1 gene polymorphism C-509T CC, CT and TT was no significant (p = 0.588) between obese and non-obese group. After adjusting risk factors, the logistic regression showed subjects with CT and TT genotypes compared with CC genotype have a higher risk of obesity, but not significant (OR = 1.05 and 1.13, 95% CI = 0.54-2.05 and 0.54- 2.36). In non-obese group TGF-) 1 genotypes were associated with BMI (p = 0.002) and waist circumference (p = 0.018) respectively. In the obese group TGF-) 1 genotypes were significantly associated with waist circumference (p = 0.031). The C-509T variant of TGF-) 1 was not associated with obesity, but results showed that subjects with the TT genotype expressed higher obesity-related biochemical indicators than with the CC genotype. This study may be due to sampling bias, smaller sample size and other environmental factors were not considered. The study may provide a suggestion for obesity prevention. In future, we need more extensive samples to confirm that TGF-) 1 C-509T plays an important role in obesity.

The effect of a family history of myocardial infarction on the risk of venous thromboembolism among White and Black Americans. *F.D. Mili[1], W.C. Hooper[1], C. Lally[2], H. Austin[2].* 1) Research Laboratory Branch, Division of Blood Disorders, Centers for Disease Control and Prevention, Atlanta, Georgia, USA; 2) Department of Epidemiology, Emory University Rollins School of Public Health, Atlanta, Georgia, USA.

There is evidence that venous thrombosis and arterial thrombosis are part of a continuous spectrum of the same disease and might have a common pathogenesis, risk factors and clinical manifestations. Family history of venous thromboembolism (VTE) is a risk factor for VTE, and family history of myocardial infarction (MI) is a risk factor for MI. Findings from the TromsØ study, a prospective study conducted in Norway, indicated that a family history of MI was a risk factor both for MI and VTE, supporting the existence of a link between arterial and venous thrombosis. To confirm and extend the TromsØ study's findings to different populations, we analyzed data from the Genetic Attributes and Thrombosis Epidemiology (GATE) study, a matched, case-control study of VTE that enrolled 1,123 Blacks and 1,235 Whites aged 18-70 years residing in Atlanta, Georgia, United States. A total of 1,094 case patients with a first or recurrent episode of deep vein thrombosis or pulmonary embolism and 1,264 control patients were interviewed about their family history of thrombosis. We found that a positive family history of MI was associated with VTE among Whites only (odds ratio [OR] = 1.3, 95% confidence interval [CI] 1.03-1.8; P = 0.03). In addition, a family history of MI was associated more strongly with VTE among Whites who had diabetes (OR = 3.1, 95% CI 1.2-8.0; P = 0.017) compared with Whites who did not have diabetes (OR = 1.2, 95% CI 0.92-1.6; P = 0.2) (P for interaction = 0.004). Among Whites with plasma fibrinogen levels⁄ 3 grams per liter, we also found that the association between VTE and a family history of MI was stronger among Whites with diabetes than those without diabetes (OR = 2.3, 95% CI 1.2-4.5; P = 0.01 vs. OR = 1.1, 95% CI 0.86-1.5; P = 0.4, respectively) (P for interaction = 0.02). Furthermore, the association between a family history of MI was statistically significant among Blacks aged 18-44 years who experienced a recurrent episode of VTE compared with Blacks with a first VTE event (OR = 2.3, 95% CI 1.1-4.7; P = 0.02). From a public health perspective, our study showed that the attributable fraction of VTE due to family history of MI (adjusted for covariates) was 4.5% among Blacks and 11% among Whites. We concluded that a family history of MI is a risk factor for VTE among certain populations stratified by race, age, and co-morbid conditions.

Previously identified obesity loci display longitudinal differences in their effect on BMI through adolescence. *S.D. Bailey[1], J. O'Loughlin[2], N.C. Low[3], E. Dugas[7], N. Rudzicz[4], K. Desbiens[4], M.-H. Roy-Gagnon[2,5], M. Lambert[5], J.C. Engert[1,4,6].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Department of Social and Preventive Medicine, University of Montreal, Montreal, Quebec, Canada; 3) Department of Psychiatry, McGill University, Montreal, Quebec, Canada; 4) The Research Institute of the McGill University Health Centre, Montreal, Quebec, Canada; 5) Sainte-Justine Hospital Research Centre, Montreal, Quebec, Canada; 6) Cardiology Division, Department of Medicine, McGill University Health Centre, Montreal, Quebec, Canada; 7) University of Montreal Hospital Research Center, Montreal, Quebec, Canada.

Several genetic loci are known to contribute to obesity and recent genome-wide association (GWA) studies have identified additional loci that are associated with obesity-related traits in adults. Relatively few studies have examined these variants in childhood or in adolescence. From the Quebec based Nicotine Dependence in Teens (NDIT study), a prospective cohort recruited from schools beginning at grade 7 and followed until age 22, we genotyped 571 Quebec adolescents of European origin for 35 SNPs in from 35 obesity genes. Body mass index (BMI) was available from each participant for up to three time points through adolescence (mean age of at each time point: 13, 15, 17 years). Using linear regression adjusting for age and sex the variants in FTO and in LYPLAL1 were significantly associated with BMI in all three age groups with similar effect sizes. Eight SNPs demonstrated significant longitudinal trends. Interestingly, a SNP in TNFA (rs1800629) demonstrated a trend of increasing BMI effect size and only became significant in the oldest age group. Conversely, (rs1778323) a SNP in MC4R was significant in the youngest age group and displayed a significant trend of decreasing BMI effect size. Thus, we have identified several genetic variants that may display differential effects on BMI through adolescence.

689W

The developmental signature of steroid response genes in the human fetal lung. *S. Sharma[1], A. Kho[1], W. Qiu[1], R. Gaedigk[2], J.S. Leeder[2], S.T. Weiss[1], K.G. Tantisira[1].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) Children's Mercy Hospital and Clinics, Kansas City, MO.

Rationale: Asthma is the most common chronic respiratory disease of childhood. Inhaled corticosteroids (ICS) are an essential treatment for asthma and decrease exacerbation rates in children. While corticosteroids enhance lung maturation, it is unclear whether steroid response genes are important during human lung development. **Objective**: To determine whether steroid response genes are important in lung development and influence early response to asthma therapy. **Methods**: Immortalized lymphoblastoid cell lines were obtained from 164 adolescent subjects with asthma participating in the Childhood Asthma Management Program (CAMP). Cells were cultured, split, and treated with either 10-6 M dexamethasone or vehicle in a paired fashion. RNA was run on Illumina HumanRef8 v2 microarrays. Differential expression by steroid exposure was performed using t-tests with multiple comparison adjustment. Using gene expression profiles from 36 human fetal lung tissue samples, we next tested whether steroid response genes were enriched during lung development. Principal components analysis (PCA) was performed to identify the principal component (PC) most highly correlated with gestational age. A chi square test was used to determine whether the top 5% of genes contributing to this PC were enriched for genes in the steroid pathway. We then tested the association between variants in the most differentially expressed gene with asthma susceptibility and severity in 403 CAMP trios using family-based association tests under a dominant model with covariate adjustment. **Results**: Treatment of cell lines with dexamethasone resulted in differential expression of 6,385 genes. PCA of the fetal lung data demonstrated that PC1 was associated with age. Of the differentially expressed genes during lung development 903 of these genes were also involved in steroid response(p=3.12 x10-18). Gene ontology demonstrates involvement of these genes in cell cycle and DNA repair (p<0.05). *SPRY2* was the most differentially expressed gene, therefore, we tested four variants in *SPRY2* for association with asthma and disease severity. SNP rs9545409 was associated with asthma(p=0.003) and rs504122 with airway responsiveness (p=0.009) and lower FEV_1 (p=0.02). **Conclusions**: Genes involved in human lung development are enriched for elements of the steroid response pathway. These genes may influence ICS response in asthmatics and may provide further insight into novel therapeutic targets for asthma.

690W

FTO genotype independently and strongly influences both adiposity and insulin resistance in the Mapuche of Chile. *M.E.S. Bailey[1], C.A. Celis-Morales[1,2], N. Ulloa[3], C. Calvo[3], F. Pérez-Bravo[4], J.M.R. Gill[2].* 1) School of Life Sciences, College of Medical, Veterinary and Life Sciences, University of Glasgow, Glasgow, United Kingdom; 2) Institute of Cardiovascular and Medical Sciences, CMVLS, University of Glasgow, Glasgow, UK; 3) Department of Clinical Biochemistry and Immunology, Faculty of Pharmacy, University of Concepcion, Chile; 4) Laboratory of Nutritional Genomics, Department of Nutrition, Faculty of Medicine, University of Chile, Santiago, Chile.

FTO is the gene with the strongest influence on adiposity/BMI yet discovered. In populations of European ethnicity, *FTO* influences diabetes risk only via this effect on adiposity, but recent studies of other ethnic groups have challenged this conclusion. We present here evidence that *FTO* strongly influences insulin resistance in a non-European population. We conducted a cross-sectional study of a population sample (n=472) from Chile, recruiting adults from four population groups - a native American ethnic group, the Mapuche, living in traditional rural environments or Westernised urban environments, and rural and urban citizens of European origin. All participants underwent comprehensive assessment in the field (Celis-Morales et al., submitted) of a wide range of physical, metabolic, social and environmental variables, including insulin resistance (HOMA-IR). rs17817449, a SNP in intron 1, was used to assess the influence of variation in *FTO* on BMI and HOMA-IR in the whole cohort. The G allele was associated with higher BMI and with greater insulin resistance (GLM tests: $p \leq 0.000001$). Adding ethnicity as a factor in a regression model of additive allelic effects revealed a significant genotype x ethnicity interaction ($p = 0.0002$ for HOMA-IR). In this model genotype explained 18.2% of the variance in HOMA-IR in the Mapuches. After adjustment for multiple factors in a full model with HOMA-IR as the outcome variable (76% of variance explained; urban/rural environment, smoking status and sedentary time were significant as main effects, $p < 0.0003$; age, sex, socioeconomic status, BMI and adiposity variables, activity and fitness variables and dietary intake variables were not significant), the genotype x ethnicity interaction remained ($p = 0.00014$). After stratification, *FTO* genotype explained only 0.6% of the variance in HOMA-IR in Europeans, but 6.7% in Mapuches ($p=0.000003$), with a per allele effect size in this group of 0.26 S.D., or 1.46 HOMA-IR units. Our results reveal that *FTO* has a large effect on insulin resistance in this small sample of Chilean Mapuches, independent of its influence on adiposity/BMI and after adjustment for many other factors. If generalizable to other non-European populations, this may point to the existence of modifier genes that reduce the influence of *FTO* on insulin resistance in Europeans. Such genetic differences may contribute to the larger increase in diabetes risk on urbanisation observed in non-European populations.

691W

TCF7L2 polymorphisms/haplotypes association with T2D in an Italian population and correlation with some complications. *C. Ciccacci[1], D. Di Fusco[1], L. Cacciotti[2], V. Spallone[2], G. Novelli[1,3], P. Borgiani[1].* 1) Department of Biopathology and Diagnostic Imaging, Medical Genetics Section, School of Medicine, Tor Vergata University, Rome, Italy; 2) Endocrinology, Department of Internal Medicine, Tor Vergata University, Rome, Italy; 3) Medical Genetics Unit, San Pietro FBF Hospital , Rome, Italy.

Type 2 diabetes (T2D) is a complex disease resulting by the contribution of both environmental and genetic factors. Recently the list of genes implicated in the susceptibility with T2D has grown substantially due to the great development of the genome wide association studies (GWAs). Among these genes, the TCF7L2 genes, identified by GWAs in 2007, has shown the strongest effect. TCF7L2 is a transcription factor which regulates embryogenesis, cell proliferation, myogenesis and adipogenesis via the Wnt signaling pathway. Several studies have demonstrated that TCF7L2 influences the rate of progression from impaired glucose tolerance to T2D. The aim of our study is to confirm the TCF7L2 role in the susceptibility to T2D in the Italian population. At this purpose we have perfomed a case-control association study in an Italian sample of 150 T2D patients and 170 healthy controls and a genotype/phenotype correlation analysis. We investigated three TCF7L2 polymorphisms (rs7903146, rs7901695 and rs12255372) by allelic discrimination assays (TaqMan technology). Differences in allelic, genotypic and haplotypic frequencies between cases and control were evaluated by Pearson $\chi 2$ test. All three SNPs resulted highly associated with susceptibility to T2D both at allelic and genotypic level. Rs7901695 resulted the mostly associated SNP: patients carry the C allele in heterozygote status has an OR=1.6 (P= 0.057), and patients carry the C allele in homozygote status has an OR=3.03 (P=0.0009) respect to the TT carriers. From the haplotypic analysis, the CTT haplotype (carrying all three variant alleles) resulted to be highly associated with the T2D risk (OR= 1.86 with P=0.0019), while the TCG haplotype (carrying the wildtype alleles) resulted to have a protective effect (OR= 0.55 with P=0.0003). The phenotype/genotype analysis revealed a significant correlation with T2D complications. In particular the rs7901695 and rs7903146 resulted associated with the presence of cardiovascular disease (P=0.033 and P=0.18 respectively). Moreover, the rs7903146 and rs12255372 resulted associated with the presence of retinopathy (P=0.048 and P=0.014). In conclusion, we confirmed that polymorphisms/haplotypes in TCF7L2 gene play a significant role in the T2D pathology in the Italian population. Moreover, we observed a significant association with the risk to develop cardiovascular disease and retinopathy in the T2D affected patients carrying the variant TCF7L2 alleles.

692W

Investigating the *PARL* / *ABCC5* gene region as a susceptibility locus for type 2 diabetes. *K. Direk[1], W. Lau[2], K. Small[1,3], H. Elding[2], N. Maniatis[2], T. Andrew[1].* 1) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 2) Genetics, Evolution & Environment, University College London, Gower Street, UCL, London; 3) MuTHER Consortium, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom.

The *PARL* gene coding for a mitochondrial protease, has recently been identified as a potential candidate gene for type 2 diabetes (Walder *et al*., 2005; Civitarese *et al*., 2010). There is conflicting evidence regarding the association between the non-synonymous Leu262Val (rs3732581) polymorphism in *PARL* and fasting insulin serum levels - the initial observation (Walder *et al*., 2005) has failed to replicate in subsequent studies (Fawcett *et al*., 2006; Powell *et al*., 2008; Hatunic *et al*., 2009). However, functional evidence (Walder *et al*., 2005; Civitarese *et al*., 2010) exists that empirically demonstrates down-regulation of *PARL* expression in diabetic subjects. Mitochondrial dysfunction is thought to be a major etiological component of insulin resistance (Turner & Heilbronn, 2008; Patti & Corvera, 2010). Using TwinsUK cohort data, approximately 3000 twins were genotyped for rs3732581. No association was observed between fasting serum insulin and glucose levels and any genotyped *PARL* SNPs, including Leu262Val. Analyses were conducted using individual SNP association and a multi-locus Malecot model for the *PARL*/*ABCC5* gene region. Using the Wellcome Trust Case Control Consortium (WTCCC) type 2 diabetes data, we also observed no evidence of genotypic association with *PARL*. However, strong evidence of association for type 2 diabetes was observed in the neighbouring gene *ABCC5*, immediately upstream of *PARL* (Malecot model χ^2 = 21.7, p = 1.54 x 10^{-6}). In addition, despite no evidence of association with fasting insulin levels in the TwinsUK cohort, *ABCC5* and *PARL* expression levels for subcutaneous adipose tissue samples measured for 776 twins from the same cohort, did show evidence of association (p =< 10^{-3}) between *ABCC5* expression and *ABCC5* SNPs, but not between *PARL* expression and *PARL* SNPs. As *PARL* and *ABCC5* are situated in a region of substantial linkage disequilibrium (LD), we tested the hypothesis that the association between rs3732581 and insulin may be the result of rs3732581 being in LD with intra-genic *ABCC5* SNPs, particularly those associated with *ABCC5* expression. We also used *in silco* analyses to examine this region for evidence of regulatory elements. Given the two independent lines of evidence implicating *ABCC5*, we will test whether there are either two co-located, but independent susceptibility genes for type 2 diabetes in this region, or that the contradictory reports of genotypic association with *PARL* may just reflect LD with *ABCC5*.

Comprehensive evaluation of type 2 diabetes susceptibility in the Japanese population by genome-wide imputation analysis using the 1000 Genomes Project data. *K. Hara[1], H. Fujita[1], T.A. Johnson[2], M. Horikoshi[3], S. Maeda[2], T. Tsunoda[2], M. Kubo[2], Y. Nakamura[2], T. Kadowaki[1].* 1) Department of Metabolic Diseases, University of Tokyo, Tokyo, Japan; 2) Center for Genomic Medicine, RIKEN, Yokohama, Japan; 3) The Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom.

We had previously identified several type 2 diabetes (T2D)-associated polymorphisms in *UBE2E2* (rs7612463) and *C2CD4A-C2CD4B* (rs7172432) using genome-wide association analysis of 4,470 cases and 3,071 control cases that were genotyped for 459,359 single-nucleotide polymorphisms (SNPs). To identify additional T2D susceptibility loci and to fine-map the location of functional variants for the previously identified T2D loci, we imputed genotypes of 10,524,368 single-nucleotide polymorphisms (SNPs) from the 1000 Genomes Project data set (388 Asian haplotypes) using MACH software. We then performed genome-wide association tests for T2D before and after adjusting for possible confounding factors such as age, sex, and BMI (body mass index). In addition to variants in or near the previously reported loci, we found that SNPs in *CTBP1* (C-terminal-binding protein 1) - *MAEA* (macrophage erythroblast attacher) region (rs730831, rs4974585, and rs4974586) were possibly associated with T2D. Subsequent genotyping of these SNPs in an independent sample set of 1,175 cases and 839 controls showed evidence for replication of association (P values between 1.7×10^{-2} and 2×10^{-3}), and combined P values reached genome-wide significance (ranging from $P = 5 \times 10^{-8}$, OR = 1.18 [1.03 - 1.35] to $P = 1 \times 10^{-10}$, OR = 1.25 [1.08 - 1.44]). Conditional logistic regression analyses were performed to assess the independence between SNPs, with results identifying rs730831 in *CTBP1* as the best significant SNP in this region. The CTBP1 expression level was higher in visceral adipose tissue (V) than in paired subcutaneous tissue (S)(P = 0.0061), while there were no differences in expression levels between V and S for genes surrounding *CTBP1*. Subjects with the risk allele of rs730831 tended to have a higher expression level of *CTBP1* (P = 0.043). These results indicate that *CTBP1* is a plausible candidate for a novel T2D gene. The association with T2D was no stronger in the present lead SNPs than in the previous lead SNPs detected in previously reported loci in our population except in *CDC123/CAMK1D* and *ZFAND6*. Our study highlights the benefit of mapping T2D variants in combination with data derived from next-generation sequencing of the human genome. We are currently conducting a replication study to see if the present results would be confirmed in another sample of 1,634 T2D cases and 21,697 controls.

694W

Modeling HLA epistatic interactions using a unified GWAS and linkage analytical method maps new putative genes for Type 1 Diabetes. *Y. Huang[1], Y. Tomer[2], VJ. Vieland[1].* 1) Battelle Ctr Math Med, the Res Inst at Nationwide Childrens Hospital, Columbus, OH; 2) Division of Endocrinology, Department of Medicine, Mount Sinai Medical Center, and James J. Peters VA Medical Center, New York, N.Y.

The PPLD is an association statistic developed under the PPL framework. It is tailored to detection of association due to linkage disequilibrium (LD) for complex disorders, and can uniquely combine different types of genetic information obtained from disparate data structures for single-locus and two-locus (2L) epistasis analyses. Here we combine publicly available Type 1 Diabetes (T1D) case-control GWAS data from the Wellcome Trust Case Control Consortium (WTCCC) with a separate family dataset, for combinined linkage and LD analyses, taking advantage of strong LD to the HLA region to search for novel HLA-interacting genes. The PPLD agreed with the primary previously reported findings for the WTCC data and identified some new regions as well. In at least one case combining the GWAS and family data provided evidence of LD to a known candidate gene that did not show LD on its own (CTLA4). Novel PPLD findings included a 67% probability of LD between T1D and ACOXL (rs10187034) and 55% probability of LD with ADAMTSL1 (rs949682). Allowing for 2L epistasis involving HLA-DQA1 boosted these PPLDs to 99% and 82%, respectively. Epistasis analysis also implicated association to ADAMTS1 (2L PPLD = 21%), a member of the ADAMTS (a disintegrin and metalloproteinase with thrombospondin motif) protein family found in the extracellular matrix, which showed no evidence of LD in single-locus analysis. Both ADAMTSL1 (ADAMTS -like protein 1) found in the single locus analysis and ADAMTS1 from the 2L epistasis analysis may be associated with inflammation processes. Finding two genes with similar putative functions in non-syntenic chromosomal regions supports the power of epistasis analyses to reveal gene families underlying complex disorders.

695W

Admixture Mapping Reveals Potential Novel Loci for Type II Diabetes in African Americans Using Electronic Medical Records as a Tool for Genome Science. *J. Jeff[1], L. Armstrong[7], M. Ritchie[1], J. Denny[2,3], A. Kho[6], M. Basford[4], W. Wolf[9], J. Pacheco[8], K. Doheny[11], D. Mirel[12], E. Pugh[11], A. Crenshaw[12], R. Li[10], T. Manolio[10], R. Chisholm[8], D. Roden[2,4,5], G. Hayes[7,8], D. Crawford[1].* 1) Center for Human Genetics, Vanderbilt Univ, Nashville, TN; 2) Department of Medicine, Division of Clinical Pharmacology,Vanderbilt Univ, Nashville, TN; 3) Department of Biomedical Informatics,Vanderbilt Univ, Nashville, TN; 4) Office of Personalized Medicine,Vanderbilt University, Nashville, TN; 5) Department of Pharmacology,Vanderbilt University, Nashville, TN; 6) Division of General Internal Medicine,Northwestern University, Chicago, IL; 7) Division of Endocrinology, Metabolism, and Molecular Medicine, Northwestern University, Chicago, IL; 8) Center for Genetic Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 9) Division of Genetics, Children's Hospital Boston, Boston, MA; 10) Office of Population Genomics, National Human Genome Research Institute, Bethesda, MD; 11) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD, USA; 12) Genetic Analysis Platform and Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA.

Type 2 diabetes (T2D) is a complex metabolic disease that disproportionately affects African Americans compared to European Americans. Obesity is a major risk factor for T2D, and it is postulated that chronic inflammation possibly stemming from adipose tissue macrophages and T cells plays a key role. Genome-wide association studies (GWAS) have identified over 20 disease loci that contribute to T2D in European American but few studies have been performed in diverse or admixed populations. Admixture mapping disease loci in recent mixed populations, such as African Americans is potentially a more powerful alternative to GWAS. As part of the electronic Medical Records and Genomics (eMERGE) network, we performed an admixture scan in 1,563 African Americans from the Vanderbilt Genome-Electronic Records Project and Northwestern University NUgene Project. T2D cases were identified from the electronic medical record (EMR) using a combination of billing codes, T2D medications, and abnormal glucose or glycated hemoglobin (HbA1c) labs. Exclusions included patients diagnosed with T1D and patients who were undertaking insulin only with no records on T2D medications, abnormal glucose and/or HbA1c were excluded. Controls had to have ⁄ 2 clinical visits, ⁄ 1 normal glucose labs, no diabetes-related billing codes, no diabetes or insulin-related medications, and no family history of T2D. With these criteria, we identified 736 cases and 827 controls for Illumina 1M-Duo BeadChip genotyping. Using ANCESTRYMAP, we performed an admixture scan with 4,208 autosomal ancestry informative markers (AIMs) derived from the 1M dataset, assuming a 1.2 relative risk score for T2D. The average genome-wide European ancestry was similar between cases (20.3%) and controls (20.6%; p= 0.72). The average genome-wide LOD score, the likelihood of being a disease locus, was 0.55, and scores ranged from -0.89 to 2.30. Of the 22 autosomes tested, chromosome 11 was the only chromosome with a significant genome-wide LOD score (LOD >2). The admixture peak encompassed multiple genes, including TCIRG1, a T-cell immune regulator expressed in the pancreas and liver and not previously implicated in T2D.Several isoforms of TCIRG1 have been described, including the short isoform b (TIRC7) required for normal T cell activation. Our results suggest a novel region on chromosome 11 identified by admixture mapping associated with T2D in African Americans and warrants additional fine-mapping in these regions.

A MAGIC study of genome-wide joint meta-analysis of SNP by BMI interaction identifies 14 common variants associated with fasting insulin and glucose homeostasis. *A. Manning[1], R.A. Scott[2], M.-F. Hivert[3,4], J. Grimsby[4,9], C.-T. Liu[5], H. Chen[5], L. Bielak[6], L. Rasmussen-Torvik[7], J. Dupuis[5, 8], J.C. Florez[1, 4, 9], R.M. Watanabe[10, 11], C. Langenberg[2], J.B. Meigs[4, 9], MAGIC.* 1) Broad Institute, Cambridge, MA; 2) Medical Research Council (MRC), Epidemiology Unit, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, UK; 3) Centre de Recherche Medicale de l'Universite de Sherbrooke, Sherbrooke, Quebec, Canada; 4) Massachusetts General Hospital, Boston, MA; 5) Biostatistics Department, Boston University, Boston, MA; 6) Department of Epidemiology, School of Public Health, University of Michigan, Ann Arbor, MI; 7) Department of Preventive Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 8) National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 9) Harvard Medical School, Boston, MA; 10) Department of Physiology and Biophysics, Keck School of Medicine, University of Southern California, Los Angeles, CA; 11) National Institute of Health and Welfare, Oulu, Finland.

Recent genetic studies have identified many loci implicated in type 2 diabetes (T2D) pathophysiology, most of which are associated with beta-cell dysfunction rather than insulin resistance. We hypothesize that accounting for (1) heterogeneity in body mass index (BMI) and (2) potential SNP×BMI interactions, will increase our ability to identify genetic loci associated with traits associated with insulin resistance. We developed the joint meta-analysis (JMA) approach, which tests both the main genetic effect and any potential interaction between a SNP and BMI, and provides increased power for detecting the association signal when underlying interaction effects are suspected but unknown. Here, we present the results of a genome-wide study by the Meta-Analysis of Glucose and Insulin-related traits Consortium (MAGIC) wherein we jointly meta-analyze SNP and SNP×BMI effects to screen for genetic loci associated with log(fasting insulin) and fasting glucose in 47 cohorts comprising up to 88,771 individuals. After discovery analyses, we promoted 51 loci (JMA $P<10^{-6}$) to a follow-up phase (31 for fasting insulin, 21 for fasting glucose, one overlap). In addition to loci previously associated with T2D or glycemic related traits, 14 new loci reached genomewide significance in combined discovery and follow-up analysis in either JMA or main effects models. The nearest genes and JMA P values for fasting insulin are *COBLL1*/*GRB14* ($P=8\times10^{-14}$), *IRS1* ($P=7\times10^{-14}$), *PPP1R3B* ($P=7\times10^{-14}$), *PEPD* ($P=8\times10^{-8}$), *UHRF1BP1* ($P=1.4\times10^{-7}$), *PDGFC* ($P=7.2\times10^{-10}$), *LYPLAL1* ($P=2.1\times10^{-8}$), and for fasting glucose are *PCSK1* ($P=2\times10^{-9}$), *OR4S1* ($P=1\times10^{-8}$), *ARAP1* ($P=1\times10^{-12}$), *FOXA2* ($P=3\times10^{-11}$), *GRB10* ($P=6\times10^{-8}$), *PPP1R3B* ($P=1.8\times10^{-9}$ in main effects models adjusting for BMI), *DPYSL5* ($P=1\times10^{-12}$), *CREB3L1* ($P=3.4\times10^{-8}$ in main effects models without adjustment for BMI). Four loci have nominally significant interaction tests: *COBLL1*/*GRB14* ($P=0.0005$) and *IRS1* ($P=0.02$) for fasting insulin and *PCSK1* ($P=0.04$) and *OR4S1* ($P=0.009$) for fasting glucose. Our study demonstrated that by allowing for interaction with adiposity using the JMA method, we can more readily detect loci associated with insulin resistance traits at genome-wide significance levels. The identification of these new loci offers the potential to further characterize the role of insulin resistance in T2D pathophysiology.

697W

Impact of loci contributing to type 2 diabetes susceptibility on variation in physiologic glycaemic traits in healthy individuals. *M. McCarthy[1,2,3], A.S Dimas[2,4], V. Lagou[2], R. Mägi[2], A. Genome-wide association studies (GWAS) have identified multiple genetic loci contributing to risk of type 2 diabetes (T2D), a condition characterized by beta-cell dysfunction and insulin resistance. The aim of this study was to uncover the mechanistic basis of these T2D associations by exploring the effects of T2D-risk alleles on intermediary metabolic phenotypes in healthy individuals. We considered 38 established T2D susceptibility variants and their effects on validated indices of insulin processing, secretion and sensitivity gathered from both basal (fasting glucose, insulin, HOMA-B, HOMA-IR, proinsulin) and dynamic measures (insulin sensitivity [ISI] and insulinogenic indices derived from oral glucose tolerance tests [OGTTs]). An additive genetic model with adjustment for sex, age and BMI was applied for cohort analyses followed by fixed effects inverse variance meta-analysis. Sample sizes ranged from 11,282 to 58,614 for basal and from 11,889 to 13,829 for dynamic tests. Based on a cluster analysis of these data, the 38 loci fell into 5 major groups. Variants near *PPARG*, *KLF14*, *IRS1* and *GCKR* loci were characterized by a primary effect on insulin resistance (HOMA-IR, ISI) with compensatory improvements in beta-cell function (insulinogenic index, HOMA-B). Risk-alleles at the *ARAP1* locus demonstrated a pronounced impact on proinsulin and insulinogenic index indicating a defect in insulin processing. Variants near *MTNR1B* and *GCK* displayed elevations in fasting glucose and concomitant reductions in HOMA-B and insulinogenic index. *TCF7L2*, *SCL30A8* and *HHEX/IDE* risk-alleles combined defects in insulin processing and secretion (insulinogenic index). For all other loci, there were, despite the sample sizes, no clear-cut associations with either basal or OGTT-derived measures. Data were also available for up to 4,169 individuals from 7 cohorts with more detailed measures of insulin sensitivity derived from euglycemic clamps (M-value), insulin suppression tests (SSPG) or intravenous glucose tolerance tests (Si). Meta-analysis of these three highly correlated intravenous assessments were broadly consistent with the ISI and HOMA-IR data; though reduced sample size compromised power at many loci. The T2D-risk allele was associated with reduced insulin sensitivity at *IRS1* ($p=7x10^{-4}$) and at *ADCY5* (p=0.006). Our findings indicate that T2D-susceptibility variants exert their effects on glucose homeostasis through a variety of mechanisms.

Large-scale sex-differentiated meta-analysis reveals four novel susceptibility loci for type 2 diabetes. *A.P. Morris[1], T. Ferreira[1], T.M. Teslovich[2], A. Mahajan[1], B.F. Voight[3], DIAGRAM Consortium.* 1) Wellcome Trust Centre for Human Genetics, Univ Oxford, Oxford, United Kingdom; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 3) Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Despite the success of genome-wide association studies (GWAS), much of the genetic component of the T2D is unexplained. One source of genetic variation which may contribute to this “missing heritability” is that with effects that differ between sexes. We have undertaken the first large-scale meta-analysis of sex-specific T2D GWAS to: (i) assess the evidence of heterogeneity of allelic effects between males and females at confirmed disease loci; and (ii) identify novel sex-differentiated associations with the disease.

We performed sex-specific meta-analysis of association studies of T2D (total effective sample size of 47,917 males and 39,454 females) incorporating: (i) 12 GWAS of European descent, imputed for up to 2.5 million SNPs; and (ii) 25 additional cohorts of European descent and 1 cohort of Pakistani descent, genotyped using the Metabochip. Each SNP was tested for association, separately for each sex, under an allelic-dose model. For each sex, allelic odds ratios (OR) were then combined across cohorts through fixed-effects meta-analysis. A sex-differentiated test of association, allowing for heterogeneity in allelic effects between sexes, was then performed. Heterogeneity in allelic OR between sexes was assessed by Cochran's Q-statistic.

Among confirmed T2D loci, there was nominal evidence of heterogeneity in allelic effects between the sexes at 3 loci, all showing stronger association in males: KCNQ1 (p=1.1x10-3, male OR = 1.12 [1.09-1.16], female OR = 1.05 [1.01-1.08]), DGKB (p=6.1x10-3, male OR = 1.15 [1.11-1.19], female OR = 1.06 [1.02-1.11]) and BCL11A (p=1.1x10-2, male OR = 1.10 [1.06-1.13], female OR = 1.04 [1.00-1.07]). Our sex-differentiated meta-analysis revealed genome-wide significant evidence of association ($p<5x10-8$) at 4 novel loci. The strongest signal of association was observed at CCND2 (p= 6.6x10-10), which also is much stronger in males (male OR = 1.12 [1.08-1.16], female OR = 1.04 [1.00-1.09]). However, the other 3 loci show stronger effects in females: GIPR (p=1.3x10-8), RREB1 (p=3.5x10-8) and TMEM154 (p=3.9x10-8). These loci would not have been identified through traditional sex-combined meta-analysis, and thus highlight the importance of allowing for heterogeneity in allelic effects between males and females in sex-differentiated analyses in searching for complex trait loci.

Recently, numerous genotype-phenotype associations have been identified for a variety of traits through genome-wide association (GWA) studies. The majority of these, and subsequent replications, were discovered primarily in individuals of European (EU) ancestry. These EU genotype-phenotype associations may fail to replicate in populations of African ancestry due to differences in effect sizes, allele frequencies, and linkage disequilibrium with the true underlying functional SNP. The Metabochip is a high-density 200K SNP array with content selected from HapMap and the 1,000 Genomes Project across several ancestral populations to fine-map GWA regions found in association with metabolic traits including type 2 diabetes (T2D). We, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study, have utilized this high-density array to characterize genetic risk for T2D in an African American sample of 1,233 T2D cases and 3,896 population-based controls from the Atherosclerosis Risk in Communities Study and Women's Health Initiative. Overall, 161,098 polymorphic SNPs passed quality control and were tested using an additive genetic model adjusting for age, sex, BMI, recruitment center, and population structure with unconditional logistic regression in a pooled analysis. Uncorrected p-values are presented. We reproduced significant (P<0.01) associations with several EU T2D index SNPs, such as *TCF7L2* rs7903146 [OR=1.3; P= $4.5x10^{-7}$] and *NOTCH2* rs10923931 [OR= 1.2; P=$4.6x10^{-3}$] in our African American T2D sample. Within several T2D risk loci we observed stronger associations for SNPs correlated with the EU index SNP (CEU r^2>0.3), such as *CDNK2A/2B* rs10757283 (P=$3.3x10^{-3}$) vs EU SNP rs2383208 (P=0.8), as well as associations that appear to be independent of the EU index SNP (CEU r^2<0.01), such as *JAZF1* rs73297579 (P=$3.4x10^{-4}$) vs EU SNP rs864745 (P=0.04). Other suggestive associations (P<$5.0x10^{-5}$) for novel loci were observed and require further evaluation. Additional analyses of T2D-related traits (e.g. baseline glucose and insulin levels) are ongoing. Overall, we demonstrate utilizing ancestral populations differing from the discovery population may be informative for discovering secondary signals independent of the index SNP, localizing biologically relevant variants and prioritizing SNPs for functional evaluation in known T2D risk loci.

Objective: Circulating metabolites may represent useful biomarkers, but their causal role in diabetes disease processes is less certain. We aimed to identify common genetic variants associated with 14 insulin sensitivity related metabolites, and assess whether these metabolites have causal effects on diabetes and insulin sensitivity. Research Design and Methods: Using 1,004 non-diabetic individuals from the RISC study we performed a genome wide association study on 14 insulin sensitivity related metabolites. We assessed the association of these variants with diabetes related traits in meta-analyses (MAGIC, DIAGRAM and GENESIS) and using Mendelian randomisation approaches. Results: We identified eight association signals with four metabolites: adrenate (rs174541 at *FADs* (*P*=2.9×10^{-9})); betaine (rs499368 at *SLC6A12*(*P*= 8.10×10^{-9}), rs17823642 at *BHMT* (*P*=1.40×10^{-6})); glycine (rs715 at *CPS1* (*P*=5.30×10^{-30}), rs1107366 at *ALDH1L1* (*P*=8.00×10^{-5})); serine (rs478093 at *PHGDH* (*P*=1.50×10^{-9}), rs4275190 at *PSPH* (*P*=4.00×10^{-4}), rs13233754 at *PSPH* (*P*=2.00×10^{-5})). The association between rs715 and glycine levels has a highly sex-specific effect (P=2.7×10^{-13} for female-specific effect). The allele in the *ALDH1L1* gene associated with raised glycine levels was associated with increased clamp based measures of insulin sensitivity (*P*=5.50×10^{-3}, (+0.09 umol.min^{-1}kgFFM^{-1}, 95%CIs 0.03, 0.15)), an effect consistent with a causal effect of glycine levels on insulin sensitivity, although further studies are needed to confirm this association. The associations observed between metabolite SNPs and fasting insulin were lower than those expected based on the SNP-metabolite and metabolit×10fasting insulin associations. Conclusions: Genetic variants influence insulin sensitivity related metabolites and can help understand the role of metabolites in diabetes related traits.

Assessing RNA-seq differential expression levels with low-confidence mapped reads. *M. Pongpanich, J.Y. Tzeng, D. Nielsen.* North Carolina State University, Raleigh, NC.

RNA-seq is a promising approach for understanding transcriptomes due to its accuracy, large dynamic range of expression level and ability to detect novel transcripts. In RNA-seq experiment, millions of reads are generated from high-throughput sequencer. Before these reads can be used to estimate the expression level of a gene, they have to be mapped against a reference genome or transcript set using a certain alignment tool. It is often that a fair amount of reads cannot be mapped by the aligners and will be excluded from down-streaming analyses (e.g., 40%-50% reads unmapped using TopHat with defaults parameters in our datasets). To maximize the potential utility of sequenced reads, we study the characteristics of the unmapped reads and identify the major causes of reads fail to be aligned. Specifically, we use BLAST to align the unmapped reads, which allows a read to be aligned even if a sub-segment of the read is perfectly or partially consistent with the reference sequence. From the loosely mapped results of BLAST, we find that one key feature of the reads that are mapped by BLAST but not TopHat is the high level of dissimilarity occurring in the head region (>10 bp), or the tail region (>10bp), or both regions of a read. We then construct a statistical method to incorporate these low-confidence mapped reads by assigning weights that reflect the mapping confidence of a read. We investigate the pros and cons of incorporating the low-confidence mapped reads in detecting genes with differential expressions.

Quantitative trait analysis for next-generation sequencing. *Y. Zhu[1], L. Luo[2], M. Xiong[1].* 1) University of TexasSchool of Public Health, Houston, TX; 2) University of New Mexico School of Medicine.

Next-generation sequencing (NGS) technologies will generate unprecedented massive, high-dimensional, and nonlinearly-structured data which combined with the biological, genetic and environmental heterogeneity of the populations present formidable challenges to data analysis. The current platform for quantitative trait analysis is single-variant regression (SVR) in which a quantitative trait is regressed on a single variant at a time. This platform provides useful tools for identifying the association of common variants with quantitative traits, but has limitations in analyzing thousands of sequences collected for very large population-based studies of humans. It is increasingly realized that a single polymorphic site is not the unit of genetic analysis (UGA), but that variation in a particular phenotype is influenced by variation in combinations of multiple common and rare variants in a genomic region. Simple linear regression which tests the genetic effect of an individual variant has limited power to detect association of rare variants. The classical multiple regressions also suffer from two serious problems: presence of multicolinearity and overfitting. To overcome these limitations, we propose smoothed functional linear models (FLM) for sequence-based quantitative trait analysis in which all variants in the genomic region are are collectively incorporated into the analysis as a UGA. The smoothed FLM can substantially reduce the multicolinearity in the genomic data and effectively control overfitting. We develop a novel statistic for testing the association of UGA with a quantitative trait in FLM. Extensive simulations are conducted to evaluate its type 1 error rates and compare its power with regressions. To further evaluate its performance, the proposed FLM is applied to two datasets of genetic studies of expressions which consists of 60 CEU and 57 YRI with expressions generated by RNA-seq and SNPs generated in 1000 Genomes Project. A number of genomic regions that contributes to the variation of overall expression levels of the genes is identified. We also observed that large proportion of identified genomic regions is overlapped in two datasets. Our preliminary results show that the smoothed FLM has much higher power to detect genomic regions that include entire spectrum of variants than the simple and multiple regressions. The smoothed FLM might emerged as a major tool for sequence-based quantitative trait analysis.

Heritability of densitometric, structural and strength properties of bones in extended pedigrees from Spain: data from the GAO Project. *G. Athanasiadis[1], J. Malouf[2], A. Laiz-Alonso[2], A. Marin[2], A. Martinez-Perez[1], L. Rib[1], R. Perez[1], A. Buil[3], J. Casademont[2], J. Farrerons[2], JM. Soria[1].* 1) Unitat de Genòmica de Malalties Complexes, Institut de Recerca, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 2) Servei de Medicina Interna, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 3) Department of Genetics and Development, University of Geneva, Geneva, Switzerland.

The genetic basis of primary osteoporosis is complex, with multiple genes and environmental factors acting jointly to determine its risk. In order to shed more light in the genetics of osteoporosis, we designed the Genetic Analysis of Osteoporosis (GAO), a study based on extended pedigrees from Spain. For the purpose of the present analysis, a total of 110 individuals from five extended families were considered. All families were recruited on the basis of a proband with osteoporosis and the participants signed an informed consent statement. Spine, femur and whole body densitometry was performed using a Discovery densitometer with the Apex 2.3 software from HOLOGICH. Hip strength and geometrical properties were analyzed using the HSAH software included in Apex. Maximum likelihood-based covariance decomposition analysis was used to assess heritabilities (h2) and the genetic and environmental correlations (rG and rE) between phenotypes. This work presents the heritability found among the phenotypes. This is the first study that quantifies the genetic component of several important parameters involved in osteoporosis and fracture risk in extended pedigrees. The high heritability found for most of them indicates that genetic effects account for a significant proportion of the observed phenotypic variation of these parameters. Thus, a family-based strategy through a genome scan can be used to identify the genes involved in osteoporosis and fracture risk, hopefully leading to clinical applications.

Estimating causal effects in Mendelian Randomization studies: how different is that from Randomized Controlled Trials? *K. Fischer[1,2], M. Kals[1,2], A. Metspalu[1,2].* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Center of Translational Genomics, University of Tartu, Estonia.

The aim of many studies in epidemiology is to estimate causal effects of an exposure phenotype on an outcome phenotype. However, even the best possible study designs cannot completely exclude the possibility of unobserved confounding, leading to biased estimates of the effects of interest. One way out is so-called Mendelian Randomization, provided there is a genetic marker (or a set of markers) that is predictive for the exposure, but does not have any effect on the outcome (except the possible indirect effect via the exposure). Now the genetic marker resembles a random assignment, creating groups of individuals that are comparable with respect to all possible confounding factors influencing the outcome. The causal effect is then estimated using Instrumental Variables (IV) estimation techniques, where the marker is used as an instrument. Such estimation techniques resemble the estimation of the effect of non-compliance (some patients not receiving their assigned treatment) in Randomized Controlled Trials (RCTs). Therefore the IV analysis methods that are used for the analysis of RCTs, have recently been implemented in the context of Mendelian Randomization. However, the interpretation of the resulting estimates in Mendelian Randomization studies is usually not the same in the context of RCTs. We will discuss three possible causal parameters in the context of RCTs - Complier Average Causal Effect (CACE), Average exposure Effect in the Exposed (AEE) and the marginal causal effect. We will show that the same IV estimator can be interpreted as an estimate for any of the three parameters, depending on the level of untestable assumptions one is ready to make. Using an example based on the data of the Estonian Genome Center, we will discuss the meaning of the same parameters in the context of Mendelian Randomization. We will argue that in this context, AEE is possibly the most natural parameter to aim for, whereas CACE is most difficult to interpret. We will also show that in order to achieve the interpretation of AEE for the IV estimate, a set of untestable assumptions is needed, such as the assumption of no-treatment-effect-heterogeneity. We will argue that the latter may often be implausible. As an alternative, we propose a sensitivity analysis approach, where possible lowest and highest values for the causal parameter are found. This idea will be implemented using the data of the Estonian Genome Center.

Novel genetic locus for kidney stone using diverse ancestry populations: the Women's Health Initiative study. *N. Franceschini[1], A. Reiner[2,3], T. Chi[4], M.L. Stroller[4], A. Kahn[5], C. Carty[2], Y. Li[6], T.L. Edwards[7], R. Jackson[8].* 1) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) University of Washington, Seattle, WA; 4) Department of Urology, University of California, San Francisco, San Francisco, CA; 5) San Francisco Coordinating Center, California Pacific Medical Center, San Francisco, CA; 6) Department of Biostatistics and Department of Genetics, University of North Carolina, Chapel Hill, NC; 7) Department of Medicine, Center for Human Genetics Research, Institute for Medicine and Public Health,Vanderbilt University, Nasville, TN; 8) Division of Endocrinology and Center for Clinical and Translational Science The Ohio State University, Columbus, OH.

Background. Kidney stones are highly prevalent in the US and have a known genetic component. Ethnic variation appears to play an important role in determining the risk for stone disease, as prevalence varies by ethnicity. **Methods.** To search for sequence variants accounting for kidney stone risk across populations of diverse ancestry, we conducted genome-wide association analyses in 8,400 African American and 3,587 US Hispanic women in the Women's Health Initiative SHARe cohort. Kidney stone was self-reported at study recruitment. Genotyping was performed using Affymetrix 6.0 and standard quality control was applied. Genome-wide ancestry estimates were calculated using Frappe. Imputation to 2.5 million single nucleotide polymorphisms (SNPs) was done in African Americans using a 1:1 ratio of HapMap Phase II CEU and YRI haplotypes as the reference population. Analyses used logistic regression and additive genetic models adjusted for age, body mass index and ancestry. **Results.** Overall mean age was 62 years, and 49 percent of women lived in Southern US. There was little evidence for genomic inflation in both African American and Hispanic samples (lambda 1.02) after adjusting for ancestry. Among 8,067 African American women with genotypes and phenotype data (cases=267), we identified several SNPs associated with kidney stones (lowest P=4.3 x 10^{-8}, minor allele frequency [MAF]= 0.37, imputation rsq 0.99) in a novel locus on 10p15.3. The SNPs have low frequency in CEU samples (MAF < 0.02). We then explored associations at this locus in our Hispanic genotyped sample (180 cases) and identified an associated proxy SNP (P=0.004, MAF= 0.05, D'=1.0 in HapMap CEU). Replication in additional African Americans is currently underway. For loci previously reported to be associated with kidney stones, we identified associations near the calcitonin receptor gene (*CALCR*, rs2106432, P=0.0001, African Americans), which has been implicated in kidney stone in children, but not 21q22.13 locus identified in Iceland. **Conclusions.** We identified a new locus for kidney stones in African Americans. The implicated SNPs have low MAF in both our Hispanic sample and in the HapMap CEU, suggesting that this effect may be relatively population-specific to persons of recent African Ancestry, who also experience a lower incidence of urinary stones. Our findings, if confirmed, demonstrate the utility of using samples of subjects with diverse ancestry in gene discovery.

G80A polymorphism in the RFC-1 gene in rheumatoid arthritis Mexican mestizo patients treated with methotrexate. *M.G. González-Mercado[1,2], M.P. Gallegos-Arreola[2], M.C. Morán-Moguel[2], M. Salazar-Páramo[3], J.F. Muñoz-Valle[4], A. Moreno-Andrade[5], G. Martínez[6], J.I. Gámez-Nava[3], L. González-López[3], I.P. Dávalos[1,2].* 1) Doctorado en Genética Humana, IGH, CUCS, Universidad de Guadalajara; 2) División de Genética y Medicina Molecular, CIBO, Instituto Mexicano del Seguro Social; 3) División de Investigación, UMAE, HE, CMNO, Instituto Mexicano del Seguro Social; 4) Doctorado en Ciencias Biomédicas, IIRSME, CUCS, Universidad de Guadalajara; 5) Universidad Autónoma de Guadalajara; 6) Hospital Civil “Fray Antonio Alcalde”, OPD, Guadalajara, Jalisco, México.

Introduction. Rheumatoid arthritis (RA) is a common rheumatic disease. Methotrexate (MTX), a folic acid antagonist, is a disease modifying antirheumatic drug (DMARD) commonly used in AR. MTX is introduced to cell by the reduced folate carrier (RFC-1). Several studies have associated RFC-1 G80A polymorphism with a different response to MTX in RA patients. There are few studies in Mexican RA patients related to RFC-1 G80A polymorphism. Objective. To determine the frequency of RFC-1 G80A polymorphism in patients with RA treated with MTX (RA-MTX). Methods: Group RA-MTX consisted in 30 RA mestizo Mexican patients diagnosed according to the American College of Rheumatology 1987 and Group M in 121 normal Mexican mestizo individuals (Rodarte et al 2007). RFC-1 G80A genotypification by PCR/RFLP's HhaI method. Results. Genotype frequencies (GF) for RFC-1 G80A in group M (%,n) were: GG 28% (34), GA 54% (65), AA 18% (22). In group RA-MTX: GG 10%(3), GA 77% (23), AA 13% (4). Allelic frequency (AF) in group M for allele A was 45% (109) and in group RA-MTX was 52% (31). Statistically differences (p=0.04) was observed in the genotype GG with OR 0.28 (CI 95% 0.05-1.03), and GA genotype with OR 2.83 (CI 95% 1.07-8.36); p=0.03. Conclusions. The genotypic and allelic distribution between both groups (group AR-MTX and group M) were similar. However the analysis with codominant (RFC-1 GA) and dominant (RFC-1 GG) models showed statistically difference between both groups.

707W

Genotype imputation in African Americans: an evaluation for selecting an optimal reference panel. *D.B. Hancock, J.L. Levy, G. Page, E.O. Johnson.* Research Triangle Institute International, Research Triangle Park, NC and Atlanta, GA.

Genotype imputation is often conducted to expand coverage of single nucleotide polymorphisms (SNPs) in genome-wide association studies by using reference haplotype panels at a dense set of SNPs. In African Americans, imputation has relied on HapMap phase II reference populations of Africans (YRI), European Americans (CEU), and Asians (CHB/JPT). HapMap phase III now offers admixed populations that provide a closer genetic match, such as ASW (African ancestry in Southwest USA). There has been limited evaluation of imputation with phase III samples. Here, we compared imputation results in African Americans using 15 different reference panel combinations with 117 YRI, 121 CEU, 170 CHB/JPT, and 68 ASW population samples, by imputing with a single reference panel from one population, imputing with a combined panel of two or more populations, or sequentially imputing with single panels and then merging the imputed genotypes. After applying standard quality control, we imputed chromosome 22 SNPs using MACH in 1,070 African Americans genotyped on the Illumina HumanHap550.v1 BeadChip, available from Illumina's iControl database. We evaluated 20,085 genotyped and imputed SNPs with the following metrics: (1) number of SNPs with minor allele frequency (MAF)>1%; (2) efficiency rate defined as the percentage of SNPs with r^2>0.3 between imputed and true genotypes; and (3) concordance rate based on masking 2% of the genotyped SNPs and comparing imputed and true genotypes (averaged over 10 sets of randomly masked SNPs). When using one reference population, YRI and ASW had similar rates of concordance (~90%) and efficiency (96-98%), but the smaller ASW panel captured more phase III SNPs with MAF>1% [17,961 SNPs (89%) for YRI and 19,118 SNPs (95%) for ASW]. When using two or more reference populations, sequential imputation with YRI, CEU, and ASW provided the largest number of SNPs with MAF>1% [19,540 SNPs (97%)], but combining YRI, CEU, and ASW into one reference panel gave the highest rates of concordance (93%) and efficiency (99%). The imputation patterns were similar in 595 African Americans genotyped on HumanHap550.v3 from the iControl database. Our findings show that imputation performance in African Americans was optimized by using reference panels which include ASW. Selection of the best procedure for including different reference population samples appears to require the investigator to balance maximal SNP coverage with imputation quality.

FCGR2A is the first Ulcerative Colitis susceptibility gene in African Americans. *C. Huang[1], S.E. Ellis[1], B. Kuhr[1], K.L. Isaacs[2], A.L. Silverman[3], J.D. Lewis[4], D.T. Smoot[5], J.F. Valentine[6], H.A. Kader[7], J.H. Cho[8], R.H. Duerr[9], J.D. Rioux[10], M. Silverberg[11], K.D. Taylor[12], Y. Wu[1], S. Hooker[13], R.A. Kittles[14], L.W. Datta[1], S.R. Brant[1], NIDDK IBD Genetics Consortium.* 1) Johns Hopkins University, Baltimore, MD; 2) University of North Carolina, Chapel Hill, NC; 3) Henry Ford Health System, Detroit, MI; 4) University of Pennsylvania, Philadelphia, PA; 5) Howard University College of Medicine, Washington, DC; 6) University of Florida , Gainesville, FL; 7) University of Maryland School of Medicine, Baltimore, MD; 8) Yale University, New Haven, CT; 9) University of Pittsburgh, Pittsburgh, PA; 10) Université de Montréal and the Montreal Heart Institute, Research Center, Montreal, QC, Canada; 11) University of Toronto, Samuel Lunenfeld Research Institute and Mount Sinai Hospital, Toronto, ON, Canada; 12) Cedars-Sinai Medical Center, Los Angeles, CA; 13) University of Chicago, Chicago, IL; 14) University of Illinois at Chicago, Chicago, IL.

BACKGROUND Ulcerative Colitis (UC) is a disease of chronic inflammation of the colon. It occurs in 0.2% of Americans, but is less frequent in African Americans (AA). Multiple genetic loci have been identified for UC in whites and in East Asian populations. Three UC susceptibility loci (FCGR2A, SLC26A3, and a locus at 13q12) were previously identified in a genome-wide association (GWA) study in Japanese samples. We evaluated these GWA signals in the under-studied AA population. METHODS A case-control study was carried out in 104 UC patients and 268 healthy controls. These samples were genotyped by either Taqman® SNP Genotyping Assay or direct sequencing. Loci that showed significant association were also genotyped in 293 samples of Crohn's disease, the other major inflammatory bowel disease phenotype. Allele-based and haplotype-based statistical analyses of the genotyping data were performed in PLINK. 97 Admixture Informative Markers (AIM) were genotyped to control for variation in admixture in 76% of study subjects. RESULTS The non-synonymous SNP (rs1801272, H131R) demonstrated significant association with UC (OR=1.638 (1.169-2.300) p-value=0.003). West African and European admixture did not differ between cases and controls (p=0.398), and UC association (in AIM genotyped samples) with H131R adjusted for admixture was similar (OR= 1.815 (1.248-2.642) p=0.002). Association for CD did not reach 0.05 alpha level (OR= 1.223 (0.960-1.559) p-value=0.094). To better localize the association at this gene five more SNPs in the haplotype block were genotyped. Only one SNP upstream of rs1801274, rs10800309, showed marginal association (OR=1.382 (0.970-1.963) p-value=0.065). The haplotype analysis of these two SNPs demonstrated that the haplotype consisted of the two major alleles was protective (=0.605 (0.434-0.844) p-value=0.003). This association was driven by the known functional SNP, rs1801274. The p-value of independent effect test was 0.062. Our results in the AA population were consistent with the previous findings in the Japanese population and in the recent UC GWA meta-analysis in whites. CONCLUSION UC risk in AA has molecular genetic causes. FCGR2A H131R was associated with UC in AA's. It is a gene polymorphism that alters function of a receptor for the Fc portion of IgG, and also has been found associated with lupus, rheumatoid arthritis and susceptibility to pseudomonas infection. Further research on genetic causes of UC in AA's are greatly anticipated.

Association of osteoarthritis and serum bilirubin level -- a Framingham Heart Study. *J. Lin[1], N. Jeffries[1], F. Kronenbery[2], S. Hwany[3], L. Vitek[4], H. Schwertner[5].* 1) Office ob Biostatistics Research, Division of Cardiobascular Science, National Heart, Lung and Blood Institutes, National Institutes of Hearth, Bethesda, MD; 2) Division of Genetic Epimiology, Innsbruck Medical University, Innsbruck, Austria; 3) Framingham Heart Study, National Heart Lung and Blood Institute, National Institutes of Health, Framingham MA; 4) Department of Internal Medicine and Institute of Clinical Biochemistry and Laboratory Diagnostics, 1st Faculty of Medicine, Charles Universtiy In Pragur, Czech Republic; 5) Clinical Research, Wilford Hall Medical Center, San Antonio, TX.

The anti-oxidant properties of bilirubin exert a physiologic anti-inflammatory effect which might provide protection against rheumatoid arthritis. On the other hand, experimental data on mouse collagen-included arthritis exhibited a retarded elimination of bilirubin and was therefore associated with high serum bilirubin levels. Arthralgias after quinupristin-dalfopristin therapy demonstrated a strong association with elevated bilirubin levels at baseline. To date, no association study between human osteoarthritis and serum bilirubin levels has been reported. We investigated in the Framingham Heart Study population whether serum bilirubin levels are associated with osteoarthritis. The study population included 1597 individuals of Framingham Offspring cohort, mean age 53 years, 46.8% male. Bilirubin levels were measured during Offspring exam 1, in the early 1970's, and osteoarthritis was diagnosied in the exam 5 between 1993 and 1994. Of 1597 individuals, 456 had osteoarthritis, having a baseline age of 29-81 years, and 46.8% male. Logistic regression was used to test the association between osteoarthritis and bilirubin levels, adjusting for age, gender and BMI. Bilirubin levels are positively associated with osteoarthritis (p=0.001), with a doubling bilirubin associated with a 33% increase in the odds of osteoarthritis. Osteoarthritis has an opposite association with bilirubin levels as rheumatoid arthritis, but has the same positive association with mouse collagen-included arthritis and arthralgias after quinupristin-dalfopristin therapy.

Distribution of Mitochondrial Haplogroups in the National Health and Nutrition Examination Surveys. *S. Mitchell, K.D. Brown-Gentry, P. Mayo, M. Allen, N. Schnetz-Boutaud, D. Murdock, D.C. Crawford.* Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt Univ, Nashville, TN.

Mitochondrial haplogroups are defined by combinations of mitochondrial DNA (mtDNA) polymorphisms inherited from a common ancestor. A number of studies report that mitochondrial haplogroups confer disease risk or even protection from disease. The National Health and Nutrition Examination Surveys (NHANES) are large, population-based surveys conducted in the United States by the National Center for Health Statistics at the Centers for Disease Control and Prevention (CDC). Each NHANES collects demographic, lifestyle, and health data from participants using surveys, laboratory measures, and medical examinations. For participants consenting to Genetic NHANES, DNA samples were collected for NHANES III (1991-1994), NHANES 1999-2000, and NHANES 2001-2002. Approximately 15,000 DNA samples representing 6,605 non-Hispanic whites (NHW), 3,477 non-Hispanic blacks (NHB), 3,950 Mexican Americans (MA), and 1,004 participants of other race/ethnicity are available for research purposes. The goal of the present work is to classify and describe the distribution of mitochondrial haplogroups in the NHANES samples. Ten SNPs were genotyped in all NHANES samples and 360 samples from the International HapMap Project using Sequenom. These ten SNPs were selected to determine major European haplogroups (H, I, J, K, T, U, V, W, and X) and are located throughout the coding and control regions of the mitochondrial genome. The major mitochondrial haplogroups were determined for 90% of NHW, 12% of NHB and 13.5% of MA. Additionally, 22% of participants of other self-declared racial/ethnic groups were successfully classified. As expected, among the NHW, haplogroup H was the most common classification (42%). The frequency of haplogroup H observed in our NHW population is similar to the frequency in the European descent (CEU) HapMap samples (44%). Other haplogroups identified among NHW included: U (15%), J (10%), T (9%), and K (7%), with the remaining haplogroups (I, V, W, X) found among fewer than 5% of NHW participants. With these ten SNPs, we were able to classify mitochondrial haplogroups for the majority of NHW in the combined NHANES sample. As expected, we were able to assign mitochondrial haplogroups for only a small fraction of NHB and MA individuals based on the SNPs genotyped. Additional SNPs are required to resolve haplogroups for NHB and MA participants, and full haplogroup resolution is ideal for downstream genotype-phenotype correlations in NHANES.

Identifying Independent Genetic Associations in Complex Disease using Penalised Multivariate Logistic Regression and Hierarchical Modelling: A Case Study on Systemic Lupus Erythematosus. *D.L. Morris[1], J. Bentham[1], M.E. Alarcón-Riquelme[2], J.D. Rioux[3], T.J. Vyse[1], BIOLUPUS.* 1) Department of Medical and Molecular Genetics, King's College London, London, SE1 9RT. United Kingdom; 2) GENYO. Centro de Genómica e Investigación Oncológica Pfizer. Universidad de Granada, Junta de Andalucía, Avda de la Ilustración 114, Granada, Spain. 18007. +34 958 637 078; 3) Université de Montréal, Montreal Heart Institute, 5000 rue Belanger, Suite S-6300, Montreal, Quebec, Canada. H1T 1C8.

Delineating the genetic contribution to the risk of developing a complex disease is complicated by the likelihood that disease is caused by multiple genes. The search for disease causing loci will therefore require the identification of multiple markers, each contributing individually perhaps a small increase in risk. Rather than performing multiple individual tests for single marker association, we propose that information should be shared between markers in Genome Wide Association Studies (GWAS). This can be achieved using multivariate penalised regression or hierarchical modelling with hyper-parameters that are shared across all markers. In this setting, the size of the data is a strength rather than a weakness. In this study we compare the use of stepwise regression, penalised logistic regression (PLR) and hierarchical modelling, applied to the largest GWAS in Systemic Lupus Erythematosus (SLE) (4,254 Cases and 8,578 Controls typed on the Illumina Omni-Quad chip) in a European population. SLE is one of the many complex diseases that are still without an adequate explanation for the known heritability (>66% in the case of SLE), and many studies have analysed genetic variation within the genome with the aim of identifying multiple loci independently associated with SLE. The results from the SLE GWAS study show that PLR is more robust against false positives than stepwise regression, but without loss of power. We demonstrate the benefits of PLR with an analysis of the MHC region. Stepwise regression was sensitive to the metric used for including variables and identified more than ten loci in some cases (depending on the metric) while PLR using the Hyper Lasso (and one SR approach with the FDR) selects five, two of which were previously known to be associated and three which are novel. We also show, analysing each chromosome separately (Number of markers: 20k-60k), that hierarchical modelling accounts for multiple testing (MT) naturally, without user specification of hyper-parameters or pre-defined adjustments. We argue therefore that there is enough information in current GWAS to estimate hyper-parameters shared across markers. These hyper-parameters act as a penalty against the inclusion of multiple correlated markers and avoid the requirement for arbitrary adjustments for MT. We conclude that GWAS should exploit the data size by sharing information between markers in the search for multiple disease associated loci.

Prevalence of Spinocerebellar ataxia type15 in Japan screened with Taqman PCR assay. *M. Obayashi[1], M. Takahashi[1], Y. Niimi[1], N. Sato[1], O. Onodera[2], K. Ishikawa[1], M. Nishizawa[2], H. Mizusawa[1].* 1) Department of Neurology and Neuroscience, Tokyo Medical and Dental University, Bunkyo-ku, Tokyo-to, Japan; 2) Department of Molecular Neuroscience, Niigata University.

Spinocerebellar ataxia type 15 (SCA15) is a slowly progressive neurodegenerative disorder characterized by almost pure cerebellar ataxia. The cause of SCA15 is mutation of the ITPR1 gene (inositol 1,4,5-triphosphate receptor, type 1). Many SCA15 families have partial deletions and one family has a missense mutation. prevalence of SCA15 were reported from Europe. In Japan some SCA15 families were reported. We perfomed Taqman PCR assay to search for ITPR1 deletions in all 225 patients' samples which were gathered to SCA genetic diagnosis but were negative for mutations in SCA1, 2, 3, 6, 31, and DRPLA genes. We identified only one patient with an ITPR1 deletion. She developed gait disturbance at 51 years old, and progressed to show pure cerebellar ataxia. Her two brothers have ataxic symptoms. In our study, ITPR1 deletions were rare in Japan, comprised 0.03% in all SCA in our cohort. This indicates that SCA15 is much rare in Japan than in Europe.

Centro de Genómica e Investigacion Oncológica Pfizer-Universidad de Granada-Junta de Andalucía.

Background: Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease characterized by the presence of auto-antibodies and immune-complexes and with diverse clinical manifestations. The prevalence and severity of SLE has a wide variation among different ethnic groups. SLE occurrence is three to four times higher amongst Asian and African-American women. In addition, Hispanics, Asians and African-Americans have an excess morbidity from SLE and higher prevalence of lupus nephritis than Caucasians. Probably both genetic and environmental factors are involved in these disparities. Objective: To analyze the relationship between genetic ancestry and socio-demographic characteristics and clinical features in a large cohort of Hispanics SLE patients. Material and methods: A total of 922 SLE patients and healthy controls of Hispanic origin with socio-demographic data and a total of 1274 SLE patients with clinical data were used in the study. Genotyping of 347 continental ancestry informative markers (AIMs) was performed on the Illumina platform. The STRUCTURE software was used to determine genetic ancestry of each individual. Correlation between ancestry and socio-demographic and clinical data were analyzed using logistic regression. Results: The total Amerindian genetic ancestry for 1274 SLE patients is 36.4% ± 0.20. After logistic regression analysis we found a correlation between increased Amerindian ancestry and low medical coverage (p= 0.002) and less years of education (p= 0.0003). However, there were no significant differences between a low socio-economic level using the Graffar scale and Amerindian ancestry. We found no differences between age of onset and Amerindian ancestry. We found a decrease in Amerindian ancestry in SLE patients with photosensitivity (p= 0.004) and an increase in Amerindian ancestry in patients with renal involvement (p= 0.0012). Renal involvement did correlate with early age of onset, independently of the ancestry (p< 0.0001). Conclusion: In general, genetic Amerindian ancestry correlates with lower educational level, worse medical coverage and renal disease than genetic European ancestry, which correlates with photosensitivity. Age of onset correlated with renal disease independently of the ancestry.

Using Multiple Measures for Quantitative Trait Association Analyses : Application to Estimated Glomerular Filtration Rate (eGFR). *A. Tin[1], B.C. Astor[1], E. Boerwinkle[2], E. Colantuoni[1], J. Coresh[1], W.H. Kao[1].* 1) 1. Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, 615 N. Wolfe Street, Baltimore, MD; 2) 2. Human Genetics Center, University of Texas School of Public Health, Houston, TX 77030, USA.

Background: Although non-genetic studies have shown that multiple measures of a quantitative trait can improve the efficiency (i.e. reduce standard error) of subject level parameter estimates, little is known about the improvement in efficiency in genome-wide association studies (GWAS) that utilize multiple measures of a trait. Methods: We conducted a simulation study to examine how efficiency, for a fixed sample and genetic effect size, is affected by the number of measures, the variance of and the correlations between measures, and the missing data rate. We used linear regression for single measure and mixed effect model for multiple measure model. For ease of comparison, the gain in efficiency in the multiple measures model versus the single measure model was expressed as a gain in equivalent sample size. We also compared the empirical results from 3 GWAS of renal function in 9049 European American participants of the Atherosclerosis Risk in Communities (ARIC) study: a single measure of eGFR, a 3-measure model of eGFR based on serum creatinine and a 6-measure model using six outcomes derived from four biomarkers (serum creatinine, cystatin C, beta trace protein, and beta-2 microglobulin). Results: Given similar effect sizes across measures, the gain in efficiency increased as the correlation or variance of outcome measures decreased. When the variances and effect sizes were the same from two different measures, the equivalent sample size gain in using two measures was approximately 30% for a correlation of 0.5 between measures, but only 9% for a correlation of 0.8. The addition of a third measure brought further gain albeit smaller. When the variance of the additional measures exceeded the variance of the first measure given similar effect sizes, the gain in equivalent sample size was much reduced. When the variance of the second measure was 70% larger than the first measure, the gain in equivalent sample size dropped to 16% for a correlation of 0.5 between the two measures. In the GWAS of renal function, the single measure model detected one genome-wide significant (p<5x10-8) locus while the 3-measure model detected three, and the 6-measure model detected two. Conclusion: Multiple measures of a quantitative trait can increase the efficiency, thus the power, of a study without additional recruitment. However, careful attention must be paid to the effect sizes and variances of and the underlying correlations between the measures.

715W

A Comparison of Approaches to Control for Confounding Factors by Regression Models. *C. Xing[1], G. Xing[2].* 1) McDermott Ctr, Univ Texas SW Med Ctr, Dallas, TX; 2) 1Bristol-Myers Squibb Company, Pennington, NJ.

A common technique to control for confounding factors in practice is by regression adjustment. There are various versions of regression modeling in the literature, and in this paper we considered four approaches often seen in genetic association studies. We carried out both analytical analyses and simulation studies comparing the bias of effect size estimates and examining the test sizes under the null hypothesis of no association between an outcome and an exposure. Further, we compared the methods in a genome-wide scan for plasma lipoprotein(a) levels in the Dallas Heart Study. We found that a widely employed approach that models the covariate-adjusted outcome and the exposure leads to an infranominal test size and underestimation of the exposure effect size. In conclusion, we recommend either using multiple regression models or modeling the covariate-adjusted outcome and the covariate-adjusted exposure to control for confounding factors.

Association between 11q23-25 region and triglyceride in metabolic syndrome. *M.S. Fallah[2], M.S. Daneshpour[1], S. Alfadhli3[3], A. Rebai[4], M. Hedayati[1], M. Zarkesh[1], F. Azizi[5].* 1) 1. Obesity Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti MC, Tehran, Iran; 2) 2. Kawsar Human Genetics Research Center (KHGRC), Tehran, Iran; 3) 3. Department of Medical Laboratory Sciences, Faculty of Allied Health Sciences, Kuwait University, Kuwait; 4) 4. Centre of Biotechnology of Sfax, Tunisia; 5) 5. Endocrine Research Center, Research Institute for Endocrine Sciences, Shahid Beheshti MC, Tehran, Iran.

Introduction: Metabolic syndrome is common and has a rising prevalence worldwide. Raised serum triglyceride is one of the risk factors of metabolic syndrome. Here we tried to find the association between triglyceride level and metabolic syndrome using micro-satellite as genetic markers. Materials and methods: Twelve microsatellites in 4 different chromosomes were selected to investigate possible genes linked to the serum triglyceride level. 65 families with metabolic syndrome pattern who were participated in Tehran lipid and glucose study included in the study. Family based association test (FBAT) used to test the association and linkage. LOD score was calculated by Merlin. Result: Family Based Association Tests (FBAT) under the bi-allelic mode showed that serum triglyceride is linked with D11S1304 after bonferroni correction for multiple testing (p<0.05). Max LOD score calculated by non-parametric linkage analysis in dominant model was 0.96 in 16q23-24 region (D16S3096). Conclusions: Serum triglyceride is one of the main components of metabolic syndrome and the result of this study showed that genetic variation could play a significant role in this regard. To find a candidate gene responsible for triglyceride change in metabolic syndrome, these associated regions should be investigated further.

Using linkage data to prioritize analysis of data from whole exome sequencing. *T. Foroud[1], D. Koller[1], D. Lai[1], H. Lin[1], N. Pankratz[1], Y. Liu[1], R. Deka[2], L. Sauerbeck[2], H. Ling[3], K. Doheny[3], E. Pugh[3], J. Broderick[2], Center for Inherited Disease Research and The FIA Study.* 1) Indiana Univ Sch Med, Indianapolis, IN; 2) University of Cincinnati Sch Med, Cincinnati, OH; 3) Center for Inherited Disease Research, Johns Hopkins University School of Medicine, Baltimore, MD.

Whole exome sequencing is becoming a relatively common approach to identify genes contributing to Mendelian disorders. It can also be used to identify genes contributing to diseases with complex genetic etiology, particularly in subsets of families that might segregate a highly penetrant rare variant(s). In these families, prior linkage data is often available and can be used to prioritize chromosomal regions for initial review of sequencing data. We are currently performing whole exome sequencing in 7 families selected because of the high density of affected members with intracranial aneurysms (IA). In each family we had at least 3 affected individuals, all with either a ruptured or unruptured IA. In one family, there is an additional member with an abdominal aortic aneurysm. Prior to performing whole exome sequencing (Agilent© SureSelect™ 50Mb Human All Exon Kit), an Illumina® OmniExpress array was genotyped for each affected family member. In addition, both affected and unaffected family members were previously genotyped using the Illlumina 6K linkage screen. Some families were also genotyped with microsatellite markers. We performed linkage analysis using both dominant and recessive models employing all available marker data. We assumed that each family might have a unique genetic etiology and reviewed LOD scores across the genome for each family. We identified chromosomal regions providing LOD scores greater than 1.5 with support from multiple markers. We reviewed each interval in detail to identify SNPs that could delimit the region of linkage and provided definitive evidence of recombination. Five of the seven families generated LOD scores greater than 1.5. We also identified chromosomal regions with more modest evidence of linkage but which overlapped across families. Preliminary next generation sequencing data in six of the seven families was recently generated. Comparison of genotypes from the OmniExpress and sequencing data had greater than 99.9% concordance. Average per sample exon coverage (at > 8x) was 89.4% and the average missing exon coverage (no coverage) was only 3%. These measures support the high quality of the sequencing. The preliminary linkage results are currently being used as an early filter to identify promising variants and genes. This approach may be very helpful, particularly in families with autosomal dominant inheritance in which many variants will be identified and prioritization will be essential.

Age-related macular degeneration in an Amish population: the reliability of self reporting disease. *J.L. Haines[1], A.C. Cummings[1], D. Fuzzell[1], A. Agarwal[2], J. Gauthier[1], R. Laux[1], W.K. Scott[3], M.A. Pericak-Vance[3].* 1) Ctr Human Genetics, Vanderbilt Univ Medical Ctr, Nashville, TN; 2) Vanderbilt eye Institute, Vanderbilt Univ Medical Ctr, Nashville, TN; 3) Dr. John T. Macdonald Foundation Department of Human Genetics, Univ of Miami, Miami, FL.

Age-related macular degeneration (AMD) is a complex disorder that attacks the central retina, causes drusen, atrophy, and choroidal neovascularization, and causes debilitating vision loss in approximately 1.5 million Americans affected by advanced forms of the disease. Genes known to increase risk for AMD are *CFH*, *ARMS2*, and *C3*. Cigarette smoking also increases risk. The gene *CFB* decreases AMD risk. We have been working with the elderly population (age 65+) of the well-defined and genetically isolated Amish communities of Holmes County and surrounding counties in Ohio as part of a larger study of other elderly phenotypes. Seventy three individuals, who connect into a single 1505-member pedigree obtained from the Anabaptist Genealogy Database, have been examined by an ophthalmologist and self reported to have been or to not have been given a previous diagnosis of AMD. Forty two of those individuals were diagnosed with AMD, and thirty nine of the 42 diagnosed with AMD had previously self reported to have ever been diagnosed with AMD. Thirty one individuals were determined to not have AMD, and only five of those individuals self reported to have ever been diagnosed with AMD. We found the false positive rate of reporting AMD when AMD diagnosis was denied by an ophthalmologist to be 16%, and the false negative rate of not reporting previous AMD affection when an ophthalmologist confirmed AMD to be 7%. The corresponding positive predictive value for those that truly had AMD out of those that self reported to be affected is 89%, and the negative predictive value for those determined to not have AMD out of those reporting no previous diagnosis of AMD is 90%. Therefore, self report of AMD can be used as a reliable proxy for actual AMD affection status. This information paves the way for future studies of AMD genetic risk factors in the Amish population, through which we can determine if currently known risk genes have an effect on this population. We have already determined that a small subset of the affected individuals do not harbor *CFH* risk alleles. This unique genetically and environmentally homogeneous population also provides the opportunity for discovering novel risk variants for AMD.

Identification of loci enriched for nuclear-encoded mitochondrial proteins underlying mobility in oldest-old Amish. *J.E. Hicks[1], J.R. Gilbert[1], L. Jiang[1], A.C. Cummings[2], L. Caywood[1], L. Reinhart-Mercer[1], D. Fuzzekk[2], C. Knebusch[2], R. Laux[2], C.E. Jackson[3], M.A. Pericak-Vance[1], J.L. Haines[2], W.K Scott[1].* 1) Hussman Institute for Human Genomics University of Miami, USA; 2) Center for Human Genetics Research Vanderbilt University, USA; 3) Scott & White Temple, TX.

Gait speed is heritable and strongly predicts incipient disability and mortality. To examine genetic influences on aging-related traits such as gait speed, adults over 80 were enrolled in a population based survey of Amish communities in Indiana and Ohio. The Anabaptist Genealogy Database was used to connect all 407 participants in a 13-generation pedigree. Genotyping was performed using the Affymetrix Genome-Wide Human SNP Array 6.0. Gait speed was measured by timing subjects on a 10ft walk. The large pedigree was cut down into 46 computationally feasible families, containing 273 mobile individuals (those with gait speeds greater than 0.52 m/s, representing the top 2/3 of all individuals). These were then analyzed using multipoint non-parametric linkage (LOD*) analysis implemented in Merlin. PLINK was used to select a set of 4966 SNPs in linkage equilibrium (pairwise r2 < 0.16 for all markers). Sex equal inter-marker map distances (in Kosambi cM) were obtained from the Rutgers Combined Physical-Linkage Map. Associations within linkage signals were tested using the MQLS test for correlated data. Linkage analysis identified 7 regions significantly linked to mobility: two regions on chromosome 1 (LOD*=3.62, 1 LOD unit support interval (SI): 9.25cM to 21.14cM; LOD*=3.15, SI: 36.54cM to 48.45cM), and regions on chromosome 4 (LOD*=4.20, SI: 182.30cM to 192.06cM), chromosome 5 (LOD*=3.08, SI: 114.77cM to 146.73cM), chromosome 10 (LOD*=3.181, SI: 122.93cM to 146.73cM), chromosome 17 (LOD*= 3.19, SI: 120.68cM to 131.38cM) and chromosome 19 (LOD*=4.01, SI: 46.58cM to 52.69cM). No SNPs in the seven SI were associated with mobility after correcting for multiple comparisons. The chromosome 4 interval overlaps just one gene, ODZ3. The interval on chromosome 19 overlaps a previously observed osteoarthritis locus and contains UQCRFS1, a protein in the mitochondrial electron transport chain. Indeed, six of the seven intervals contain excellent candidate genes that localize to the mitochondrial membrane, suggesting that maintenance of mitochondrial function may be important in preserving mobility, and lending support to theories of mitochondrial involvement in aging processes.

Pedigree-based Imputation Infers Pure *in-silico* Genotypes and Improves Power for Genetic Associations: the Framingham Heart Study. *J. Huang[1, 2], MH. Chen[1,3,4], WM. Chen[5], C.J. O'Donnell[1,2,6], Q. Yang[1,4].* 1) Framingham Heart Study, National Heart Lung & Blood Institute, framingham, MA; 2) Division of Intramural Research, National Heart, Lung and Blood Institute, Bethesda, MD; 3) Department of Neurology, Boston University School of Medicine, Boston, MA; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 5) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 6) Cardiology Division, Department of Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Background: The Framingham Heart Study started in 1948 and has recruited 3 generations of participants over more than 60 years. The majority of participants are in multigenerational families. 9,247 out of 14,531 participants were genotyped with Affymetrix 550K panel while the rest do not have genome-wide genotypes mainly due to lack of DNA samples. Our objective is to examine validity and potential power gain from imputing completely un-genotyped individuals using genotyped relatives in genome-wide association studies in this large family cohort. **Methods**: Large pedigrees over 20 bits were split into sub-pedigrees equal to or less than 20 bits, using a strategy to maximize the number of genotyped relatives for each un-genotyped individual. With the input of 8,520 individuals with high quality genome-wide genotyping and 150 individuals with sparse genotyping (N SNPs=5,749), we imputed genome-wide genotype data for the 150 sparse and 2,971 un-genotyped participants who have one or more genotyped relatives. For these 2,971 un-genotyped individuals, 1990, 931, and 50 belong to the first, second, and third generations, respectively. A SNP was defined as "well imputed" when the most likely genotype could be estimated with over 95% certainty. The imputed dosage was used in association analysis. We used an established association (*FGB* with fibrinogen) as a positive control to evaluate the power for association analysis when purely inferred genotype dosage is included. **Results**: For the 150 individuals with sparse genotype, 98 were imputed attaining more than 75% of well imputed SNPs genome-wide. For the 2,971 un-genotyped individuals, 271 have more than 75% well imputed SNPs, and the number increases to 738 and 1,440, respectively, for 50% and 25%. For the SNP rs2227426 within *FGB*, previously found to be associated with fibrinogen ($p=1.66x10^{-10}$) with genotyped individuals only, the significance improves to $p=5.38x10^{-11}$ when the imputed samples are included. We will present genome-wide association results for several phenotypes, where a significant number of cases have only imputed genotypes. **Conclusion**: This is the first study that demonstrated pedigree structure could be used to impute genome-wide genotype data for samples originally without any genotype. Our findings suggest that purely imputed *in-silico* genotypes based on informative family structures can be used to increase power in genome-wide association studies.

721W

Integrating sparse and dense marker data to interrogate a linkage signal. *E. Marchani[1], E. Wijsman[1, 2, 3].* 1) Div Med Gen, University of Washington, Seattle, WA; 2) Dept Biostat, University of Washington, Seattle, WA; 3) Dept Genome Sci, University of Washington, Seattle, WA.

Linkage analysis is an important step toward disease gene identification, but it is rarely the final one. Here, we combine a genome-scan panel of microsatellites (STRs) with dense SNPchip data to explore a linkage region in a large Alzheimer's disease pedigree. We defined a linkage region to encompass all STRs with single-marker evidence of linkage, plus two flanking markers on either side. We then combined the underlying STRs with SNPs selected for high heterozygosity and low missingness to create a 1cM marker map across the linkage region. Our primary goals were validate and narrow our linkage region and to identify probable carriers of the segregating trait locus.

We found that dense SNP data reduced the uncertainty caused by missing genotype data by increasing the constraints on ancestral genotypes. We observed a dramatic reduction in the number of equivalent sets of inheritance vectors at a given locus, estimated by the MORGAN programs gl_auto and IBDgraph, when using a dense rather than sparse marker panel. We also found that dense marker data replicated our linkage signal and improved its strength, likely because of this reduction in uncertainty. The denser marker map consistently increased the posterior probability of linkage relative to the original genome scan when analyzed using Markov chain Monte Carlo (MCMC) methods. We finally identified SNPs to tag the chromosomal segment co-segregating with the underlying trait locus. We investigated 11,313 SNPs across the linkage region using a measured genotype approach, and examined in greater detail those SNPs explaining the greatest amount of genetic variance in the trait. The SNPs falling within the 99th percentile spanned the entire linkage region, had minor allele frequencies ranging from 0.1 to 0.5 at the population level, and reduced the linkage signal when included as a covariate in the trait model. This highlights the importance of examining an entire linkage region, rather than the linkage peak alone, and not focusing too heavily on rare variants. In the future, we will combine genotypes at these influential SNPs with the inheritance vectors estimated from the 1cM marker panel to build a SNP haplotype tagging the chromosomal segment co-segregating with the trait. Relatives sharing that haplotype are most likely to share an underlying trait variant, and will be targeted for additional sequencing and functional analyses.

The Role of Rare Genetic Variation in Asperger Syndrome in Finnish Families. *M. Rossi[1,2], K. Rehnström[3], H. Kilpinen[3], I. Hovatta[1,4,5], S. Ripatti[1], A. Palotie[1,3].* 1) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 3) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 4) Research Program of Molecular Neurology, University of Helsinki, Helsinki, Finland; 5) Department of Medical Genetics, University of Helsinki, Helsinki, Finland.

Background: Asperger syndrome (AS) belongs to autism spectrum disorders (ASD). AS is differentiated from autism by later onset of symptoms, lack of mental retardation and lack of language development delay. Recent studies have estimated the prevalence of AS as 2.5-2.9 per 1000. The etiology of AS has remained unknown but it is generally considered as a multifactorial disorder with several predisposing genes. However, gene mapping of AS candidate genes has been hindered by significant clinical and genetic heterogeneity, whereupon the search for common variants has not been successful. Aim of the study: The aims of the study are to 1) Identify genomic regions shared identity-by-descent in the Finnish AS families, 2) Identify rare functional variants within localized regions, and 3) Identify CNVs modifying the risk for AS. Materials and methods: The AS family sample consists of 175 individuals from 25 large families (naffected=123) genotyped with Illumina HumanOmni1-Quad BeadChip and Illumina HumanHap550 BeadChip. Multipoint linkage was performed with 19 000 SNPs using Merlin, and singlepoint linkage with 150 000 SNPs using ANALYZE 1.9.4.beta. Exome seguencing has been performed in Wellcome Trust Sanger Institute, Cambridge, UK. Results: Two loci in the whole AS study sample result in NPL>1.5; 3p22-3p14 (NPLall=1.93) and 20q12-20q13 (NPLall=1.52). This region in 3p22-3p14 overlaps with the region identified in a previous microsatellite linkage scan by our group, although NPLall=3.83 was observed using microsatellites. The region on chromosome 20 did not show evidence for linkage in the original microsatellite scan. Conclusions: Our preliminary results reveal several IBD shared regions within families, which suggests there are familial effects contributing to AS risk. Exome sequencing data will be followed up for these regions with an initial focus on families that show limited number of IBD shared regions in all together 15 genomic loci. The aim is to identify functional variants contributing to AS risk in each family.

723W

Individuals with both type 1 diabetes and celiac disease autoimmunity carry private risk variants for both diseases. *J. Romanos[1], G. Trynka[1], L. Franke[1], M. Platteel[1], S.A. Medema-Jankipersadsing[1], A.K. Steck[2], J.M Norris[3], G. Eisenbarth[2], M. Rewers[2], E. Liu[2], C. Wijmenga[1].* 1) Department of Genetics, University Medical Center Groningen, Groningen, Netherlands; 2) Barbara Davis Center for Childhood Diabetes, University of Colorado Denver, Aurora, Colorado, USA; 3) Epidemiology Department, Colorado School of Public Health, Aurora, Colorado, USA.

Type 1 diabetes (T1D) and celiac disease (CD) cluster in families and co-occur in patients. Some of the genetic regions and even some SNPs have been associated with both diseases. Our aim was to determine the genetic differences between individuals developing both diseases and those having only T1D or only CD. In a pilot study, we genotyped 48 established CD and/or T1D associated SNPs in 1115 non-Hispanic white American (NHWA) T1D patients, in 803 Dutch CD patients (confirmed by biopsy) and in 260 NHWA T1D patients with CD-autoimmunity (CDA&T1D group), defined as persistent tissue-transglutaminase positivity on two consecutive visits. Our analysis showed that individuals with both diseases accumulate private T1D and CD risk variants. To improve the study, we genotyped 196,524 SNPs present on Immunochip in 257 American and 4 Dutch CDA&T1D patients, and 1146 Dutch CD patients. The immunochip (Illumina iSelect custom array) includes variants from the 1000 Genomes pilot CEU and re-sequencing study variants for 183 loci associated to 12 immune-mediated diseases. Association analysis was performed using logistic regression, adjusting for gender and the first two components from the multidimensional scaling to adjust for the different ethnic backgrounds of our samples. We saw an enrichment of association signals in the autoimmune disease regions, but not for 1753 SNPs associated to bipolar disorder. This indicates that the association signals are true and our data set shows no stratification. We calculated a platform-specific significance threshold to be 1.9e-6 at 5% false discovery rate and identified two regions, IRF4 locus (OR=2.6 [1.9-3.7]) and a new signal on chromosome 11 (OR=1.7 [1.4-2.1]), reaching this threshold. Another three loci were suggestive at p-value <1e-5. These regions include PTPN22 (OR=2.0 [1.5-2.7]), CTLA4 (OR=1.7 [1.4-2.1]) and INS (OR=2.0 [1.5-2.7]) loci, which are known to be associated to T1D. We acknowledge that the CDA&T1D group was small so we are now expanding it by adding cases from the Type 1 Diabetes Genetics Consortium samples. We are also performing the same analysis to compare the genetic background of individuals with only T1D to those who develop both T1D and CDA. Finally, despite its limitations, this study suggests that individuals with both T1D and CDA do carry the celiac risk variants as well as private T1D risk variants but do not have enrichment for those that are shared between both diseases.

Genome-wide interaction analysis of exogenous estrogen in age-related macular degeneration (AMD): Novel association of Retinitis Pigmentosa and Retinoblastoma loci. *MD. Courtenay[1], AC. Naj[2], WH. Cade[2], PL. Whitehead[2], I. Konidari[2], SG. Schwartz[3], JL. Kovach[3], A. Agarwal[4], G. Wang[2], JL. Haines[5], MA. Pericak-Vance[1,2], WK. Scott[1,2].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 4) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN; 5) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

AMD is the leading cause of irreversible vision loss in developed countries. Its multifactorial etiology includes both genetic and environmental risk factors. Previous studies have shown that women who take exogenous estrogen in the form of hormone replacement therapy (HRT) or birth control pills (BCPs) have reduced risk of developing AMD. The purpose of this study was to detect novel gene-environment interactions with these established risk factors using case-only analysis (CO). Affymetrix 6.0 chipsets were used to genotype 668238 SNPs in 540 Caucasian females with early and late AMD. After quality control checks, imputation against the HapMap CEU reference panel was used to generate genotypes for a total of 2.5 million SNPs with imputation quality R^2>0.3. History of ever taking HRT or BCPs was collected with a self-administered questionnaire. Next, CO tests were conducted for association between each SNP and HRT (278 Ever, 262 Never) or BCPs (108 Ever, 426 Never) using logistic regression models adjusted for age and smoking. Tests were conducted overall and in the neovascular AMD subset. Although no results met Bonferroni-corrected genome wide significance, there were 33 SNPs with $p<10^{-5}$ and several were in genes associated with retinal diseases. For all AMD cases, a variant in PCDH19 had suggestive association with ever taking BCPs (rs12861320: interaction odds ratio (ORi)=6.78, $p=4.7x10^{-6}$). For neovascular AMD (150 Ever HRT, 173 Never), an imputed SNP in PCDH15 was inversely suggestively associated with ever taking HRT (rs10763126: ORi=0.45, $p=7.1x10^{-6}$). Mutations in PCDH15, which is expressed in retina, are associated with retinitis pigmentosa (RP) in individuals with Usher Syndrome type 1F, and PCDH19 is from the same family of cell-cell adhesion molecules. Also, an imputed variant in RB1CC1 (rs10504143) was suggestively associated with BCPs in all (ORi=5.25, $p=2.2x10^{-6}$) and neovascular AMD cases (ORi=8.95, $p=2.3x10^{-6}$). RB1CC1 is a transcription factor associated with retinoblastoma (RB) gene expression and its function in regulating cell growth, proliferation, and migration also make it a promising gene for the development of neovascularization. Also, progesterone, a key component of BCPs, was previously shown to increase the expression of RB1CC1 mRNA. These results demonstrate that genome-wide environmental interaction studies can implicate novel loci for complex traits and suggest a novel role for other retinal disease genes in AMD.

O. Box 20334, Houston, Texas 77225.

For complex diseases, the relationship between genotypes, environment factors and phenotype is usually complex and nonlinear. Our understanding of the genetic architecture of diseases has considerably increased over the last years. However, both conceptually and methodologically, detecting gene-gene and gene-environment interactions remains a challenge, despite the existence of a number of efficient methods. One method that offers great promises but has not yet been widely applied to genomic data is the entropy-based approach of information theory. In this paper we first develop entropy-based test statistics to identify 2-way and higher order gene-gene and gene-environment interactions. We then apply these methods to a bladder cancer data set and thereby test their power and identify strengths and weaknesses. For two-way interactions, we propose an information-gain approach based on mutual information. For three-ways and higher order interactions, an interaction-information-gain approach is used. In both case we develop one-dimensional test statistics to analyze sparse data. Compared to the naive chi-square test, the test statistics we develop have similar or higher power and is robust. Applying it to the bladder cancer data set allowed to investigate the complex interactions between DNA repair gene SNPs, smoking status, and bladder cancer susceptibility. Although not yet widely applied, entropy-based approaches appear as a useful tool for detecting gene-gene and gene-environment interactions. The test statistics we develop add to a growing body methodologies that will gradually shed light on the complex architecture of common diseases.

Genotype x Sex Interactions in Asthma: Genome-Wide Studies in the EVE Consortium Data. *R. Myers[1], N. Scott[1], C. Ober[1], D. Nicolae[1,2], The Eve Consortium.* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Department of Statistics, University of Chicago, Chicago, IL.

Asthma is a complex disease with contributions from genes, environment, and interactions between them. Sex, which can be considered an `environmental' exposure, affects asthma risk: the prevalence is highest among boys in early childhood but is highest among women in adulthood. Here, we investigate genotype x sex interactions using nearly all of the North American genome-wide association study data sets making up the EVE Consortium. Combining these ethnically diverse datasets allows us to increase sample size and, subsequently, increase the power to detect interactions that may be undetectable at the single study level. We performed case-only genome-wide interaction studies (GWIS) for all EVE component studies, using approximately 2.5 million SNPs. Meta-analysis was used to combine individual study results, yielding a total sample size of 2513 asthmatic males and 2671 asthmatic females. We observe a significant enrichment (penrichment = 0.023) of SNPs with association p-values < 10-5. Among the most significant associations is a series of non-coding SNPs, including rs10117983 (T/C, p = 3.2 x 10-8), on chromosome 9 ~200 KB upstream of the gene SMARCA2. Further analysis confirmed that the allele frequency differences between the males and females are specific to affected individuals; there is no difference in allele frequency between male and female controls. The interaction model is a `flip-flop': the C allele is associated with protection from asthma in males (odds ratio (OR) = 0.76; 95% CI: 0.65 - 0.88) but with risk for asthma in females (OR = 1.12; 95% CI: 0.97-1.3). This result suggests the presence of sex-specific asthma risk alleles in the human genome that can be discovered through the use of existing data sets. Supported by RC2 HL101651.

The association between genetic polymorphism of LEP and obesity in Remote area in Taiwan. *R. Wang[1], L. Ke[1], C. Chen[1], F. Wu[1], T. Wu[1,2].* 1) Department of Public Health, China Medical Univ, PhD; 2) Graduate Institute of Biostatistics, China Medical Univ, PhD.

The prevalence of obese and overweight was surveyed by Nutrition and Health Survey in Taiwan, NAHSIT,2005-2008 is more than half in male and larger than 1/3 in female. However, obesity is an important risk factor for cardiovascular disease, chronic disease and is an important issue in public health. Obesity is regulated by genetic effects, environmental factors and interaction. The -2548 polymorphism of LEP gene was suggested to have a genetic effect on obesity. This is a cross-sectional study, and the aim of this study is to evaluate the association between G-2548A polymorphism of LEP gene and obesity in remote area at Sinyi downtown, Nantou County in Taiwan in 2008. Our study aim is to investigate the association between LEP -2548 polymorphism and obesity. A total of 281 individuals were recruited. Those subjects with a BMI ⁄ 27 (kg/m^2) are classified as obese (n=77) and 204 normal subjects. We collected peripheral blood, determined the biochemical data, and also administrated a questionnaire with interview for demographic information. The genotypes of LEP G-2548A were carried out by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP). The result showed that G allele frequency of G-2548A polymorphism in obesity patients was more significantly than normal subjects (p=0.5099). The results demonstrated that obese had a higher mean BMI (30.1±2.9) than non- obese (23.0±2.2).The odds ratio of obesity who carried GA and AA genotype are 2.0 (95% confidence interval, 1.35-7.92) than GG genotype were analysed by logistic regression model after adjusting age and gender. In conclusion, our study suggested that LEP gene G-2548A polymorphism is associated with obesity in remote area in Taiwan. This study might provide a suggestion for obesity prevention. In the future, extensive studies to reconfirm the association will be warranted.

A unified Bayesian framework for analyzing heterogeneous genetic association data: meta-analysis and GxE interaction. *X. Wen[1], M. Stephens[1,2].* 1) Dept Statistics, Univ Chicago, Chicago, IL; 2) Dept Human Genetics, Univ Chicago, Chicago, IL.

In genetic association analysis it is often desired to analyze data from multiple potentially-heterogeneous subgroups. For example, 1. To detect modest genetic association signals that are too weak to be detected in smaller individual studies, meta-analysis of multiple studies are often required. Th ese studies are typically carried out by different investigators, at different centers, which might be expected to exhibit heterogeneity of genetic effects. 2. In analysis of a single study, genuine environmental interactions may cause some genetic variants to have different effects on individuals in different su bgroups. We propose a unified Bayesian framework to deal with potentially heterogeneous genetic association data. Within this framework, We address the problems of WHETHER and HOW a particular genetic variant acts on the phenotype of interest by Bayesian testing and model comparison approaches in a systematic way. We propose Bayesian models, derive easy-to-compute Bayes Factors for this purpose and discuss the general strategy for exploratory analysis in these settings. To demonstrate our methods, we apply our Bayesian approach in two different real data examples. The first example is the meta-analysis of global lipids originally repor ted by Teslovich et al (2010, Nature). In the second example, we analyze the data from Dimas et al (2010, Science) to map tissue-specific eQTLs.

729W

Genome-wide interaction analysis of two independent schizophrenia datasets. *D. Xie[1], Y. Zhu[1], J. Chen[2], M. Xiong[1], X. Chen[2].* 1) Department of Biostatistics, University of Texas Health Science Center, Houston, TX; 2) Department of Psychiatry and Virginia Institute for Psychiatric and Behavioral Genetic, Virginia Commonwealth University, Richmond, VA 23219.

The essential problems in performing genome-wide interaction analysis are the power of test statistics, feasibility of computations, and efficient methods for P-value correction of multiple tests. Due to the lack of power of the widely used statistics for testing interaction between loci and its computational intensity, exploration of genome-wide gene-gene interaction has been limited. Many geneticists question the universe presence of significant gene-gene interaction. In this report, we develop a novel LD-based statistic for testing interaction between linked or unlinked loci and apply this statistic and another recently developed haplotype odds-ratio based statistic for testing interaction to two independent GWA datasets of SZ (MGS_GAIN and MGS_nonGAIN) from dbGaP. The MGS_GAIN dataset included 1,135 individuals with SZ and 1,362 controls with 727,479 typed SNPs. The MGS_nonGAIN dataset included 1,089 individuals with SZ and 1,273 controls with typed 696,510 SNPs. The total number of SNPs matched in two studies was 693,772. We identified 7,697 interacting pairs of SNPs (P-value < 1.89E-13) in the MGS_GAIN dataset, and 5,268 pairs in the MGS-nonGAIN dataset. Among them, 17 pairs were shared in the two datasets. We also identified 3,576 and 2,481 pairs of interacting genes in MGS_GAIN and MGS_nonGAIN respectively, and a total of 848 pairs of shared genes in the two datasets. These genes have at least one common pair of significantly interacting SNPs or more than one pair of independent significantly interacting SNPs in the two datasets. It is interesting that these gene pairs form gene interaction networks. The largest connected interaction network involves 122 genes that were shared in two datasets. Of the 11 hub genes (defined as interacting with at least 5 genes) in the network, 8 of them have been shown to have significant functions in neuronal cells/neurons. KCNIP4, CTBP2 and RORA have been shown to play a role in increasing suicide ideation, development of Alzheimer's disease and synaptic actions, all of these conditions are directly related to schizophrenia.

Characterization of the Associations between rs2231142 (Q141K) in *ABCG2* and Serum Uric Acid and Gout in Four U.S. Populations: the PAGE Study. *L. Zhang[1], K.L. Spencer[2], V.S. Voruganti[3], N. Jorgensen[4], M. Fornage[5], L. Best[6], K.D. Brown-Gentry[2], S. Cole[3], D.C. Crawford[2], N. Franceschini[7], A. Gaffo[8], K.R. Glenn[2], G. Heiss[7], N.S. Jenny[9], A. Köttgen[10], Q. Li[2], K. Liu[11], K.E. North[7], J.G. Umans[12], W.H. Kao[1].* 1) Department of Epidemiology, Johns Hopkins School of Public Health, Baltimore, MD; 2) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 3) Department of Genetics, SW Foundation for BioMedical Research, San Antonio, TX; 4) Department of Biostatistics, University of Washington, Seattle, WA; 5) Health Science Center, University of Texas, Austin, TX; 6) Missouri Breaks Industries Research, Inc., Timber Lake, SD; 7) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 8) University of Alabama, Birmingham Division of Clinical Immunology and Rheumatology, Birmingham, AL; 9) Department of Pathology, University of Vermont College of Medicine, Burlington, VT; 10) Renal Division, University Hospital Freiburg, Freiburg, Germany; 11) Northwestern University, Department of Preventive Medicine, Chicago, IL; 12) Penn Medical Laboratory, Hyattsville, MD.

The *ABCG2* gene encodes the protein ATP-binding cassette sub-family G member 2, which has been shown to be a urate efflux transporter in the brush broader membrane of kidney proximal tubule cells. Associations between a missense coding variant rs2231142 (Q141K) in *ABCG2* and serum uric acid concentration and risk of gout in populations of European descent are well established; however, less is known about the magnitude of these associations in other ethnicities or whether these associations are modified by non-genetic factors. *ABCG2* rs2231142 was genotyped in 39,853 individuals from four different populations from the U.S. as part of the Population Architecture using Genomics and Epidemiology (PAGE) study. Multivariate linear and logistic regressions were performed to assess the associations between rs2231142 and serum uric acid levels and gout prevalence, respectively. Meta-analysis was conducted to obtain joint estimates, and Cochran's Q test was used to assess heterogeneity across subgroups (P_{het}). A total of 22,734 European Americans (EA), 9,720 African Americans (AA), 3,849 Mexican Americans (MA) and 3,550 American Indians (AI) were included. Data on prevalence of gout was not available in AI. Mean uric acid concentration (and gout prevalence) in EA, AA, MA, AI, was 5.7 mg/dL (4.4%), 5.7mg/dL (5.9%), 5.2mg/dL (1%), and 5.1mg/dL. The Frequency of the T allele of rs2231142 was 0.11, 0.03, 0.19 and 0.20 in EA, AA, MA, AI, and it was associated with higher serum uric acid levels ($P=2.37\times10^{-67}$, 3.98×10^{-5}, 6.97×10^{-9}, and 5.3×10^{-4}) and prevalent gout ($P=2.83\times10^{-10}$, 0.01 and 0.01) in EA, AA, MA, and AI. After meta-analysis across populations, the T allele was associated with a 0.24 mg/dL increase in uric acid levels (95%CI 0.17-0.31, $P=1.37\times10^{-80}$) and a 1.75-fold increase in odds of gout (95%CI 1.50-2.04, $P=1.09\times10^{-12}$). Significantly stronger association was observed in men than in women for both uric acid ($P_{het}=1.64\times10^{-5}$) and gout ($P_{het}$= 0.03). The association between rs2231142 and uric acid was stronger in postmenopausal women compared to premenopausal women (P_{het}=0.02) and in hormone replacement therapy users compared to non-users (P_{het}= 0.03). In conclusion, rs2231142 of *ABCG2* is significantly associated with serum uric acid and gout in four U.S. populations, with stronger association observed in men than in women. In addition, menopausal status and hormone replacement therapy may modify the association between rs2231142 and serum uric acid levels.

Prostate Cancer Risk Prediction using a genetic profile in an international consortium (PRACTICAL). *A. Amin Al Olama[1], S. Benlloch[1], D.A. Leongamornlert[2], E.J. Saunders[2], M. Tymrakiewicz[2], M. Guy[2], K. Govindasami[2], Z. Kote-Jarai[2], R.A. Eeles[2,3], D.F. Easton[1], PRACTICAL.* 1) Public Health & Primary Care, University of Cambridge, Strangways Laboratory, Cambridge, Cambridgeshire, United Kingdom; 2) The Institute of Cancer Research, 15 Cotswold Road, Sutton, Surrey, SM2 5NG, UK; 3) Royal Marsden NHS Foundation Trust, Fulham and Sutton, London and Surrey, UK.

Genome-wide association studies have identified multiple genetic variants associated with prostate cancer risk, opening up the possibility for using genetic profiling in risk prediction. To evaluate the potential for risk prediction, we genotyped 25 known prostate cancer susceptibility SNPs in 31 case-control studies in an international consortium (PRACTICAL), and analysed data from 20,132 prostate cancer cases and 20,234 male controls of European ancestry. Odds ratios (OR) associated with each SNP genotype, and genotypes for pairs of SNPs, were estimated using unconditional logistic regression. We found some evidence for weak departures from a multiplicative model for pairs of loci (10 pairs significant at P<0.01 compared with 3 expected by chance), but no individual pair was significant after correction for multiple testing., Based on the assumption of a log-additive model, we constructed a risk score from the summed genotypes weighted by the per-allele log-odds ratios. Using this score, the top 1% of the population had an estimated increased risk of 40 fold compared with the bottom 1% of the population, and 4.2 fold compared with the average population risk, while the bottom 1% of the population had an estimated risk of 11% of the population risk. These results demonstrate that genetic risk profiling may play an important role in targeted prevention.

A simulation pipeline for genetic disease models. *H. Baurecht[1,2], T. Augustin[3], S. Wagenpfeil[4], K. Strauch[1], P.A. Scheet[5].* 1) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 2) Department of Dermatology, Allergology and Venerology, University Hospital Schleswig-Holstein, Kiel, Germany; 3) Department of Statistics, Ludwig-Maximilians Universität München, Munich, Germany; 4) Institute of Medical Statistics and Epidemiology, Technische Universität München, Munich, Germany; 5) Department of Epidemiology, University of Texas, MD Anderson Cancer Center, Houston, USA.

The advent of next-generation sequencing and generation of large data sets of population genetic data have allowed interrogations of association between phenotype and increasingly rare forms of genetic variation. To detect association with extremely rare variants some form of aggregation is necessary to combine the effects of variants from multiple affected individuals; for example, one way this is done is on the genic level. Evaluation of these procedures may involve simulated data, and these simulations typically assume independence among alleles at variant sites within genes. While this may be a reasonable approximation for some extremely rare variants, LD at moderate frequencies may affect association detection. Here we aim to address this phenomenon in data simulation. We develop an R package to simulate case-control data using externally generated haplotype data, such as those from a coalescent simulator. We explore various ways to partition population attributable risk (PAR), which is used for specifying the disease model, among non-independent variant sites to maintain an overall PAR. Our simulation pipeline provides a flexible tool for simulating a varierty of scenarios for validating statistical methods in the context of next-generation sequencing data, GWAS or even candidate genes.

733W

***APOL1* variant modifies the HDL-kidney function association in populations of African Ancestry.** *A.R. Bentley, A. Doumatey, H. Huang, J. Zhou, D. Shriner, A. Adeyemo, C. Rotimi.* Center for Research in Genomics and Global Health, National Human Genome Research Institute, Bethesda, MD.

Low levels of high-density cholesterol (HDL) are known to accompany chronic kidney disease (CKD), but the association of HDL and the estimated glomerular filtration rate (eGFR, an index of kidney function) in the general population is unclear. We investigated the relationship between HDL and eGFR in Han Chinese (Ch, n=1100), West Africans (Af, n=1497), and African Americans (AA, n=1539). Generalizability of observed associations was tested in European Americans (NHEA, n=859) and African Americans (NHAA, n=326) of NHANES, a national population-based survey. The HDL-eGFR association varied by population: in Ch, increased HDL was associated with improved eGFR (1.2 ml/min/1.73 m^2 for a 10 mg/dl increase in HDL [same units throughout], p<0.0001), but with worse eGFR among Af (-2.1, p<0.0001) and AA (-0.8, p=0.04). In NHANES, the association also differed by African ancestry: NHEA (0.8, p=0.05) and NHAA (-1.3, p=0.1). Given this surprising but consistent inverse relationship between HDL and eGFR in African-ancestry populations, we investigated the potential role of a newly-identified risk variant for kidney disease (rs73885319 in the *apolipoprotein L 1* (*APOL1*) gene) that is absent in East Asians and Europeans. Data show that this risk variant likely rose to high frequency in Africa because it confers resistance to trypanosomal infection and protects against African sleeping sickness. Although rs73885319 did not predict eGFR in AA or Af, HDL was 4-5 mg/dl higher among those with the CKD risk genotype (GG vs. GA/AA) in AA women (p=0.04) and in Af men and women (p=0.03). There was an interaction between rs73885319 and HDL in AA (p=0.04), with a stronger negative HDL-eGFR association with the risk genotype (-3.5 vs. -0.6); a directionally similar but not significant (p=0.1) result was observed in Af. These findings support a role of HDL in kidney function in the general population. Among non-African ancestry populations, HDL was positively associated with eGFR, consistent with expectations of the broadly protective role of HDL in a variety of chronic diseases. The inverse association between HDL and eGFR in African-ancestry populations is unexpected. The discovery of an interaction between *APOL1* genotype and HDL in AA suggests that genetic factors contribute to this paradoxical association. Notably, these findings suggest that the unexplained mechanism by which the *APOL1* locus affects the risk of kidney disease involves HDL.

Fine-mapping *CASP8* risk variants in Breast Cancer. *N.J. Camp[1], M. Parry[2], S. Knight[1], R. Abo[3], L.A. Cannon-Albright[1], G. Elliot[4], S. Rigas[2], S.P. Balasubramanian[5], A. Cox[2].* 1) Division of Genetic Epidemiology, University of Utah, Salt Lake City, UT; 2) Institute for Cancer Studies, Department of Oncology, University of Sheffield, Sheffield, UK; 3) Department of Molecular Pharmacology and Experimental Therapeutics, Mayo Clinic, Rochester, MN, USA; 4) University of Manchester, Manchester, UK; 5) Academic Unit of Surgical Oncology, Department of Oncology, University of Sheffield, Sheffield, UK.

Multiple genomewide and candidate gene association studies have been performed in search of common risk variants for breast cancer. Recent large meta analyses, consolidating evidence from these studies, have been consistent in highlighting the caspase-8 (*CASP8*) gene as important in this regard. Previously, we described a breast cancer risk haplotype across variants in *CASP8* identified using genotype data for 14 tagging-SNPs (tSNPs) from a single data set. In order to further refine a risk haplotype and map the *CASP8* gene with respect to underlying susceptibility variant/s, we broadened our search to four genes in the 2q33-q34 region based on their physical proximity to *CASP8* and/or role in apoptosis. Here, we have studied two independent data sets from the United Kingdom and the United States, including 3,888 breast cancer cases and controls for 45 tSNPs in the expanded *CASP8* region. We identified a three-SNP haplotype significantly associated with breast cancer ($p<5\times10^{-6}$), with a dominant risk ratio and 95% confidence interval of 1.28 (1.21-1.36) and a frequency of 0.29 in controls. Evidence for this risk haplotype was extremely consistent across the two study sites and also consistent with prior single SNP associations and our prior risk haplotype. This three-SNP risk haplotype represents the best characterization so far of the chromosome upon which the susceptibility variant resides and provides a strong foundation for re-sequencing efforts. Identification of the underlying risk variant may prove useful for individual-level risk prediction, provide novel insights into breast carcinogenesis, and potential for improved prevention and treatment.

A Weighted Fisher's Method to Detect Rare-Variant Complex Trait Associations using Next Generation Sequence Data. *Y.H. Cheung[1], G. Wang[2,3], S.M. Leal[2,3], S. Wang[1].* 1) Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Statistics, Rice University, Houston, TX.

Next generation sequencing technology has enabled the paradigm shift in genetic association studies from the common disease/common variant to common disease/rare variant hypothesis. It has been shown that analyzing individual rare variants is underpowered and therefore methods have been developed that aggregate variants across a genetic region. For exome sequence data, the number of variants which are analyzed jointly can range from dozens within a gene to hundreds in a biological pathway. The foreseeable wide-spread use of whole genome sequencing, despite opening up unprecedented opportunities, poses challenges in statistical analysis. One particular problem is the attenuation of signal due to inclusion of high proportions of non-causal variants because of difficulties in determining region boundaries and inclusion of non-coding regions. These obstacles call for new rare variant association methods that are statistically powerful, robust against high levels of noise due to inclusion of non-causal variants, and yet computationally efficient. Here we proposed a new statistic that combines the disease-associated p values of individual variants using a weighted Fisher's approach, with the weights being the inverse of the expected standard deviation of the allele frequencies under the null. The Weighted Fisher's method is extremely robust to the presence of a high proportion of non-causal variants (e.g. >80%). It is also demonstrated that this method is powerful in the situation where both detrimental and protective variants are present within a genetic region. We tested the performance of the Weighted Fisher's method using realistic population demographic and disease models to simulate data and the power is compared to several previously published methods. The results demonstrate that the Weighted Fisher's method generally outperforms other rare variant association methods over a wide range of models. Additionally, sequence data on the ANGPTL family of genes from the Dallas Heart Study were tested for associations with eight metabolic traits and both known and novel associations were uncovered using the Weighted Fisher's method.

How can genotype imputations contribute to the identification of disease causal variants in genome-wide association studies (GWAS)? *E. Corda[1,2,3], M. Brossard[1,2,3], M.M Iles[4], J.H. Barrett[4], A.M. Goldstein[5], P. Kanetsky[6], E.M. Gillanders[7], B. Bakker[8], N. Gruis[9], J.A. Newton-Bishop[4], D.T. Bishop[4], F. Demenais[1,2,3], Melanoma Genetics Consortium (GenoMEL).* 1) Fondation Jean Dausset-CEPH, Paris, France; 2) INSERM U946,Paris, France; 3) Université Paris Diderot, Paris, France; 4) Section of Epidemiology and Biostatistics, Leeds Institute of Molecular Medicine, Leeds, UK; 5) Genetic Epidemiology Br., DCEG, National Cancer Institute, NIH, Bethesda, MD; 6) Dept of Biostatistics and Epidemiology, University of Pennsylvania, PA; 7) Inherited Disease Research Br., National Human Genome Research Institute, NIH, Baltimore, MD; 8) Dept. of Clinical Genetics, Leiden University Medical Centre, Leiden, The Netherlands; 9) Dept. of Dermatology, Leiden University Medical Centre, Leiden, The Netherlands.

GWAS have been successful in uncovering many loci associated with multifactorial diseases. However, the causal variants within these loci are unknown for the most part. Our goal was to investigate to what extent imputations based on Hapmap3 and/or 1000 Genomes reference panels were able to identify disease-causing variants. We used as a paradigm *MC1R*, a gene known to be involved in melanoma, located in the 16q24 region strongly associated with this cancer in a previous GWAS from the GenoMEL consortium, but with no functional variant present on the genotyping chips. We conducted genotype imputations over 1.9 Mb on 16q24 in 10,772 GenoMEL subjects (2,985 cases, 7,787 controls) using the IMPUTE2 software and either Hapmap3 or Hapmap3+1000 Genomes reference panels. After applying stringent quality control criteria, 351 SNPs (Hapmap3) and 1,543 SNPs (Hapmap3+1000G) were available for analysis. We carried out univariate population-adjusted logistic regression with each SNP followed by joint analysis of all SNPs using a Bayesian-inspired penalised maximum likelihood approach (HyperLasso software). Four known functional *MC1R* variants (R151C, R160W, V92M, R163Q) were imputed using either reference panel and passed QC filtering. Univariate analysis of all imputed SNPs showed the strongest association signal with R151C ($p=3.6x10^{-30}$) while R160W had $p=9.3x10^{-10}$ and from 22 (Hapmap3) to 70 (Hapmap3+1000G) SNPs in other genes reached the genome-wide threshold ($p\leq10^{-8}$). Joint analysis of all Hapmap3 imputed SNPs, using 100 iterations of HyperLasso, showed significant effects of *MC1R* variants (R151C and/or R160W) in all models which converged plus the effects of SNPs in other genes. Similar conclusions were reached when using imputed SNPs from Hapmap3+1000G. We also sequenced the whole *MC1R* gene in 1,844 subjects (937 cases, 907 controls). Stepwise regression of 8 sequenced *MC1R* non-synonymous variants (MAF／ 1%) alone or together with imputed SNPs associated with melanoma showed significant effects for R151C ($p=4.0x10^{-15}$), R160W ($p=1.2x10^{-9}$) and D294H ($p=2.0x10^{-4}$), a rare variant (MAF=2%) absent from the imputation reference panels. In conclusion, this study shows that imputations can be of great use in pinpointing a gene that has a functional role in disease but may not be identified through genotyping alone. However, a full picture of the effect of causal variants on disease risk is revealed only by resequencing.

A novel pairwise shared genomic segment statistic comparing cases and controls: application to polycythemia vera. *K. Curtin[1], S. Swierczek[2], F. Lorenzo[2], A. Thomas[1], K. Wang[3], H. Hakonarson[4], J. Prchal[2], N. Camp[1].* 1) Internal Medicine Div. Genetic Epidemiology, Univ Utah Health Sci Ctr, Salt Lake City, UT; 2) Intern Medicine Div. Hematology, Univ Utah Health Sci Ctr, Salt lake City, UT; 3) Zilkha Neurogenetic Inst., Univ Southern California, Los Angeles, CA; 4) Chilren's Hospital of Pennsylvania, Div. Human Genetics, Univ of Pennsylvania, Philadelphia, PA.

Dense SNP genotyping has been used to identify identity-by-state (IBS) genomic regions shared between distantly-related cases in large pedigrees. Excessively long regions shared IBS likely contain identity-by-descent regions that can be used for localization of disease-susceptibility genes. For diseases with substantial genetic heterogeneity it is unlikely that all cases will be attributable to the same underlying causal variant. Examining sharing among pairs, rather than across all affected individuals, will likely have more power. We previously developed a novel method that examines paired shared genomic segments in related individuals in pedigrees using a mean sharing test statistic. Here we describe a method that compares homozygous sharing (pHGS) in cases and controls; significance is empirically assessed conditional on local linkage disequilibrium (LD) patterns. Using this pairwise statistic, we studied high-density SNP genotypes (Illumina 610Q) from granulocyte (somatic) and T-cell (germline) DNA in 34 unrelated individuals with polycythemia vera (PV), a myeloproliferative neoplasm (MPN). Genotypes of 60 unrelated HapMap CEU founders on the same platform were used as controls to provide an LD model and expected sharing. Pairwise(pHGS) sharing across all possible [n(n-1)/2] pairs of PV cases were examined for evidence of a deletion/acquired uniparental disomy across chromosomes 1, 7, and 9 which contain previously-identified MPN and leukemia candidate regions. Nominal and chromosome-wide significance were derived from 10,000 null simulations. No suggestive regions were identified on chromosomes 1 and 7 for either granulocyte or T-cell samples. On chromosome 9, we observed three broad regions of pHGS sharing in granulocyte samples which reached suggestive significance. The longest runs (average sharing 15-20 SNPs, 4.3 Mb) occurred upstream of the miR-101-2 and *JAK2* locus. Additionally, slightly shorter runs from 8.2-12.4 Mb and 16.7-17.4 Mb occurred further downstream. In contrast, no homozygous sharing was observed in T-cell samples. Using a new case-control method of assessing pairwise genomic sharing, we detected regions of homozygosity in somatic DNA on chr. 9 (up- and downstream of *JAK2* not evident in germline DNA. This illustrates the potential utility of shared segment techniques for independent individuals and case-control designs and suggests if germline susceptibility variants exist in *JAK2* they are unlikely to be homozygous in nature.

Gene set analysis of GWAS data for human longevity highlights the relevance of the insulin/IGF-1 signaling and telomere maintenance pathway. *J. Deelen[1,2], H.W. Uh[2,3], R. Monajemi[3], D. van Heemst[4], P.E. Thijssen[1,5], S. Böhringer[3], E.B. van den Akker[1,6], A.J.M. de Craen[4], F. Rivadeneira[7,8], A.G. Uitterlinden[2,7,8], R.G.J. Westendorp[2,4], J.J. Goeman[3], P.E. Slagboom[1,2], J.J. Houwing-Duistermaat[3], M. Beekman[1,2].* 1) Section of Molecular Epidemiology, Leiden University Medical Center, Leiden, The Netherlands; 2) Netherlands Consortium for Healthy Ageing, Leiden University Medical Center, Leiden, The Netherlands; 3) Section of Medical Statistics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Gerontology and Geriatrics, Leiden University Medical Center, Leiden, The Netherlands; 5) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 6) Department of Mediamatics, Delft Bioinformatics Lab, Delft University of Technology, Delft, The Netherlands; 7) Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 8) Department of Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands.

Genome-wide association studies (GWAS) using single SNP analysis have been very successful in identifying disease loci for various traits. However, this approach has been less successful for complex traits, like human longevity, limited by the small sample sizes that can be achieved. Analyzing the combined effect of a SNP set grouped per pathway or gene region, instead of single SNPs, is a way to overcome this limitation. We used this approach to study the joint effect on human longevity of genetic variation in two candidate pathways, the insulin/insulin-like growth factor (IGF-1) signaling (IIS) and telomere maintenance (TM) pathway. For the analyses we used genotyped GWAS data of unrelated nonagenarian cases (n = 403, mean age 94 years) from long-lived families from the Leiden Longevity Study and a younger set of population controls (n = 1670, mean age 58 years) from the Rotterdam Study. We analyzed SNPs within a 10 kb window around genes encoding proteins that belonged to the IIS and TM pathway. In total, 1021 SNPs in 68 IIS pathway genes and 88 SNPs in 13 TM pathway genes were analyzed. To investigate the association of the SNP sets from the IIS and TM pathway with longevity, three self-contained (PLINK set-based test, Global test, GRASS) and one competitive (SNP ratio test) pathway test were used. Although we observed small differences between the results of the pathway tests, they all showed consistent nominal significant association ($P < 0.05$) of the IIS and TM pathway with longevity. To determine which genes were mainly responsible for the observed association of the pathway SNP sets with longevity, we also investigated the association of gene SNP sets from these pathways. Seven of the IIS pathway gene SNP sets (*AKT1, FOXO4, IGF2, INS, PIK3CA, SGK1* and *SGK2*) and one of the TM pathway gene SNP sets (*POT1*) showed a nominal significant association ($P < 0.05$) with longevity. In conclusion, this study shows that genetic variation in genes involved in the IIS and TM pathway is associated with human longevity. In addition, since self-contained tests, as compared to competitive tests, are less computational elaborate and provide comparable results, we recommend self-contained tests for candidate-based pathway analysis.

739W

THE ANO3/MUC15 LOCUS IS ASSOCIATED WITH ECZEMA IN FAMILY SAMPLES ASCERTAINED THROUGH ASTHMATICS. *M.H. Dizier[1], P. Jeannin[1], A.M Madore[2], J. Esparza[3,4], M. Moffatt[5], E. Corda[1], F. Monier[1], I. Annesi[6], J. Jsut[7], I. Pin[8], F. Kauffmann[9], W. Cookson[5], Y.A. Lee[3,4], C. Laprise[2], M. Lathrop[10], E. Bouzigon[1], F. Demenais[1].* 1) U946, INSERM, Paris, France; 2) Université du Québec, Chicoutimi, Canada; 3) Max-Delbrück-Center for Molecular Medicine (MDC), Berlin, Germany; 4) Charité Universitätsmedizin Berlin, Germany; 5) National Heart Lung Institute, Imperial College, London, UK; 6) Inserm U707, Paris, France; 7) Centre de diagnostic et traitement de l'asthme, Hôpital Trousseau, Paris, France; 8) Département de Médecine Aigüe Spécialisée, CHU Michallon, Grenoble, France; 9) Inserm U1018, Paris, France; 10) CEA-CNG, Evry, France.

A previous genome-wide linkage scan in 295 families of the French Epidemiological study on the Genetics and Environment of Asthma (EGEA) reported strong evidence of linkage of 11p14 to eczema. Our purpose was to conduct fine-scale mapping of the 11p14 region to identify the genetic variants associated with eczema and to investigate the influence of the mode of ascertainment of the data on the association outcomes. Association analyses were conducted in the EGEA discovery dataset using two statistical methods for internal validation: the family based association method (FBAT) and logistic regression. Replication of the EGEA findings was sought in French Canadian (SLSJ study) and UK (MRCA study) family samples, which similarly to EGEA, were ascertained through asthmatic subjects. We also tested for association in two German samples ascertained through subjects affected with eczema. We found significant association of eczema with 11p14 SNPs in the vicinity of the linkage peak in EGEA (p=10-4 for rs1050153 using FBAT, that reached the multiple testing-corrected threshold of 1.3x10-4; p=0.003 using logistic regression). Pooled analysis of the three asthma-ascertained samples (EGEA, SLSJ, MRCA) showed strong improvement in the evidence for association (p=6x10-6 for rs293974 (OR= 0.66), p=3x10-5 for rs1050153 (OR=0.68), p=6x10-5 for rs15783 (OR=0.69). No association was observed in the eczema-ascertained samples. The significant SNPs are located within the overlapping ANO3 and MUC15 genes. Several lines of evidence suggest that MUC15 is a strong candidate for eczema. Further investigation is needed to confirm and better understand the role of ANO3/MUC15 locus in eczema and its relationship with respect to asthma.

Distinguishing gene-gene interaction from heterogeneity. *E.N. Drill[1], R.L. Subaran[1,2], D.A. Greenberg[1,2].* 1) Division of Statistical Genetics/Biostatistics, Columbia Univ Sch Pub Hlth, New York, NY; 2) Dept. of Psychiatry, New York State Psychiatric Institute, Columbia-Presbyterian Medical Center, New York, NY.

Introduction: Identification of gene-gene interaction in complex human disease has remained elusive and has been implicated as a factor in the heritability not explained by common variants. Here, we develop binary classification tests to distinguish between gene-gene interaction and genetic heterogeneity using multipoint linkage analysis. Our goal is to use the information from linkage analyses to distinguish epistasis from heterogeneity. Multiple analyses of the same dataset but assuming different genetic models result in differing degrees of evidence for linkage (e.g. maxLODs determined assuming recessive and dominant modes of inheritance, assuming heterogeneity, and using maxNPL). We hypothesize that, given the presence of two disease loci, these statistics taken together can yield information about the way the two loci interact to influence disease.

Methods: We simulated dense SNP data using a number of 2-locus disease models. Generating models had either heterogeneity or gene-gene (epistatic) interaction. Performing multipoint linkage analysis, we used the MOD score, the HLOD and the NPL to develop binary classification tests to identify heterogeneity or epistatic gene-gene interaction where there was at least suggestive evidence for linkage at the two loci. Our interaction test uses the difference between the MOD score and the NPL expressed on a LOD scale (Δ_I) to indicate presence or absence of interaction: $\Delta_I > t_I$, where t_I is a threshold determined through simulation. Our heterogeneity test compares the difference between the HLOD and the MOD score (Δ_h) to a threshold, t_h, to indicate presence or absence of heterogeneity: $\Delta_h > t_h$.

Results: Our test for interaction had a sensitivity of 90% and a specificity of 84% for t_I=1. When t_I=1.5, sensitivity is 82% and specificity is 90%, while t_I=2 gives a sensitivity of 73% and a specificity of 94%. For the heterogeneity test, when t_h=0, the sensitivity is 97% and the specificity is 34%. For t_h=1 the sensitivity decreased to 65% and specificity increased to 99%. An in-between threshold value of 0.5 resulted in a sensitivity of 83% and a specificity of 96%. For both tests, the area under the curve (AUC) representing the trade-off between sensitivity and specificity (the Receiver Operating Characteristic curve) is .94, indicating high performance as binary classifiers.

Using known genotype-phenotype associations to detect sample mix-up. *C.T. Ekstrom[1], B. Feenstra[2].* 1) Statistics, Basic Sci & Environment, Univ Copenhagen, Copenhagen, Denmark; 2) Statens Serum Institut , Copenhagen, Denmark.

Genome-wide association studies (GWAS) have rapidly become a standard method for identification of disease genes and genes influencing quantitative traits. GWAS typically uses unrelated individuals which makes detection of sample mix-up errors more problematic than for studies where related individuals are available.

We present a method for identifying potential sample mix-ups in GWAS (and other genetic studies) building on ideas from forensic sciences. A widely used ad-hoc method for error detection is to check if the sex of an individual matches its X-linked genotype. This idea can be generalized to less stringent associations between known genotypes and phenotypes, and if several known association are combined then the power to detect sample mixups is increased substantially. Individuals with an unlikely set of phenotypes given their genotypes are more likely to be flagged as potential errors.

Analytical and simulation results show that only a few (around 10) highly informative genotype-phenotype associations are needed to have a sensitivity and specificity above 95%. The odds that the genotype and phenotype are both from the same individual are compared for different information content and for different number of available genotype-phenotype associations. The method is applied to data from a larger Danish GWAS study where random errors are introduced to evaluate the effectiveness in a real dataset.

Fine mapping in over 10,000 Rheumatoid arthritis cases and 14,000 controls refine associations to known loci, indicate multiple independent affects and reveal novel associations. *S. Eyre[1], J. Bowes[1], A. Barton[1], S. Raychaudhuri[2,6,7], C. Amos[5], D. Diogo[2], A. Lee[3], L. Klareskog[4], L. Padyukov[4], E. Stahl[2,6], P.K. Gregersen[3], R. Plenge[2,6], J. Worthington[1].* 1) Arthritis Research UK Epidemiology Unit, Stopford Building, The University of Manchester, Manchester, UK; 2) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Boston, MA, USA; 3) The Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset, NY, USA; 4) Rheumatology Unit, Department of Medicine, Karolinska Institutet at Karolinska University Hospital Solna, Stockholm, Sweden; 5) University of Texas M.D. Anderson Cancer Center, Houston, Texas, USA; 6) Broad Institute, Cambridge, Massachusetts, USA; 7) Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts, USA.

Genome wide association studies (GWAS) have been tremendously successful in identifying loci associated with a range of traits and disorders. Indeed, there are over 240 confirmed susceptibility loci reported for nine autoimmune diseases alone. One task now is to take these findings and translate them into clinical utility. The first step in this is to elucidate the genetic architecture of the loci in each disease with fine mapping experiments. These are expected to localise the association signal, indicate whether multiple, independent genetic affects are present and may point to the casual gene. The aim of this study was to fine map loci significantly associated with autoimmune disease in a large cohort of 10,000 rheumatoid arthritis (RA) cases and 14,000 controls using the custom Illumina Immunochip. The chip was designed by a consortium of researchers investigating 12 autoimmune diseases and represents all known genetic variation from dbSNP, 1kG and sequencing projects for approximately 200 validated loci. The genotyping for the RA samples was performed in multiple centres and therefore all raw genotyping data was collated centrally for combined clustering and analysis. The data was first re-clustered and after applying strict QC metrics (99% SNP and 98% sample) the samples were subjected to further pruning for relatedness and ancestral outliers. In the initial analysis we have examples of re-focusing of the strongest association signal(e.g.2q11), evidence for multiple independent associations within a locus (e.g.PADI4) and associations to previously unconfirmed RA loci (e.g.TMEM170). Within the 2q11 locus the peak of associations has moved 76kb to now lie within the AFF3 gene. The PADI4 gene has, for the first time, been robustly associated with RA in a Caucasian population (p=3x10-7). There is also evidence for two independent affects in this region, one of which is correlated with the variant previously reported to be associated with RA in Japanese populations. TMEM170, a type 1 diabetes susceptibility locus, is an example of a novel region robustly associated with RA (p=1x10-5) and adds to the growing number of overlapping autoimmune susceptibility genes. Acknowledgments:We kindly acknowledge the Wellcome Trust Sanger Institute for the generation of RA case and control data, the WTCCC for the provision of control data and the Steve Rich laboratories at the University of Virginia for the generation of control data for this project.

Re-ranking sequencing variants in the post-GWAS era. *L.L. Faye[1,2], S.B. Bull[1,2], L. Sun[2,3].* 1) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto; 2) Samuel Lunenfeld Research Institute, Mount Sinai Hospital; 3) Department of Statistics, University of Toronto, Toronto, ON.

Whole-genome next-generation sequencing (NGS) dramatically increases our ability to pin-point disease-causing variants by providing information at all variant SNPs. To reduce cost and heterogeneity, among other reasons, GWAS samples are often used for NGS. To increase power, associated regions identified by significance at GWAS tag SNPs are often prioritized for sequencing analysis and the locations of causal variants are refined using the sequencing data. This analytic strategy introduces bias into the ranking of sequencing SNPs, increasing the probability that non-causal SNPs will be top-ranked. This bias is most pronounced when the tag and causal SNPs are in moderate LD. We quantify this bias analytically and show that selection at the tag alters the joint distribution of the sequencing association statistics. Simulation studies comparing the ranking of SNPs using the combined GWAS sequencing analysis to the ranking of SNPs in an independent sequencing sample verify these effects. In the independent sequencing sample, the top-ranked SNPs tend to be the causal SNP or SNPs in highest LD with the causal SNP. In contrast, when associated regions are selected by GWAS, high LD with the tag tends to increase the rank of a SNP, even when it is not highly correlated with the causal SNP. When the tag and causal SNPs are in moderate LD, this increases the probability that SNPs in high LD with the tag will out-compete the causal SNP for the top ranks. To improve causal SNP identification, we develop a re-ranking procedure that re-calibrates the association evidence for all GWAS and sequencing variants in a given region. We use BR-squared (Faye et al, 2011) to estimate the amount of bias induced by selection, that is the difference between the observed test statistic at the GWAS tag SNP and the mean of its underlying distribution. The degree of this bias depends on GWAS power. The amount of GWAS tag bias that carries through to the sequencing SNPs depends on the LD between the GWAS tag and sequencing SNPs. Therefore, we adjust each sequencing SNP test statistic by the estimated bias at the tag, scaled by the LD between the tag and sequencing SNPs. The sequencing SNPs are then re-ranked using the adjusted test statistics. Simulation studies show that when bias is detrimental to the rank of the causal SNP, the re-ranking procedure tends to improve the rank of the causal SNP and SNPs in high LD with the causal SNP.

DNA methylation involved in chemobrain. *R. He[1], J. Eggert[1], P. Tate[1], L. Larcom[1], C. Chen[2].* 1) Clemson University, Clemson, SC; 2) Greenwood Genetic Center, Greenwood, SC.

Chemotherapy may initiate or potentiate memory loss and other cognitive impairments experienced by cancer patients. Loss of memory may persist following treatment and can significantly impact the quality of life for a subset of cancer survivors. Many studies have linked epigenetic mechanisms to memory formation postulating that transient reprogramming of epigenetic codes such as DNA methylation and histone modifications is required for memory consolidation. This poster will share results of a preliminary in vitro study designed to determine if doxorubicin chemotherapy causes morphological and epigenetic changes in the PC12 neuron cells. Experiments were conducted separately on a group of non-treated PC12 neuron cells and a group of PC12 neuron cells treated with doxorubicin chemotherapy. The cell morphology, cell viability and epigenetic changes are compared before and after treatments. Results suggest that minute amounts of doxorubicin chemotherapy decrease metabolic activity and neurite outgrowth of PC12 neurons, and DNA methylation is a mechanism that is associated with this process.

Advanced methods for genome-wide methylation detection reveal novel epigenetic dynamics of leukemia. *A. Akalin[1,2], M. Figueroa[1], F. Garrett-Bakelman[1], M. Kormaksson[1], J. Busuttil[1], A. Melnick[1], CE. Mason[1,2].* 1) Weill Cornell Medical College, Cornell University, New York, NY 10065, USA; 2) HRH Prince Alwaleed Bin Talal Bin Abdulaziz Alsaud Institute for Computational Biomedicine, Weill Medical College, Cornell University, New York, NY 10065, USA.

DNA methylation is a critical epigenetic modification that regulates gene expression and mediates cellular differentiation states. Recently, methylation signatures have been utilized to stratify different sub-types of leukemia, which indicate their important relevance for clinical applications. Current high-throughput methods for examination of the epigenome, such as reduced representation bisulfite sequencing (RRBS), ameliorate the cost of sequencing after bisulfite treatment but limit the number of regions that can be examined. Here, we report biochemical and bioinformatics improvements in the RRBS method, creating a new technique called enhanced RRBS (eRRBS). We show extremely high reproducibility with this technique (R>0.96), even with very-low input levels (5ng vs. 1ug). Our method also shows an improved conversation efficiency of the non-methylated cytosines (>99.5%). We also find an increased number (11-61%) of CpG sites that can be detected and quantified in all areas: CpG islands, promoters, CpG shores, introns, and exons. Moreover, we can use this method to effectively determine differentially methylated regions (DMRs) and shores (DMSs) that reveal new regions of the genome that are altered in acute lymphoblastic leukemia.

Epigenomic dysregulation of enhancer elements in cancer. *B. Akhtar-Zaidi[1], A. Saiakhova[1], J. Willis[2,3], S. Markowitz[2,4,5], P. Scacheri[1].* 1) Genetics, Case Western Reserve University, Cleveland, OH; 2) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH; 3) Department of Pathology, Case Western Reserve University, Cleveland, OH; 4) Department of Medicine, Case Western Reserve University, Cleveland, OH; 5) Howard Hughes Medical Institute, Cleveland, OH.

Recent studies have highlighted a central role for enhancer elements in establishing gene expression programs that drive development and differentiation. Far less is known about enhancer dysregulation in human disease processes. To investigate the role of enhancer activity in carcinogenesis, we used the method of ChIP-seq to map the genome-wide distribution of mono-methylated lysine 4 of histone H3 (H3K4me1), the epigenetic signature of gene enhancer elements, in primary cell lines derived from human colorectal tumors. We have identified thousands of loci that have either gained or lost the H3K4me1 signal in colon cancer compared to normal colon crypts. We call these regions variant enhancer loci, or VELs. The data further reveal a strong association between VELs and gene expression patterns that distinguish individual colon cancers from each other and collectively from normal colon epithelium. Based on our finding that approximately 200 VELs are shared between all colon cancer samples, we propose that the epigenetic landscape at distal enhancers is far more homogeneous than the mutational landscape of protein coding sequences in colon cancer. High-frequency VELs are robustly associated with genes aberrantly expressed across multiple colon tumors, and are enriched near genes and pathways extensively implicated in colon cancer. Lastly, we describe a strong association between lost VELs and DNA hypermethylation that we subsequently validated in an independent set of primary colon tumors. Taken together the data are consistent with a model of colon cancer in which targeted dysregulation of enhancers by a mechanism involving both H3K4me1 and DNA methylation is a major feature of carcinogenesis.

Methylation Signature of Breast Cancer Metastasis. *Z. Barekati, R. Radpour, XY. Zhong.* Laboratory for Gynecologic Oncology, Women's Hospital/ Department of Biomedicine, University of Basel.

Invasion and metastasis are two important hallmarks of malignant tumors that followed by complex of genetic and epigenetic alterations. Present study investigated the contribution of aberrant methylation profile of twelve cancer related genes in paired metastasis and non-metastasis axillary lymph nodes in comparison to the primary tumor tissue and the adjacent normal tissue from the same breast cancer patients. The quantitative methylation analysis of the candidate genes showed higher methylation proportion for the primary tumor tissue versus matched normal tissue and the differences were significant for APC, BIN, BMP6, BRCA1, CST6, ESR-b, P16, PTEN and TIMP3 promoter regions (P<0.05). Among the significant methylated genes, APC, BMP6 and BRCA1 represented high methylation proportion in paired metastasis and non-metastasis lymph nodes compared to the normal tissue (P<0.05) whereas the P16 promoter was methylated only in the metastasis lymph node (P<0.05). We identified even greater hypermethylation proportion of BMP6 in the metastasis lymph node than the primary tumor tissue (P<0.05). Conversely, the promoter region of BIN1, GSTP1 and P14 significantly showed less methylation proportion in both the lymph node metastasis and non- metastasis compared to the matched normal tissue (P<0.05). Taken together present study showed methylation heterogeneity between primary tumors and metastatic lesion. Contribution of aberrant methylation alterations of APC, BMP6, BRCA1 and P16 genes in metastasis lymph node suggests more investigation for the pathways and networks related to these genes which might improve knowledge of mechanism underlying metastasis and might improve prognosis and therapeutic strategies for the breast cancer patients.

Epigenetic pattern, mRNA and protein expression of E-cadherin and Caveolin-1 in gastric adenocarcinoma. *C.O. Gigek[1], M.F. Leal[1], P.N.O. Silva[1], L.C.F. Lisboa[1], E.S. Chen[1], D.Q. Calcagno[1], E.M. Lima[2], P.P. Assumpção[3], R.R. Burbano[4], M.A.C. Smith[1].* 1) Disciplina de Genética, Departamento de Morfologia e Genética, Universidade Federal de São Paulo, SP, Brasil; 2) Laboratório de Genética Humana e Oncogenética, Departamento de Biologia Molecular, Universidade Federal do Piauí, PI, Brasil; 3) Serviço de Cirurgia, Hospital Universitário João de Barros Barreto, Universidade Federal do Pará, PA, Brasil; 4) Laborátorio de Citogenética Humana e Genética Toxicológica, Departamento de Biologia, Centro de Ciências Biológicas, Universidade Federal do Pará, PA, Brasil.

Plasma membrane proteins play a role in cell signalling, adaptation to environment and cell-matrix interactions, and are also involved in the acquisition and maintenance of invasive and metastatic properties of tumour cells. E-cadherin is a member of calcium-dependent adherins and contributes to cell-cell adhesion. Caveolin-1 is an integral membrane protein and it has been implicated in diverse cellular processes such as cholesterol homeostasis, vesicular transport, cell migration, regulation of cell transformation and signal transduction. Their respective genes have potential sites embedded within CpG islands, being potential sites for epigenetic regulation by DNA methylation. Epigenetic modifications have a central role in several types of cancer, including gastric adenocarcinoma. In the present study, E-cadherin and Caveolin-1 immunostaining were analyzed in about 50 gastric neoplastic and 20 non-neoplastic gastric mucosa samples. DNA methylation and mRNA were also investigated through methylation specific PCR and qRT-PCR. Statistical analyses were performed to assess associations between protein and mRNA expression and methylation status with clinicopathological characteristics. Absence of E-cadherin immunostaining was associated with gastric carcinogenesis (p<0.0001) and with metastasis (p= 0.0035). 84.2% of neoplastic samples had positive immunostaining for Caveolin-1 (p<0.0001) and this protein was also more frequently observed in intestinal than in diffuse type gastric cancer (1 vs 0.6786, p=0.0008) and in H. pylori infected samples (p=0.0196). Our data showed an inverse relationship between E-cadherin and Caveolin-1 expression. CAV1 mRNA levels of 37-paired samples showed a significant increase in tumors samples (5.3781 ± 1.6950) when compared to non-neoplastic gastric mucosa (4.2630 ± 1.5015) (p=0.0004). We observed an association between hypermethylated tumor samples status and lack of Caveolin-1 expression (p=0.001). Therefore, we originally demonstrated epigenetic regulation of CAV1 by DNA methylation in gastric cancer. This event has been previously reported in different tumors, such as breast and sporadic colorectal cancer and hetapatocellular carcinoma. In conclusion, E-cadherin was associated with gastric cancer and with a metastatic phenotype and Caveolin-1 seems to have a role as a pro-tumorigenic factor and might be a good marker for gastric cancer. Financial Support: FAPESP and CAPES.

ASSOCIATION OF DNA METHYLATION PATTERN WITH PARENTAL SMOKING IN ACUTE LYMPHOBLASTIC LEUKEMIA CASES. *L. Hsu[1], J. Xiao[2], A. Chokkalingam[1], C. Metayer[1], P. Buffler[1], J. Wiemels[2].* 1) School of Public Health, University of California Berkeley, Berkeley, CA; 2) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA.

PURPOSE: Childhood acute lymphoblastic leukemia (ALL) is a multifactorial disease. Evidence has suggested that environmental exposures may affect DNA methylation at specific genomic loci in certain smoking-related cancers, which could serve as an important intermediate between exposure and cancer. GoldenGate DNA methylation profiling on a series of leukemia bone marrows demonstrated that DNA methylation patterns are associated with parental smoking. Here we attempt to validate methylation at individual gene loci identified through pilot profiling as markers of parental smoking in leukemic cells. METHODS: Leukemia bone marrow DNA was isolated and bisulfite-treated prior to Sequenom methylation analysis. We examined the association between parental smoking (yes/no) during several critical developmental periods (pre-pregnancy, during pregnancy and postnatal) and methylation at 38 individual CpG loci among 206 B-cell leukemia cases. The association between methylation levels at specific loci and parental smoking variables assessed using Student's T-test (parametric) or the Wilcoxon rank-sum test (non-parametric). RESULTS: Among the 38 CpG units, methylation at two CpG loci in two genes (TSP50, C4B) were significantly associated with maternal smoking during pregnancy (p=0.003) and maternal smoking after giving birth (p=0.04) respectively, but only TSP50 remains significant after adjustment for multiple testing. CONCLUSIONS: The results from our study suggest that individual methylated CpG loci are associated with maternal smoking, and that maternal smoking may affect childhood leukemia risk via its impact on DNA methylation processes.

The difference in methylation status of the p53 gene in smokers versus non-smokers. *M. Simkin[1,2], M. Abdalla[2], M. Elmogy[2], Y. Haj-Ahmad[1,2].* 1) Brock University, St. Catharines, Ontario, Canada; 2) Norgen Biotek Corp, Thorold, Ontario, Canada.

DNA methylation is a valuable epigenetic alteration that could be used for cancer screening, prevention and therapeutics. DNA methylation is easier to detect than mutations, and methylation changes usually occur early in tumour progression. DNA methylation is also reversible; allowing potential treatments to begin before cancer even develops. The tumour-suppressor protein p53 is responsible for cell cycle arrest and DNA repair. Mutations in the p53 gene have been found in more than half of all cancers, and hypermethylation of the promoter sequence adjacent to p53 has been found to lead to cancer. Smoking has been demonstrated to lead to hypermethylation of tumour-suppressor genes in many tissues, including both cancerous and non-cancerous lung biopsy tissues. This association has never been explored in young, healthy individuals, with no clinical signs of cancer. The present study looked at DNA isolated from urine and saliva samples taken from 56 healthy participants, male and female smokers and non-smokers, aged 18-25. Using GAPDH as a negative control, p53 gene promoter methylation was assessed using methylation-sensitive restriction enzymes HpaII and HhaI followed by end-point PCR and agarose gel electrophoresis. This study demonstrated that qualitatively, DNA derived from both the saliva and urine of smokers and non-smokers were equivalent in that none of the samples obtained were found to show p53 gene promoter hypermethylation. Quantitatively, however we found that the DNA concentration is greater in the smoker samples (both urine and saliva) than the non-smokers. Saliva and urine have been recognized as a non-invasive method of obtaining a blood sample, with both representing total systemic cell apoptosis. The findings from this study indicate that urine and saliva represent a good source of total systemic DNA for downstream molecular biological analyses, and that both samples are robust enough to study epigenetic alterations in human DNA.

The role of MBD2 in hypomethylation and activation of pro-metastatic genes in liver cancer. *B. Stefanska[1], B. Bhattacharyya[1], M. Suderman[1], J. Huang[2], M. Hallett[3], Z.G. Han[2], M. Szyf[1].* 1) Pharmacology and Therapeutics, McGill University, Montreal, Quebec, Canada; 2) Shanghai-MOST Key Laboratory for Disease and Health Genomics, Chinese National Human Genome Center at Shanghai, Shanghai, China; 3) McGill Centre for Bioinformatics, McGill University, Montreal, Canada.

DNA hypomethylation, a process of losing methyl marks, may play an important role in cancer, especially through activating genes that promote metastasis. Using whole genome promoter methylation microarrays, we previously delineated the landscape of DNA hypomethylation in liver cancer, which is one of the most common cancers worldwide. Our studies revealed that 50% of differentially methylated promoters are hypomethylated in tumors, compared to adjacent normal tissue. In these studies, using liver cancer cell lines as a model system, we evaluated the importance of the identified hypomethylated genes in liver cancer development and progression. We tested whether the hypomethylation observed in liver cancer is driven by MBD2, a protein reported previously to be implicated in DNA demethylation, which we found to be overexpressed in liver cancer patients. Following siRNA MBD2 depletion in HepG2 liver cancer cells, we used methylated DNA immunoprecipitation, chromatin immunoprecipitation (ChIP) and 60K custom microarrays covering 12K bp upstream and 10K bp downstream of transcription start site to determine changes in methylation as well as MBD2 binding and RNA polymerase II binding in response to MBD2 depletion in 306 top genes that were found to be hypomethylated and/or induced in liver cancer patients and/or HepG2 cells. The array data were validated by quantitative ChIP and/or pyrosequencing. We discovered MBD2 binding peaks in 172 genes that are located mostly within their promoter regions and overlap or are in the vicinity of RNA polymerase II binding peaks that mark transcription start sites. Using bioinformatic tools, we identified MBD2 binding motif and established putative transcription factors recognizing this sequence which may play a key role in recruiting MBD2 to target genes. 41% of those genes were hypermethylated in HepG2 cells after MBD2 depletion in the region corresponding to the identified MBD2 binding site. In addition, expression analysis for some of the genes showed a reduction in response to MBD2 depletion. The genes that are regulated by MBD2 in liver cancer are important for the cancer phenotype since siRNA depletion of these genes reverses the transformed phenotype. Our results establish a role for MBD2 in coordinating inhibition of a panel of genes involved in cancer growth and metastasis. This study was supported by a grant from the MDEIE program of the government of Quebec and National Cancer Institute of Canada to MS.

OxLDL causes both epigenetic modification and signaling regulation on the microRNA-29b gene: novel mechanisms for cardiovascular diseases. *K.C. Chen[1], I.C. Hsieh[2], Y.S. Wang[1], Y.C. Liao[3,4,5], C.Y. Hu[1], S.H.H. Juo[1,2].* 1) Department of Medical Research, Kaohsiung Medical University Hospital, Kaohsiung, Taiwan; 2) Department of Medical Genetics, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 3) Graduate Institute of Medicine, College of Medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; 4) Section of Neurology, Taichung Veterans General Hospital, Taichung, Taiwan; 5) Department of Neurology, National Yang-Ming University School of Medicine, Taipei, Taiwan.

We previously reported that microRNA-29b can epigenetically regulate proatherogenic genes in response to oxLDL stimulation. However, the mechanisms underneath the transcriptional regulation of miR-29b gene remain to be explored. The present study aims to investigate whether transcription factor activation or histone modification is involved in oxLDL-induced miR-29b upregulation. We first demonstrated that mice fed with a high-fat diet had an increased miR-29b expression, which was consistent with our previous findings in the cellular studies. We found that oxLDL enhanced miR-29b expression through activating the transcription of miR-29b-1/miR-29a cluster gene. We used the promoter assay and chromatin immunoprecipitation to confirm the binding between miR-29b-1 promoter and activator protein-1 (AP-1), a transcriptional activator. By using the MAPTAM (Ca^{2+} chelator), NAC (ROS scavenger), U0126 (ERK inhibitor) and c-Fos shRNA, we found the signal pathway of LOX-1/Ca^{2+}/ROS/ERK/c-Fos was involved in oxLDL-mediated miR-29b overexpression. We also showed that down-regulation of HDAC1 and the modifications on histone 3 lysine 4 (H3K4) and H3K9 significantly affected miR-29b expression. Furthermore, knockdown of c-Fos expression attenuated oxLDL-induced histone modifications on miR-29 gene. To conclude, transcription factors activation and histone modifications are both important regulatory mechanisms of oxLDL-induced atherogenic process.

Epigenetics and genomics of constitutional trisomy 8: a uniqe model system for chromosome gain. *J. Davidsson[1], S. Veerla[2], B. Johansson[1].* 1) Dept. of Clinical Genetics, Skåne University Hospital, Lund, Sweden; 2) Dept. of Oncology/SCIBLU DNA Microarray Resource Centre, Lund University, Lund, Sweden.

Aneuploidy is frequently seen in cancer cells and constitutional genetic disorders, but how chromosomal imbalances produce pathophenotypes is currently not well understood. Gene expression and epigenetic patterns of gained chromosomes have previously only been studied *in vivo* by comparing triploid cells with unrelated disomic cells from healthy individuals. Our novel approach aimed to characterize cells with and without trisomy, derived from the same cell type and individual. Using fibroblasts from a carrier of trisomy 8 mosaicism, we by single cell suspension assays cloned cultures purely 46,XY or 47,XY,+8, as confirmed by FISH. Utilizing microarrays and methylated DNA immunoprecipitation we profiled gene and miRNA expression, as well as DNA methylation and hydroxymethylation patterns in three 47,XY,+8 cultures, three 46,XY cultures, as well as in two reference fibroblast cultures. Unsupervised clustering and principal component analysis of the methylation, hydroxymethylation, miRNA and gene expression data demonstrated that the 47,XY,+8 cells in each individual dataset clearly separated from the 46,XY cells, with the latter clustering together with the two reference fibroblast cultures. Genes on chromosome 8 were generally overexpressed in the 47,XY,+8 cells, but significantly altered expression patterns were detected also on other chromosomes, supporting that downstream effects of trisomy is not restricted solely to the gained chromosome. A number of differentially expressed miRNAs and genes were identified, which could be candidate contributors to both the phenotype and increased risk for malignant disorder seen in patients with the trisomy 8 mosaicism syndrome. Performing pathway analysis of genes differentially expressed in the 47,XY,+8 cells, cancer and genetic syndromes were the most significant diseases, whereas cell morphology and cellular development were the top scoring pathways. Several genes and miRNAs were differentially hypermethylated and underexpressed in 47,XY,+8 compared to 46,XY cells, indicating that methylation and hydroxymethylation of DNA is a functional downstream response to trisomy 8 in human cells. Moreover, on the additional chromosome 8 in the 47,XY,+8 cells, a global hypomethylation of gene-poor regions could be detected, something that is generally seen as a hallmark of X-chromosome inactivation and have previously only been reported in association with chromosome gain in neoplasia, not in constitutional disorders.

EFFECT OF HISTONE 4 METHYLATION AT *BDNF* EXPRESSION AFTER ANTIDEPRESSANT TREATMENT ON HUMAN PREFRONTAL CORTEX. *E.S. Chen[1], C. Ersnt[2], M.A.C. Smith[2], G. Turecki[1].* 1) Morfologia e Genética, UNIFESP, São Paulo, São Paulo, Brazil; 2) Department of Psychiatry, McGill University, Montreal, Quebec, Canada.

Antidepressant drugs have been reported to increase BDNF expression levels in brain and might reverse the depression-associated decrease in BDNF expression both in human and rat, suggesting a relationship between BDNF expression and antidepressant action. One of the variants of BDNF, transcript IV, has been related to psychiatric disorders in some animal models. To date, the mechanisms underlying this event are poorly understood. Our group has previously showed that antidepressants are associated with decreased methylation at H3K27 and an increase in BDNF IV expression. In this study, we aimed to investigate whether methylation at H4K20 lead to altered BDNF IV expression in prefrontal cortex of control subjects with no psychiatric history (N=9; C), depressed patients without positive toxicology for antidepressants or history of antidepressants use (N=11; AD-), and depressed patients with a history of antidepressant use and with antidepressant detected in blood post-mortem, using MS (N=7; AD+). Antidepressants used included: fluoxetine (1/7), venlafaxine (2/7), clomipramine (1/7), amytriptyline (1/7), citalopram (1/7) and doxepine (1/7). qRT-PCR and ChIP were performed. All analyses were carried out using SPSS v18.0. ANOVA analysis showed a significant higher levels of BNDF promoter IV expression in AD+ group when compared to AD- (F=4.395; p=0.024). We found a significant difference in H4K20 methylation levels among groups (F=8.419, p=0.001). These results suggest a relationship between antidepressant use, methylation at H4K20, and BDNF IV expression, with similar results to that obtained previously by our group when another histone residue was analyzed. Thus, we may conclude that antidepressants treatment may lead to gene expression alterations in prefrontal cortex of suicide patients by chromatin remodelling. Financial support: CAPES, FAPESP.

Epigenetic regulation of polyamine biosynthetic genes in suicide. *J. Gross, L. Fiori, B. Labonté, G. Turecki.* Douglas Mental Health University Institute, Montreal, Quebec, Canada.

Suicide is among the leading causes of death worldwide. Recently, the polyamine system has become an interesting target of research aimed towards understanding the neurobiological alterations associated with suicide. Previous research has linked suicide behavior with genetic variations in the promoter of spermidine/spermine N1-acetyl transferase, the rate-limiting enzyme in polyamine catabolism. However, the epigenetic regulation of other polyamine biosynthetic genes has yet to be elucidated. Using quantitative real time polymerase chain reaction (qRT-PCR), expression of ornithine decarboxylase antizymes 1 and 2 (OAZ1 and OAZ2), S-adenosylmethionine decarboxylase (AMD1), and arginase, type 2 (ARG2) was assessed in Brodmann area 44 of 80 French-Canadian males comprising 40 suicide completers and 40 non-suicide control subjects. Using chromatin immunoprecipitation (nChIP) and antibodies targeting histone H3 trimethylated at lysine 4 (H3K4me3) and at lysine 27 (H3K27me3), markers of open and closed chromatin respectively, DNA nucleosomes were extracted from a group of the above subject in which expression of each of the four genes was significantly higher in suicide completers compared to controls. The resulting products were analyzed by qRT-PCR. In addition, Sequenom's EpiTYPER was used to characterize differentially methylated CpGs in the promoter region of each gene mentioned above. We found significant increase in H3K4me3 in suicide completers for OAZ1, and the levels of this modification were significantly correlated with expression of this gene. Levels of H3K27me3 in OAZ1 were not nominally significant, however, our results indicated a trend of increased H3K27me3 in the suicide group as compared to the control subjects. Finally, we found site-specific differences in methylation in the promoter regions of each gene between suicide completers and controls, however only those of AMD1 and ARG2 correlated significantly with gene expression. These preliminary findings suggest that epigenetic modifications are involved in regulation of genes associated with polyamine biosynthesis and that this might contribute to the complexity of suicide behavior.

Impact of genetic variation on chromatin state and genome-wide gene expression phenotypes. *H. Kilpinen[1], S. Waszak[2], R.M. Witwicki[3], A. Orioli[3], S. Raghav[2], M. Gutierrez-Arcelus[1], L. Romano-Palumbo[1], N. Hernandez[3], B. Deplancke[2], A. Reymond[3], E.T. Dermitzakis[1].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School; Geneva, Switzerland; 2) Laboratory of Systems Biology and Genetics, Institute of Bioengineering, École Polytechnique Fédérale de Lausanne (EPFL); Lausanne, Switzerland; 3) Center for Integrative Genomics, University of Lausanne; Lausanne, Switzerland.

During the last few years, genome-wide chromatin state and histone modification profiling has generated information about specific chromatin signatures related to different functional elements of the genome in multiple cell types. However, the degree of stability and the genetic basis of such signatures across individuals remain largely unknown. We have used ChIP-seq to produce genome-wide enrichment profiles of three transcription factors, RNA Pol II, MYC, and SPI1, as well as histone modifications H3K4me1, H4K20me1, H3K27me3, and H3K4me3, from lymphoblastoid cell lines of two trios sequenced as part of the 1000 Genomes project. In the second phase of the study these marks will be profiled in 100 individuals from the 1000 Genomes CEU population for which low coverage genome sequence and genotype data is available. We will also produce genome-wide mRNA and miRNA sequencing data from the same 100 individuals. For the two trios, additional functional data such as global DNA methylation profiles will be produced, which allows us to overlay multiple layers of genomic information for a comprehensive picture of the transcriptional state of the cells. With this dataset we will (i) compare the enrichment patterns of chromatin and transcription factor signatures across individuals and around key sequence elements such as expression quantitative trait loci (eQTLs), shown to affect transcript levels in these individuals (ii) estimate the degree of heritability of such signatures (iii) analyze the allele-specific effects of DNA sequence variation on chromatin structure and correlate this information with allele-specific gene and miRNA expression levels from the same individuals (iv) explore the factors which affect the general transcriptional state of the cell. This study will significantly improve our understanding of the biological landscape around regulatory and other functional elements of the genome, and provide better means to address the cellular basis of phenotypic diversity, such as disease susceptibility, in humans.

Analysis of DNA methylation supports variable spread of X-chromosome inactivation into X;Autosome translocations. *A. Cotton[1,2], L. Lam[1,3,4], M. Kobor[1,3,4], C. Brown[1,2].* 1) Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Molecular Epigenetics Group, Life Sciences Institute, Vancouver, BC, Canada; 3) Child & Family Research Institute, Vancouver, BC, Canada; 4) Centre for Molecular Medicine and Therapeutics, Vancouver, BC, Canada.

X-chromosome inactivation (XCI), the mammalian dosage compensation process, is normally random, with either X being transcriptionally silenced early in development. In unbalanced X;autosome (X;A) translocation carriers the translocated chromosome is usually inactivated; however, the spread of XCI into the autosomal portion of the translocated chromosome is variable. At X-linked CpG island promoters the inactive X is hypermethylated compared to the active X, while autosomal CpG island promoters generally show low levels of methylation on both chromosomes. Having previously shown that the methylation of CpG island promoters can be used to predict the XCI status of X-linked genes, we investigated if methylation could be used to determine the extent of spread of XCI into the autosomal portion of unbalanced X;A translocations. Using the Illumina 450K array to examine the methylation of unbalanced X;A translocations we designated CpG island promoters on the autosomal portion of the X;A translocation that showed hypermethylation as being subject to XCI, while those which remained unmethylated were predicted to escape XCI. For five unbalanced X;A translocation cell lines we observed an average of 19% of autosomal genes showing evidence for being subject to XCI, with the frequency of genes subject to XCI decreasing with distance from the translocation breakpoint. Genes located in a region of autosomal trisomy showed a higher frequency of inactivation (27%) than those in regions of disomy (6%), likely reflecting an ascertainment bias for translocations in which the spread of XCI has minimized the impact of aneuploid regions. DNA methylation was also used to refine the previous determined breakpoint regions from an average of 12 Mb to an average of 3.6 Mb. The spread of XCI into the autosomal portions of X;A translocations provides a unique opportunity to study chromosomal features involved in XCI and we used methylation in these cells as a means to refine models of the elements involved in the spread of silencing distinct from the evolutionary history of the sex chromosomes. The clustering of autosomal genes subject to XCI on X;A translocations supports a model in which elements or `waystations' capable of spreading silencing are also present on the autosomes. That autosomal genes which escape XCI are found in close proximity to genes subject to XCI further supports the presence of boundary elements which confer the ability to avoid inactivation signals.

Neuron-specific impairment of inter-chromosomal pairing and transcription in a novel model of human 15q-duplication syndrome. *S. Horike[1], D.H. Yasui[2], W. Powell[2], D.I. Schroeder[2], M. Oshimura[3], J.M. LaSalle[2], M. Meguro-Horike[1].* 1) Frontier Science Organization, Kanazawa University, 13-1 Takaramachi, Kanazawa 920-0934, Japan; 2) Department of Medical Microbiology and Immunology, Genome Center, and M.I.N.D. Institute, University of California Davis School of Medicine, 1 Shields Avenue Davis, CA 95616; 3) Department of Biomedical Science, Tottori University, 86 Nishi-cho, Yonago, Tottori 683-8503, Japan.

Although the etiology of autism remains largely unknown, cytogenetic and genetic studies have implicated maternal copy number gains of 15q11-q13 in 1-3% of autism cases. In order to understand how maternal 15q duplication leads to dysregulation of gene expression and altered chromatin interactions, we used microcell-mediated chromosome transfer to generate a novel maternal 15q duplication model in a human neuronal cell line. Our 15q duplication neuronal model revealed that by quantitative RT-PCR transcript levels of *NDN*, *SNRPN*, *GABRB3*, and *CHRNA7* were reduced compared to expected levels despite having no detectable alteration in promoter DNA methylation. Since 15q11-q13 alleles have been previously shown to exhibit homologous pairing in mature human neurons, we assessed homologous pairing of 15q11-q13 by fluorescence in situ hybridization (FISH). Homologous pairing of 15q11-q13 was significantly disrupted by 15q duplication. To further understand the extent and mechanism of 15q11-q13 homologous pairing, we mapped the minimal region of homologous pairing to a ~500 kb region at the 3' end of *GABRB3* which contains multiple binding sites for chromatin regulators MeCP2 and CTCF as well as long-range interactions with the imprinting control region. Using RNA interference, we show that MeCP2 and CTCF are required for the homologous pairing of 15q11-q13 during neuronal maturational differentiation. These data support a model where 15q11-q13 genes are regulated epigenetically at the level of both inter- and intra-chromosomal associations and that chromosome imbalance disrupts the epigenetic regulation of genes in 15q11-q13.

759W

Copy number variation and chromatin structure. *R.M. Witwicki[1], E. Migliavacca[1], N. Gheldof[1], G. Didelot[1], A. Kurg[2], A. Reymond[1].* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Institute of Molecular and Cell Biology, University of Tartu, Estonian Biocenter, Tartu, Estonia.

Copy number variation (CNV) was shown to influence the phenotype by modifying, in a somewhat dose-dependent manner, the expression of genes that map within them, as well as that of genes located on their flanks. To assess the possible mechanism(s) behind this neighboring effect, we compared the histone modification status of cell lines from patients affected by genomic disorders (WBS, WBRdup, DGS and SMS) and control individuals. Consistent with the changes in expression levels observed for multiple genes mapping on the entire length of chromosomes affected by structural variants, we detected regions with modified histone status between samples, up- and downstream from the critical regions, up to the end of the rearranged chromosome. Coherently, we pinpointed alteration of intrachromosomal interactions (chromosomal looping) between affected genes loci and the rearranged interval using an unbiased variant of chromosome conformation capture (3C-seq).

We conclude, that large genomic rearrangements can lead to changes in the state of the chromatin spreading far away from the critical region, thus possibly affecting expression globally. For example, we observe that the chromatin conformation of the *FoxP2* gene, mutations of which are associated with language and speech disorders, is modified in Williams-Beuren region duplication syndrome patients, who present language difficulties.

Methlyation differences between discordant monozygotic twins: a role for cysteine sulfinic acid decarboxlase (CSAD) in type 1 diabetes susceptibility. *E. Elboudwarej[1], J. Jeffrey[2], P.R. Fain[2], P.P. Ramsay[1], H. Quach[1], J.A. Lane[3], G.S. Eisenbarth[2], L.F. Barcellos[1], J.A. Noble[3].* 1) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, CA; 2) University of Colorado Health Sciences Center, Barbara Davis Center for Childhood Diabetes, Denver, CO; 3) Children's Hospital Oakland Research Institute, Oakland, CA.

Type I diabetes (T1D) has a substantial genetic component; however, traditional genetics cannot completely explain susceptibility, as evidenced by varying levels of disease discordance among monozygotic (MZ) twin pairs. In this matched case-control study, four MZ twin pairs, selected for T1D discordance of at least 8 years, were examined for differences in DNA methylation at 27,578 CpG sites across the human genome using the Illumina Infinium HumanMethylation27 BeadChip. Although global methylation levels did not differ significantly between the affected and unaffected twin in a pair, 12 CpG sites were found to have greater than 10% difference in DNA methylation between the twins in a pair, including sites within: ABCC12, ATP2B4, C14orf48, C1orf107, CA2, CDC2L2, CSAD, CUEDC1, EED, PTRH2, SOAT2, and ZNF671. A site within CSAD (cg03933322) demonstrated > 20% difference in methylation for all four twin pairs (20.4%, 23.0%, 26.5%, 35.8%) and was consistently hypomethylated in the twin with diabetes. The trend toward hypomethylation of the affected twin at the CSAD locus was reproduced for three of the four original pairs in a repeat experiment using new samples, although the effect was less pronounced. Furthermore, five additional MZ twin pairs were tested, four of which were consistent with the initial result. CSAD encodes cysteine sulfinic acid decarboxlyase, an intracellular enzyme that controls the rate-limiting step in biosynthesis of taurine, an amino acid involved in glucose homeostasis. CSAD shares a 50% amino acid sequence identity with GAD65 (glutamic acid decarboxlyase), a pancreatic enzyme that is a major target of autoantibodies in T1D. The strong and reproducible methylation differences observed in the T1D discordant MZ twin pairs, combined with the biological role of CSAD and its sequence similarity to GAD65 support the notion that CSAD methylation may play a role in T1D susceptibility and/or progression. Our results indicate CSAD is a good candidate locus for targeted follow-up methylation studies in both discordant MZ twins and large case-control cohorts.

Influence of DNA modification on INS gene expression in thymus and implications in Type I diabetes (T1D). *T. Khare[1], M. Pal[1], S.C Chong[2], A. Pugliese[3], A. Paterson[4], J. Mill[5], A. Petronis[1].* 1) Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Systems Biology and Bioinformatics, National Central University, Taiwan; 3) Diabetes Research Institute University of Miami Miller School of Medicine ,USA; 4) Department of Medicine, University Health Network, University of Toronto, Toronto, Canada; 5) MRC Social, Genetic and Developmental Psychiatry Centre, King's College London, UK.

During embryogenesis, low abundance of insulin (INS) in thymus is linked to deficient thymic learning and to the higher risk of T1D. It is well established that VNTR at INS gene promoter has association with INS mRNA expression and also to the increased susceptibility to T1D, however the underlying mechanism is still not clear. Human insulin gene is mapped on Chr11p15.5, in the vicinity of an imprinting cluster and exhibits sporadic parent of origin dependent mono-allelic expression in thymus, spleen and pancreas. These observations make INS a viable target for epigenetic studies of T1D. In the present study an attempt is made to understand the influence of DNA methylation on INS expression in thymus tissue samples from human embryos and paediatric patients, followed by comprehensive analysis of peripheral blood tissue of T1D patients and matched controls. The working hypothesis is that mono versus biallelic INS gene expressing thymii share similar DNA regions for epigenetic aberrations as diabetic patients, and these epimutations can be detected on the unaffected tissues of the patients. Out of 52 thymus samples, we identified monoallelic (n= 14) and biallelic (n=15) INS expressing thymii. These were quantified for INS steady state mRNA expression and investigated for DNA methylation by a restriction enzyme based method developed at our lab. The DNA methylation profiling method allows enrichment of unmethylated genomic DNA fraction which is then hybridized to human tiling array (covering human chr8, 11 & 12). Our preliminary results indicate that INS expression is correlated to the VNTR type, consistent with earlier reports, but independent of the INS allelic state. We also identified a modest correlation (r2=0.53) in individuals homozygous for VNTR type III between DNA methylation to INS expression at a region ~500kb away from INS gene. Interestingly, diabetic patients homozygous for VNTR III also showed aberrant DNA methylation compared to matched controls. (~10% difference; p=0.001 after bonferroni correction). Aim of our ongoing analysis is to compile common genomic regions with alterations in DNA methylation in thymus and in the T1D patients' genomic DNA. T1D is a complex non-mendelian disorder with possibly multiple epigenetic risk factors. Our long term goal is to identify these risk factors by a comprehensive DNA methylome (5mC and 5hmC) study in multiple tissues from T1D patients and controls.

Epigenetic alterations and stress among new mothers and infants in the Democratic Republic of Congo: A biocultural look at the intergenerational effects of war. *C.J. Mulligan, N. D'Errico, J. Stees, C.C Gravlee, T.P. Yang.* University of Florida, Gainesville, FL.

Adaptation is a complex process involving genetic, physiological, and behavioral mechanisms. There is growing evidence that epigenetic modifications may serve as an intermediate adaptive mechanism that mediates between the rapidly changing environment and our slowly evolving genome. The current proposal is one of the first to investigate epigenetic alterations as a possible mechanism for phenotypic plasticity during fetal development. We are testing the idea that epigenetic modifications may create heritable changes in response to extreme environmental stressors that affect infant health in a multigenerational manner. Maternal blood and umbilical cord blood samples were collected from 25 mother-infant dyads in the eastern Democratic Republic of Congo. Detailed ethnographic interviews and perinatal trauma surveys were administered to all mothers including questions designed to develop emic measures of stress. Medical histories of mothers were accessed and birth weights and gestational age of infants were recorded. DNA was extracted and treated with sodium bisulfite. A 321 bp promoter of NR3C1 with 39 CpG sites was amplified, cloned and sequenced. Twenty clones per sample were sequenced. NR3C1 is a glucocorticoid receptor that was previously implicated in methylation-mediated changes in gene expression associated with differences in childhood trauma. Our preliminary results show increased methylation in stressed mothers (material deprivation, emotional stress, recent rape), but infants show the opposite trend regardless of maternal stress exposure. When comparing mothers to their infants, no infants show an increase in methylation when compared to stressed mothers (emotional stress, recent rape) but a majority of infants show increased methylation when compared to less stressed mothers. Our results suggest that methylation patterns are different between mothers and infants and may correlate with specific maternal stress exposures.

Role of CTCF protein in regulating FMR1 gene transcription. *G. Neri, S. Lanni, M. Goracci, L. Borrelli, E. Tabolacci.* Istituto di Genetica Medica, Università Cattolica , Rome, Italy.

Fragile X syndrome (FXS, OMIM #300624) is the commonest cause of inherited mental retardation, due to mutation of FMR1, an X-linked gene containing a CGG repeat in its promoter region. Expansion of this sequence beyond 200 repeats and consequent epigenetic changes (full mutation, FM) cause the transcriptional inactivation of FMR1 and lack of the FMRP protein. Rare individuals of normal intelligence, carrying an unmethylated full mutation (UFM), have been reported and the epigenetic modifications in their FMR1 gene were characterized [Pietrobono et al., 2005; Tabolacci et al., 2008]. Cell lines from these individuals may reflect the status of FXS cells before the silencing of FMR1 during development (approximately 11 weeks of gestation). CTCF (CCCCTC-binding factor), a zinc-finger protein which binds to the chromatin insulators, is an important regulator of the transcription of genes harbouring trinucleotide repeats, acting as insulator between different chromatin domains. We started to investigate the role of CTCF in regulating FMR1 gene expression and observed that the amount of CTCF bound to FMR1 was slightly higher in the UFM cell lines, compared to normal controls, while in the FXS cells this amount was low. On the other hand, knock-down of CTCF (around 85%) with anti-CTCF siRNA transfected into normal and UFM fibroblasts, resulted in a 50% reduction of FMR1 transcript, both sense and antisense (AS-FMR1), with respect to untreated controls. After CTCF knock-down, the epigenetic analysis of the FMR1 promoter region demonstrated a reduction of H3-K4 methylation and an increase of H3-K9 methylation, while the DNA methylation of the FMR1 promoter region and of the upstream methylation boundary [Naumann et al., 2009] remained unmodified. ChIP assays demonstrated that CTCF knock-down affected specifically its binding to the 5' UTR of the FMR1 gene. These results suggest that CTCF is a modulator of the FMR1 transcription, given that its depletion causes FMR1 transcript reduction and the transition to a heterochromatic configuration. The elucidation of the mechanism sparing UFM males from inactivating their full mutation is important for planning therapeutic attempts at converting methylated into unmethylated full mutations, restoring the expression of the FMR1 gene. Supported by FRAXA Foundation and Telethon Onlus.

DNA methylation of multiple promoter-associated CpG islands in gastrointestinal stromal tumors (GIST). *M. Ravnik-Glavač, D. Glavač.* Department of Molecular Genetics, Faculty of Medicine, Vrazov trg 2, 1000, Ljubljana, Slovenia.

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasms in the gastrointestinal tract. Important prognostic factors for estimating malignant potential are: tumor size and mitotic rate and, to a more variable degree, the proliferation index or tumor site. Other potential and promising markers of GIST malignancy are molecular alterations. GIST is primarily defined by activating mutations in the c-KIT or PDGFRA receptor tyrosine kinases. To identify additional alterations we investigated the methylation status of ten methylation-sensitive CpG islands of (hMLH1, RARB, CHFR, IGSF4, APC, RASSF1, p15, p27, p73, and PTEN) in 54 patients with GIST. Aberrant DNA methylation of these loci was found in 73 % of all GIST. The rates of DNA methylation at each locus were as follows: hMLH1, 60%; CHFR, 45% , IGSF4, 41%, RASSF1, 38%, APC, 32 %, TIMP3, 18%, p15, 8%, p27, 5%, p73, 48 % and PTEN 0,0%. CpG islands methylator phenotype, which was defined as methylation involving more than three gene promoters, was found in 75% of all GIST. According to the risk categories, CpG islands methylator phenotype was present in 45% of low-risk GIST, and in 65% of high-risk GIST. CIMP was found to be much lower 45% of GIST with c-KIT gene mutations. Our results suggested that, the aberrant methylation of CpG islands, especially of hMLH1, CHFR, IGSF4 and p73, may play an important role in the tumorigenesis of GIST.

Epigenetic studies of a newborn twin cohort: insights into pre- and postnatal development. *J.M. Craig[1], E.J. Joo[1], R. Andronikos[1], M. Ollikainen[1,5], X. Li[1], Y-J. Loke[1], B. Novakovic[2], R. Morley[1], J. Carlin[3], L. Gordon[4], R. Saffery[2].* 1) Environment, Genes & Health, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 2) Cell Biology, Development and Disease, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 3) Clinical Epidemiology and Biostatistics Unit, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 4) Bioinformatics Unit, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 5) Twin Study, Hjelt Institute, Department of Public Health, P.O. Box 41, FI-00014 University of Helsinki, Finland.

The Peri/postnatal Epigenetic Twins Study (PETS) is a cohort of 250 mothers and their twins. Women were recruited from three Melbourne hospitals midway through their second trimester. Recruiting at this time enabled measurement of maternal and fetal factors at multiple time points and minimization of recall bias in dietary questionnaires. The aims of the PETS cohort are to study the plasticity of epigenetic marks and the genes they control during the intrauterine period and in early childhood. It also aims to apply the classical twins model to determine the genetic and environmental factors they are influenced by. We focused on obtaining extensive data on maternal factors during pregnancy, collection of multiple biological specimens (cord blood, cords, placenta and buccal samples at birth, blood and buccals at 18 months), and on state-of-the art technologies using both gene-specific and genome-wide approaches. Furthermore, because of the mitotic heritability of epigenetic marks, we are treating epigenetic state at birth as an intermediary between the intrauterine exposures that influence birth weight and the risk of chronic disease later in life. We measured DNA methylation on a genome scale in DNA from three cell types from 22 MZ and 11 DZ twin pairs using Illumina Infinium HumanMethylation27 BeadChip arrays. This platform interrogates 27,578 CpG dinucleotides covering 14,475 transcription start sites. Using a single, compound measurement of with-pair discordance we found that both MZ and DZ pairs exhibited a range of within-pair discordance greater than for technical replicates and that DZ twins were more discordant than MZ twins. Using gene-specific measurements we identified groups of genes consistently discordantly methylated within twin pairs and using regression analysis, identified genes whose methylation levels correlated with birth weight in MZ pairs. Many of these genes were linked with cardiovascular and metabolic function, providing a plausible biological mechanism for the previously described link between low birth weight and increased risk of later complex disease. We also measured DNA methylation on a genome scale in DNA from buccal cells at birth and 18 months using Illumina Infinium arrays interrogating >485,000 CpG dinucleotides and detected extensive postnatal age-associated epigenetic change. To our knowledge, this is the first study to demonstrate genome-wide epigenetic differences within newborn and very young twin pairs.

Genome-wide DNA methylation in sib-pairs discordant for autism. *R.S. Alisch, P. Chopra, K.E. Szulwach, B.G. Barwick, B. Lynch, J. Mowrey, G.A. Satten, K.N. Conneely, P. Jin, S.T. Warren.* Dept Human Gen, Emory Univ Sch Med, Atlanta, GA. 30322.

The autism spectrum disorders (ASD) comprise a broad group of behaviorally related neurodevelopmental disorders affecting as many as 1 in 110 children. Family, twin and epidemiological studies reveal a strong familial component to ASD risk, suggesting a polygenetic and/or epistatic susceptibility model involving many genes. However, despite great effort only a few genes have been linked conclusively to ASD risk and, even then, only in a small minority of ASD cases suggesting that the etiology of ASD is likely to be complex and may also include both epigenetic and environmental factors. Here we investigate a potential epigenetic component to ASD by interrogating DNA methylation using an established high-throughput assay that interrogates DNA methylation (DNAm) at 27,578 highly informative CpG dinucleotides (spanning 14,495 genes). DNAm profiles from whole blood-extracted DNA of 448 male sib-pairs discordant for ASD do not reveal loci with significant DNAm differences associated with autism, suggesting that this epigenetic component does not play a role in ASD. However, this assay does not distinguish between 5-methylcytosine (5-mC) and the recently identified modification of cytosine, 5-hydroxymethylcytosine (5-hmC), which was identified in stem cells and post-mitotic neurons and raises new questions as to the role of cytosine modifications in mediating epigenetic effects. As a preliminary analysis, we profiled 5-hmC throughout the genomes of two dizygotic twin sib-pairs discordant for autism and find a consistent reduction in 5-hmC in the exonic sequences of the ASD individuals; this reduction is not present in intronic or intergenic genomic sequences. Consistent with this finding, we identify 114 ASD-associated loci that are deficient in the autistic boys as well as fourteen ASD-associated loci that are enriched for 5-hmC, both of which are more prevalent than would be expected by chance alone ($p < 10^{-6}$). A closer examination within these 128 ASD-associated 5-hmC loci in 403 sib-pairs discordant for ASD at 485,764 CpG dinucleotides again does not reveal DNA methylation differences associated with autism, suggesting that the total DNAm content in ASD individuals remains static and the ASD-associated epigenetic information is contained in the 5-hmC profile, which ultimately may serve as ASD peripheral biomarkers.

Familial and environmental determinants of methyl quantitative trait loci genome-wide in nuclear families. *L. Liang[1], S.G. Willis-Owen[2], K.C.C. Wong[2], A. Binia[2], P.J. Farrell[3], G.M. Lathrop[4], G. Abecasis[5], M.F. Moffatt[2], W.O.C.M. Cookson[2].* 1) Epidemiology, Harvard Sch Public Health, Boston, MA; 2) National Heart and Lung Institute, Imperial College, London SW3 6LY, UK; 3) Section of Virology, Imperial College Faculty of Medicine, London W2 1PG, UK; 4) CEA / Centre National de Genotypage, 91057 Evry, France; 5) Center for Statistical Genetics, Dept. of Biostatistics, SPH II, Ann Arbor, MI 48109-2029, USA.

Epigenetic variation in the methylation patterns of DNA is thought to regulate gene expression. Familial transmission of methylation patterns is recognised for a few genes that exhibit genomic imprinting, but the extent of epigenetic inheritance in the genome and its relevance to common diseases is not known. We therefore studied the genome-wide distribution of methylation status at approximately 27,000 CpG islands in peripheral blood leukocytes (PBL) from a panel of 95 nuclear families recruited through an asthmatic proband. We found that 17.9% of the average variation in methylation across all loci (meQTL) was explained by age and 2.9% by sex. 25% of the residual familial variation in meQTL was attributable to the shared family environment. Only 10% appeared heritable and could be attributed to epigenetic or genetic effects. We observed true genetic influences on methylation at approximately 10% of loci, with significant SNP associations (meSNPs) (false discovery rate (FDR) <5%) present at 2079 loci in cis and at 522 loci in trans. The peak meSNP at these loci explained 22.3% of their variation. Individual variance components estimations identified loci primarily influenced by genetic, epigenetic or environmental factors. Methylation status in PBL (predominately T lymphocytes) was highly correlated (R2=0.92) with meQTL in Epstein-Barr virus (EBV) infected lymphoblastoid cell lines (LCL) derived from B lymphocytes, although LCL showed constant differences in methylation at distinct loci. Methylation status was related to gene expression, as 666 (25%) of the peak meSNPs were in linkage disequilibrium (R2>0.5) with expression quantitative trait loci (eQTL). We were able to map multiple meQTL associated with age (Pmin=1x10-24) and the total serum IgE concentration (Pmin=1.7x10-9). These results indicate that meQTL mapping in DNA derived from existing large-scale collections of PBL may be of value to understanding mechanisms underlying common diseases, but emphasise the necessity of analytical strategies that take into account the complexity of influences on methylation at individual loci.

Alterations in DNA and Nuclear Lamina Interactions and Chromatin Organization in Hutchinson-Gilford progeria syndrome. *A. Nazario-Toole, K. Cao.* Molecular and Cellular Biology, University of Maryland, College Park, MD.

Hutchinson-Gilford progeria syndrome (HGPS) is a genetic premature aging disorder. The majority of HGPS cases are caused by a de novo point mutation at position 1824 of the LMNA gene. This nucleotide substitution activates a cryptic splice donor site and causes in frame deletion of 150 base pairs within the prelamin A mRNA. This is translated into a mutant lamin A protein, known as progerin, with 50 internally deleted amino acids near the C terminus. Recent studies have demonstrated that progerin accumulation leads to progressive alterations in epigenetic controls and the gradual loss of peripheral heterochromatin. The Polycomb repressive complex 2 (PRC2) catalyzes the tri-methylation of H3K27 (H3K27me3). Quantitative RT-PCR analysis showed down-regulation of the PRC2 core components EZH2, SUZ12 and EED in HGPS fibroblasts. To map the changes in H3K27me3 in HGPS fibroblasts, we performed ChIP-seq with antibodies against HeK27me3 and found that the reduction in H3K27me3 consistently occurred in the regions of low-gene density. To compare the regions of interaction between DNA and A-type lamins, we performed ChIP-seq using two anti-lamin A/C antibodies in normal and HGPS fibroblasts. Bioinformatics analysis demonstrated a loss of chromatin binding in gene-desert regions in HGPS fibroblast. Consistently, Hi-C analysis revealed a less defined compartmentalization in HGPS fibroblasts. Together, our results suggest a model that down-regulation of PRC2 leads to the global alterations in chromatin compartmentalization in HGPS fibroblasts, and implies that H3K27me3 plays a role in controlling the association of chromatin and nuclear lamins.

Reversal of cocaine-conditioned placed preference through methyl supplementation: altering global DNA methylation in the prefrontal cortex. *M. Zhao[1], W.P. Tian[2], M. Li[5], T.B. Song[2], M.Z. Li[3], L. Quan[3], S.B. Li[2], Z.S. Sun[4,5].* 1) Institute of Psychology Chinese Academy of Science, Beijing, China; 2) Department of Forensic Science, School of Medicine, Xi'an Jiaotong University, Xi'an, Shaanxi, China; 3) Department of Molecular Immunology, Capital Institute of Pediatrics, Beijing 100020, China; 4) Beijing Institutes of Life Science, Chinese Academy of Sciences, Beijing 100101, China; 5) Institute of Genomic Medicine, Wenzhou medical college, Wenzhou 325000, China.

Purpose: Recent studies suggest that epigenetic regulation through DNA methylation is responsible for adaptation induced by addictive drugs. Examination of global methylation in cells has revealed correlations of overall DNA methylation status with some biological states. However, there is no investigation to determine the global DNA methylation status after exposure to addictive drugs. Methods: An unbiased conditioned place preference protocol was used to determine the rewarding effects of food, morphine and cocaine. To exam the effects of methionine treatment on rewarding responds to food, morphine and cocaine, mice were administrated systemically methinonine or saline twice a day for 15 consecutive days before and during CPP training. Global DNA methyaltion was analyzed on An Agilent 1200 series rapid resolution liquid chromatography-QQQ mass spectroscopy system. Real-time PCR was used to exam the expression of DNA methytransferase (Dnmt) and methylcytosine binding domain protein 2 (Mbd2). Results and conclusions: In the present study, we found that the global DNA methylation in the mice prefrontal cortex (PFC) was decreased after cocaine conditioned place preference (CPP) training. The expression of DNA Dnmt 3a was upregulated, whereas Dnmt3b and Mbd2 were downregulated following testing CPP. Global DNA hypomethylation in the PFC induce by cocaine CPP was reversed by repeated methionine, the precursor of S-adenosylmethionine (SAM) administration. The downregulation of Dnmt3b and Mbd2 were reversed, but the upregulation of DMNT3a was unchanged. Strikingly, chronic treatment with methionine specifically inhibited the expression of cocaine-CPP without affecting the expression of morphine- or food-CPP. Our study provides new evidence to suggest the causal role of DNA hypomethylation in certain aspects of drug addiction and reversal of DNA hypomethylation may have important therapeutic implication of cocaine addiction.

Diverse neurodevelopmental abnormalities in a novel mouse model of Rett syndrome. *J. LaSalle[1], D. Yasui[2].* 1) Microbiol & Immunology, Genome Center, Univ California Davis Sch Med, Davis, CA; 2) Microbiol & Immunology, Univ California Davis Sch Med, Davis, CA.

Rett syndrome is a neurodevelopmental disorder which presents as loss of speech and motor skills along with breathing abnormalities and seizures with onset from 6-18 months of age. Mutations in MECP2 on Xq28 are observed in greater than 80% of Rett syndrome patients, the vast majority of which are heterozygous females. Two protein isoforms, MeCP2e1 and MeCP2e2 are created by translation of alternatively spliced exon 1 and exon 2 containing mRNAs respectively. Almost all MECP2 mutations in Rett patients occur in exons 3 and 4. Thus, previous attempts to model Rett syndrome in mice focused on genetic deletion of exons 3 and/or 4. These Mecp2 knockout mice recapitulate some features of the Rett syndrome phenotype but appear to have milder symptoms as Mecp2 hemizygous males are viable for up to 12 weeks and heterozygous females remain symptom free until 3 months of age. Recently, Saunders et al identified MECP2 exon 1 translational start site mutations in patients with Rett syndrome. As Mecp2e1 is the predominant isoform expressed in normally developing brain, our hypothesis was that MECP2 exon 1 mutations contribute to the Rett phenotype. To test this hypothesis we generated transgenic mice with a Mecp2 exon 1 translational start site mutation based on the human mutation. Heterozygous (-/+) and hemizygous (-/y) mice were born at the expected frequency from mating of heterozygous females and C57BL/6 wild-type males. Prior to weaning at 3 weeks, hemizygous males were indistinguishable from wild-type littermates. However, starting at 5 weeks post-natal, hemizygous males developed hind limb clasping, along with gait and grooming abnormalities similar to those observed in mice deficient in exons 3 and 4. Mecp2 exon 1 hemizygous males also have spontaneous trembling and increased anxiety compared to wild-type controls. Interestingly, some of the Mecp2 hemizygous males also developed an unusual forelimb hand washing motion in response to tail suspension and open skin lesions consistent with obsessive grooming. Such behavioral abnormalities had not been observed in previous Mecp2 knockout mice and may result from the selective loss of the Mecp2e1 isoform. Formal assessment of social behavior, anxiety and motor function in hemizygous male, and control littermates is currently underway. These studies will help define the overlap between Mecp2e1 and Mecp2e2 biologic function and provide a new and relevant system for testing potential Rett therapies.

Involvement of genes encoding epigenetic regulators in genomic imbalance pathogenic for Intellectual Disability. *F.R. Zahir[1], T. Tucker[1], S. Adam[1], D. Chai[1], A.D. Delaney[2], P. Eydoux[3], M. Griffiths[2], S.L. Langlois[3], J.L. Michaud[4], E. Tsang[1], J.M. Friedman[1].* 1) Medical Genetics, Univ British Columbia, Vancouver, BC, Canada; 2) British Columbia Genome Sciences Center, Vancouver, BC, Canada; 3) Provincial Medical Genetics Program, Children's and Women's Health Center of British Columbia, Vancouver, BC, Canada; 4) Center for Excellence in Neuromics of Universite de Montreal, CHU Sainte-Justine Research Center, Montreal, Canada.

Intellectual Disability (ID) affects 1-3% individuals globally, and for ~50% of cases, the cause is unknown. Microarray genomic hybridization has shown that submicroscopic genomic imbalance causes ID in at least 10% of idiopathic cases. In previous microarray studies we have found a high incidence of genes encoding epigenetic regulators to be involved in potentially pathogenic imbalance. Genes belonging to this category are also known to be causative for well characterized ID syndromes, e.g., Rett Syndrome. Therefore we hypothesized that dosage change of epigenetic regulators would be frequently causative for ID.

We have designed a custom microarray that probes all known genes encoding epigenetic regulatory proteins with exonic resolution. Epigenetic regulatory proteins include those with DNA methylation, histone modifications and chromatin remodeling activity. We have conducted comparative genome hybridization on our cohort of 177 trios with idiopathic ID. and have found 16 de novo CNVs that involve epigenetic regulators in 15 patients (8.5%). Of these, the CNVs most likely to be pathogenic are five that produce SMARCA2 loss, MEF2C loss, CHD6 loss, JMJD1A loss and ARID2 gain. A high copy number gain for CHD7 is also likely to be pathogenic, while copy number gains for ARID1B, ARID4B, and JMJD1C may possibly be pathogenic. We observed 7 recurrent copy number losses and copy number gains of exon 5 of JARID2 that are unlikely to be pathogenic for ID. In contrast, only 19 de novo CNVs (in 19 patients, 10.7%) were found that included other candidate genes included in the design, viz., genes involved in synaptogenesis, genes known to be causative for ID syndromes or representative of larger reported pathogenic CNVs. Therefore, the rate of confirmed CNVs identified for genes in the epigenetic regulatory class (46% of the total from 36% of the probes on the array) is higher than that of all of the other classes put together (54% of the total CNVs from 64% of the probes on the array (chi square test = 4.30, degrees of freedom = 1, two tailed P = 0.0372). We discuss genotype-phenotype correlations for these cases and show that epigenetic perturbation as a whole is a significant cause for ID pathogenicity.

Epigenetic induction of Fetal Hemoglobin in CD133+ Stem Cells in vitro. *D. Ali[1], M. Ahmadvand[1], M. Mahmoodinia Maymand[2], M. Soleimani[1], S. Abroun[1], S. kaviani[1], M. Noruzinia[3].* 1) Department of Hematology , TarbiatModares University, Tehran, Tehran, Select a Country; 2) Sarem Cell Research Center, Sarem Hospital, Tehran, Iran; 3) Department Of Medical Genetic, Tarbiat Modares University, Iran.

) -hemoglobinopathies are) -globin gene disorders that result in considerable morbidity and mortality throughout the world.Sickle cell disease (SCD) and) -thalassemia are two common types of) -hemoglibinopathies due to identified gene mutations. New therapies based on epigenetic patterns of globin genes are tried to increase the levels of fetal hemoglobin (HbF). In this regard, . -globin gene inducers including hydroxyurea, HDAC (Histone Deacetylase) inhibitor compounds such as sodium butyrate, azacytidine, decitabineas well as new immunomodulator drugs such as pomalidomide, lenalidomide and thalidomide can improve (/) chain imbalance which is considered as the most crucial complication in) thalassemia. In this research we set out to investigate the mechanism of regulation of thalidomide and sodium butyrate. CD133+stem cells were enriched using a magnetic activated cell sorting (MACS) CD133 isolation kit (Miltenyi Biotech,Germany), according to manufacturer's instruction. The cells were differentiated to erythroid lineage by IL3 and EPO then treated with combination of sodium butyrate and thalidomide. Total RNA was extracted from progenitor cells and RT-PCR was performed for the first strand cDNA synthesis. For analysis of . -globin gene expression, we performed real-time PCR using cDNA, . -globin gene specific primers and SYBR Green master mix. Flow cytometry analysis showed over 90% purity for CD133+ stem cell expanded. Interestingly, the results of RT-PCR and real-time PCR showed a remarkable increase in . -globin gene expression using these two agents in comparison with control group. In addition, real-time PCR confirmed synergistic effects of sodium butyrate and thalidomide. More effective and safer agents with capacity to induce higher levels of HbF are clearly needed for treatment of) -hemoglobinopathic patients. Hence, in vitro induction of . -globin gene expression by single and combination treatments with different agents could be a prospect for specific targeted therapies and in vivo applications.

Investigation exon 1 in FRDA gene in Suspect Friedreich Ataxia patients. *m. naseroleslami[1], k. Parivar[1], s. sanjarian[1], m. houshmand[2].* 1) Science and Research Branch, Islamic Azad University ,Tehran-Iran; 2) Institute of Genetic Engineering.

Introduction:Friedreich ataxia (FA) is an autosomal recessive disorder that is typically associated with dysarthria, muscle weakness, spasticity in the lower limbs, scoliosis, bladder dysfunction, absent lower limb reflexes, and loss of position and vibration sense. Approximately two-thirds of this patient have cardiomyopathy; up to 30% have diabetes mellitus.Individuals with FRDA have identifiable mutations in the FXN gene. The most common type of mutation, which is observed on both alleles in more than 98% of individuals with FRDA, is a GAA triplet-repeat expansion in intron 1 of FXN. Approximately 2% of individuals with FRDA are compound heterozygotes for a GAA expansion in the disease-causing range in one FXN allele and another inactivating FXN mutation in the other allele. Aim of present study was to investigation exon 1 in FRDA gene in patients with Clinical symptomatic of Friedreich Ataxia that they havent GAA triplet-repeat expansion in intron 1 of FXN. Materials and Methods:we analyzed exone 1in7 patient suspect to FA with using PCR and sequencing.results: Change of nucleotide A to G was detected in exon 1` nt:815284 in our patients.discusion:we believed in this report because of consanguinity marriage in Iran some patients with homozygote mutation may show FA phenotype.

Alternative splicing associated with unclassified variants in CFTR exon 3: implications for CFTR-related disorders. *A. AISSAT[1,2], A. de Becdelièvre[1,2,3], L. Golmard[1,3], C. Costa[1,3], A. Chaoui[1], N. Martin[1], B. Costes[1,3], M. Goossens[1,2,3], E. Girodon[1,3], P. Fanen[1,2,3], A. Hinzpeter[1].* 1) INSERM U955, CRETEIL, 94000, France; 2) Université Paris Est, CRETEIL, 94000, France; 3) AP-HP; CHU H. Mondor, Génétique, CRETEIL, France.

With the introduction of high-throughput sequencing, a great number of sequence variations have been identified. Most of them, not functionally characterized, are named unclassified variants (UVs). Among the 1800 mutations within the extensively analyzed *CFTR* gene responsible of cystic fibrosis (CF, MIM#219700), the p.Arg75Gln sequence variation is usually considered as a neutral polymorphism but is frequently identified in patients affected with CFTR-related diseases. As this amino-acid substitution has been shown to lead to a functional protein, we searched for another defect such as an associated splicing defect.

We identified an alternative exon 3 splicing (13%) in two heterozygotes carriers of the c.224G>A (p.Arg75Gln) sequence variation. This alternative splicing was reproduced *in vitro* in bronchial epithelial cells using a minigene model which produced a 39% skipping of exon 3. A small set of mutations located within exon 3 was tested with this assay and the c.220C>T (p.Arg74Trp) and c.224G>T (p.Arg75Leu) mutations also induced a partial skipping of exon 3. *In silico* predictions suggested a key role for the SF2/ASF splicing protein in the vicinity of the substituted nucleotides sites. Namely, some nucleotides induced a putative loss of the binding of this protein with the mRNA strand, directly emphasized with changes in its predicted local RNA 2D structure. Direct association was validated by EMSA experiments with recombinant SF2/ASF. Additionally, over-expression of SF2/ASF enabled to partially correct exon 3 exclusion for both c.224G>A and c.220C>T.

All these results led to the definition of an enhancer motif within CFTR exon 3. We demonstrated that c.224G>A (p.Arg75Gln), a common sequence variation that does not provoke cystic fibrosis *per se*, induced a decrease in full-length functional CFTR mRNA. This could explain in part its high frequency in CFTR-related disorders such as chronic pancreatitis (CP), congenital bilateral absence of vas deferens (CBAVD) or chronic obstructive pulmonary disease (COPD). Thus, variants that are often unnoticed in molecular diagnostic laboratories because of their apparent neutral effects on proteins, may induce pathogenic consequences on mRNAs through splicing.

775W

Identification and tissue distribution of alternative splice variants in the ATP-binding cassette transporter ABCA2. *R.M. Grimholt[1], C. Stormo[1], M.K. Kringen[2], J.P Berg[1], A.P Piehler[1].* 1) Department of Medical Biochemistry, Oslo University Hospital, Ulleval, Oslo, Norway; 2) Department of Pharmacology, Oslo University Hospital, Ulleval, Oslo, Norway.

Background ABCA2 is the second member of the A-subfamily of ABC transporters. It is predominantly expressed in the brain and may play a role in lipid transport in brain cells and neural development. ABCA2 shows a particularly compact structure with 48 exons within a genomic region of only 21 kb. ABC transporters, like most other human genes, undergo alternative splicing, which is an important post-transcriptional regulation mechanism. In the present study, we sought to identify novel splice variants in the ABCA2 gene and investigate their tissue distribution. **Methods** To identify alternative splice variants, primer pairs were designed to amplify overlapping cDNA fragments spanning from exon 1 to exon 48 in a cDNA pool of 44 different human tissues. PCR products were separated and analyzed by agarose gel electrophoresis. Bands of interest were excised and the purified DNA was sequenced. Alignment of the predicted ABCA2 splice variants with the reference sequence (NM_001606) was performed using the Smith-Waterman algorithm from the software package EMBOSS. To investigate the relative expression of the predicted splice variants, primer pairs specific to each splice variant and to the canonical ABCA2 transcript were designed. Quantitative real-time PCR was performed on an ABI 7900HT Real-Time PCR System using SYBR Green. **Results** Two novel splice variants of ABCA2 were identified in a variety of human tissues showing intron retention of intron 15 and intron 47, respectively (named ABCA2Δ+int15 and ABCA2Δ+int47). We were also able to confirm the existence of two other splice variants, ABCA2Δ+int6 and ABCA2Δ+int39. Interestingly, all the splice variants in our study, seems to derive from intron retention, which has proved to be the rarest type of alternative splicing in humans. RT-qPCR analysis demonstrated that ABCA2 and its predicted splice variants were abundantly expressed in spinal cord, cerebellum and whole brain. A distinct expression pattern of the splice variants were detected in 44 different human tissues and in tissues from different developmental stages and regions of the human brain for all the ABCA2 splice variants. **Conclusion** We identified two novel splice variants of ABCA2 and demonstrated their differential expression in a variety of human tissues. Further work will show whether these splice variants have a distinct physiological role or reflect the mere noise of the splicing machinery.

776W

Pharmacological inhibition of JNK/ERK MAP kinase pathways attenuates mutant DFNA5 induced apoptosis. *K. Op de Beeck[1], A. Schepers[1], N. Cools[2], VFI. Van Tendeloo[2], G. Van Camp[1].* 1) Center for medical genetics, University of Antwerp, Edegem, 2650 Antwerp, Belgium; 2) Vaccine & Infectious Disease Institute (VIDI), Laboratory of Experimental Hematology, University of Antwerp, 2610 Antwerp, Belgium.

DFNA5 was identified in 1998 as a gene responsible for an autosomal dominant form of inherited deafness. After the initial report, 4 additional DFNA5 mutations have been identified. DFNA5 mutations leading to hearing loss are in fact gain of function mutations, where only mutations leading to skipping of exon 8 result in hearing loss while mutations in other parts of the gene do not. At the time of its identification in 1998, it was unknown how mutations in this gene could lead to hearing loss. Now, it is clear that DFNA5 is able to induce apoptosis and, in line with its role in the apoptotic pathway, there is strong evidence that this gene is a tumor suppressor gene as it is frequently methylated in breast, colon and gastric cancer. However, the molecular mechanisms leading to DFNA5 induced apoptosis remain largely unknown. Using transcriptomics analysis, we show that specific JNK and ERK MAP kinase pathways are activated in vitro after transfections of mutant DFNA5 and that inhibition of this pathway is able to attenuate the resulting cell death. Furthermore, we report that specific upregulation of the EGR1 gene is involved in the molecular mechanisms leading to DFNA5 induced apoptosis. Moreover, we show that DFNA5 induced apoptosis is accompanied by an increased production of reactive oxygen species (ROS) and by depolarization of the mitochondrial membrane. We believe that these findings may yield possible therapeutic targets for DFNA5 induced hearing loss and shed more light on the role of DFNA5 in some of the most frequent forms of cancer.

Quantification of chitinase transcripts in mouse tissues. *M. Ohno, K. Tsuda, M. Sakaguchi, Y. Sugahara, F. Oyama.* Kogakuin Univ, Hachioji, Tokyo, Japan.

Chitin, the second most abundant polysaccharide in nature, is a component of the exoskeletons of crustaceans and insect, and in the microfilarial sheaths of parasitic nematodes. Chitin is also an important structural polymer in fungal cell walls. Although mammals do not have chitin and chitin synthase, two active chitinolytic enzymes, chitotriosidase and acidic mammalian chitinase (AMCase), have been identified in mouse and human. Increased expression of both chitinases has observed in different pathological conditions: chitotriosidase in lysosomal lipid storage disorders like Gaucher disease and AMCase in allergic airway responses in mouse models of asthma. Little is known, however, about the pathophysiological functions of these chitinases in mammals. We determined the absolute expression levels of chitotriosidase and AMCase mRNAs in mouse tissues by means of real time RT-PCR. We found that mouse tissues express more AMCase than chitotriosidase. Stomach, lung, spleen predominantly express AMCase mRNA, whereas chitotriosidase was prevalent only in eye. Our study indicates that AMCase is the major chitinase in mouse tissues.

778W

Regulation of gene expression of mammalian chitinases. *F. Oyama, M. Ohno, K. Tsuda, M. Sakaguchi, Y. Sugahara.* Dept Applied Chemistry, Kogakuin Univ, Hachioji, Tokyo, Japan.

Chitin is the second abundant polysaccharide in nature. It is an integral component of the fungal cell walls, the exoskeletons of crustaceans and insects, and the microfilarial sheaths of parasites. Although mammals do not have chitin and its synthase, genes encoding chitotriosidase and acidic mammalian chitinase (AMCase) and their translation products have been found in both human and mouse. Marked elevation of plasma chitotriosidase activity was reported in Gaucher disease, an autosomal recessive lysosomal storage disorder, whereas significant increases in AMCase were detected in an induced asthma mouse model. We investigated gene expression of AMCase in mouse tissues by real-time PCR and found that AMCase mRNA is predominantly expressed in stomach and moderately in lung. We raised specific antibody against mouse AMCase and found that the antibody recognized a single protein band in the extracts of the stomach and lung. The relative protein expression levels between stomach and lung were comparable in their mRNA levels. We determined the chitinolytic activity at multiple pHs by using a synthetic substrates and found strong chitinase activity at acidic pH in the extract of stomach. These results indicate that the high level of chitinase activity in stomach results from high level expression of AMCase gene.

779W

Expression of mouse chitinase in Escherichia coli and characterization of its properties. *A. Kashimura, K. Ishikawa, K. Sekine, Y. Kida, M. Sakaguchi, Y. Sugahara, F. Oyama.* Applied Chemistry, Faculty of Engineering, Kogakuin University, Hachioji, Tokyo, Japan.

Chitinase hydrolyzes chitin, a polymer of N-acetyl-D-glucosamine, which is present in a wide range of organisms, including fungi, insects, and parasites. Although chitin is not present in mammals, chitinase genes are found in both human and mouse genomes. It has been known that chitinase activity is significantly increased in plasma from patients with Gaucher disease, an autosomal recessive lysosomal storage disorder. Recent researches have shown that elevated expression of chitinases is closely associated with progression of allergy and asthma. The pathophysiological role for the mammalian chitinases remains unproven. To understand how chitinase interacts with chitin and degrades it, we expressed the mouse chitinase in Escherichia coli as a fusion protein. The recombinant fusion protein with full length chitinase was capable of cleaving artificial chitin-like substrates and natural substrates, whereas fusion protein without it was not. Thus, this recombinant protein can be used to elucidate detailed biological functions of the mouse chitinase.

780W

Novel mutations in CYP21A2 gene and their influence on the enzyme activity and protein structure. *A.L.G. Lusa[1], F.C. Soardi[1], G. Guerra-Junior[2], S.H.V. Lemos-Marini[2], M.P. de-Mello[1].* 1) CBMEG, UNICAMP, Campinas, São Paulo, Brazil; 2) Department of Pediatrics, UNICAMP, Campinas, São Paulo, Brazil.

Mutations in CYP21A2 gene cause steroid 21-hydroxylase deficiency, an inherited disorder of adrenal steroidogenesis. It leads to the accumulation of metabolic intermediates, progesterone and 17-hydroxyprogesterone. The disease occurs in a wide spectrum of clinical forms, including a severe (salt-wasting) with impairment in both aldosterone and cortisol biosyntheses, a form with apparently normal aldosterone biosynthesis (simple virilizing) and a mild nonclassical form that may be asymptomatic or may be associated with androgen excess during childhood or at puberty. We describe four patients with 21-hydroxylase deficiency. A boy admitted to the hospital with dehydration and presenting hyponatremia (Na = 112 mEq/L) and hyperkalemia (K = 7.7 mEq/L). Salt-wasting CAH due to 21-hydroxylase deficiency, confirmed by elevated levels of 17-hydroxyprogesterone, was diagnosed. A female patient presenting ambiguous genitalia with no palpable gonads was diagnosed as salt-wasting indicated by serum sodium of 123 mEq/L and potassium of 9.1 mEq/L and elevated basal serum levels of 17-hydroxyprogesterone. The two other patients were female with the nonclassical form. Novel mutations were identified in the CYP21A2 gene: p.S113F, p.P267L, p.V358I, p.R426C, however the p.V358I and p.R426C occurred in the same allele with pI172N and p.V281L, respectively. Using site-direct mutagenesis, each nucleotide variant and both combinations were introduced into a cloned wild-type cDNA and the mutant proteins were expressed in COS-7 cells to compare the enzymatic activity between the wild-type and mutant proteins. The enzymatic conversion of 17-hydroxyprogesterone into 11-desoxycortisol was decreased in the CYP21A2 enzymatic activity for all mutants. The enzymatic activity for CYP21A2 mutant proteins bearing p.S113F, p.R426C, p.I172N+p.V358I and p.V281L+p.R426C mutations was null. Whereas the p.V358I mutation itself presented some residual enzymatic activity and the p.P267L mutation demonstrated a enzymatic activity similar to the wild-type. The putative pathogenic mechanisms for the novel protein variants were evaluated in silico. The mutations caused protein changes in the whole structure and altered intra-molecular amino acid interactions. The analysis of mutant enzymes also revealed changes either in protein stability or in the surface charge in addition to the decreased enzymatic activity, which can correlate the genotypes found for each patient to the clinical manifestation.

Functional study of Peptidylarginine deiminase type 4 as genetic risk factor for RA. *A. Suzuki[1], Y. Kochi[1], H. Shoda[2], K. Fujio[2], M. Yamanaka[1], E. Kanno[1], T. Sawada[3], R. Yamada[1, 4], K. Yamamoto[1, 2].* 1) Ctr for Genomic medicine, Kanagawa, RIKEN, Yokohama City, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo; 3) Department of Rheumatology, Tokyo Medical University; 4) Ctr for Genomic Medicine, Kyoto University.

Rheumatoid arthritis (RA) is well-known as an autoimmune disease and is a chronic inflammatory disorder characterized by the destruction of multiple joints. Many genome wide association studies were performed and multiple RA-susceptibility loci and autoimmune-susceptibility loci have been identified. These studies suggested that multiple genes and its functions were related with disease causing and development. Previouly, peptidylariginine deiminase type 4 (PADI4) was identified as a susceptibility gene for RA in a Japanese population by case-control association study (Ref 1). PADI4 is a member of the PADI gene family and converts arginine residue (peptidylarginine) to citrulline residue (peptidylcitrulline). PADI4 is highly expressed in bone marrow, macrophages, neutrophils and monocyte. Peptidylcitrulline is an interesting molecule in RA, because it is an antigen of ACPA and only PADs (translated protein from PADI genes) can provide peptidylcitrullines, via modification of protein substrates. To evaluate the importance of PADI4 gene in the progression of RA, we generated Padi4 -/- C57BL/6 (B6) mice by speed congenic method. We used Padi4-/- mice to show that PAD4 is affected to development and progression of collagen induced arthritis (CIA), well known as an RA model animal. Padi4-/- B6 and WT mice were immunized with Chicken type II collagen (CII) for CIA. Clinical disease score was reduced and the incidence of WT and Padi4-/-mice were 56% and 44%, respectively. Padi4-/- mice also significantly reduced concentrations of serum anti-CII IgM and IgG compared with WT mice. Resulting from these studies, we suggested that Padi4 enhanced collagen-initiated inflammatory responses. 1) Suzuki, A. et al Nat. Genet.34, 395-402 (2003).

Models of , -Sarcoglycan knock-down and their Implications for the Pathology of Myoclonus Dystonia. *A. Given[1 2], D.E. Bulman[1 2], D.A. Grimes[1 3].* 1) Ottawa Hospital Research Institute 501 Smyth Road Ottawa, ON K1H 8L6, Canada; 2) University of Ottawa; 3) The Ottawa Hospital 501 Smyth Road Ottawa, ON K1H 8L6, Canada.

Myoclonus Dystonia (MD) is a movement disorder characterized by bilateral myclonic jerks paired with dystonia. Mutations have been mapped to the epsilon-sarcoglycan (SGCE) gene in about 40% of patients. The purpose of this project is to examine the properties of SGCE in the CNS and use this knowledge to elucidate the pathology of MD. Although Sgce forms known sarcoglycan complexes (SGC) in other tissues, little is known about its interactions in the CNS. Mutations found in MD patients produce a null SGCE protein therefore; Sgce knock out (KO) models should approximate MD conditions both in vivo and in vitro. Of the SGs, , -SG is the most widely expressed with high expression in the CNS. Sgce is known to form heterotetrameric SGCs with) -, > and +-SGs in smooth muscle, retina and the PNS but its pattern of interaction in the CNS has yet to be elucidated. In muscles where they are known to form, the SGCs are located at the sarcolemma within the dystrophin-glycoprotein complex (DGC), stabilizing it. The SGC maintains the presence of sarcospan at the sarcolemma and aids in anchoring signalling proteins, such as neuronal nitric oxide synthase (nNOS). To determine changes in neuronal cell functions due to loss of , -SG, siRNA was designed to knock-down the expression in N1E-115 neuroblastoma cells. A clone was isolated displaying a 77% decrease of Sgce mRNA. This clone also displayed a 50% decrease of nNOS protein and a 50% increase in proliferation. qRT-PCR was used to show that the decrease of nNOS protein resulted in approximately a 1.5 fold up-regulation of nNOS mRNA. Chemically inhibiting nNOS in N1E cells also results in increased proliferation as well as a decrease of NO metabolites. These results suggest that loss of SGCE may disrupt the SGC and destabilize nNOS. A previous mouse model was developed to KO exon 4 of Sgce. This model is currently unavailable. Therefore we will investigate the role of sgce in the brain through the establishment of two new transgenic mouse models. The first model will conditionally KO exon 4 of sgce and the second model will conditionally repair sgce by removing an artificial splice-stop site placed in intron 1. Embryonic stem cell clones have been isolated and are currently being screened for correct mutation inclusions. These mice will hopefully corroborate in vitro work and allow further insight into the importance of developmental time points and tissue specific effects.

Rajcan-Separovic[1,2].* 1) Pathology & Laboratory Medicine, University of British Columbia, Vancouver; 2) Child & Family Research Institute, Vancouver; 3) Human DNA Damage Response Disorders Group, Genome Damage & Stability Centre, University of Sussex, Brighton, UK; 4) Department of Biological Sciences, Simon Fraser University, Burnaby; 5) Department of Psychiatry, UBC, Vancouver; 6) St. Luke's Health System, Boise; 7) Clinical Genetics, McMaster University Medical Centre, Hamilton; 8) Medical Genetics, Quebec City; 9) Cytogenetics Laboratory, Royal Columbian Hospital, New Westminster; 10) Department of Medical Genetics, UBC, Vancouver; 11) Department of Psychiatry, Queen's University, Kingston; 12) Genetics and Genomics Research Laboratory, Ongwanada, Kingston.

We have previously described a microdeletion syndrome involving chromosome 2p15-16 which includes congenital and neurodevelopmental abnormalities. Additional cases with similar phenotypes and overlapping microdeletions with variable breakpoints have been reported. **Methods:** We characterized 5 subjects with 2p15-16 deletions using high resolution whole genome (WG) SNP array and WG expression arrays to delineate a minimal deletion region (MDR) and to look for candidate genes affected by copy number (CN) change. Furthermore, we are investigating the function of candidate genes from the MDR in a) *C. elegans* by RNAi and transgenic studies b) in control mouse and human tissues as well as in patient lymphoblasts using immunohistochemistry (IHC) and Western blotting to determine protein expression. **Results:** The MDR for currently reported 2p15-16 deletion cases contains two known genes, XPO1 and USP34. Knock-down of XPO1 by RNAi in *C. elegans* is early embryonic lethal while transgenic XPO1::GFP expressing *C. elegans* strains show ubiquitous XPO1 expression throughout development and in the adult worm. XPO1 is expressed in adult mouse brain, gut and lung. In human fetal brain, mild positivity for XPO1 is seen in the immature ependyma and in Cajal-Retzius cells (cerebellar cortex). USP34 expression in human fetal brain is seen in grey matter but not white matter, and is strong in the Purkinje cell layer (cerebellar cortex). In human mature brain, positivity is visible both in white and grey matter remaining strong in the Purkinje cell layer. Whole genome expression shows expression fold changes corresponding to reduction of copy number for 4 genes (COMMD1, USP34, AHSA2, and REL), but not for XPO1. Preliminary studies confirm a decrease in COMMD1 protein levels in a subject's lymphoblast cell line. **Conclusions:** Our preliminary studies suggest functional involvement of COMMD1 in the 2p15-16 microdeletion. COMMD1 is essential for copper homeostasis and changes in copper levels are detrimental to brain and liver function. USP34 is also of interest as it is expressed strongly in Purkinje cell layer of human brain, which shows degeneration in neurodevelopmental disorders (e.g. fragile X, autism). Further functional investigations of all candidate genes are underway.

Neuronal Differentiation Effect of Huntingtin Associate Protein 1. *A. Li, H. Yang, S.H Li, X.J Li.* Human Genetics, Emory University, Atlanta, GA.

Polyglutamine (PolyQ) expansion is the cause for 10 inherited neurogdegenerative diseases, including Huntington disease (HD); SCA-1. 2, 3, 6, 7, 17; DRPLA; SBMA and HDL2. Despite its widespread expression throughout the body and brain, the HD protein huntingtin causes selective neurodegeneration, which preferentially occurs in the striatum and extends to other brain regions as the disease progresses. It has been thought that mutant huntingtin abnormally affects the function of other neuronal proteins to mediate neuropathology. Huntingtin associate protein 1 (HAP1) is the first Huntingtin associated protein identified by the yeast two hybrid system and is a neuronal protein enriched in brain. The binding of HAP1 to huntingtin is enhanced by the length of the polyglutamine tract in huntingtin, suggesting that Hap1 dysfunction may be involved in HD neuropathology. Mice homozygous for the targeted deletion of HAP1 show decreased feeding, growth retardation, early postnatal death (P1-P3), and hypothalamic neurodegeneration. Examination of the brains from postnatal HAP1 null mice revealed a decrease in Brdu incorporation, suggesting that Hap1 is important for neuronal proliferation. Using Hap1 siRNA in PC12 cells, a neuronal cell line, we found that decreasing Hap1 can impair the proliferation of PC12 cells in response to various neurotrophic factors. In addition, differentiation signaling of neurotrophic factors is also affected when Hap1 expression is reduced. Moreover, overexpression of mutant huntingtin also suppresses neurite outgrowth of PC12 cells. These findings raise the possibility that the abnormal interaction of mutant Htt with HAP1 may impair HAP1 function to affect neuronal proliferation and differentiation. Supported by NIH grants NS036232 and AG019206.

Sub-cellular localization of Y-Box Protein 1 regulates proliferation, invasion, and increased mesenchymal phenotype in astrocytomas. *X. Liu[1], D. Faury[2], C. Sollier[1], B. Meehan[2], N. Gerges[1], Z. Dong[3], P. Siegel[3], A. Korshunov[4], S. Pfister[4], J. Rak[2], N. Jabado[1,2].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Montreal Children's Hospital, McGill University Health Centre, Montreal, Quebec, Canada; 3) Rosalind and Morris Goodman Cancer Research Centre, McGill University, Montreal, Quebec, Canada; 4) Division of Molecular Genetics, German Cancer Research Centre, Heidelberg, Germany.

Y-Box-Protein-1 (YB1) is a transcriptional and translational regulator implicated in cancer progression. Previously, using gene expression microarray, we established elevated YB1 levels in pediatric Glioblastoma (GBM), an aggressive high-grade astrocytoma, possibly driving oncogenesis in this cancer. The purpose of this study is to investigate the role of YB1 in astrocytoma genesis and its possible association with poor prognosis. We overexpressed or silenced YB1 protein in pediatric GBM (SF188), adult GBM (U87) and normal human astrocytes cell lines (NHA). Proliferation, migration, soft agar colony formation assays were performed in vitro, accompanied by in vivo mice xenograft to assess the tumorigenic and metastatic ability of these cells. Meanwhile, tissue microarrays including 150 pediatric GBM and 70 Grade I Astrocytoma were IHC stained with YB1. YB1 expression and sub-cellular localization were scored and analyzed in association with patient prognosis and tumor grades. YB1 silencing using shRNA reduced YB1 level by 90%, and surprisingly increased cell proliferation. As YB1 is predominantly cytoplasmic in physiological conditions, and nuclear YB1 is known to associate with increased cell growth, sub-cellular localization of YB1 was investigated. In the YB1 silenced clones, YB1 was greatly reduced in cytoplasm, but enriched in nucleus, explaining the increase in cell proliferation. YB1 overexpression was mainly cytoplasmic; it decreased cell proliferation and increased mesenchymal phenotype including migration. Importantly, although YB1 overexpression decreased size of tumor formed in SCID mice, it increased tumor metastasis into the liver. IHC on tissue microarrays of patient tumors showed strong YB1 expression in 66% of pediatric GBM samples, but only 8% in Grade I astrocytoma, suggesting a role of YB1 overexpression in a more invasive tumor phenotype. Further, nuclear YB1 expression indicated worse progression free survival compared to cytoplasmic YB1 in 150 pediatric GBM tumor samples. This is the first time nuclear YB1 was associated with poor patient outcome in pediatric GBM. Our results suggest that YB1 modulates cellular proliferation and mesenchymal properties, based on its sub-cellular localization. Nuclear YB1 drives cell proliferation, whereas cytoplasmic YB1 promotes cell migration and metastasis. The association of nuclear YB1 with worse patient prognosis argues for caution in targeting YB1 for therapeutic intervention.

Functional analysis of a SNP in TSLP associated with asthma. *L. Akhabir, A.J. Sandford.* UBC James Hogg Research centre, Vancouver, BC, Canada.

TSLP is a cytokine secreted by epithelial cells in response to different stimuli such as TLR ligands or viruses. TSLP has been shown to be sufficient to initiate experimental allergic airway inflammation and its gene expression has been shown to be increased in murine and human asthmatic lungs. The binding of TSLP to its receptor on mast cells, dendritic cells and activated T cells results in the promotion of a Th2-type inflammation. rs1837253 was identified as a putative causal SNP based on consistent association data both from candidate gene and genome-wide association studies; as well as the absence of significant linkage disequilibrium with other SNPs in the region. The aim of this work was to perform functional assays to uncover the mechanism underlying the involvement of rs1837253 in asthma pathogenesis. DNA samples from the lungs of asthmatics and controls were genotyped using TaqMan assays and quantitative PCR (qPCR) assays were performed to compare levels of gene expression between genotypes. qPCR experiments were conducted for both TSLP isoforms. In silico analysis was performed to predict binding of regulatory proteins. Electrophoretic mobility shift assays (EMSA) were performed to test for potential differential binding of a regulatory protein to the SNP. The TaqMan genotyping was successful with 100% call rate; the data were in Hardy Weinberg equilibrium. No homozygotes for the minor allele were present. qPCR did not demonstrate differential gene expression between phenotypes (fatal asthma or non asthma) or between genotypes. This was most likely due to a low N and the fact that these data were solely for the short isoform as we were unable to detect high enough levels of the long isoform. Efforts are underway to increase production of the long isoform by stimulation of airway epithelial cells, increase the number of samples and pursue samples from a different source (blood). Preliminary EMSA data showed binding of a nuclear protein derived from A549 cells to the T allele and little or no binding to the C allele. *In silico* analysis resulted in the identification of candidates for the binding as FOX family proteins, GR receptor alpha and HMG box group proteins. Cold completion experiments using consensus sequences of candidate factors are in progress. The objective of this research is to explain the asthma association of a singleton SNP 2.5 Kb from the TSLP gene and hopefully participate in the identification of novel therapeutic targets.

DYX1C1 affects cell migration by regulating neuronal migration genes and by interacting with cytoskeleton proteins. *K. Tammimies[1], M. Vitezic[2], H. Matsson[1], S. Le Guyader[1], T. Burglin[1], T. Ohman[3], S. Stromblad[1], CO. Daub[2], TA. Nyman[3], J. Kere[1,4], I. Tapia-Paez[1].* 1) Biosciences & Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Omics Science Center, RIKEN Yokohama Institute, 1-7-22 Suehiro-cho, Tsurumi-ku, Yokohama 230-0045 Japan; 3) Protein Chemistry Research Group, Institute of Biotechnology, University of Helsinki, 00014 Helsinki, Finland; 4) Department of Medical Genetics, Haartman Institute, University of Helsinki, and Folkhälsan Institute of Genetics, Helsinki, Finland.

The Dyslexia susceptibility 1 candidate 1 (DYX1C1) gene has been implicated in developmental dyslexia and reading ability. It has been shown to affect neuronal migration and modulate estrogen receptor signaling. Developmental dyslexia is a complex neurodevelopmental disorder with a genetic basis. Disturbances in neuronal migration might be one of the mechanisms leading to this disorder. In addition to DYX1C1 three other susceptibility genes are involved in this process; DCDC2, KIAA0319 and ROBO1. Subtle disturbances in cortex organization have also been found in post-mortem brain of dyslexic individuals. The molecular pathways in which the dyslexia genes are involved during neuronal migration remain to be identified. Here, we study the role of DYX1C1 in migration using live cell imaging, transcriptome and interactome profiling. We demonstrate that upregulation of DYX1C1 increases random migration about 30% when comparing to control using neuroblastom SH-SY5Y cells which is mediated by TPR and a newly defined DYX domains. Interestingly, we could also detect some of DYX1C1 protein in the centrosome and for this localization the TPR-domains were also necessary. We also measured the changes at the transcriptome level after perturbation of DYX1C1. When DYX1C1 was overexpressed or silenced, 376 and 88 genes were differentially expressed (p-value <0.01), respectively. Gene ontology analysis revealed significant over-representation of cell migration, and neuron migration genes. Interestingly, Reelin and DCX, two of the most studied examples of neuronal migration genes, were regulated by DYX1C1. To find new interacting partners for DYX1C1, we used co-immunoprecipitations followed by protein identification by mass spectrometry. We found 65 new proteins interacting with DYX1C1. We also tested interactions by a candidate approach, and could show that DYX1C1 interacts with LIS1, DCDC2 and KIF3A. Among all the DYX1C1 interacting partners, there was an overrepresentation of cytoskeleton proteins. We conclude that DYX1C1 affects random migration via the TPRs and DYX domains. The migration phenotype produced by DYX1C1 appears to be mediated by the regulation of neuronal migration genes and its interaction with relevant cytoskeletal proteins. Our results contribute to the hypothesis that dyslexia is a neuronal migration disorder by linking DYX1C1 with genes involved in other neuronal migration disorders such as lissencephaly.

NNK metabolism by CBR1 and HSD11B1. *A. Hull[1], J. Engle[2], N. Fredericksen[1], C. Gallagher[2, 3], G. Chen[2], P. Lazarus[2, 3], J. Muscat[2].* 1) Biol Dept, Lincoln University, Lincoln University, PA; 2) Dept of Public Health Sciences, Penn State College of Medicine, PA; 3) Department of Pharmacology,Penn State College of Medicine, PA.

One of the major carcinogens in tobacco smoke is the nicotine derived nitrosamine 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK). NNK is reduced to 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL). Both NNK and NNAL are metabolically activated by cyotchrome P450s, whereas detoxification by glucuronidation occurs for NNAL only. Metabolism of NNK to NNAL is carried out by carbonyl reductase 1 (CBR1), hydroxysteroid dehydrogenase 11B1 (HSD11B1) and the aldo-keto reductase 1C1, 1C2 and 1C4 (AKR1C1, AKR1C2 and AKR1C4). We aim to determine whether variability in gene expression in each of these five genes affects the variability of enzymatic activity in NNK reduction and the risk of developing tobacco-related cancers. The current study focuses on the genes CBR1 and HSD11B1. We measured mRNA expression (n=106), protein levels (n=48) and enzymatic activity for each of these two enzymes using human liver microsomes (n=97) and cytosols(n=89). High performance liquid chromatography was used to measure carbonyl reductase activity in cytosol, which contains CBR1 and AKR, and in microsomal extracts which contain HSD11B1. Gene expression levels on the same samples were measured using real-time PCR. No correlation between mRNA levels and enzymatic activity was found for either CBR1 or HSD11B1. Protein levels of CBR1 and HSD11B1 were measured by Western Blots from the same samples. CBR1 was found to be correlated with NNK reduction in the cytosol (R= 0.49 , p=0.001). No correlation was observed for HSD11B1. The current data shows that variation in activity levels are not explained by either DNA sequence variation or mRNA expression. Interindividual variations in NNK reduction may be due to post-transcriptional control of CBR1.

Identification of Novel Fatty Acid Desaturase 1 Isoforms: Localization and Differential Expression in Tissues and Mammalian Cells. *W.J. Park, K.S.D. Kothapalli, H.T. Reardon, P. Lawrence, J.T. Brenna.* Division of Nutritional Sciences, Cornell University, Ithaca, NY.

Omega-3 (=3 or n-3) and omega-6 (=6 or n-6) long chain polyunsaturated fatty acids (LCPUFA) are nutrients and bioactive metabolites that are associated with most of the human diseases and play important roles throughout development and aging. Desaturases (FADS1, FADS2 and FADS3) are key enzymes for LCPUFA biosynthesis and regulation. The enormous diversity that can be produced at the RNA level is increasingly recognized as a significant mechanism in the regulation of gene expression and in expanding the function of the proteome. Recently, we showed for the first time the existence of alternative transcripts (ATs) for FADS2 and FADS3 genes generated by alternative splicing events, as well as their conservation in several vertebrate species. Here we report identification of novel FADS1 transcripts generated by alternative selection of 5'untranslated regions, Poly A sites, and by internal exon deletions from neonatal baboon liver, using rapid amplification of cDNA ends (RACE) technique. Importantly, we show the detection of protein isoforms by immunoblot in neonate stage and mammalian cells, protein isoform expression and fatty acid changes in response to human neuronal cell differentiation, and isoform specific subcellular localization by live cell imaging using confocal microscopy with confirmation by purification of specific organelles. Our results indicate that FADS isoforms may have critical roles as mediators of LCPUFA biosynthesis and/or regulation depending on tissues, organelles and developmental stage.

Adams-Oliver syndrome is a congenital condition characterized by aplasia cutis congenita (ACC, terminal transverse limb defects(TTLD) and associated features. Genome-wide linkage analysis has identified a locus for autosomal dominant ACC-TTLD on chromosome 3. Candidate-gene and exome-based sequencing identified premature truncating mutations in the terminal exon of the Rho GTPase-activating protein 31 gene(ARHGAP31). ARHGAP31 is a member of the RhoGAP family of proteins known to inactivate the Rho GTPases Cdc42 and Rac1. Mutant transcript stability was assessed by quantitative RT-PCR in patient lymphoblastoid cells, and localisation of the protein was mainly observed to the Golgi.Protein immunoprecipitation analysis has demonstrated an interaction between the C terminus of ARHGAP31 and the N-terminal RhoGAP domain indicating the exposure of a constitutively active RhoGAP catalytic site by the truncated ARHGAP31 C-terminal domain in mutant proteins. Whole-mount in situ hybridization in mouse embryos has detected Arhgap31 expression to the terminal limb buds and craniofacial processes during development indicating possible sites of impaired organogenesis characteristic of the disease phenotype. We sought to expand on our preliminary findings to functionally validate the putative role of Arhgap31 in the regulation of Cdc42 and/or Rac1 signalling, which is critical during development. Expression of mutant ARHGAP31 resulted in increased rates of cell migration and significantly decreased proliferation rates in mutant fibroblasts, suggesting unregulated suppression of Cdc42/Rac1 function. Importantly, time-lapsed microscopy of single-cell random migration showed that mutant fibroblasts exhibit increased speed of cell movement, but with disorganised direction and altered adhesion properties, supporting the notion that defective Cdc42 and/or Rac1 signalling alters directed migration, proliferation, and differentiation. To further elucidate the role of ARHGAP31 in vivo, we injected zebrafish embryos with mutant ARHGAP31 mRNA and examined its effect on embryonic development. We showed that mutant ARHGAP31 expression disturbs epiboly and convergent-extension cell movements during gastrulation, exhibiting distinct morphological defects in 24-48 hours post fertilization. To further understand how mutations in ARHGAP31 regulate convergence and extension cellular movements, we are currently analysing cellular migration in different regions of gastrulating embryos.

792W

The retinoic acid induced one gene (*RAI1*) is a positive regulator of *CLOCK* and an essential component of the circadian feedback loop of transcription. *S.R. Williams[1], D. Zies[2], S.H. Elsea[1,3].* 1) Dept of Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 2) Dept of Biology, University of Mary Washington, Fredericksburg, VA; 3) Dept of Pediatrics, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA.

Mutation or deletion of the retinoic acid induced one gene (*RAI1*) results in Smith-Magenis syndrome (OMIM#182290), an intellectual disability and multiple congenital anomalies syndrome characterized by obesity, neurobehavioral abnormalities and a disrupted circadian sleep-wake pattern. An inverted melatonin rhythm (peak melatonin in day instead of night time) and associated sleep phase disturbances in persons with SMS, as well as a short period circadian activity rhythm in mice with a chromosomal deletion of *Rai1*, support SMS as a circadian rhythm dysfunction disorder. Circadian rhythms are endogenous ~24 h cycles in physiology and behavior characterized by central and peripheral feedback loops. The circadian oscillator in mammals temporally orchestrates metabolism, physiology, and behavior largely through transcriptional modulation. Data support RAI1 as a transcriptional regulator, but its molecular function, including the genes it may regulate, co-factors, and temporal expression pattern, are still unclear. Molecular investigation into the role that RAI1 plays in gene regulation and circadian regulation revealed that RAI1 regulates transcription of *CLOCK*, a key component of the mammalian circadian oscillator that transcriptionally regulates many downstream genes via E-box enhancer elements. Additionally, heterozygous loss of *RAI1/Rai1* in SMS fibroblasts and mouse hypothalamus results in transcriptional dysregulation of the circadian clock, causing altered expression and regulation of multiple circadian genes, supporting the observed disruption of circadian activity in humans and mice with reduced expression of *RAI1/Rai1*. These data suggest that genetic disruption of *RAI1/Rai1* leads to a disrupted circadian oscillator, resulting in abnormal sleep-wake cycle, abnormal feeding pattern, and dependent learning and cognitive deficits. Finally, we conclude that RAI1 is a positive transcriptional regulator of the *CLOCK* gene, pinpointing a novel and important role for this gene in the circadian oscillator.

793W

Evaluation of maternal and fetal effects of polymorphisms involved in the folate metabolism on Down syndrome. *J.M. Biselli[1], F.A. Poletta[2], B.L. Zampieri[1], C.C. Mendes[1], F.B. Machado[3], A.F.A. Silva[4], E. Medina-Acosta[4], J.S. Lopez-Camelo[2], E.E. Castilla[2], E.M. Goloni-Bertollo[1], E.C. Pavarino[1].* 1) Genetics and Molecular Biology Research Unit, Sao Jose do Rio Preto Medical School, São José do Rio Preto, São Paulo, Brazil; 2) Clinical investigation and Medical Education Center, Genetic Epidemiology Laboratory, Buenos Aires, Argentina; 3) São Paulo University (USP), Ribeirão Preto, São Paulo, Brazil; 4) Alvaro Alvim School Hospital, Benedito Pereira Nunes Foundation, Campos dos Goytacazes, RJ, Brazil.

Down syndrome (DS) is resulting from a failure of chromosome 21 segregation during maternal meiosis in about 80% of cases. Although advanced maternal age is the only well-established risk factor for DS, many DS children are born to mothers aged less than 35 years-old, suggesting other factors influencing DS etiology. Several studies have showed that genetic polymorphisms involved in folate pathway can modulate the maternal risk for DS. In addition, studies from DS family triads have questioned if these polymorphisms could be involved in embryo viability or fetal survival. Folate metabolism is a complex pathway that involves multiple enzymes which play key roles in purine and pyrimidine synthesis; and DNA methylation, an epigenetic process that acts on the control of gene expression and genomic stability. The role of genetic polymorphisms involved in this pathway as maternal risk factors for DS is attributed to the association between some genetic variants with enzyme alterations that could result on DNA hypomethylation and, consequently, chromosome 21 nondisjunction. Regarding embryo viability or fetal survival hypothesis, these genetic variants could promote the increase of homocysteine concentration, an amino acid essential for folate-dependent DNA synthesis and for cellular methylation reactions, important for fetal development. DS individuals present disturbed folate metabolism due to the presence of the CBS gene in triplicate and it subsequent overexpression, leading to reduced concentrations of some metabolites. We used a multi-marker procedure for testing association between 10 genetic polymorphisms involved in the folate pathway, considered as “haplotypes”, and maternal or “fetal” effects in DS etiology. There were included in the study 86 family triads comprising the DS individual with free trisomy 21 and their parents (mother and father). The analyses were made using the TRIMM (TRIad Multi-Marker test) program. First, it was evaluated the effect of maternal genotypes, including only informative families for testing this association. Second, the effect of “fetal” genotypes was evaluated, also considering only informative families. There was no evidence of association (transmission disequilibrium) between maternal (P=0.61) or “fetal” (P=0.67) genotypes and DS considering the 10 SNPs evaluated. In conclusion, the folate-polymorphisms combinations evaluated as “haplotypes” by multi-marker test were not associated with DS.

794W

A novel BBSome interacting protein is an ADP/ATP translocase, SLC25A31. *X. Chamling[1], S. Seo[2], V.C. Sheffield[1,2,3].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Ophthalmology and Visual Sciences, University of Iowa Carver College of Medicine, Iowa City, IA; 3) Howard Hughes Medical Institute, Iowa City, IA.

Bardet-Biedl syndrome (BBS) is a genetically heterogeneous autosomal recessive disorder characterized by obesity, retinal degeneration, polydactyly, hypogenitalism and renal defects. At least 15 different BBS genes have been reported. Recent findings have implicated BBS with primary cilia dysfunction, and BBS proteins are thought to be involved in the trafficking of various ciliary proteins. Specifically, the BBSome, a stable complex of seven highly conserved BBS proteins, BBS1, BBS2, BBS4, BBS5, BBS7, BBS8, BBS9 and a novel protein, BBBIP10, is believed to traffic to cilia bringing various cargoes along with it. In recent studies, various different interacter proteins including the leptin receptor, Rabin 8, PCM1 and few others have been associated with the BBSome. Due to the pleiotropic nature of the disease and the abundance of proteins in and around cilia where BBS proteins localize, we hypothesized that there are other proteins that interact with the BBSome which have not been identified. To investigate this hypothesis we generated a transgenic (LAP-BBS4) mouse line that expresses LAP tagged BBS4 in multiple different tissues including eye, brain and testis. Using lysates from brain and testis of the transgenic mouse, we pulled down BBSome interacters. Mass spectrometry confirmed one specific interacting protein to be SLC25A31 (solute carrier family 25 member 31), also known as ADP/ATP translocase 4 or Ant4.

Cep290 function in localization of cilia proteins resulting in phenotypic heterogeneity of CEP290-associated disease. *Y. Zhang, Q. Zhang, C. Searby, S. Seo, V.C. Sheffield.* Howard Hughes Medical Institute and Department of Pediatrics, The University of Iowa, Iowa City, IA.

Nephronophthisis (NPHP) is a heterogeneous, autosomal recessive medullary cystic kidney disease affecting children. CEP290/NPHP6 can cause several cilia-related disorders (ciliopathies), including NPHP, Leber congenital amaurosis (LCA) and Meckel-Gruber syndrome (MKS). This suggests that Cep290 interacts with different proteins to accomplish different functions. CEP290 is known to localize to the centrosome and basal body of ciliated kidney cells and to the connecting cilium of retinal photoreceptors. The majority of NPHP and MKS proteins co-localize with CEP290. In this study, we examined cellular phenotypes in CEP290 knock down cells and in cells over-expressing parts of the CEP290 protein. We generated several truncated CEP290 protein fragments containing various domains of the whole protein. We tagged these fragments with GFP and examined their localization in both 293T and RPE cells. We also evaluated the physical interaction between these truncated proteins and other cilia proteins by co-immunoprecipitation. The results show that the N-terminal and C-terminal fragments of CEP290 both localize to the centrosome. The N-terminus interacts with NPHP2 and NPHP5, whereas the C-terminus interacts with MKS1. We used siRNA to knock down CEP290 in 293T and RPE cells, and then examined the expression level and localization of other related proteins. We found that the NPHP2 level is decreased in the CEP290 knock down cells, while the NPHP3 level is increased in knock down cells. In addition, we found that several proteins, including NPHP2 and NPHP5, are mislocalized in the CEP290 knock down cells. We conclude that CEP290 plays a role in regulating the protein stability and correct localization of NPHP related proteins, which plays a role in the phenotypic heterogeneity resulting from CEP290 mutations.

796W

Loss of SQSTM1 copy number in Paget's disease of bone. *S. Guay-Belanger[1,2], E. Gagnon[2], J. Morissette[2], J. P. Brown[1,2,3], L. Michou[1,2,3].* 1) Laval University, Quebec (Quebec) Canada; 2) CHUQ (CHUL) Research Centre, Quebec (Quebec) Canada; 3) Rheumatology Department, CHUQ (CHUL), Quebec (Quebec) Canada.

Purpose: Paget's disease of bone (PDB), a common disorder affecting up to 3% of the population over 55 years of age, has an autosomal-dominant mode of inheritance with incomplete penetrance in one-third of cases. PDB is characterized by unifocal or plurifocal hyper-remodelling secondary to activation of osteoclasts, resulting in weakened bone structure and strength. To date, only the SQSTM1 gene has been linked to PDB, with more than 20 reported heterozygous mutations. The SQSTM1 gene P392L mutation was the first described and remains the most common mutation in PDB. Recently, a new prevalent form of genomic variation has emerged. Copy number variation (CNV) is described as a segment of DNA that is 1 kb or larger and is present in variable copy numbers in comparison with a reference genome. Three CNV have already been reported in the SQSTM1 gene region. The objective of this study was to determine if CNV of the SQSTM1 gene was associated with PDB. Methods: This investigation focussed on the CNV_0068 since it covers the whole SQSTM1 gene, including exons 7 and 8, where SQSTM1 mutations are located. We analysed 298 healthy donors, 244 unrelated PDB-affected patients and 54 patients with a familial form of PDB, of whom 42 were carriers of a P392L mutation. We used the TaqMan Copy Number Assays according to the manufacturer's protocol. We performed case-control comparisons of individuals with loss of copy (ie less than two copies) of the SQSTM1 gene or with gain of copy (more than two copies), to individuals with two copies, who were considered the reference. Also, the subgroup of patient carriers of a P392L mutation was compared to healthy controls. Statistical analyses included Fisher's exact test, odds radio (OR) and 95% confidence interval calculations. Differences were considered statistically significant when $P < 0.05$. Results: The comparison of pagetic patients to healthy controls demonstrated that loss of SQSTM1 copy number was significantly more frequent in patients than in controls (14.5% versus 9.5%, P=0.035, OR=1.77 [1.01-3.12]), particularly in the subgroup of patient carriers of a P392L mutation, in whom loss of SQSTM1 copy number was even more frequent than in controls (20% versus 9.5%, P=0.014, OR=3.47 [1.14-10.03]). Conclusion: This study suggests that there is a loss of SQSTM1 copy number in PDB, particularly in the subgroup of patient carriers of the P392L mutation within the SQSTM1 gene.

Functional Evaluation of CLEC16A: Role in Type 1 Diabetes. *M. Bakay[1], R. Pandey[1], L. Monaco-Shawver[2], J. Glessner[1], C. Kim[1], F. Mentch[1], J. Bradfield[1], S. Grant[1], C. Polychronakos[3], J. Orange[2], H. Hakonarson[1].* 1) The Center for Applied Genomics, Children's Hosp Philadelphia, Philadelphia, PA; 2) Division of Immunology, The Children's Hospital of Philadelphia. Philadelphia, PA 19104; 3) McGill University Health Centre. Montreal, Quebec H3H-1P3, Canada.

Type 1 Diabetes (T1D) is a multifactorial childhood disease with a strong genetic component. Several GWAS recently showed association of CLEC16A with T1D. CLEC16A has homology domains that identify it as a C-type lectin. Still, the protein has no known function. Other C-type lectins have been shown to powerfully influence growth, survival, and autoimmune attack of pancreatic)-cells. The highest levels of CLEC16A expression were identified in NK cells, which are required for development of T1D. Therefore, defining the role of CLEC16A in NK cells will provide insight into the pathogenesis of T1D. We reported previously that protective alleles of CLEC16A [A/A] are associated with higher levels of mRNA. Recent studies of CLEC16A orthologue have defined regulatory roles for the protein in regulating endosomal trafficking. Thus, we hypothesize that CLEC16A functions in NK cells to restrain secretory functions including cytokine release and cytotoxicity after activation. To address the role of CLEC16A in T1D we studied consequences of knockdown and overexpression of this protein in NK cell lines. Using a retroviral expression system we created NK cell lines stably overexpressing different levels the canonical form of CLEC16A with a GFP expression reporter. Expression has been validated by Western blot analysis and functional studies, such as cytotoxicity and cytokine release assays, of these cells are in progress. We also designed small-interfering (si) RNA directed against CLEC16A that should impact all isoforms. Optimized protocols using CLEC16A siRNA enabled a 70% reduction in Clec16A protein levels in NK cells. Interestingly, this resulted in a 35% increase in cytotoxicity compared to cells receiving control siRNA. Our results indicate that CLEC16A serves a role in restraining NK cell function. The mechanism for this effect and its impact upon other secretory functions such as the release of inflammatory mediators represents our immediate focus. We predict a role for CLEC16A in regulating the secretory pathway in NK cells. Our ongoing mechanistic studies will give unprecedented insight into in the immunopathogenesis of T1D and will ultimately link back to patient-derived cells. Improved understanding of this novel T1D-linked gene and the protein it encodes will likely suggest new therapeutic interventions relevant to regulating autoimmune reactivity in patients progressing toward T1D.

Genotype-function Correlation of APOE Gene Promoter Polymorphism: in Transcription Control and in Type 2 Diabetes Susceptibility. *Y.Y. Ho[1,4], H. Geng[1], P. Law[1], M. Ng[2], T. Li[1], L.Y. Liang[1], T.F. Ge[1], K.B. Wong[1], C. Liang[3], R.C. Ma[2], W.Y. So[2], J.C. Chan[2].* 1) Department of Biochemistry, The Chinese University of Hong Kong, Hong Kong, China; 2) Department of Medicine and Therapeutics, Prince of Wales Hospital, The Chinese University of Hong Kong, Hong Kong, China; 3) Department of Biochemistry, Hong Kong University of Science and Technology, Hong Kong, China; 4) Departments of Biostatistics and Psychiatry, Columbia University, New York, NY, USA.

The apolipoprotein E gene (APOE) encodes three major protein isoforms (apoE2, apoE3, apoE4) and is a risk modifier of Alzheimer's disease, type 2 diabetes (T2D), and coronary heart disease. Aside from the coding variants, single nucleotide polymorphism (SNP) of the APOE promoter has also been shown to modify the risk of Alzheimer's disease. Whether APOE promoter polymorphism is associated with the risk of T2D is unknown. In this study we aimed at investigating the genotype-function correlation of APOE promoter polymorphism at molecular level and at physiological level: i.e., in transcription control of the gene and in T2D susceptibility, respectively. In molecular studies, the effect of the APOE promoter -491A/T polymorphism on transcription was accessed by dual-luciferase reporter gene assays. Substitution of -491A to T decreased ($p<0.05$) the activity of the cloned APOE promoter (-1017 to +406). Using the -501 to -481 nucleotide sequence of the APOE promoter as a `bait' to screen the human brain cDNA library by yeast one-hybrid system yielded ATF4 (Activating Transcription Factor 4, an endoplasmic reticulum stress response gene encoding a regulator of lipid and glucose homeostasis in mammals) as one of the interacting factors. Electrophoretic-mobility-shift assays (EMSA) and chromatin immuno-precipitation (ChIP) analyses further substantiated the physical interaction between ATF4 and the APOE promoter. Over-expression of ATF4 stimulated APOE expression whereas siRNA blockage of ATF4 suppressed APOE expression. However, interaction between the APOE promoter and ATF4 was not -491A/T-specific. The genotype-function relationship of APOE promoter polymorphism at physiological level was studied in the context of T2D. In a case-control study (630 cases and 595 controls), three APOE promoter SNPs -491A/T (rs449647), -219G/T (rs405509), and +113G/C (rs440446) were genotyped and tested for association with T2D in Hong Kong Chinese. There was no association between these SNPs and T2D. In conclusion, at molecular level, -491A/T polymorphism and the ATF4 transcription factor elicit independent control of APOE gene expression. At physiological level, APOE promoter polymorphism is not associated with T2D susceptibility in Hong Kong Chinese. Acknowledgement: This study was supported by Direct Grant No. 2041183, The Chinese University of Hong Kong, Hong Kong, China and Grant No. T32-MH-65213, National Institute of Mental Health, USA.

ITGAM coding variant, rs1143679 (R77H), is associated with systemic lupus erythematosus (SLE) susceptibility and affects its own expression in monocytes of SLE patients. *A.K. Maiti[1], P. Motghare[1], C. Sandel[1], X. Kim-Howard[1], J-M. Anaya[2], S.K. Nath[1].* 1) Gen Epidemiology Unit, A&I, OMRF, Oklahoma city, OK; 2) Universidad del Rosario-Corporación para Investigaciones Biológicas, Bogota, Colombia.

Background: We recently identified ITGAM (CD11b) as a novel SLE susceptibility gene. To date, ITGAM and its associated variant rs1143679 (R77H) is one of the few SLE susceptibility genes consistently replicated in multiple populations with European, African, Hispanic, and Asian ancestries. However, functional significance of this missense mutation is not known. CD11b mainly expresses in neutrophil, monocyte, and macrophages and it is known to have numerous biochemical functions. Though there are no prior indication about its involvement in SLE, its role in phagocytosis, aggregation, leukocyte adhesion, and cellular signaling are well established. Since this exonic SNP is located at the ninth base from exon-intron boundary and includes an enhancer/silencer sequences we hypothesize that it can change its own expression. Methods: We purified monocytes from patient's PBMC with fluorescent activated cell sorting (FACS) using fluorescent labeled CD14 antibody. Total RNA was isolated and cDNA from these cells were subjected to RT-QPCR. Surface expression of CD11b was measured with FACS using CD11b antibody. Allele specific expression was quantitated by sequencing either allele carrying 30 clones from each heterozygous (GA) patients. Splicing abnormalities were assessed with splicing specific PCR, and methylation of promoter was checked with pyrosequencing. Results: Expression analysis of mRNA and surface protein (CD11b) in SLE patient's monocyte showed that both expressions are significantly reduced in risk genotype (AA) patients in compare to non-risk (GG) genotype carrying patients. Furthermore, allelic expression suggests that risk allele (A) carrying mRNA is 4 to 10 fold reduction in monocytes of SLE heterozygous patients. Subsequent experiments suggest that risk allele specific mRNA degradation, or any aberrant splicing, are not observed in patient's monocytes Conclusion: Expression differences due to allelic differences indicate functional significance of rs1143679. Risk allele specific methylation or silencing of its own expression could explain reduced expression of this allelic mRNA. In conclusion, apart from the predicted misfunction of the mutated protein (Arg>his), G>A nucleotide transition in ITGAM also affects its expression leading to immune modulation in SLE pathogenesis.

High-Fidelity Mapping Of Exome Sequences Improves Outcomes In Disease Studies. *T. Gaasterland[1], L. Edsall[1], A. Patel[1], S. Soares[1], R. Thompson[1], A. Wu[1], S. Head[2], P. Lee[2], D.E. Gaasterland[3], R. Ayyagari[4].* 1) Laboratory of Computational Genomics, Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA; 2) Department of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, CA; 3) Eye Doctors of Washington, Chevy Chase, MD; 4) Department of Ophthalmology, University of California San Diego, La Jolla, CA.

Purpose: Maximize discovery of real, disease-related genome variations while minimizing false positive variant calls through DNA capture of exons genome-wide ("exome capture"), applied to eye disease and focused on glaucoma and retinal degenerations, both of which are neurologic-related afflictions. The study of neurologic eye diseases will lay genetic foundations for wider understanding of neurodegenerative processes. Methods: After consent, DNA was extracted from blood of individuals affected, or not affected, with one of several eye diseases. Commercial exome capture kits were applied to hybridize probes to target DNA in solution. For each person, captured DNA was sequenced (Illumina Genome Analyzer IIx or HiSeq) generating at least ~80 million pairs of 100-base reads. Initially, reads were mapped to a reference human genome (hg18; hg19) and SNPs (single nucleotide polymorphisms) identified using published parameters and methods. To overcome deficiencies, we devised a new tiered strategy that maps perfectly matching reads and then iteratively relaxes match stringency. Exome SNPs were compared with known SNPs found independently with the more accurate, low throughput, Sanger sequencing of the same samples. Results: Some of the exome SNPs were from pseudogenes. The tiered strategy mapped reads correctly to pseudogenes rather than genes, thus ensuring each exome SNP mapped to its true location. Further, this new tiered read mapping strategy partitioned reads into those that matched uniquely to exactly one position in the genome, or to two, to 3-5, or to 6-10. This allowed not only SNPs, but also insertions and deletions, to be predicted iteratively with strict subsets of mapped reads, and labeled according to mapping quality. Conclusions: Tiered mapping and variant calling allows multi-mapped reads, which identify otherwise weakly supported genome variants. Such variations are identified as ambiguous and possibly resulting from gene conversion (a process by which pseudogene sequences are inserted into actual genes). With this method, in comparison with conventional mapping strategies, variant calls are ranked by the mapping quality of supporting reads. It also identifies possible gene conversion, increases sensitivity and specificity, and enhances potential to discover disease-related genes.

mRNA diversity of genes by alternative splicing during neuronal differentiation of NT2 pluripotential human embryonal carcinoma cells by retinoic acid. *T. Isogai[1], A. Wakamatsu[1], H. Sasaki[1], J. Imai[2], S. Watanabe[2].* 1) Grad Sch Pharmaceutical Sci, Univ Tokyo, Tokyo, Japan; 2) Fukushima Med. Univ., Fukusima, Japan.

To elucidate cause of disease related to neuronal differentiation, we analyzed genes and the protein-coding transcripts by alternative splicing (AS) using NT2 pluripotential human embryonal carcinoma cells which differentiates toward a neuron by all-trans retinoic acid (RA) induction. Gene could produce multiple protein-coding transcripts (MPCTs) by AS. It was known that AS particularly occurs in the mammalian nervous system and plays an important role in neuronal differentiation in generating biological and functional diversity. We analyzed expression levels by NT2 cells treated with RA using DNA microarray, and then identified 358 RA-responsive genes. mRNA diversity analysis revealed that 274 genes (77%) produced MPCTs by AS. Among 274 genes, we chose 16 genes producing MPCTs using alternate N-terminus (Alt. N-term), 30 genes producing MPCTs using alternate C-terminus and 12 genes producing MPCTs using alternate cassette-exon for further analysis. Using transcript-specific primers, we performed quantitative real-time PCR analysis to examine the expression profiles of the protein-coding transcripts produced by each one of these genes. Furthermore, we previously analyzed expression profiles of the genes containing alternative TSSs (transcription start sites), multiple variable first exons, by AS, and then found that alternative TSSs were shown to be utilized for tissue-specific expression. We think that the same gene could code for proteins with diverse function in different tissues by the proper utilization of alternative TSS. Analyzing expression profiles of 10,069 cDNAs, which corresponded to 5,542 genes, out of our identified 11,769 cDNAs, we found that the TSSs of 263 cDNAs, which correspond to 156 genes, showed specific expression patterns that were different from those already obtained for the genes with alternative TSSs. Using transcript-specific primers designed for their TSS regions, we analyzed expression profiles of 51 out of 156 selected genes by NT2 cells treated with RA using real-time PCR. Consequently, we identified genes which showed different RA-induced changes in the expression of their protein-coding transcripts by using Alt. N-term. The mRNA diversity of genes was occurred by not only genetic risk factors but also environmental risk factors. To clarify which risk factor caused their mRNA diversity, it will be important to discover novel target genes of new drugs for disease.

Global alternative splicing variation reflects ethnical diversity. *J.W. Li[1,2], T.F. Chan[1,2].* 1) School of Life Sciences, Biochemistry Program, The Chinese University of Hong Kong, Hong Kong; 2) Hong Kong Bioinformatics Center, The Chinese University of Hong Kong, Hong Kong.

Population structure based on single nucleotide polymorphism (SNPs) and micro-satellites has demonstrated drastic population stratification among human populations. Expression phenotypic variations among the 3 HapMap populations (CEU, YRI, JPT/CHB) were well characterized. Relatively less known is the extent of global splicing variations (ASV) in the context of ethnicity.

We are interested in human diversity in molecular level. We used RNA-Seq to characterize 20 transcriptomes of CEU and CHB individuals. Compared to Reference Sequences alone, we were able to identify 447 genes that show differential splicing ratios. Ethnical splicing ratios were validated in 10 healthy unrelated Chinese individuals sampled in Hong Kong. Besides, thousands of ethnic specific splice junctions were pinpointed. We further analyzed 5634838043 sequencing reads retrieved from NCBI SRA, revealing thousands of novel transcribed exons in each ethnic group. RT-PCR and northern blot validation are in progress. Interestingly, meta-analysis on YRI showed a largely different spectrum of baseline splicing variations. Such observations suggest ASV as another molecular phenotype that delineates ethnical diversity. In addition, we observed minimal overlap in genes that showed inter-ethnic variations in gene expression and splicing. This suggests a complementary role of gene expression variation and splicing in functional diversity between and among populations. This study uncovers natural ASV with implications in complex human traits.

While numerous studies had revealed the linkage of drug susceptibility and clinical outcomes to molecular phenotypes, under-representation of certain ethnic groups in clinical trials contributes significantly to worldwide healthcare disparities. Evaluation of ethnical diversity in additional of individuals' molecular and expression phenotype in clinical examination will assist physicians in practice of evidence-based medicine.

Alternative exon 1 usage defines a novel human Hydroxymethylglutaryl-CoA reductase (HMGCR) gene splice variant. *C. Stormo[1], M.K. Kringen[2], R.M Grimholt[1], J.P Berg[1], A.P Piehler[1].* 1) Medical Biochemistry, Oslo University Hospital, Ullevål, Oslo, Norway; 2) Department of Pharmacology, Oslo University Hospital, Ullevål, Oslo, Norway.

Background: 3-Hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) encodes the rate limiting enzyme in cholesterol biosynthesis and the main target of commonly used LDL lowering drugs (statins). Previous studies have shown that a HMGCR splice variant lacking exon 13 has decreased enzymatic activity and is less sensitive to statin inhibition. The aim of this study was to identify putative novel HMGCR splice variants and to study their expression patterns and responses to atorvastatin treatment. Methods: An alternative splice variant, amplified from a RNA pool of human skin by RT-PCR, was cloned into a TOPO vector and sequenced. Expression of the splice variant and the canonical form was investigated in 36 different human tissues and in HepG2 cells upon 24 h atorvastatin (10 μM) treatment. Relative mRNA levels were obtained by RT-qPCR using custom Taqman qene expression assays specific for either transcript. Results: We have cloned a novel alternative HMGCR transcript containing an alternative exon 1 (HMGCR1b) compared to the canonical transcript (HMGCR1a). The open reading frame of the novel transcript predicts a protein with additional 20 amino acids at the N-terminus compared to HMGCR1a. Sequencing of HMGCR1b clones revealed that HMGCR1b, like the original HMGCR1a transcript, can be subjected to exon 13 skipping (HMGCR1bΔex13). HMGCR1b was expressed at various levels in 36 different tissues. Unlike HMGCR1a, the alternative transcript showed highest expression levels in skin, esophagus and uterus. Furthermore, results from in vitro experiments revealed an upregulation of HMGCR1b upon atorvastatin treatment in HepG2 cells compared to non-treated cells. Conclusion: We have identified and cloned a novel transcript of the human HMGCR gene exhibiting alternative exon 1 usage. Both the differential expression of HMGCR1b in a wide variety of healthy tissues and the mRNA upregulation of HMGCR1b upon statin treatment indicate a distinct physiological function of the HMGCR1b gene transcript.

Optimized Filtering of High Throughput Sequence Variants in Clinical Cases from the National Institutes of Health Undiagnosed Diseases Program. *D.R. Adams[1,3], M. Sincan[1], K. Fuentes Fajardo[1], C. Toro[1], C.F. Boerkoel[1], C.J. Tifft[2], W.A. Gahl[1,2,3], T.C Markello[1,3], NIH Intramural Sequencing Center.* 1) Undiagnosed Diseases Program, Office of the Director, NIH, Bethesda, MD; 2) Office of the Clinical Director, NHGRI, NIH, Bethesda, MD; 3) Medical Genetics Branch, NHGRI, NIH, Bethesda, MD.

High Throughput Sequencing (HTS) of exomes and genomes is rapidly becoming incorporated into the standard armamentarium of basic scientists and is making inroads into clinical molecular genetics. Several publications have discussed the data acquisition phase of HTS including alignments, base calling and annotation. The challenge of sorting through the resulting large list of candidate DNA variations is also well known, but has been evaluated to a lesser extent in the literature. We have explored the various means of filtering and sorting HTS variant lists using data from the NIH Undiagnosed Diseases Program (UDP). We present an analysis of the methodology and stringency considerations at each data filtering step, and discuss the integration of HTS data with genetic and clinical information from other sources. For this study, 30 probands plus additional family members were subjected to HTS of their exomes or genomes. In each case, extensive clinical evaluation at the NIH Clinical Center was used to attempt diagnosis and perform phenotyping. Analysis of the HTS variants generated for each individual or family was performed using both published and novel techniques, including the incorporation of data from high-density SNP arrays. The presence of four successful, verified molecular diagnoses provided a positive control for the efficacy of filtering methods and strategies. Filtering procedures at each step were tuned to match the clinical information available for the family or individual. Marked improvements in HTS variant filtering corresponded with improvements in filtering methodology and other resources such as successive dbSNP releases. Careful design of each filtering step allowed for optimization of the exclusion of false-positive variants. At the same time, flexible parameterization of each step allowed for systematic stringency adjustments. Laboratory confirmation of a DNA sequence variants of unknown significance can be time consuming and expensive. Therefore, careful filtering of HTS variant lists is essential for excluding candidates that can be either ruled out or de-emphasized prior to experimental validation.

CIDRSeqSuite 2.0: An Automated Analysis Pipeline for Next-Generation Sequencing. *M. Barnhart, S. Griffith, K. Hetrick, J. Goldstein, B. Marosy, D. Mohr, B. Craig, L. Watkins, Jr., K. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to common disease. In January 2011, CIDR began offering sequencing services using the Illumina® HiSeq™ 2000 sequencing platform. CIDRSeqSuite, an early version of which was presented at the 2010 ASHG meeting, was developed to automate a variety of bioinformatic workflows and analyses. Over the past year, the primary analysis workflow of CIDRSeqSuite has been redesigned and new features have been added. Like its predecessor, CIDRSeqSuite 2.0 is designed to run on 64-bit Linux and is written in Java SE 6 and Perl 5. CIDRSeqSuite's new primary analysis workflow glues custom tools to numerous third-party secondary and tertiary analysis software including ANNOVAR, SAMtools, Picard, BWA, the Genome Analysis Toolkit (GATK), VCFtools, and tabix. Beginning with the qseq.txt files produced from BCL files by the Illumina BCL converter, CIDRSeqSuite demultiplexes samples based on their indexes, then combines and converts them into FASTQ files. From there, independent analyses by sample are launched: aligning the FASTQ files with BWA to a reference genome for a paired-end sequencing run; conversion to BAM with Picard; local realignment around indels using GATK; synchronizing mate-pair information and flagging of molecular duplicates with Picard; recalibration of base call quality scores with GATK; variant calling with SAMtools, producing VCF output; annotation of variants with ANNOVAR; and other QC metric reports. Current work involves parallelizing these independent sequencing analysis runs across an Oracle (formerly Sun) Grid Engine-managed cluster. The ability to resume an analysis is now included; following a crash or cancellation, the pipeline can resume from the last step completed. For a single sample, a complete analysis runs to completion in ~ 24-36 hours, depending on factors such as network traffic, amount of sequencing data produced per sample, and hardware factors. However, since samples are analyzed in parallel, it is theoretically possible to analyze a large number of samples in roughly the amount of time that it takes to analyze a single sample, provided that appropriate resources are available.

DCAURS: a database for the identification of disease-causing regulatory SNPs. *P. Beaulieu[1], D. Sinnett[1,2].* 1) Centre de recherche, Hopital Ste-Justine, Montréal, QC, Canada; 2) Departement de Pédiatrie, Université de Montréal, Montreal, QC, Canada.

Previous efforts to identify functional disease-causing DNA variants were essentially oriented towards the coding regions of candidate genes since these variants have a direct impact on the structure and function of the affected proteins. However, abnormal expression of finely regulated genes can also lead to disequilibria in different metabolic pathways and/or biological processes. Thus, investigation of the functional impact of polymorphisms as well as the determination of the importance of evolutionary conservation in the regulatory regions of candidate genes should improve our knowledge of complex disease aetiologies. Towards this goal we have screened extended regions of DNA around disease-associated polymorphisms for potential regulatory hotspots. Analysed regions encompassed 250kb upstream and downstream of every SNP present in the NHGRI GWAS catalog. We integrated several layers of information such as gene structure, predicted TFBS binding sites, conservation, chromatine structure, CPG islands and known regulatory elements. We developed a detailed computational analysis of potential disease-associated regulatory regions and attempt to improve our understanding of their content. Here we present the Disease CAUsing Regulatory Snps (DCAURS) database, containing all known SNPs in the screened regions as primary data. Users can interrogate the database to find regulatory SNPs according to several search criterias, namely: genomic region, co-location with various types regulatory features, LD with disease-associated SNPs, proximity to disease-associated SNPs from a given GWAS study or phenotype. Such functional annotation provide a more effective selection of regulatory targets and thereby facilitates our efforts understand human complex diseases.

807W

Exome sequencing identifies CCDC8 mutations in 3-M syndrome, suggesting CCDC8 contributes in a pathway with CUL7 and OBSL1 to control human growth. *S. Bhaskar[1,3], D. Hanson[2,3], P.G. Murray[1,2,3], J. O'Sullivan[1,3], J. Urquhart[1,3], S. Daly[1,3], L.G. Biesecker[4,5], M. Skae[1], C. Smith[6], T. Cole[7], J. Kirk[8], K. Chandler[1,3], H. Kingston[1,3], D. Donnai[1,3], P.E. Clayton[1,3], G.C.M. Black[1,3].* 1) Central Manchester University Hospitals Foundation Trust, UK; 2) Endocrinology, Manchester Academic Health Sciences Centre (MAHSC), School of Biomedicine, University of Manchester, UK; 3) Genetic Medicine, Manchester Academic Health Sciences Centre (MAHSC), School of Biomedicine, University of Manchester, UK; 4) National Institutes of Health (NIH) Intramural Sequencing Center (NISC), National Institutes of Health, Bethesda, MD, USA; 5) National Human Genome Research Institute, NIH, Bethesda, MD USA; 6) East Lancashire Hospital NHS Trust, UK; 7) West Midlands Regional Genetics Service, Birmingham Women's Hospital, Birmingham, UK; 8) Department of Paediatric Endocrinology, Birmingham Children's Hospital, Birmingham, UK.

3-M syndrome is a primordial growth disorder characterised by postnatal growth restriction, dysmorphic facial appearance and prominent heels. Mutations in both CUL7 and OBSL1 are known to cause 3-M. CUL7 is an E3 ubiquitin ligase protein known to target the growth factor signalling molecule IRS-1 for degradation. OBSL1 is a cytoskeletal adaptor protein and we have previously shown that siRNA knockdown of OBSL1 leads to concomitant loss of CUL7 suggesting both are part of a common pathway. We now report a cohort of 3-M patients of South Asian descent who did not carry either CUL7 or OBSL1 mutations. Autozygoisty mapping using 3 such unrelated individuals identified a third 3-M syndrome locus on chromosome 19q13.2-q13.32. Exome sequencing capture revealed two different duplication mutations in CCDC8, coiled coil domain containing protein 8. Further screening by Sanger sequencing in additional patients revealed in total, 2 distinct mutations (c.84dup and c.612dup) in 5 families. Co-immunoprecipitation assays show that CUL7 and OBSL1 physically interact and that OBSL1 and CCDC8 also interact. This is first reported identification of CCDC8 mutations as a cause of 3-M and broadens the hypothesis that 3-M is a disorder of a common biochemical pathway comprising of at least CUL7, OBSL1 and CCDC8. The data presented here suggests that OBSL1 is likely to act as the adaptor protein linking CUL7 and CCDC8 and infers that all 3 proteins are required for the control of human growth.

808W

Integration of Transposable Elements Dependent on Genome Landscapes. *R. Campos-Sanchez[1], F. Chiaromonte[2], K. Makova[1].* 1) Biology Department, Pennsylvania State University, University Park, PA; 2) Department of Statistics, Pennsylvania State University, University Park, PA.

Transposable elements (TEs) constitute a large portion of every eukaryotic genome studied so far. Their insertions have been also associated with multiple human diseases. Recently, the integration preferences of Alu and L1 elements in primate genomes have been analyzed via a multiple linear regression framework (MLR, regressing the counts of these elements on a list of regional genome features and chromosome type). Here, we analyzed DNA transposons in the human genome in order to explain their genome densities as predicted from genomic landscape features. The responses for each MLR were the content within 1-Mb windows (fraction of a window in bp) of a group of DNA transposons classified by age of integration and family. A comprehensive literature search guided us into the selection of the most appropriate predictors (i.e. such genome landscape features as location on sex chromosomes vs. autosomes, gene content, GC content, replication timing, etc.). The genomic features were extracted from the UCSC Genome Browser or from primary publications and were localized into the same 1-Mb windows. In order to select the best set of predictors for all the analysis, we conducted a hierarchical cluster analysis on the correlations among predictors, and then applied the appropriate transformations for the data. Our preliminary results revealed that DNA transposons are underrepresented on sex chromosomes. Also, the distribution of certain DNA transposons (Tc-Mar Tigger and hAT-Charlie) appears to associate positively with L1 target primed reverse transcription, telomerase-dependent RNA retrotranscription, non-canonical L1 integrations, and with the presence of other transposable elements as short (SINE) and long (LINE) interspersed nuclear elements. These predictors highlight the molecular mechanism of DNA transposon integration. Our regressions explain up to 36% of variation in density of some DNA transposon groups and allow us to explain their distribution in the human genome. This study reveals some remarkable details about the integration preference of these transposable elements, knowledge of which is vital for understanding human genome evolution and origins of some genetic diseases.

Resources for the 1000 Genomes Project. *L. Clarke, H. Zheng Bradley, R. Smith, E. Kulesha, I. Toneva, B. Vaughan, P. Flicek, The 1000 Genomes Project Consortium.* Vertebrate Genomics, EBI, Cambridge, United Kingdom.

The 1000 Genomes Project is producing a deep catalogue of human variation, to provide a better baseline to underpin human genetics. The main data resource for the 1000 Genomes project is the project ftp site (ftp://ftp.1000genomes.ebi.ac.uk/vol1/ftp ftp://ftp-trace.ncbi.nih.gov/1000genomes/ftp). This represents more than 120TB of data and 200,000 files and presents a challenge for the average user to navigate. New tools to notify users when new data appears and to assist users in finding the data that is relevant to their own enquires. Data releases are announced by email on announce@1000genomes.org and there is also an rss and twitter feed for the announcements as they are made on the 1000 genomes website. Variant calls are made available initially in vcf format on the ftp site and are subsequently loaded into the 1000 genomes Ensembl browser. The browser allows users to discover variants in their genomic context and shows the consequence of the variant with respect to Ensembl's gene annotation. The browser also holds tools to allow uses to interact with both bam and vcf files. Attachment of remote files allows uses to see remotely visible bam and vcf files along side the annotation within ensembl. Ensembl's variant effect predictor has been setup and this can give users functional consequences for their own variants including polyphen and sift scores for non synonymous changes. We have also provided a data slicing tool which gives users easy access to subsections of all our bam and vcf files. It will also work for other remotely accessible and indexed bams and vcfs. http://browser.1000genomes.org With more than 100Tbytes and 20000 files on the ftp site it can be difficult to find the precise information that you are looking for. Newly developed search tools for both the ftp site and the website have been created to help users find the information they are looking for. http://www.1000genomes.org/ftpsearch With these tools and many other developments should enable all users to get better access to the wealth of new information provided by the project.

810W

Expanding the annotation of the human genome: transcripts targeted for degradation and the noncoding genes. *G. Despacio-Reyes, M. Suner, M. Thomas, A. Frankish, L. Wilming, J. Mudge, D. Manthravadi, M. Kay, V. Boychenko, A. Bignell, J. Gilbert, E. Griffiths, J. Loveland, C. Steward, J. Harrow, T. Hubbard.* The Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom.

The Human And Vertebrate Analysis and Annotation (HAVANA) Team has been at the forefront of GENCODE, a sub-project of the ENCODE program (Encyclopaedia of DNA Elements), which aims to create an encyclopaedia of gene features in the human genome by evidence-based manual annotation. We use the in-house developed and maintained Otterlace annotation suite to produce a gold standard set of annotation for coding genes, noncoding genes, alternative splicing events, and pseudogenes. We routinely update our annotation guidelines to incorporate new data sources and new trends in transcriptomics, proteomics and genomics. Such examples include transcripts destined for degradation by regulatory mechanisms either via the nonsense-mediated decay (NMD) pathway or the non-stop mediated decay (NSD) pathway. As a basic rule, the presence of a premature termination codon upstream of a splice junction predisposes a transcript for degradation by NMD mechanism. However, more than 70 transcripts have been identified as coding despite containing a premature stop codon. These transcripts were able to escape the cellular quality control process and produce a viable protein. We have therefore had to strengthen our annotation guidelines, adding flexibility to account for the NMD exception . The presence of poly-adenylation at the end of an NSD transcript, without any prior termination codon, would signify degradation by NSD mechanism. It remains to be seen if this rule would be true across all known cases. For noncoding genes, we have developed initial annotation which will be further enriched as developments and interests in the noncoding genes continue to emerge. So far, we have created five biotypes for representing both novel and known noncoding loci, i.e., lincRNA, antisense, 3' overlapping ncRNA, sense overlapping and sense intronic. The current GENCODE (v.7) geneset has about 7000 non-coding RNA genes that we have manually annotated. As more evidence becomes available, the way we annotate noncoding genes will continue to evolve as well. The recent explosion in the production of transcriptomics data in the form of RNAseq means that our annotation procedures must adapt quickly. These data will be used to provide information on alternative splicing patterns, tissue / developmental specificity and transcription levels, all of which are presumably subject to variation.

811W

Connecting the genome with the metabolome: novel bioinformatic approaches for integration and visualization. *H.K. Dharuri[1], P. Henneman[1], K. Willems van Dijk[1,2], C.M. van Duijn[3], B.A. Oostra[3], P.A.C. `tHoen[1], G.J.B. van Ommen[1].* 1) Department of Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Department of Internal Medicine, Leiden University Medical Center, Leiden, Netherlands; 3) Department of Epidemiology, Erasmus Medical Center, Rotterdam, Netherlands.

GWAS studies explain only a minor part of the heritability of metabolic syndrome (MetS) and related clinical outcomes. In addition, the biological context of candidate genes detected by means of GWAS often remains unclear. The association of genetic polymorphisms with metabolite levels has recently sparked interest. These intermediate phenotypes generally demonstrate larger effect sizes and potentially point at pathways relevant to disease. However, association of all SNPs with all measured metabolites comes with considerable multiple testing problems. Our objective is to increase the power in the identification of loci associated with metabolite traits through the use of background knowledge on metabolic pathways. We have used NMR to measured metabolite levels in the serum of subjects in genotypically and genealogically well characterized Erasmus Rucphen Family (ERF) cohort. Preliminary genetic association analysis on just 20 metabolites already yielded considerable amount of data in the form of significant SNP-metabolite pairs (6 traits, 13 loci, P< 10-8). Therefore, it is imperative we build efficient, high throughput bioinformatic tools that help us to place these hits in a biological context. We have developed a software tool that automates the association of metabolites with SNPs near genes in the pathway relevant to the synthesis and degradation of the metabolite. An important aspect of this tool is the ability to handle a large amount of data and visualization techniques to help the biologist verify if the SNP-metabolite pair of interest does indeed have a convincing biological explanation. The software makes use of work flow management technologies like Taverna and Galaxy. This allows us to conduct our analysis across diverse datasets and applications like the UCSC Genome Browser, and metabolite and pathway databases like BioCyc, KEGG, and HMDB. Apart from curated entries in database, we have also used text mining to include biologically relevant connections between genes and metabolites that are not necessarily already present in pathway databases. The challenge here was to map metabolites to unique literature concepts, given the ambiguity surrounding metabolite names and their usage in the literature. The increased power of these tools to identify mechanistically relevant SNP-metabolite pairs will be demonstrated.

812W

Unbiased cataloging of novel variations across the complete genome. *S. Ghosh, J. Ebert, G. Nilsen, K. Pant, R. Drmanac.* Complete Genomics, Mountain View, CA.

A primary benefit of complete genome sequencing is the potential to identify rare variants implicated in complex diseases. The most challenging aspect of this is to discriminate causal variants from those that are neutral. One of the fundamental steps in this process is to catalog the frequency of variants in a normal population in an unbiased manner. This facilitates the identification of previously undiscovered/unstudied repertoire of genetic variants and the characterization of the causative disease variant. Complete Genomics has recently released complete genome sequence data from a diversity panel comprised of 69 normal samples representing 11 different populations. Samples are from the NHGRI (HapMap and 1000 Genomes Project) repositories. The purpose of sequencing the diversity panel is to provide a gender-balanced, high coverage - 50x median - complete genome data set across a spectrum of populations. This panel includes individuals of European, Asian, African descent and American admixture. Sequencing was performed on Complete Genomics DNA nanoarrays using a non-sequential, unchained read technology to generate 70mer paired end reads. Assembly was performed using the Complete Genomics pipeline, which performs an initial fast alignment to a reference followed by local *de novo* assembly in those regions of the genome that appear to contain variations. Both alleles were called in 95.03-97.43% of the genomes, with only one allele being called in an additional 0.25-1% of the genome. Median concordance with HapMap3 and 1000 Genomes Project were 99.73% and 99.83% respectively. A validation rate of greater than 93% was determined on loci absent from the 1000 Genomes Project data. The variations have been classified as SNPs, indels and substitutions. On a genome-wide scale, the median novelty rate(compared to dbSNP 130) is higher for indels at 25.49% (9=5.37%) compared to SNPs at 8.35% (9=4.11%). The median SNP novelty rate for Africans is 15.4%, Europeans is 6.78% and Asians is 8.31%. Similar trends are observed for the other variant types. The ratios of SNPs and indels in coding regions compared to the complete genome are 0.006 and 0.001 respectively. The median Ti/Tv ratios for genome-wide versus exome are 2.13 and 3.2 respectively, corroborating a negative selection pressure for variants at and proximal to coding regions. Detailed characterization of the population panel, including concordance with other published data will be discussed.

Identity by descent in sequenced exomes. *A. Gusev, J. Zhuang, I. Pe'er.* Columbia University, New York, NY.

The identification of co-inherited genomic regions, referred to as being Identical by Descent (IBD) has traditionally been used to make inferences regarding population genetics, detect association, and correct errors in genotyping and phasing. In particular, recent family studies have used putative IBD segments detected from high-throughput sequence data to restrict the list of candidate disease linked variants by focusing on co-inherited regions. The distribution of such segments depends on population structure but scales quadratically with sample size, with standard techniques that rely on exhaustive search becoming intractable in large cohorts. However, discovering long IBD segments can be done efficiently by looking for short, identical matches between many individuals and extending from these “seeds” to long segments that are likely to be the products of recent co-inheritance. This approach depends significantly on dense SNP data with high-quality phasing to guide the initial seed process. We have previously presented GERMLINE, an algorithm to identify such segments in dense genotype array data; accurately detecting segments down to 3cM in length. Here we evaluate the effectiveness of this technique in whole-exome sequence data. We examine whole-exome sequence from a cohort of Ashkenazi Jewish origin, where we have previously observed an abundance of recent sharing, and compare detection accuracy to large-scale array data from the same samples. We find many long segments of 100% IBS identity in the exome data that are unsupported by analysis in the array. Such segments would be falsely identified as co-inherited in whole-exome data and could introduce biases into downstream analysis. Indeed, of such segments that are greater than 10cM, less than 10% are supported by array data. We explore various potential metrics for improving IBD detection in such data and find that the ratio of SNP density and recombination rate to be most effective. However, we find that such long false-positive segments cannot be entirely excluded from analysis without dramatically reducing sensitivity. We conclude that distant IBD detection in exome data must be performed with care and can still result in many spurious, seemingly identical segments.

Using GWAs SNP arrays for quality control of DNA sequencing data. *K. Hetrick, H. Ling, E.W. Pugh, B.D. Craig, B.A. Marosy, J.M. Romm, K.F. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping, and statistical genetics consultation to investigators working to discover genes that contribute to disease. Currently we offer NGS services using the Illumina® HiSeq™ 2000 sequencing platform and Agilent© SureSelect™ XT Library preparation and enrichment for whole exome (WES) and custom targeted sequencing. In order to ensure that there is not sample mis-identity issues, samples are run in a SNP assay prior to processing the sample for sequencing analysis (GWAs array for WES and 96 SNP barcode + 10% on GWAs arrays for custom targeted). This augments our ability to assess the DNA quality of the sample as well as identify sample misidentification (by checking gender and IBD). For WES, we identify large chromosomal anomalies prior to sequencing and allow the PI the option to replace the sample or provide us with a new aliquot of that subject. After sequencing, we utilize these genotypes to verify that the sequencing experiment is correctly identified as well as other QC assessments. The two most useful analyses for achieving this are; (1) the concordance between the sequencing variant calls for the experiment and the genotypes on the SNP array; (2) the proportion of heterozygous (het) calls on the SNP array that were detected from the sequence analysis. Having the GWAs genotypes for samples has allowed us to identify and later correct sample identification mis-mapping for the sequencing run and when two (or more) samples were run in the same flowcell lane with the same barcode index via concordance of variant calls between the two platforms. Calculating the proportion of het SNP calls on the array that were called as variant from the reference genome during the sequencing experiment helps us to assess whether there is enough sequencing coverage for a particular experiment. The proportion of het calls on the array detected as variants from the reference genome in the sequencing analysis is approximately linearly correlated with the percent of selected bases covered at a set minimum depth used to filter the variant calls. When experiments deviate from this trend line, we can then investigate. In a targeted sequencing experiment with much higher depth than WES, we were able to determine that a loss of heterozygote sensitivity was due to using our default parameters which resulted in over filtering variant calls.

EpiCenter: a novel framework for accurately identifying genome-wide changes with next-generation sequencing data. *W. Huang[1], D.M. Umbach[1], N.V. Jordan[2], A.N. Abell[2], G.L. Johnson[2], L. Li[1].* 1) NIEHS, NIH, Res Triangle Pk, NC 27709, USA; 2) University of North Carolina at Chapel Hill, Chapel Hill, NC 27599, USA.

The next-gen sequencing based mRNA-seq and ChIP-seq are increasingly used for identifying genome-wide epigenetic/genetic changes. The new type and huge volume of data from these technologies, however, pose computational challenges unmet by existing methods. We propose a new and effective statistical framework for identifying differential epigenetic/genetic changes with these next-gen sequencing data. The key features of our framework are: 1) providing multiple normalization methods to achieve appropriate normalization under different scenarios, 2) using a sequence of three tests to eliminate background regions and to account for different sources of variation in determining statistical significance of changes, 3) allowing adjustment for multiple testing to control false discovery rate or family-wise type I error. We develop a new software tool EpiCenter that can efficiently use our framework to analyze both mRNA-seq and ChIP-seq data. EpiCenter can perform multiple data analytic tasks including: 1) detecting changes in epigenetic marks, 2) identifying differentially expressed genes, 3) finding transcription factor binding sites, 4) converting multiple-sample sequencing data into a single read-count data matrix. EpiCenter also supports major read alignment formats including SAM, BAM, ELAND export, and MAQ. By simulation, we show that our method robustly achieves a low false discovery rate in detecting differential change, and performs markedly better than some existing tools. Through two real examples, we demonstrate the features and effectiveness of our method and highlight the differences in analysis between mRNA-seq and histone ChIP-seq data. Our software EpiCenter is freely available at http://www.niehs.nih.gov/research/resources/software/epicenter.

Joint genome assembly of populations, and potential impact on personal genomes. *Z. Iqbal[1], G. McVean[1,2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Statistics, University of Oxford, South Parks Road, Oxford, United Kingdom.

The need for high quality assemblies of individual human genomes from high throughput whole genome shotgun sequence data is a major challenge for the genetics community. Standard assembly tools use large amounts of sequencing data from a single individual. This approach is partially inherited from the time when sequencing multiple individuals was prohibitively expensive, but also reflects the computational complexity of existing algorithms, and the lack of data structures to handle multiple genomes. In the light of low cost sequencing, it is worthwhile revisiting the potential benefits of assembly in a population context. We have previously demonstrated that it is possible to incorporate the sequence data of up to ten human individuals in a single data structure (a de Bruijn graph) in which variants and paralogs produce similar motifs. We have also shown that using a probabilistic model based on the graph, it is possible to calculate genotype likelihoods even for variants that create highly complex and overlapping paths in the graph. We have now extended our methods in two directions. Firstly, we have made computational advances enabling joint assembly of 200 human genomes on a single large-memory (256Gb RAM) server. Secondly, we now incorporate population information into our models. We show with simulated data that using information on contig-sharing between samples allows one to to distinguish paralogs from variants, by investigating putative segregating sites and comparing likelihoods under a repeat-model and a polymorphism-model. This opens the door to integrating new constraints into genome assembly which should be informative even in circumstances when standard approaches (longer reads, longer insert libraries) struggle. For typical assemblers, contig generation is based on navigation through the graph structure of a single individual, and mistakes can occur when decisions need to be made at junctions. In that context, polymorphisms are not informative, but play the role of errors. However if one examines an individual in their population context, LD between SNPs on either side of a junction should allow the assembler to distinguish between local sequence and distant paralogs. Beyond this, more sophisticated incorporation of LD and haplotype structure promise even greater ability to resolve allelic structure. We will discuss quantitative aspects of the benefit of incorporating population information into personal genome assembly.

Functional consequences of human genetic variant covariance. *M. Kaganovich, M. Snyder.* Genetics, Stanford University , Palo Alto, CA.

Much effort is currently being expended to document human genetic variation. As DNA sequencing technology continues to advance, an ever-increasing amount of genetic variation will be documented. We investigate whole genome sequencing data from the 1000 Genomes Project, and other sequencing efforts, to better understand covariance of rare variants. The ongoing advances in “phasing” (i.e. the identification of haplotypes; variants stringed together on the same chromosome), make it possible to calculate the frequency of correlation among many of the millions of variants identified so far. We utilized this to identify highly correlated or highly anti-correlated variants, which we term complements and substitutes, respectively. Substitutes are compensatory in relation to each other, whereas complements may work in concert as a compensatory allele relative to alternative alleles. To better understand the functional consequences of complement and substitute variants we intersected them with existing genomic annotation data. We found evidence of predicted Transcription Factor binding site loss, appearance, and turnover. Understanding the covariance matrix of human genetics is key to identifying the basis vectors of the space, which in turn is necessary for performing dimension reduction that is required to interpret phenotype-genotype association experiments. The presence of correlated predictor variables in regression analysis diminishes the contribution of any one predictor in determining the response. Hence, the recalculation and analysis of the covariance matrix of continuously updated publicly available phased genomic sequence variation is essential for understanding the relationship of genotype to phenotype. Our work provides a new approach for categorizing compensatory and non-compensatory mutation by calculating genomic covariance.

Using LifeScope™ software through cloud computing to analyze targeted resequencing enrichment data. *D. Leon.* Biological Information Systems, Life Technologies, Foster City, CA.

Investigators who use second generation sequencing technologies for their research often need to analyze millions of sequence reads, which requires huge computing capabilities. Hence, purchasing powerful compute clusters and hiring additional system administrators can be costly for a small laboratory. An alternative for researchers who do not want to implement a computational infrastructure for their data analysis needs is cloud computing. To demonstrate the practical and reliable workflow of using cloud computing, we investigated the transferring and loading of data into a cloud environment, used the mapping and data analysis workflows of LifeScope™ Genomic Analysis Software and reviewed the final results for biologically relevant information. The targeted resequencing data from a human genomic sample that were analyzed contained 2.8 Million reads where each was 50 bases in length. The complete targeted resequencing workflow included pre-processing with SAET to improve mapping, mapping the sequencing reads to the human genome (Hg18 assembly), performing SNP calling (with the DiBayes algorithm), comparing against dbSNP with the targeted regions, and using annotation to identify genes associated with these SNPs. The mapping and the additional analyses required a processing time of less than 24 hours. Statistics were generated from the BAM file, and information about the target enrichment was reported through the graphical user interface. Heterozygous and homozygous SNPs were reported and were automatically correlated to known gene regions in the human genome. Analyzing this targeted resequencing data showed that using cloud computing for next generation sequence data analysis is a viable, reliable and efficient approach for focused, research projects. In terms of end-user experience, it was concluded that the cloud option was similar to running an on-site compute cluster.

Common SNPs in Expression Microarray Probes Impact eQTL Studies. *C. Liu[1], C. Zhang[1], K. Zhang[2], c. Chen[1], E. Gamazon[3], X. Zhang[3], J.A. Badner[2].* 1) Dept of Psychiatry, Univ of Illinois at Chicago, Chicago, IL; 2) Dept of Psychiatry, Univ of Chicago, Chicago, IL; 3) Dept of Medicine, Univ of Chicago, Chicago, IL.

The hybridization of expression microarray probes to their targets can be affected by genetic variants within these probes, particularly single nucleotide polymorphisms (SNPs). Therefore, gene expression data produced by oligonucleotide microarrays with SNP-containing probes could be inaccurate. Previous reports that the Affymetrix Human Exon Array contained many SNPs did not differentiate between common and rare SNPs, and the impact of SNP-containing probes on analysis of expression quantitative trait locus (eQTL) is unknown. Using the latest HapMap and 1000 Genomes Project data, we evaluated common SNPs of three major populations (of European, Asian and African ancestry) in the three most recent Affymetrix expression arrays (Human Gene 1.0 ST, Human Exon 1.0 ST and Human Genome U133 Plus 2.0) and two Illumina BeadArrays (Human RefSeq-8 and HumanHT-12). We found that all five arrays had a small proportion of probes containing common SNPs. These probes are scattered across up to 50% of the transcripts that Affymetrix arrays target and up to 8% of genes that the Illumina arrays target. We further examined the effects of SNP-containing probes on eQTL results using two sets of Human Gene 1.0 ST data. Removal of SNP-containing probes reduced the numbers of eQTLs by 3-6% for transcript-level analysis and 20-64% for exon-level analysis. Therefore, removal of SNP-containing probes is a more critical step for exon-level eQTL analysis. To facilitate SNP-free microarray expression analysis, lists of affected probes in the five microarrays/Beadarrays and associated library files are provided at our website: http://bioprogramming.bsd.uchicago.edu/SNPsInProbes.jsp.

dbNSFP 1.1: An integrated database of human non-synonymous substitutions and their functional predictions. *X. Liu, X. Jian, E. Boerwinkle.* Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, Texas.

dbNSFP (database for non-synonymous SNPs' functional predictions) is an integrated database of functional predictions from multiple algorithms for the comprehensive collection of human non-synonymous SNPs (nsSNPs). It compiles predictions and scores from four new and popular algorithms (SIFT, Polyphen2, LRT and MutationTaster), along with a conservation score (PhyloP) and other related information, for every potential nsSNP in the human genome (a total of 75,931,005). Functional prediction (of being deleterious) for nsSNPs plays an important role in exome sequencing based study of human diseases, especially rare Mendelian diseases. The main purpose of this database is to facilitate the tedious and time consuming process of querying predictions from different databases/web-servers for different prediction algorithms.

For each nsSNP, the original dbNSFP has entries of genomic coordinates based on human reference hg18 and hg19, gene name, gene Entrez ID, CCDS ID, reference codon, variant position on the codon (1, 2 or 3), degenerate type (0, 2 or 3), AA position as to the protein, coding sequence (CDS) strand, and estimated nonsynonymous-to-synonymous-rate ratio. Version 1.1 added the following entries: rs numbers from UniSNP (a cleaned version of dbSNP build 129), allele frequency recorded in dbSNP, allele frequency reported by 1000 Genomes Project, alternative gene names, descriptive gene name, and database cross references (gene IDs of HGNC, MIM, Ensembl and HPRD). This will further accelerate the filtering/prioritizing nsSNPs based on their novelty or allele frequencies as well as gene information. dbNSFP along with a companion search program written in Java is freely available for download at http://sites.google.com/site/jpopgen/dbNSFP.

Novel Adipose and Blood Transcriptomic Signatures of Evoked Inflammation in a Healthy Human Subject. *Y. Liu[1], J.F. Ferguson[2], B. Keating[3], Yi. Guo[3,4], B.D. Gregory[5], D.J. Rader[2], M. Li[1], M.P. Reilly[2].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA; 2) Cardivascular Institute, University of Pennsylvania, Philadelphia, PA; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Beijing Genomics Institute, Shenzhen, China; 5) Department of Biology, University of Pennsylvania, Philadelphia, PA.

Chronic activation of innate immunity and insulin resistance are major pathogenic pathways in diet-induced obesity, type 2 diabetes and atherosclerotic cardiovascular disease. Inappropriate inflammatory response to diet and lifestyle factors in genetically prone individuals may contribute to disease initiation and clinical complications. However, little is known for the modulation of the transcriptome by inflammatory atherogenic stress in disease relevant human tissues. Here we utilize a low dose endotoxemia model (LPS) to study inflammatory metabolic and atherogenic perturbations in human adipose and blood tissues. We applied RNA sequencing to a Caucasian female individual to identify novel adipose and blood transcriptomic signatures that may be directly relevant to human cardiometabolic diseases. On average, we generated ~10 million 75 bp paired-end reads for each of the four RNA-Seq samples (adipose and blood, before and after LPS). We aligned and processed sequence reads using programs Tophat, SAMTOOLs and Cufflinks, and then searched for tissue specific and LPS induced transcriptomic variations. First, we tested for differential expression before and after LPS and found 1,857 and 1,389 transcripts are differentially expressed at 5% FDR level in adipose and blood tissues following LPS. Second, we searched for transcripts with exon specific differential expression before/after LPS or between adipose and blood tissues to detect LPS induced or tissue specific alternative splicing. We recovered PRKAG, a gene that is well-known to be related to cardiometabolic diseases, to show LPS induced alternative splicing in adipose. Third, we identified potentially novel transcripts and segments that overlap with known non-coding RNA (ncRNA), including NEAT1 (suppressed by LPS in blood), MIR374AHG (induced by LPS in adipose) and PPP4R1L (induced by LPS in blood). We are currently undertaking wet-lab experiment to validate our findings. Our results show that RNA-Seq combined with human experimental models is a powerful tool for novel transcriptomic variation discovery of specific relevance to inflammatory and cardiometabolic diseases.

Multifactorial differential expression analysis to account for technical and biological variability in RNA-Seq and digital gene expression data. *D. McCarthy[1], Y. Chen[1,2], E.J.C. de Geus[4], D.I. Boomsma[4], B.W.J.H. Penninx[5], G.B. van Ommen[3], P.A.C. `t Hoen[3], G.K. Smyth[1,2].* 1) Bioinformatics Division, Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 2) The University of Melbourne, Melbourne, Australia; 3) Center for Human and Clinical Genetics and Leiden Genome Technology Center, Leiden University Medical Center, Leiden, Netherlands; 4) Department of Biological Psychology, Netherlands Twin Registry, VU University, Amsterdam, Netherlands;; 5) Department of Psychiatry, Netherlands Study of Depression and Anxiety, VU University Medical Center, Amsterdam, Netherlands.

As the cost of sequencing continues to decrease, larger and more complex sequencing-based gene expression profiling studies become feasible. For many applications, on large and small scales, multifactorial experimental designs are desirable - from studying interactions between multiple treatments to accounting for batch effects. RNA-Seq and digital gene expression (DGE) data exhibit both technical and biological variability. Models for differential expression must account for biological variability and thus the negative binomial distribution has proven successful as a count-based model for differential expression (DE). Previous efforts have focused on two-group comparisons, inappropriate for analyzing multifactorial experiments.

To analyze general multifactorial experimental designs we implemented negative binomial generalized linear models (GLMs) in the R/Bioconductor package edgeR. Using Cox-Reid adjusted profile likelihood approaches, we obtain accurate estimates of the biological coefficient of variation (BCV), even in small samples. Our model separates technical from biological variation in the data. Inspired by empirical Bayes approaches to microarray analysis we share information between genes to improve inference, with smoothed genewise BCV values providing a flexible model for DE. Likelihood ratio tests are used to identify DE genes.

We applied our methods to a large deepSAGE study (94 samples) aimed at identifying possible risk factors for type II diabetes. We were interested to find differences in gene expression between individuals with high and low fasting glucose levels. Distinct sources of variation in the data included sizable biological variability between samples, confounders such as gender and body mass index, and batch effects revealed by novel visualization techniques. Whereas existing analytical tools would be inadequate, our versatile and efficient framework allowed us to account for these sources of variability and enabled a robust DE analysis.

Taking into account technical and biological variability, the edgeR software represents a powerful and flexible modular pipeline for multifactorial statistical analysis of small- and large-scale comparative RNA-Seq and DGE experiments.

Effective Detection of Rare Variants in Pooled DNA Samples using Cross-Pool Tailcurve Analysis. *T. Niranjan[1], A. Adamczyk[1], H. Bravo[2,3], M. Taub[2], S. Wheelan[2,4], R. Irizarry[2], T. Wang[1,5].* 1) The Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Biostatistics, Bloomberg School of Public Health, The Johns Hopkins University, Baltimore, MD; 3) Center for Bioinformatics and Computational Biology, Department of Computer Science, University of Maryland, College Park, MD; 4) Department of Oncology, The Johns Hopkins University School of Medicine, Baltimore, MD; 5) Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, MD.

Rare genetic variants of large effect may confer a substantial genetic risk to common diseases and complex traits. There is a considerable interest in sequencing limited genomic regions such as candidate genes and target regions identified by genetic linkage and/or association studies. Next-generation sequencing of pooled DNA samples is an efficient way to identify rare variants in large sample sets. While sample pooling can reduce labor and costs for sequencing, it also reduces the sensitivity and specificity for effective and reliable identification of rare variants. It remains a challenge to solve these problems using currently available computational genomics tools. We developed an effective Illumina-based sequencing strategy using pooled samples and have optimized a novel base-calling algorithm (SRFIM) and variant-calling algorithm, SERVIC^{4}E (Sensitive Rare Variant Identification by Cross-pool, Cluster, Continuity & Tail-Curve Evaluation). SERVIC^{4}E analyzes base composition by cycle (tail-curves) across sample pools and employs multiple filtering strategies, including quality and continuity cluster analysis, average quality filtering, tail-curve filtering, and proximity filtering to accurately identify rare sequence variants. We validated this algorithm using different pool sizes, sequence read lengths, and sequencing chemistries. In one large sample cohort (n=480), we successfully identified 32 coding variants including 14 rare variants across 24 exons present only once. Validation of these variants by Sanger sequencing revealed an excellent detection sensitivity (96.6%) and specificity (92.8%). These algorithms are compared favorably with currently available sequence analysis programs including SAMTools, SNPSeeker, and CRISP for a reliable detection of rare variants in pooled samples.

Transcriptome and epigenome analysis in pancreatic cancer. *H. Parikh[1], J. Jia[1], W. Xiao[2], X. Liu[2,3], I. Collins[1], G. Petersen[4], J. Powell[2], S. Thorgeirsson[5], L. Amundadottir[1].* 1) Laboratory of Translational Genomics, Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD 20877, USA; 2) Bioinformatics and Molecular Analysis Section, Division of Computational Bioscience, Center for Information Technology, National Institutes of Health, Bethesda, MD 20892, USA; 3) SRA International, Fairfax, VA 22033, USA; 4) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; 5) Laboratory of Experimental Carcinogenesis, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD 20892, USA.

Although pancreatic cancer is the tenth most commonly diagnosed cancer in the U.S., it is the fourth most common cause of cancer mortality with close to 37,000 deaths per year in the U.S. To enhance our understanding of the pancreatic cancer genome we catalogued functional elements and transcribed regions in cell lines derived from normal and neoplastic pancreatic tissues by next generation sequencing analysis. We conducted high-throughput genome-wide transcriptome sequencing (mRNA-seq and miRNA-Seq) for two human cell lines derived from normal pancreatic tissues (hTERT-HPNE) and pancreatic carcinoma (PANC-1). We aligned raw reads to the RefSeq, Ensembl and Human Genome (hg19 build) databases to quantify RNA abundance (using BWA and miRNAkey) and identified a total of 11,248 genes and 216 miRNAs expressed at 1 RPKM or higher in these cell lines. A total of 1,983 genes were differentially expressed at ⁄ 3-fold change (and a FDR < 0.05) in the PANC-1 as compared to the hTERT-HPNE cells. Of these, 971 were expressed at higher levels in PANC-1 cells and 1,012 at lower levels. In addition, we identified 131 miRNAs with increased and 35 miRNAs with decreased expression in the PANC-1 compared to hTERT-HPNE cells. KEGG Pathway enrichment analysis of the differentially expressed genes in the normal vs. cancer derived cell lines identified the following enriched pathways: pathways in cancer, focal adhesion, cell adhesion and Wnt signaling. Moreover, we performed chromatin immunoprecipitation (ChIP) combined with ultra high-throughput sequencing (ChIP-seq) experiments for mono- and tri-methylation of histone H3 at lysine 4 (H3K4me1 and H3K4me3), tri-methylation of histone H3 at lysine 27 (H3K27me3) and RNA polymerase II (Pol II) using chromatin prepared from the same cell lines. The highest density of reads surrounding the TSS for H3K4me1 and H3K4me3 were seen in highly expressed genes and lower levels were seen in genes expressed at medium or low levels. The opposite was seen for H3K27me3 where the highest number of reads was seen at genes expressed at low levels or not at all .Our genome wide transcriptome and epigenome profiling of pancreatic cell lines facilitates integrative analysis of the pancreatic cancer genome and provides understanding of the regulatory mechanisms, genes and pathways involved in this disease.

Phenome-Wide Association Study (PheWAS) for Exploration of Novel Genotype-Phenotype Associations and Pleiotropy using MetaboChip in the PAGE Network. *S. Pendergrass[1,2], E.S. Torstenson[1], J.L. Ambite[3], C.L. Avery[4], C. Cai[3], M.D. Fesinmeyer[6], C. Haiman[7], G. Heiss[4], L.A. Hindorff[8], C.-N. Hsu[3], C. Kooperberg[6], L. Le Marchand[9], Y. Lin[6], T.C. Matise[11], K. Monroe[7], K.E. North[4,5], L.R. Wilkens[9], S. Buyske[10,11], D.C. Crawford[1,2], M.D. Ritchie[1,2].* 1) CHGR, Vanderbilt University, Nashville, TN, USA; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville TN, USA; 3) Information Sciences Institute; University of Southern California, Marina del Rey, CA, USA; 4) Department of Epidemiology, University of North Carolina, Chapel Hill, NC, USA; 5) Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC, USA; 6) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, USA; 7) Department of Preventive Medicine, Keck School of Medicine, University of Southern California/Norris Comprehensive Cancer Center, Los Angeles, CA, USA; 8) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD USA; 9) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI, USA; 10) Department of Statistics, Rutgers University, Piscataway, NJ, USA; 11) Department of Genetics, Rutgers University, Piscataway, NJ, USA.

A novel approach has emerged that combines both the exploration of phenotypic structure and genotypic variation, known as a phenome-wide association study (PheWAS). The Population Architecture using Genomics and Epidemiology (PAGE) network is a collection of diverse, population-based studies with a wealth of phenotypic and genotypic data for characterization and discovery, ideal for pursuing PheWAS. We describe here two initial results of a PAGE PheWAS utilizing the MetaboChip custom genotyping array and PAGE phenotypic data. The MetaboChip contains single nucleotide polymorphisms (SNPs) identified in genome-wide association studies up to 2009 (33.2% of the SNPs on the array) as well as fine mapping SNPs for select metabolic GWAS-identified variants (62.2%) drawn from multiple ethnic groups and the 1000 Genomes Project. Thus far, three groups of the PAGE network, Atherosclerosis Risk in Communities (ARIC), Multiethnic Cohort (MEC), and the Women's Health Initiative (WHI) have genotyped a total of 6,359 African-American individuals with the MetaboChip. The numbers of phenotypes available varied by study: 88 in ARIC, 26 in MEC, and 116 in WHI. After genotyping quality control, tests of association using linear/logistic regression assuming an additive genetic model were performed for all phenotypes and all SNPs on the MetaboChip (161,098 SNPs). All models were adjusted for the first two principal components of ancestry, associations not stratified by gender were adjusted for sex. An example of a potentially novel association identified in our study is the association between fibrin D-dimer and rs79266590 (p=5.10E-13) and rs74022438 (p=4.24E-12), within ARIC for the women only analysis with a sample size of 486. Fibrin D-dimer is typically used to diagnose conditions such as deep vein thrombosis. These two SNPs are in regions near an index SNP previously associated with HDL levels in European descent populations, and rs79266590 is in a proposed regulatory region. Future efforts include expanding this PheWAS to include PAGE populations of different ancestry and incorporation of additional phenotypes. A PheWAS utilizing the unique MetaboChip data has the potential to elucidate a more comprehensive picture of the associations between phenotype and genotype, help discover novel relationships between SNPs, phenotypes, and networks of interrelated phenotypes; identify pleiotropy; provide novel mechanistic insights; and foster hypothesis generation.

Validation and Comparison of Variant Calling Pipelines for Next Generation Sequence. *M. Pirooznia[1], F. Goes[1], J. Parla[2], I. Iossifov[2], R. McCombie[2], J. Potash[1], P. Zandi[3].* 1) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, Baltimore, MD, USA; 2) Cold Spring Harbor, Woodbury, NY, USA; 3) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA.

Background: The processing and analysis of the enormous amounts of data generated by Next-generation sequencing (NGS) experiments is challenging and is a burgeoning area of new methods development. Several new bioinformatics tools have been developed for calling variants from NGS data. Here, we validate the variant calling of these tools and compare their relative accuracy to determine which data processing pipeline is optimal. Methods: We developed an efficient pipeline which connects all necessary analysis steps into a unified application to address different tasks in the processing of NGS data. The pipeline uses BWA for mapping sequence reads and then incorporates two parallel approaches for further data processing and calling variants for downstream analyses. One approach uses SAMTools for duplicate removal and calling variants, while the other approach uses PICARD and GATK for duplicate removal, re-aligning reads around indels, re-calibrating quality scores and then calling variants. We processed NGS data generated on 30 bipolar subjects from an on-going whole exome sequencing project using both approaches built into our pipeline. We compared the variant calls between the two approaches and against gold-standard Sanger sequencing of 400 strategically selected variants. Results: The cleaned reads were mapped to the targeted exome sequence of human genome obtaining mean coverage of 97% at 1X, 91% at 10X and 62% at 40X coverage. Using SAMTools, a total of 12,859 variants per subject were identified, including 1,044 novel variants, of which 16 were nonsense and 634 were missense. Using GATK, a total of 13,796 variants were identified, including 1,120 novel variants, of which 17 were nonsense and 680 were missense. A total of 12,700 variants (91%) were called in common between the two approaches, while 159 (1.2%) were called unique to SAMTools and 1096 (7.8%) were called unique to GATK. We selected 400 variants that were called in common and uniquely to the two approaches and validated these in the same subjects using Sanger sequencing. The results of this validation will be reported. Conclusions: We have built a pipeline that incorporates multiple approaches for processing NGS data and calling sequence variants. We compared the results of the variant calls between two commonly used approaches, and against “gold standard” sequencing. The findings will help to determine the best approach to confidently call variants for downstream analyses.

An integrative genomics approach to detect and classify unusual patterns in glioblastoma multiforme. *C. Rangel-Escareño, K. Baca-Lopez, MD. Correa-Rodriguez, R. Flores-Espinosa, R. Garcia-Herrera, CI. Hernandez-Armenta, E. Hernandez-Lemus, A. Hidalgo-Miranda, AJ. Huerta-Verde, I. Imaz-Rosshandler, AV. Mart'inez-Rubio, A. Medina-Escareno, R. Mendoza-Smith, M. Rodriguez-Dorantes, I. Salido-Guadarrama.* INMEGEN, Mexico City, Mexico.

Computational tools and mathematical algorithms to integrate, organize and mine the wealth of information generated from modern high-throughput genomic technologies are constantly created. A 3-state model for multidimensional data integration, which is a data driven approach that not only captures the usual and meaningful hypotheses in cancer biology but also a set of unusual scenarios that could lead to new discoveries is presented. TCGA Glioblastoma multiforme data classified into 4 levels based on the degree of processing were used for this study. A multidimensional integration of 5-Technology platforms (*mRNA,methylation,miRNAs,S.Mutations*, and *CNVs*) as well as clinical data generated genes for our analysis. The N-platform integrative analysis is based on a 3-state model applied to statistically significant genes from each platform. Each state can take values in {-1,0,1} interpreted as {Down,NoChange,Up}. A list of all possible scenarios is generated through a combinatorial approach where each scenario has as many states as platforms are integrated. This list represents the universe of hypotheses that may describe structural variations in the genome as well as transcription activity in coding and non-coding regions. Hypotheses can be chosen for their biological relevance or for their quantitative importance **Results:** Single platform analysis matched results reported in the literature. A 3-platform analysis {Som.Mut, DNAmethylation, mRNA} resulted in 16 possible scenarios. We focused on scenarios with interactions that cannot be easily explained from a biological perspective such as {0,1,1} the case of a 30-gene set with a particular pattern of promoter hypermethylation and over-expression with no mutations present. Mapping those genes to CNVs and miRNA targeting genes showed significant correlation of over-expression with CNV amplification, emerging as a possible explanation for the overexpression seen even in the context of promoter hypermetylation. No miRNAs active for them. Some genes for which no CNV was detected were targeted by differentially expressed miRNAs suggesting a kind of regulation of gene expression mainly directed by miRNAs. More complex scenarios arise from this analysis, like the one in which deletions are detected, yet genes are upregulated and hypermethylated. Nevertheless, this small set of genes though possible false positives should help to define a better threshold for differential expression improving classification accuracy.

Robust statistical methods for genome-wide eQTL analysis. *M. Rantalainen[1,2], C. Holmes[1,3].* 1) Department of Statistics, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) MRC Mammalian Genetics Unit, MRC Harwell, Harwell, OX11 0RD, United Kingdom.

Expression Quantitative Trait Loci (eQTL) analysis enable characterization of how common genetic variants influence the expression of individual genes. EQTLs are commonly analysed using a linear regression model including relevant covariates, an additive genetic effect and assuming a Gaussian error term. However, Gaussianity may not hold in noisy biological data (e.g. gene expression), which may be more heavy-tailed or have outliers present. Such departures from model assumptions may result in an increased rate of both type I and type II errors. Careful model checking can reduce the risk of spurious findings, however, this may be prohibitively expensive in in the case of genome-wide eQTL analysis with a high number of models. Therefore, robust statistical methods, which are less sensitive to departures from assumption of Gaussianity and presence of outliers, provide an attractive alternative for eQTL analysis. In this study we compare eQTL results between the conventional linear model and a robust alternative (M-estimator) in two publicly available eQTL data sets and in a simulation study in respect to bias in estimates, concordance of hypothesis test results and statistical power. Our results indicate that robust statistical models provide more reliable eQTL results over conventional linear models with reduced number of both type I and type II errors. This suggests that unless careful model checking can be carried out on each evaluated model, robust alternatives provide a valuable alternative to conventional linear models in genome-wide eQTL analysis.

Meta-analysis of multiple expression quantitative trait locus (eQTL) datasets results in large gains in regulatory variant identification. *A.J. Rogers[1,3], J. Lasky-Su[1,3], B.E Himes[1,3], T. Raj[2,3], N. Morar[4], M.F. Moffatt[4], V.J. Carey[1,3], B. Stranger[2,3], L. Liang[5], B.A. Raby[1,3].* 1) Channing Laboratory, Brigham & Women's Hospital; 2) Department of Genetics and Genomics; 3) Harvard Medical School, Boston MA; 4) National Heart and Lung Institute, Imperial College London, London, UK; 5) Departments of Epidemiology and Biostatistics, Harvard School of Public Health, Boston, MA.

Rationale: Whole genome association studies for gene expression quantitative trait locus (eQTL) mapping have identified genetic variants related to thousands of genes on the genome, but a complete genetic map for most genes remains far from clear, especially for trans effect with modest effect size. Meta-analytic approaches offer an opportunity to identify additional important regulatory variants from existing data.

Methods: We performed an eQTL meta-analysis of 3 Caucasian datasets: expression profiles derived from lymphoblastoid cell lines (LCLs) from CEU founders from HapMap (N=110), LCL from 550 siblings identified from a asthma proband (MRCE), and primary peripheral blood CD4+ lymphocytes from 200 asthmatics in the Childhood Asthma Management Program (CAMP). With MaCH, we imputed SNP genotypes for ~8 million SNP using 1000 Genomes Project data. EQTL testing was performed for a subset of 8080 genes that were represented on both the Illumina Human Ref8-v1 and v2 arrays. Expression data was adjusted for PCA-derived eigenvectors to diminish the influence of non-genetic technical biases. For each population, regression models were adjusted for population stratification using Eigenstrat when appropriate. We then tested for eQTLs by combining $\chi 2$ statistics across all 3 populations and account for multiple testing using FDR < 1%.

Results: Meta-analysis resulted in substantial gains in the regulatory variants identified. In the individual cohorts, we identified cis eQTLs for 67 to 2981 genes within 50kb (at an FDR cut-off of 1% estimated within each dataset). In contrast, by combining eQTL measurements over 3 populations, we found cis-eQTL for 3969 unique genes (nearly 50% of the 8080 genes tested). eQTLs for 1419 genes were shared between CD4 and LCL, 378 are seen only in meta-analysis, and 2127 (53%) appear to be tissue specific, with 1307 in CD4 only, 865 in LCL.

Conclusion: eQTL analyses are increasingly recognized as a way of identifying important intermediate phenotypes in disease pathogenesis. We demonstrate a novel methodology of efficiently combining data across multiple populations to improve power to identify associations. These tools will be available as a Bioconductor package.

A visualization platform for interpretation of structural genomic data. *T. Sante, S. Vergult, B. Menten.* Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

Working with next generation sequencing technology such as mate-pair sequencing, is a challenge. These new high-throughput sequencing techniques allow the detection of large and small CNVs, inversions, translocations and complex rearrangements at unprecedented resolutions. The growth in data size is accelerating greatly as the sequencing technology is becoming the tool of the future in genetic diagnostics and research, generating an ever increasing amount of sequence reads. The ability to visualize this data, to aid analysis, is a challenging but essential problem. We present a visualization platform which tackles that problem by developing a graphic web interface that allows the researcher to visually explore genomic microarray data and mate-paired data, and turn abstract data files into useful information. The platform provides a genome browser to inspect the copy number profile, supporting both CNV information from genomic microarrays, sequencing depth of coverage data and MatePair/PairedEnd-data. The browser uses a zoomable sliding window to explore the data at different resolution levels, and allows easy comparison of multiple samples. A circular view is available to facilitate comprehension of intra- and interchromosomal translocations. Experimental data can be complimented with a multitude of annotation tracks, to guide the interpretation. Segmental duplications and human chained self-alignments provide information on genomic architecture, RefSeq genes track place the data in its local genetic context, OMIM morbid/gene-map and database of genomic variants track provide a biological/clinical context. The custom tracks can be used to compare individual results with existing data collections of experiments to find correlations in your internal datasets. The platform employs the latest web technologies so it can be used in any modern web browser. The visualizations use the scalable vector graphics format for optimal image quality. Selected regions of interest can be downloaded as SVG or PNG files. The platform supports genomic microarrays (Agilent, Affymetrix, Illumina, Nimblen) and MatePair/PairedEnd sequencing experiment data (BAM/SAM, read clusters) input. Our experiences as a medical genetics center, enabled us to deliver a comprehensive visualization platform for genomic microarray experiments complemented with MatePair/PairedEnd sequencing data, and can be of great value in the toolbox of any investigator, research or clinical diagnostics.

Twins, tissue and time: A comparison of genomic inference across monozygotic twins, DNA sources and longitudinal samples. *P. Scheet[1], E.A. Ehli[2,3], X. Xiao[1], A. Abdellaoui[4], R.R. Althoff[5], J.J. Hottenga[4], K.A. Nelson[2], P. Huizenga[2], Y. Hu[2], M. Bartels[4], M.M. Goen-Blokhis[4], E. de Geus[4], J. Hudziak[5], G.E. Davies[2,3], D.I. Boomsma[4].* 1) Dept. of Epidemiology, University of Texas M. D. Anderson Cancer Ctr, Houston, TX; 2) Avera Institute for Human Behavioral Genetics, Avera McKennan Hospital and University Health Center, Sioux Falls, SD; 3) Dept. of Psychiatry, University of South Dakota, Sanford School of Medicine, Division of Basic Biomedical Sciences, Sioux Falls, SD; 4) Dept. of Biological Psychology, Vrije Universieit, Amsterdam, The Netherlands; 5) Dept. of Psychiatry, University of Vermont College of Medicine, Burlington, VT.

With the desire to assess genetic variation with conveniently-obtained biological sources in large scale collaborative projects, one question is whether inference of copy number (CN) is overly sensitive to the source of material for DNA analysis (e.g. blood, buccal) or whether CN is stable over time. Here, we address these questions by analyzing data from the Affymetrix SNP 6.0 microarray applied to multiple samples from 705 individuals of the Netherlands Twin Register. We applied Birdsuite v.2 to make genome-wide CN calls, then assessed CN (and genotype) correspondence. To assess biological source consistency, we compared results from blood and buccal derived DNA in 371 individuals, including 43 monozygotic (MZ) twins. For each pair of samples, we calculated the square of the Pearson correlation coefficient (R^2), which is sensitive to deviations in CN calls in the presence of the large number of copy-neutral calls made across each individual. We found no greater discordance in CN or genotype inference between samples from different sources (blood, buccal) than within (e.g. both samples from blood). We also evaluated evidence of a temporal effect in 389 individuals that were sampled at 2 time points (over 1-12 years), and found no trend; ie. replicates collected 7 or 8 years apart were no more different than were samples collected at 2-year intervals. Copy number estimates between MZ twins are highly consistent for both deletions (R^2 _ 90%) and duplications (R^2 _ 86%), mirroring results from within-individual duplicate samples. We also assessed SNP genotype concordance between MZ twins and sample duplicates and found these to be highly consistent, (R^2 > 99%). Our experiment suggests that buccal-derived DNA is suitable for the current generation of microarray technologies, facilitating greater participation in genetic studies in a cost-effective manner.

The Importance of Variation Databases in Interpretation of Exome Sequencing. *T.E. Scheetz[1,2], A.P. DeLuca[2], T.A. Braun[1,2], L.M. Streb[1], L.M. Affatigato[1], V.C. Sheffield[1,3,4], E.M. Stone[1,4].* 1) Dept Ophthalmology, Univ Iowa, Iowa City, IA; 2) Dept Biomedical Engineering, Univ Iowa, Iowa City, IA; 3) Dept Pediatrics, Univ Iowa, Iowa City, IA; 4) Howard Hughes Medical Institute, Iowa City, IA.

Determining which of the thousands of variations identified in exome sequencing projects represent the bona fide disease-causing mutations is a challenging process. Experiment design can aid in refining this list of variations by exploiting population structure (e.g. consanguinity) or familial segregation. However, experiment design alone cannot refine the set of variations to the disease-causing mutation(s). To supplement such designs, we have developed an analysis pipeline to exclude from consideration those variations that are inconsistent with ability to cause the disease. Disease prevalence can be used to place an upper limit on the minor allele frequency of a disease causing variation. For an autosomal recessive disease with a prevalence of 1:1000, any variant present at greater than 1% frequency is incompatible with a Mendelian cause of the disease. If the disease under investigation is genetically heterogeneous, the critical allele frequency would be even lower. This practice is critical, as many disease-causing variations are present in dbSNP - making exclusion of all dbSNP variations inappropriate. Multiple exomes were sequenced as part a disease gene identification project. Analysis of these exomes using BWA and GATK identified approximately 20,000 variations per sample. We sequentially applied multiple variations sets, to remove variations observed at population frequencies incompatible with Mendelian disease. These variation sets included dbSNP as well as sets derived from previous exome capture datasets (1000 genomes, LuCamp) that we reprocessed locally to avoid bias due to differing analysis pipelines. The reduction in the number of variations is dramatic, but does exhibit diminishing returns as additional filters are applied. The removal of incompatible variants based upon dbSNP, 1000 genomes and LuCamp reduced the average number of compatible variants from 20,000 to 3,000. Interestingly, each data set contributed substantially to the process, with a shared core of common SNPs shared in all three resources, as well as hundreds of novel SNPs in each. A further comparison to exomes sequenced locally was also performed, resulting in a final set of 2,000 variations. In conclusion, a combination of intelligent experimental design, identification of SNPs compatible with the disease model, and variation prioritization methods are required to make full use of exome and genome scale data.

Comprehensive genomic analysis of tandemly repeated genes. *A. Sharp, M. Brahmachary, A. Guilmatre, C. Borel, F. Cheung, P. Warburton.* Genetics & Genomics Sci, Mount Sinai Sch Med, New York, NY.

Tandem repeats (TRs) represent a highly variable fraction of the human genome, but due to their multi-copy nature are poorly assayed by most genome-wide technologies. The human genome contains many entire genes that occur in highly polymorphic tandem arrays, and CNV of several TR genes, such as) -*defensin*, *CCL3L1* and salivary amylase, has already been implicated in human phenotypes. We identified 180 true multicopy genes by performing a self-join operation using Refseq to identify genes with >1 copy at a non-overlapping position on the same chromosome. We designed a custom Nanostring probeset to perform digital genotyping of copy number for these 180 genes, and 12 non-coding large tandem repeats, in 165 HapMap individuals and 5 primate species. We observed extreme variability in copy number of TR genes: 66% showed CNV in the HapMap, with many genes showing 5-10 fold variation in copy number between different individuals. In the most extreme case we observed 100-250 copies of *REXO1L2P* in humans, and >900 copies in Gorilla. However, this gene is only present in 4 copies in hg18. Comparison of TR copy number with flanking SNPs showed that the vast majority of TR genes show little or low LD with nearby SNPs, and are therefore invisible to standard GWAS approaches. We also identified 51 genes whose expression levels correlated with the size of nearby TRs. In several cases we observed an inverse correlation between TR size and the expression level of adjacent genes. We hypothesize that this represents an epigenetic mechanism termed repeat-induced silencing in which expanded TRs become heterochromatic, repressing flanking genes. Consistent with this we observed highly variable DNA methylation at these TRs. We also observe multiple signatures of rapid evolution in TR genes, suggesting important biological function, including i) highly divergent copy numbers between different ethnicities; ii) extreme evolutionary changes in copy number, with many TR genes showing >3-fold change in copy number versus other primate species, and iii) a significant excess of non-synonymous amino-acid changes in recent primate evolution compared to single copy genes. We conclude that TR genes represent a highly variable and biologically important fraction of the genome. We hypothesize that TR genes will be highly enriched for phenotypic effects, potentially explaining some of the `missing heritability' of the genome. Our studies provide many novel insights into the biology of TRs.

Extensive evolutionary changes in regulatory element activity during human origins are closely associated with altered gene expression and positive selection. *Y. Shibata[1], N. Sheffield[1], O. Fedrigo[2], C.C. Babbitt[2], M.J. Wortham[1], D. London[1], L. Song[1], A.K. Tewari[1], S.C. Parker[3], E.H. Margulies[3], G.A. Wray[1,2], T.S. Furey[4,5], G.E. Crawford[1,6].* 1) Institute for Genome Sciences & Policy, Duke University, Durham, North Carolina, 27708, USA; 2) Biology Department, Duke University, Durham, USA; Institute for Genome Sciences & Policy, Duke University, Durham, USA; 3) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland 20892, USA; 4) Department of Genetics, Carolina Center for Genome Sciences, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599, USA; 5) Department of Biology, Carolina Center for Genome Sciences, and Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599, USA; 6) Department of Pediatrics, Duke University, Durham, North Carolina, 27708, USA.

Understanding the molecular basis for phenotypic differences between humans and other primates remains an outstanding challenge. Mutations in non-coding regulatory DNA that alter gene expression have been hypothesized as a key driver of these phenotypic differences. Differential gene expression analyses support this hypothesis but have failed to pinpoint specific regulatory elements responsible for changes in transcription. To identify the genetic source of these regulatory differences, we mapped DNaseI hypersensitive sites (DHS), which mark all types of active gene regulatory elements, genome-wide in the same cell type isolated from human, chimpanzee, and macaque. Most DHS sites were conserved among all three species, as expected based on their central role in regulating transcription. Strikingly, however, several hundred DHS sites were apparently gained and lost on the lineages leading to human and chimpanzee using macaque as an outgroup. Species-specific DHS site gains are enriched near differentially expressed genes and are positively correlated with transcription, consistent with the hypothesis that they have functional consequences. In addition, newly evolved DHS sites showed evidence of branch-specific positive selection, as expected of regions that have acquired novel regulatory functions. These results implicate a set of several hundred regulatory elements as contributing to the genetic basis for phenotypic differences among primate species.

835W

Limitations of the human reference genome sequence. *T. Smith[1], N. Olson[1], J. Rosenfeld[2], C. Mason[3].* 1) Geospiza ((PerkinElmer) Inc. Seattle, WA 98119, USA; 2) 2. Sackler Institute for Comparative Genomics, American Museum of Natural History, New York, NY 10024, USA; 3) Weill Cornell Medical College, New York, NY 10021, USA.

The human genome reference sequence is well characterized, highly annotated, and its development represents a considerable investment of time and money. This sequence is the foundation for genotyping microarrays and DNA sequencing analysis. Yet, in several critical aspects it remains incomplete. Further, when the reference is reexamined with data available from the 1000 Genomes Project (1Kg) and Complete Genomics (CGI) genomes, it is clear that previous assumptions, based on tools and analyses guided by a single reference, about human genomics and genetics are incorrect.

We have used the 1Kg and CGI genome datasets to evaluate the increased knowledge of human variation. By analyzing identified variants within the interrogated regions of microarray probes, we have found that about 50% of probes on commonly used arrays contain confounding variation, which impact the results of 37% of GWAS studies to date. This confounding variation includes unknown variants in close proximity to the probed variant and alleles previously assumed to be di-allelic that are poly-allelic. These data also change previous assumptions regarding linkage disequilibrium (LD) between variants, which have been used to impute variation in incomplete data. When HapMap data are compared to 1Kg data, mean LD decreases from 16.4 Kb to 7.0 Kb within common samples and decreases to 5.4 Kb when random samples are compared. While many of the observations have been anecdotally understood, quantitative assessments of resources based on the reference sequence have been lacking. These findings have implications for the study of human variation and medical genetics, and ameliorating these discrepancies will be essential for ushering in the era of personalized medicine.

We investigate various solutions to these discrepancies regarding the reference genome. Some have suggested the use of either a graphical representation of the genome to allow for variation, or for population-based reference sequences, yet neither of these approaches are sufficient to encapsulate the variation with the human population. We suggest that the for loci of clinical importance, strong effort should be undertake to determine all forms of variation and evaluate whether the current genotyping techniques produce accurate results.

***In silico* analyses of promoter regulatory targets in the iron metabolism pathway.** *N.J. Strickland, M.G. Zaahl.* Genetics, Stellenbosch University, Stellenbosch, Western Cape, South Africa.

AIM To investigate the promoter region of genes involved in the iron metabolism pathway by employing comprehensive bioinformatic analyses, in order to elucidate specific mechanisms of gene regulation. INTRODUCTION The human genome is a system regulated at many different levels. Transcriptional regulation is the first, and arguably the most important, step in the process of gene expression. This process is governed by the presence of specific *cis*-regulatory regions (*cis*-motifs) residing within the promoter region of genes and the functional interactions between the products of specific regulatory genes (transcription factors-TFs) and these *cis*-motifs. Bioinformatic tools can be utilised to formulate putative predictions on how specific *cis*-motifs may influence the expression patterns of specific genes or groups of genes (e.g. iron metabolism pathway). METHOD •Retrieve the DNA sequence of the promoter region (±2 kb) of 16 genes known to be involved in the iron metabolism pathway from the human Ensembl database. •Conserved Nucleotide Sequence (CNS) analysis of promoter regions using specific software tools (e.g. VISTA). •Computational analysis and *in silico* design of promoter models using probabilistic detection methods such as expectation maximization (MEME). •Refined analysis and identification of detected motifs analyzed using TRANSFAC and JASPAR. RESULTS The promoter sequences of nine of the 16 genes when examined were found to contain a genomic region that demonstrated over 75% sequence identity between the genes of interest. This conserved region (CNS) is approximately 140 bp in size and is common to each of the promoters of the nine genes. This finding adds strength to the hypothesis that genes with similar promoter architecture, and involved in a common pathway, may be co-regulated. Within these motifs, relevant tissue- and pathway-specific TF-binding sites were predicted to occur. Several TFs of interest were selected on the basis of their known (and previously described) functions in transcriptional regulation, tissue specificity and involvement in iron metabolism in order to assess their proposed functionality in vitro. CONCLUSION Accurate analyses of *cis*-motif architecture combined with integrative *in silico* modelling (once validated by experimental analysis) could offer insights into complex mechanisms governing transcriptional regulation, serving as a refined approach for prediction and study of regulatory targets.

The eXtensible SeQuence file format: a better standard for sequencing reads. *D. Thomas, C. Yang, M. Muller, S. Utiramerur, J. Zhang, P. Suri, A. Siddiqui.* Life Technologies, Foster City, CA.

The growth of sequencing technologies has put significant pressure on data management and analysis, reinforcing the need for standards to support workflows in genomics. The primary concerns are currently i) file size required to store large datasets, ii) access to content within large files, and iii) support for associations between data elements. We have developed the eXtensible SeQuence (XSQ) file format to address these issues and are developing tools to support its use. The space saving advantage is derived from a binary encoding scheme that uses a single byte per color or base space call. Two bits are used for the call and the remainder for storing Phred scale quality values and flags for error states. This produces up to a 75% reduction in file sizes, which benefits storage and transmission needs and improves analysis times. The XSQ file format is based on the stable Hierarchical Data Format (HDF), which provides structures and tools for storing and accessing data stored in an extensible hierarchy. The HDF platform allows metadata to be stored in the same file as the data itself, and allows multiple data vectors to be present for a given fragment. Sets of data from a single fragment, such as forward and reverse reads, can be stored in parallel datasets in separate groups so that pairing is eliminated subsequent to mapping. For a single tag, reads of multiple encodings - e.g. 2 base color encoding, 3 base color encoding, and base space encoding - can be read in parallel to support Exact Call Chemistry datasets. To drive adoption, a set of utilities - XSQ Tools - is provided to ease transition to the new format. Standalone tools have been developed i) to convert legacy data (csfasta/qual) into XSQ for analysis in new pipelines, and ii) to convert XSQ into those same formats or fastq to support in older pipelines. We are also working with other platforms to expand this format into a community standard, focusing initially on flowspace data and later to include arbitrary basespace data. File format descriptions and converters are available for download here: http://solidsoftwaretools.com/gf/project/xsq/.

Yet another pipeline for the next generation sequencing analysis. *L. Tian, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

We have designed a bioinformatics pipeline to process next generation sequencing data from (1) whole genome; (2) whole exome; (3) targeted resequencing with multiple barcoded or non-barcoded samples; (4) multi-sample low-pass whole genome; (5) RNA-Seq transcriptome. Our pipeline integrates open source programs, including Bowtie, BWA, BLAT, RUM, TopHat, SpliceMap, GATK, SNVer, ANNOVAR, VAAST, PLINKSEQ, dbNSFP, into 5 stages: (1) multi-pass aligning of NGS sequencing data to the reference genome; (2) refinement of the alignment, including indel realignment, base quality recalibration; (3) genetic variant calling, including SNV, indel, and CNV; (4) variant functional annotation; (5) variant selection and prioritization based on predicted functions, family structure, rare variant test score, expression abundance, or RNA-editing events. We describe the development of the pipeline and discuss the bioinformatics challenges posed by the NGS, including data storage, variant calling, and the application of the pipeline in several Mendelian and complex diseases projects.

The importance of reproducible research and genome geography. *L.K. Vaughan, V. Srinivasasainagendra.* Section on Statistical Genetics, Dept Biostatistics, Univ Alabama, Birmingham, Birmingham, AL.

With the advent of high throughput data technologies such as expression microarrays, SNP chips and genome wide sequencing, the volume and breadth of data available has become staggering. In addition, databases such as dbSNP, GEO (Gene Expression Omnibus), KEGG (Kyoto Encyclopedia of Genes and Genomes), GO (Gene Ontology) and Entrez Gene, which provide resources to annotate, translate and connect biological data, have grown exponentially in content. The availability of such data emphasizes the importance of bioinformatics and computational biology in genetics research and has led to the development of thousands of tools that have been (and are being) developed to integrate and utilize these databases. An important concept in bioinformatics is the idea of reproducible research, which is defined by the uniform Guidelines of the International Committee of Medical Journal Editors as the responsibility of authors to “identify the methods, apparatus and procedures in sufficient detail to allow other workers to reproduce the results”. One detail that is often neglected, and has the potential to have a serious impact, is the version of different databases used for a project. This can be particularly important when exploring genome geography, identifying SNPs in candidate genes or mapping genes to markers. Here we present a timeline for version releases of the Human Genome/NCBI, dbSNP and UCSC genome databases. We also provide selected case studies identified while 1) identifying SNPs in candidate genes and 2) mapping SNPs identified in a GWAs to genes which illustrate potential sources of error which can be introduced when non-concurrent databases are employed. We also show examples using popular bioinformatic tools of a lack of transparency where these databases are concerned. These examples include changes in gene symbols/synonyms, changing gene boundaries and inconsistent mapping across databases. Through these examples we show that resources are constantly evolving and in order to provide reproducible results, researchers should be aware of and connected to the correct version or release of the data, particularly when implementing computational tools.

840W

The NCBO Annotator and enrichment analysis with the Human Disease Ontology. *P. Whetzel, P. LePendu, R. Fergerson, M. Musen, N. Shah.* Stanford University, Stanford, CA.

Researchers have turned to the Semantic Web to annotate and integrate disparate knowledge. Ontologies provide the domain knowledge to drive these processes and the successful creation of semantic applications in the healthcare and life sciences require Web services that provide access to ontologies. The National Center for Biomedical Ontology (NCBO), one of the eight National Centers for Biomedical Computing created under the NIH Roadmap, developed BioPortal (http://bioportal.bioontology.org), which provides access to one of the largest repositories of biomedical ontologies. This ontology content is programmatically accessible via a suite of Web services for use in applications, such as data annotation to natural language processing. The NCBO Annotator Web service (http://www.bioontology.org/wiki/index.php/Annotator_Web_service) tags textual metadata submitted through the Web service (e.g., text of interest to the user) with ontology terms from BioPortal. Users can customize the Web service to limit results to a particular ontology (e.g. the Gene Ontology or SNOMED CT) or to a certain UMLS semantic type (e.g. T017 for `Anatomical Structure') as well as many other parameters. The ease of access to this annotation functionality makes the task of creating ontology-based annotations accessible for any biomedical researcher. Existing uses of the NCBO Annotator include triaging literature to prioritize curation of publications and annotating free text data descriptions from databases and clinical records to enhance information retrieval by tagging text with a variety of labels (preferred name, synonyms, etc. as found in the ontology). We have recently used the NCBO Annotator to enable enrichment analysis with the Human Disease Ontology. Usually, enrichment analysis refers to identifying over- or under-represented Gene Ontology (GO) terms associated with a set of genes of interest. Our goal is to develop and apply general enrichment analysis methods to profile other sets of interest, such as patient cohorts from the electronic medical record, using a variety of ontologies including SNOMED CT, MedDRA, RxNorm, and others. Through use of Gene Ontology Annotation files annotated with disease related GO terms, we were able to identify and analyze Human Disease Ontology annotations from PubMed abstracts, demonstrating the ability to generate disease-based enrichment.

Analysis of data from whole genome sequencing in clinical practice. *e.a. Worthey[1,2], g. Kowalski[2], m. Tutaj[2], r. Lopez[2], w. Liu[2], w. Jin[2], p. Jayaraman[2], j. De Pons[2], j. Smith[2], d. Schauer[1], g. McQuestion[2,3], b. Taylor[2], d.p. Bick[1,2], h.j. Jacob[1,2], d.p. Dimmock[1,2,3].* 1) Pediatrics, The Medical College of Wisconsin, Milwaukee, WI, United States; 2) Human Molecular Genetics Center, The Medical College of Wisconsin, Milwaukee, WI, United States; 3) Physiology, The Medical College of Wisconsin, Milwaukee, WI, United States.

Rapid technological advances in sequencing have led to a dramatic increase in the number of whole genome sequencing (WGS) projects thereby furthering understanding of human traits, diversity, and disease. It is clear that WGS will transform clinical diagnostics. Over the last year, our institution has established a clinical WGS program initially focused on Mendelian disease with defined protocols for patient selection, data analysis and evaluation, informed consent and results disclosure. The major bottleneck and greatest cost is associated with data analyses; identified variants must be annotated and prioritized in order to support identification of likely disease associations. Significant IT and bioinformatics effort is required; whilst the costs associated with sequencing have dropped to $5,000, costs associated with analysis have remained constant. Tools are required to support the clinical geneticist or other clinical provider in their interpretation of whole genome data. At the Medical College of Wisconsin and the Children's Hospital of Wisconsin, we have developed just such a tool; it is certified for use in a College of American Pathologists accredited laboratory, and is being used in our regional medical center to realize the promise of personalized genomic medicine through diagnostic whole genome sequencing. The tool provides the geneticist with the ability to interprete the data in light of the clinical presentation and family history. It can be used to assign variants to pathogenic, unknown significance and benign variant not associated with disease categories using a wealth of data including; mutation type, conservation score, genic/genomic location, Polyphen/SIFT prediction, splice site association, amino acid properties, known disease association, novelty, and population frequency. Queries can be based on the hypothesized mode of inheritance, and variant report pages browsed by position or by gene or gene set allowing focus on variants in a particular set of genes of interest, or target region. Development of this system has significantly reduced both the analysis cost and time to diagnosis. Six clinical cases (in additional to over two dozen research cases) have been analyzed using the tool. To our knowledge this is the first tool to yield clinical diagnoses in a CAP/Clinical Laboratory Improvement Amendments Lab setting. We will present specific clinical cases to demonstrate the functionality of this tool in changing healthcare.

842W

An integrative variant analysis suite for whole exome next-generation sequencing data. *F. Yu[1, 2], D. Challis[1], J. Yu[1], U. Evani[1], A. Jackson[2], S. Paithankar[2], C. Coarfa[2], R. Gibbs[1,2], A. Milosavljevic[2].* 1) Human Genome Sequence Ctr, Baylor College Med, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College Med, Houston, TX.

We present the Atlas2 Suite, an integrative collection of variant analysis tools optimized for high-throughput whole-exome data. The Atlas2 Suite makes use of logistic regression models trained on validated exon-capture data in conjunction with user-defined heuristic filters to separate true genetic variants from sequencing and mapping errors. It is accomodating for all three different NextGen platforms (SOLiD, Illumina and Roche 454). We applied the Atlas2 Suite to 38 whole-exome samples from the 1000 Genomes Project to demonstrate its ability to call both SNPs and INDELs with high sensitivity and specificity. In addition to the command line version of the suite we integrated the tools into the Genboree Workbench, allowing scientists to remotely call, view and further analyze variants through a simple web interface. Non-bioinformatician users can easily carry out personal genomics analysis using the Atlas2 provided by the Genboree resources, by simple mouse clicks.

843W

Improved methods for filtering putative rare functional mutations for whole genome/exome-sequencing data analysis. *G.Y. Yu[1,2], X. Zhang[1,2], Z. Wang[1,2], S.J. Chanock[2], M. Yeager[1,2], K.B. Jacobs[1,2].* 1) Core Genotyping Facility, SAIC-Frederick, Inc., NCI-Frederick, Frederick, MD 21702, USA; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD 20892, USA.

Whole genome and exome-sequencing is becoming a common approach to identify uncommon genetic variants that contribute diseases and traits. Variants discovered by these sequencing approaches are often subjected to several progressive bioinformatic filters to determine those variants most likely to be functionally related to the disease or trait of interest. A commonly applied filtering approach uses the NCBI dbSNP database of known genetic variants. dbSNP is a general depository and it has been collecting data from thousands of submitters using many variant discovery technologies for over a decade. Many researchers used presence of a variant in dbSNP as a strong filter, with the rationale that such variants are fairly common and unlikely to be related to highly penetrant uncommon genetic diseases or traits. This is a potentially risky approach, as many databases containing catalogs of rare mutations have been submitted to dbSNP as well as variants observed in populations ascertained on having uncommon diseases or traits. We have created a new database that contains data from dbSNP where variants have been scored by two criteria: 1) those with evidence of being a common variant in one or more randomly ascertained population groups, and 2) those with evidence of functional or clinical relevance, disease links in the Online Mendelian Inheritance in Man (OMIM) or had been implicated in a prior association study. With these two scores, investigators will be able to apply more specific filters and ranking systems for variants discovered by whole genome/exome sequencing projects. This database will be available via a World Wide Web query interface, a UCSC Browser track file, and as an application that can annotate files in standard Variant Call File (VCF) file format.

844W

Comprehensive Study of *Cis* and *Trans*-acting eQTLs across 36 Gene Expression GWAS. *X. Zhang[1], V. Emilsson[2], D. Levy[1], C.J. O'Donnell[1], A.D. Johnson[1].* 1) Division of Intramural Research, National Heart, Lung and Blood Institute; the NHLBI's Framingham Heart Study; 2) The Age, Gene/Environment Susceptibility study, Reykjavik, Iceland.

Introduction: Genome-wide genetic analysis of thousands of transcript levels (eQTLs) has identified genetic variants affecting gene regulation, and may improve our understanding of disease risk and potential drug targets. We sought to standardize 36 heterogeneous datasets of many human tissues and cell types, and systematically characterize *cis* and *trans*-acting genetic variants across these studies. **Methods**: 36 eQTL datasets from distinct tissues including liver, monocytes, brain, and subcutaneous adipose tissue were collected from published results or via collaborators. Heterogeneous transcript identifiers were mapped to NCBI Entrez Gene IDs to create a common dataset for further analysis. The distance between expression-associated SNPs (eSNPs) and their associated transcripts was calculated (hg18 reference). Unsupervised hierarchical clustering was used to identify the consistency of regulatory variants' effects in different tissues and cell types. These eSNPs were cross-referenced with genome-wide significant SNPs in the NHGRI GWAS catalog, and were mapped to UCSC regulatory features to understand the wide spectrum of *cis/trans-acting* regulatory mechanisms across the human genome. **Results**: Of 60,397 significant eSNPs reported from the eQTL datasets, 38,867 are unique. Most (89.7%) of the unique eSNPs are *cis*-acting SNPs (<500kb), consistent with literature reports. Hierarchical clustering shows that several transcripts have strong genetic influences across a majority of studies (>80%), e.g., *OAS1, MTRR, PEX6, CHURC1*. eSNPs closer to their associated transcripts tend to have higher significance. Spearman correlation analysis reveals a significant correlation in strength of signal between reported eSNPs and associations with the same SNPs as described in the NHGRI GWAS catalog (P=1.3e-13). In bioinformatic analyses, binomial tests indicate that eSNPs are localized within several regulatory features in the genome more than expected by chance (P<0.001 for 11 out of a total of 17 regulatory features). **Conclusion**: These results demonstrate that many strong genetic variants coincide both with disease GWAS results and known regulatory features, suggesting that genetic analysis of gene expression can help identify functional alleles that modify disease risk. Our results imply that eQTLs will be useful in interpreting genetic associations, prioritizing replication candidates and designing follow-up experiments in the study of complex diseases.

Low BMD is a risk factor of osteoporosis and has strong genetic determination. Genes influencing BMD and fundamental mechanisms leading to osteoporosis have yet to be fully determined. Peripheral blood monocytes (PBM) could access to bone resorption surfaces and differentiate into osteoclasts to resorb bone. Herein, we attempted to identify osteoporosis susceptibility genes and characterize their functions, through initial proteome profiling of PBM in vivo, and using a strategy of multi-disciplinary and integrative studies. We recruited three independent extreme-discordant sample sets consisting of Caucasians with extremely low vs. high hip BMD (N=28, 80, 44, respectively). First, we carried out quantitative proteomics analysis in PBMs from the first extreme-discordant sample set to discover proteins, thus candidate genes, functionally relevant to low BMD. Candidate genes were then assessed for differential expression at mRNA level in PBMs from the second extreme-discordant sample set. Furthermore, DNA polymorphisms in the replicated genes were tested for association with BMD variation in the third extreme-discordant sample set and an independent sample of 1,000 unrelated Caucasians. Based on integrative evidence, gene(s) of interest were selected and subjected to functional validation in vitro. Among 1,539 proteins identified in PBMs, Anxa2 was up-regulated 2.0-fold in subjects with low BMD. Up-regulation of Anxa2 expression in low BMD subjects were verified by western blotting, and further replicated at mRNA level. Three SNPs in Anxa2 were found to be associated with BMD variation ($p<0.05$). The above integrative evidence strongly supports that Anxa2 is involved in the pathogenesis of osteoporosis in humans. Furthermore, monocyte migration across endothelial barrier in vitro was elevated up to 4.9-fold by Anxa2 stimulation, suggesting that it may stimulate more PBM to migrate from blood to bone resorption surfaces to differentiate into osteoclasts in vivo, hence leading to increased bone resorption and decreased BMD. In conclusion, this study identified a novel osteoporosis susceptibility gene, and suggested a novel pathophysiological mechanism, mediated by Anxa2, for osteoporosis in humans.

Interstitial microdeletion of chromosome 8q23-q24 in Langer-Giedion syndrome in association with maternal translocation. *B. Min[1], W. Park[1,2].* 1) Biomedical Science, Seoul National University, Seoul, Korea; 2) College of medicine, Seoul National University, Seoul, Korea, MD/Ph.D.

Langer-Giedion syndrome, also called trichorhinophalangeal syndrome type II (TRPS2) is an autosomal dominant genetic disorder characterized by skeletal abnormalities and dysmorphic facial features, including thinly-growing hair, large nose and ears, and malformed fingers and toes. We investigated family members including two Langer-Giedion syndrome patients and their parents with normal phenotype using array CGH to find chromosomal aberrations related to their clinical features. 7.3 Mb interstitial microdeletion in 8q23-q24 containing TRPS1 and EXT1 gene was detected in two patients and 1.3 Mb microdeletion in 8q24.1sharing distal breakpoint with the deletion in two patients was detected in the mother of two patients. Breakpoint and junction sequence for 2 patients were determined by using PCR and Sanger sequencing. But the microdeletion in their mother was not defined by using PCR and Sanger sequencing. Maternal translocation was confirmed by parental chromosomal analysis and the translocation might induce the 7.3 Mb interstitial microdeletion in the patients.

Aim: While genetic factors appear to confer susceptibility to the risk of fracture, no large-scale GWAS meta-analysis consortia have been undertaken to identify the common variants associated with fracture within the framework of the Genetic Factors of OSteoporosis (GEFOS) consortium. We therefore sought the largest GWAS meta-analysis to date to identify the common genetic variants associated with fracture. Methods: We broadly defined fracture, as fracture of any bone occurring in individuals 18 years and older, confirmed through medical, radiological and/or questionnaire reports regardless of trauma type. This definition maximizes the case sample size, since common variants generally confer small risks for common disease. The GWAS discovery meta-analysis comprised 13 GWAS cohorts (n=53,016, of which, 9,185 were fracture cases). Additive association with fracture risk was tested for ~2.5 million imputed SNPs (HapMap CEU release 22, build 36) employing logistic regression models adjusted for gender, age, height, weight and population stratification when applicable. Results were meta-analyzed using inverse variance fixed-effects using METAL. Genome-wide significance (GWS) was set at $P<5x10-8$ while suggestive significance at $P<5x10-6$. Results: The strongest signal included six SNPs associated at GWS (lowest P=1.7x10-10, odds ratio = 1.13, 95% CI: 1.09 - 1.17) and maps to the novel 18p11 locus recently identified as a BMD locus by our parallel GEFOS BMD effort. This locus contains a gene coding for a protein of unknown function (C18orf19) with no other clear candidate gene on the vicinity. Other suggestive signals included a known variant in LRP5 (P= 3.1x10-6) and novel signals mapping in or near MDH2 (P=4.8x10-6), RGS9 (P=4.8x10-6), FAM20C (P=2.3x10-6) and MYO3B (P=9.0x10-7). Interestingly, mutations in FAM20C cause Rayne syndrome which presents with intracranial calcification, generalized osteosclerosis and enhanced periosteal bone formation. These variants will undergo further replication through GWAS and de-novo genotyping in > 80,000 individuals (~30,000 cases). Conclusion: In this first large-scale GWAS meta-analysis assessing fracture risk we identified the BMD locus on chromosome 18p11 as associated with fracture, albeit with modest effect size, and highlighted other loci in or near genes, some known to cause skeletal monogenetic disorders. These findings help to understand the genetic basis of fracture susceptibility.

848W

A susceptible haplotype within collagen 1 alpha 1(COL1A1) gene influences bone mineral density and exacerbates risk of postmenopausal osteoporosis in India. *M. Singh[1], P.P. Singh[1], S. Singh[2], P.K. Juneja[2], T.P Kaur[3].* 1) Human Biology, Punjabi University, Patiala, Punjab, India; 2) Aggarwal Orthopaedic hospital, Ludhiana, Punjab, India; 3) Amrit Polyclinic, Ferozepur, Punjab, India.

Purpose: The association of Collagen type 1 alpha 1 (COL1A1) with bone mineral density (BMD) and risk of osteoporosis have remained unclear. The influence of COL1A1 gene polymorphisms on BMD as genetic mediators of osteoporosis risk needs to be explored in Indian postmenopausal females where this disease is rising rampantly. Methods and Results: The present study investigated the role and relevance of two pertinent single nucleotide polymorphisms (SNPs): 1997G/T (rs1107946) and +1245G/T (rs1800012, Sp1) of the COL1A1 gene in DEXA verified 349 (145 osteoporotic, 87 osteopenic and 117 normal) postmenopausal women of India, who were not taking hormone replacement therapy. Minor allele frequencies of rs1107946 and rs1800012 were 0.15 and 0.20 in osteoporotic women, 0.18 and 0.18 in osteopenic and 0.20 and 0.17 in women having normal bone mass. An allele dose effect with BMD of lumbar spine has been exhibited by major allele G of rs1107946 (GG: 0.86g/cm^2, GT: 0.91g/cm^2 and TT: 0.93g/cm^2) and minor allele T of rs1800012 (GG: 0.91g/cm^2, GT: 0.87g/cm^2 and TT: 0.81g/cm^2). Disease association analysis revealed a haplotype GT which confers approximately three fold higher risk of osteoporosis in the carriers (OR 3.12, 95% CI 1.24-8.88, P=0.008) after adjusting the confounding effect of age, BMI and years since menopause. Conclusion: These results suggest that GT haplotype of COL1A1 gene is associated with a higher risk of postmenopausal osteoporosis in Northwest Indian women.

849W

Large-scale Meta-analysis of Genome-Wide Association Studies for Bone Mineral Density at Radius identified Susceptibility Locus at Wnt16. *H.-F. Zheng[1], L. Yerges-Armstrong[2], J. Eriksson[3], E. Duncan[4], B. Mitchell[2], C. Ohlsson[3], E. Streeten[2], M. Lorentzon[3], J.B. Richards[1,5].* 1) Dept. of Epidemiology & Statistic and Human Genetics, Lady Davis Institute, Jewish General Hospital, McGill University, Montreal, Quebec, Canada; 2) University of Maryland School of Medicine, Baltimore, MD, USA; 3) Center for Bone and Arthritis Research, Institute of Medicin, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; 4) Royal Brisbane and Women's Hospital and University of Queensland Diamantina Institute, Brisbane, Qld, Australia; 5) Department of Twin Research and Genetic Epidemiology, King's College, London, UK.

Backgrounds: Recent Genome-Wide Association Studies (GWASs) have identified multiple common variants associated with bone mineral density (BMD) at lumbar spine and femoral neck sites. However, while all BMD sites across the body are partially correlated, they separately provide additional information on risks of fracture, particularly, site-specific fractures. Aim: To identify common genetic variants associated with BMD at the forearm, we performed a GWAS meta-analysis within the Genetic Factors of OSteoporosis (GEFOS) consortium. Methods: This meta-analysis comprised 4 cohorts (n=4,777). Association with radius BMD was tested for ~2.5 million imputed SNPs (HapMap CEU release 22, build 36) using linear regression models adjusted for sex, age, height, weight, family-relatedness and population stratification when applicable. Genetic effect estimates across studies were combined using an inverse-variance fixed-effects meta-analysis. We also tested the genome-wide significant SNPs for forearm BMD in an independent cohort containing 273 forearm fracture cases and 1613 controls. Results: 60 SNPs in 7q31 showed genome-wide significance (P<5x10-8), the most significant SNP was rs2536189 (P=3.99x10-14, effect -0.16 standard deviations per risk allele). This locus maps to wingless-type MMTV integration site family member 16 (Wnt16). WNT16 is a member of the Wnt signaling pathway that is known to play an important role in the regulation of bone mass and bone turnover. It is worth to point out that rs2254595 in WNT16, which was strongly associated with BMD (P=8.04x10-13, BETA=-0.14), was also moderately associated with forearm fracture (P=9.92x10-3, OR=1.28). In addition, 37 SNPs showed suggestive association signals (P<5x10-6), including 6 variants in known locus 5q14.3 (MEF2C, P=2.34x10-6) and novel signals in or near 6q23 (RPS12, P=1.29x10-6), 10p15 (DIP2C, P=1.26x10-6), and 11p13 (PDHX and CD44, P=1.39x10-6). Conclusion: In this first large-scale GWAS meta-analysis for forearm BMD, we identified Wnt16 as an important genetic determinant of forearm BMD and fracture and highlighted other novel loci. These variants will soon undergo further replication in upcoming GWAS and by de-novo genotyping for BMD and fracture. These findings increase our understanding of the genetic basis of osteoporosis. Keywords: Genome-wide association study; Osteoporosis; Bone mineral density; Radius; Meta-analysis.

Pluripotent human cells differ in their ability to accommodate retrotransposition of engineered LINE-1 elements. *J. Garcia-Perez[1], S. Heras[1], S. Morell[1], A. Macia[1], E. Blanco-Jimenez[1], M. Munoz-Lopez[1], P. Leone[2], M. Garcia-Canadas[1].* 1) Human DNA Variability, GENYO(Pfizer - University of Granada & Andalusian), Granada, Spain; 2) Andalusian Stem Cell Bank, Center for Biomedical Research, University of Granada, Spain.

Long Interspersed Element-1 (LINE-1 or L1) is the most abundant autonomous non-LTR retrotransposon that shapes the human genome, representing approximately 17% of its genomic mass. Despite their abundance, only 80 to 100 copies per human remain retrotransposition competent (RC-L1s). RC-L1s are 6-kb in length elements that encode two Open Reading Frames (ORF1 and ORF2) required for their mobilization. ORF1 encodes an RNA binding protein while ORF2 encodes a protein with both ENdonuclease (EN) and Reverse Transcriptase (RT) activities. RC-L1s encoded proteins are also used by Short Interspersed Elements (SINEs) (Alu, SVA and others selected RNAs) to mediate their mobility in trans. L1 and Alu insertional mutagenesis has resulted in a diverse range of diseases, and their retrotransposition provides a constant source of human genetic diversity. L1 and Alu might ensure their evolutionary transmission to new generations through the accumulation of new insertions during early embryonic development or in germ cells. In fact, endogenous L1s are expressed in Human Embryonic Stem Cells (hESCs) and embryonic carcinoma cell lines (hECs). In addition, engineered human L1s can retrotranspose into both hESCs and hECs. Recent reports have revealed that pluripotent cells silence de novo L1 insertions by epigenetic mechanisms. Additionally, recent findings have revealed that selected somatic tissues (like Neuronal Progenitor Cells) can accommodate the mobilization of engineered L1s. However, it remains to be determined if all cultured human cells are equally receptive to accommodate L1 retrotransposition. To obtain an overview of the retrotransposition load that human pluripotent cells can accommodate, we have compared the retrotransposition rate of engineered L1 elements in a panel of human cells (hESCs, hECs, hESC-derived NPCs, a Neuroblastoma cell line, and differentiated cell lines as control). Remarkably, we found that the rate of L1 mobilization can vary up to 200-fold among cultured pluripotent cells. Interestingly, those cell types characterized for their neuronal nature support the highest rate of engineered L1 retrotransposition. Thus, it seems that neuronal cells have the intrinsic property to accommodate higher levels of L1 mobilization, which may have a direct impact in the degree of mosaicism generated during human embryonic development.

Using the repeat architecture to discover new hotspots of copy number variation associated with autism spectrum disorder. *S. Girirajan, M.Y. Dennis, B.P. Coe, C. Baker, T.H. Vu, M. Malig, C. Alkan, E.E Eichler.* Department of Genome Sciences, Howard Hughes Medical Institute, University of Washington School of Medicine, Seattle, WA.

Repeat architecture of the human genome predisposes certain regions to non-allelic homologous recombination (NAHR) resulting in copy number variants (CNVs). Rare (<0.1% frequency) CNVs created by NAHR between large (>10 kbp) segmental duplications (SDs), termed genomic hotspots, are already implicated in >6% of pediatric cases with intellectual disability as well as more complex neurological phenotypes such as epilepsy, autism spectrum disorder, and schizophrenia. Despite advances in sequence technology, the discovery and genotyping of smaller (>5 kbp) genetic variants associated with disease have been challenging especially in repeat-rich regions. Based on the original model of NAHR, we systematically identified 1,340 gene-rich regions for recurrent CNVs ranging in size from >5 kbp to 5 Mbp. These novel hotspots (termed mini hotspots and micro hotspots) are flanked by high identity (>95%) repeat sequences including *Alu*s, LINEs, and smaller (1-10 kbp) SD blocks, or identical pairs of >100 bp sequences, respectively. We designed a custom targeted, high density (a probe every 50 bp-1 kbp) microarray to identify CNVs in a total of 1,460 hotspot regions including 120 SD-mediated hotspots, 733 mini hotspots and 607 micro hotspots with lower density (a probe every 14 kbp) in the genomic backbone. We tested 1,833 individuals with sporadic autism and compared to CNV data from 8,635 control individuals. As expected, we identified SD-mediated CNVs in 16p11.2 (8/1,833), 15q13.3 (3/1,833), 17q12 (2/1,833), 7q11.23 (3/1,833), and 1q21.1 (5/1,833). We also identified 220/1,340 mini and micro hotspot regions to be variant in one or more individuals with 35 events observed exclusively in individuals with autism spectrum disorder. Notable examples include smaller (>5 kbp) events disrupting neurologically relevant genes such as *FOXP1*, *NRXN1*, *A2BP1*, *DPP10*, *CNTN4*, *GRID1*, and *CNTNAP2* previously associated with autism spectrum disorder as well as *DISC1*, *YWHAE*, *EHMT1*, *CHRNA7*, *ATXN1*, *CDH8*, *PRDM9*, *PTCHD3*,*CTNNA3*, and *GTF2I*—genes not previously associated with autism spectrum disorder. We have identified a previously undetermined set of regions of recurrent rearrangement contributing to rare CNVs and potentially conferring risk to neurodevelopmental disorders. While the biological significance is yet to be determined, these novel hotspot events are excellent candidates for testing genomic imbalance contributing to autism spectrum disorder.

Sequencing of the 22q11.2 deletion in VeloCardioFacial syndrome to identify genetic variants predisposing to Schizophrenia. *M. Guipponi[1,2], X. Bonilla Bustillo[1], C. Gehrig[2], S. Dahoun[2], S. Eliez[3], S. Antonarakis[1,2].* 1) Genetic Medecine, University of Geneva Medical School, Geneva, Geneva 4, Switzerland; 2) Genetic Medecine, University Hospitals of Geneva, Geneva 4, Switzerland; 3) Office Médico-Pédagogique Research Unit, Department of Psychiatry, University of Geneva Medical School, Switzerland.

Hemizygous deletions of the chromosome 22q11.2 region result in the 22q11.2 deletion syndrome also known as DiGeorge or Velocardiofacial syndrome (VCFS). The phenotype is variable and includes dysmorphic features and cardiac defects. Patients with VCFS also frequently have cognitive and behavioral symptoms and about one third of them develop schizophrenia during early adulthood. The incidence of schizophrenia in patients with VCFS is 30x higher than in the general population; thus del22q11.2 is an important risk factor for schizophrenia. The 22q11.2 deletion effectively reduces the normal diploid to an haploid state and therefore can result in the unmasking of otherwise recessive alleles that may remain on the intact homolog. By sequencing the remaining copy of the chromosome 22q11.2 in patients with VCFS and comparing the detected genetic variants between schizophrenic and non-schizophrenic patients, we expect to identify variations in one or more genes or functional elements that could increase the risk for the schizophrenic phenotype. We have selected 38 VCFS patients carrying the typical deleted region of 3Mb on chromosome 22q11.2; half of them showed no psychiatric symptoms, and the rest showed delirium, hallucinations, psychosis and/or schizophrenia. Age, sex, prevalence of cardiac defects and palatal abnormalities do not statistically differ between the two groups. DNA libraries for Illumina paired-end sequencing were prepared for these 38 samples and organized in seven pools of 5 or 6 libraries, each sample being tagged with a specific barcode. The 22q11.2 3Mb deletion from the non-deleted chromosome plus 200kb of upstream and downstream genomic sequences were captured using an Agilent SureSelect custom made enrichment system. Sanger sequencing of enriched, barcoded samples revealed an average enrichment of 400x. The seven pools are currently being sequenced on an Illumina GAIIx machine. Identification of variant predisposing to schizophrenia in this discovery set will be presented and discussed. Detection of genetic variants in the remaining allele of haploinsufficiency syndromes may reveal risk alleles for specific phenotypes.

The Allen Human Brain Atlas: Multi-Scale Transcriptional Architecture of the Human Brain. *E. Shen, D. Bertagnolli, C. Dang, A. Ebbert, D. Feng, A. Guillozet-Bongaarts, M. Hawrylycz, J. Hohmann, C. Lau, C. Lee, E. Lein, J. Miller, L. Ng, J. Phillips, Z. Riley, K. Smith, S. Sunkin, P. Wohnoutka, A. Jones.* Allen Institute for Brain Science, Seattle, WA.

Neuroanatomically precise, genome-wide maps of transcript distributions are critical resources to complement genomic sequence data, yet are currently limited to rodent model systems. We report here a transcriptional atlas of the normal adult human brain, the Allen Human Brain Atlas, an online multimodal atlas of human brain that integrates anatomic and genomic information with a suite of visualization and data mining tools. A key component of the resource is genome wide microarray-based gene expression profiling across ~1,000 structures and nuclei from 2 normal non-diseased postmortem brains. The atlas contains T1- and T2-weighted magnetic resonance (MR) and diffusion tensor (DT) data as well as high-resolution histological data. An anatomic ontology was developed that enables repositioning and visualization of the 3D samples. Search functionality includes the ability to examine differences in gene expression between anatomic structures and genes. Normalized gene expression data are viewable in heatmap format across multiple structures and gene probes. Preliminary analysis reveals a dramatic multi-scale differential expression structure of the human brain with conserved architectural patterns between major structures. By using conventional and network analysis based methods, major modules of gene expression contributing to neuronal, glial, primary sensory, and certain structural patterns can be identified. Localized profiling in specific structures, such as the hippocampus or myencephelon, reveals modules for transcription machinery, metabolism, and other key functions. By combining gene expression, imaging, and supporting metadata the atlas can help elucidate the relationships between genomics and neuroarchitecture in novel ways. For example, when examining highly differentially expressed genes in the cortex, expression relationships of these genes can be shown to recapitulate the basic architectural plan of the major lobes and respective gyri. The Allen Human Brain Atlas integrates imaging, anatomy and genomics data modalities. Expression profiles from ~1,500 distinct anatomic samples from 2 individuals are currently available, with additional data and more sophisticated application features expected to be added throughout the remainder of this 5-year project. The Atlas can be accessed via the Allen Brain Atlas data portal at www.brain-map.org.

BrainSpan Atlas of the Developing Human Brain. *S. Sunkin[1], A. Bernard[1], T. Chen[2], G. Coppola[3], C. Dang[1], S.-L. Ding[1], A. Ebbert[1], O. Evgrafov[4], B. Fischl[5], M. Gerstein[6], D. Geschwind[3], A.L. Guillozet-Bongaarts[1], J. Hohmann[1], S. Horvath[3], T. Hyde[7], A. Jones[1], Y. Kawasawa[6], J. Kleinman[7], P. Levitt[4], M. Li[6], S. Mane[6], E. Shen[1], K. Smith[1], A. Stevens[5], D. Weinberger[7], P. Wohnoutka[1], M. Hawrylycz[1], J.A. Knowles[4], N. Sestan[6], E. Lein[1].* 1) Allen Institute for Brain Science, Seattle, WA; 2) USC, Los Angeles, CA; 3) UCLA, Los Angeles, CA; 4) Zilkha Neurogenetic Institute of the Keck School of Medicine of the University of Southern California; 5) Massachusetts General Hospital; Harvard Medical School, Boston, MA; 6) Yale University, New Haven, CT; 7) NIMH, Bethesda, MD.

Though the complete sequence of the human genome has been available for over a decade, similar systematic efforts to map detailed gene expression patterns in the human brain have been lacking, particularly relating to development. To fill this void, we describe here a consortium project aimed at creating a unique multimodal transcriptional atlas of the pre- and postnatal developing human brain as a publicly accessible online resource for neuroscience, genome and medical research communities. This resource integrates transcriptomic, cellular resolution histology and imaging data in the context of human brain development through a portal for viewing, searching and mining of spatiotemporal gene expression patterns. Specifically, Illumina RNA-seq was used to generate quantitative transcriptome profiles of hippocampus, amygdala, thalamus, striatum, cerebellum and 11 neocortical regions, spanning early fetal neocortical development through adulthood. This broad spatiotemporal data set is supplemented with a high anatomical resolution microarray analysis of >300 laser microdissected structures from mid-gestational fetal human brain. To complement the transcriptome data, a large scale in situ hybridization (ISH) data set was generated to analyze cellular distributions using an industrial scale histology platform. ISH gene selection was biased towards genes associated with human neurological and neuropsychiatric disorders, as well as a portion matching the NIH Blueprint NHP Atlas (www.blueprintnhpatlas.org) to allow a direct comparison of gene expression patterns between human and non-human primate model systems across postnatal brain development. Finally, de novo fetal histological reference atlases and MRI and DWI data sets spanning human brain development are being created to provide a neuroanatomical and neurodevelopmental context for understanding spatiotemporally regulated transcriptional programs. Preliminary analysis of the transcriptome profiles from the adult timepoint will be presented. The product, integrating these large-scale data sets with tools for data visualization and analysis, aims to create a lasting resource for relating specific transcriptional programs to processes of human brain development and a normative data set for understanding the genetic basis of neuropsychiatric disease. BrainSpan (http://www.developinghumanbrain.org/) is publicly accessible through the Allen Institute for Brain Science portal (www.brain-map.org).

Gene-based association analysis in pathways relevant to brain arteriovenous malformation. *S. Weinsheimer[1], L. Pawlikowska[1], N. Bendjilali[1], P.Y. Kwok[2,3], J.G. Zaroff[4], S. Sidney[4], C.E. McCulloch[5], W.L. Young[1,6], H. Kim[1,5].* 1) Dept Anesthesia, Univ California, San Francisco, San Francisco, CA; 2) Cardiovascular Research Institute, UCSF; 3) Institute for Human Genetics, UCSF; 4) Division of Research, Kaiser Permanente Northern California, Oakland, Calif., USA; 5) Departments of Epidemiology and Biostatistics, UCSF; 6) Departments of Neurology and Neurological Surgery, UCSF.

Background: The genetic basis of brain arteriovenous malformation (BAVM), a tangle of abnormal vessels directly shunting blood from the arterial to venous circulation, is unknown. However, tissue and candidate gene studies have suggested several pathways associated with BAVM biology. We performed a gene-based analysis of a case-control genome-wide association study (GWAS) dataset, focusing on 7 biological pathways implicated *a priori* in BAVM, to identify candidate genes that may not reach significance in GWAS analysis. **Methods:** Affymetrix SNP 6.0 data from a case-control study of BAVM in Caucasians (334 cases; 504 controls) was used. Gene-based analysis in PLINK was conducted as follows: 1) single SNP association was tested using multivariate logistic regression adjusting for age, gender, and top 3 principal components of population stratification; 2) gene sets were defined by subsets of unlinked, nominally associated SNPs ($p<0.05$, $r^2<0.5$, maximum of 5 SNPs per gene) mapping within 20kb of genes in 7 pathways: MAPK signaling (n=261 genes), TGF-beta signaling (n=85), VEGF signaling (n=74), NOTCH signaling (n=46), vascular development (n=57), angiogenesis (n=51), and inflammatory response (n=124); and 3) p-values controlling the error rate at the gene level were generated using 10,000 permutations of case-control status, keeping r^2 between SNPs constant. Pathway-wide level of significance was set using Bonferroni adjustment for the total gene count per pathway. **Results:** A total of 37 genes, including *THBS3*, *BMP7*, *IL18*, *NFKB2*, and *BDNF* were associated with BAVM (gene level $p<0.05$) that function in TGF-beta signaling (n=5 genes), VEGF signaling (n=1), angiogenesis (n=2), vascular development (n=2), inflammatory response (n=12), and MAPK signaling (n=15). However, none of these genes met the pathway-wide level of significance. Our top associated gene was thrombospondin 3 (*THBS3*) (Bonferroni-adjusted $p=0.06$), which is involved in TGF-beta signaling but not previously known to be a candidate for BAVM. **Conclusions:** We used a gene-based approach to study the association of genes in 7 candidate biological pathways for BAVM. Several genes were associated with BAVM at nominal $p<0.05$, including *THBS3*; however, no genes were associated at the pathway-wide level. These novel candidate genes and variants can be tested for replication in larger BAVM cohorts.

Gene-set analysis of a genome-wide association study for colorectal cancer. *S. Castellvi-Bel[1], J.J. Lozano[2], C. Ruiz-Ponte[3], C. Fernández-Rozadilla[3], A. Abulí[1], A. Castells[1], A. Carracedo[3], Gastrointestinal Oncology Group of the Spanish Gastroenterological Association.* 1) Gastroenterology Department, Hospital Clinic-IDIBAPS-CIBERehd-CEK, Catalonia, Barcelona, Spain; 2) Bioinformatics Unit, Hospital Clinic-IDIBAPS-CIBERehd-CEK, Catalonia, Barcelona, Spain; 3) FPGMX, Genomics Medicine Group, Hospital Clinico-CIBERER-USC, Santiago de Compostela, Galicia, Spain.

Colorectal cancer (CRC) is the second leading cause of cancer related death in Western countries, representing in Spain the most frequently detected neoplasm in men and women. As other complex diseases, CRC is caused by both genetic and environmental factors. Twin studies showed that genetic susceptibility plays a major role and 30 percent of CRC present familial aggregation. Familial adenomatous polyposis and Lynch syndrome are the more frequent hereditary CRC syndromes and they are caused by germline mutations in APC, MUTYH and DNA repair genes. Recently, new common low-penetrance single nucleotide polymorphisms (SNP) for CRC have been identified by case-control genome-wide association studies (GWAS) permitting to point out so far 16 loci for CRC genetic susceptibility. GWAS have become a popular strategy to find associations of genes to traits of interest. However, success of its application in real studies has been limited by the testing strategy that considers SNPs independently. Gene-set analysis (GSEA), a different approach based on testing the association of modules of functionally related SNPs/genes, takes into account the combined effect of markers and it could be considered as an alternative method. The i-GSEA4GWAS (improved GSEA for GWAS) tool was recently developed as an open platform (NAR 2010;38:W90-5). A GWAS for CRC was recently concluded in the EPICOLON consortium, a Spanish epidemiologic, prospective, multicentre and population-based study. Genotyping was performed with the Affymetrix Genome-Wide Human SNP Array 6.0 in 881 CRC cases and 667 controls. After quality control, data was available from 848 cases and 629 controls for 674.578 SNPs. The i-GSEA4GWAS tool was used to perform a GSEA analysis on our data. Pathways/gene sets with a false discovery rate (FDR)<0.05 and a p value<0.001 were considered as overrepresented in our GWAS results. They included categories such as positive regulation of cell proliferation, glycerolipid metabolism, cell death, tumor necrosis family, ERK1/ERK2/MAPK family, growth, T-cell receptor signaling, ectoderm development, cell-cell signaling, apoptosis, cell activation, NFKB, or focal adhesion. Genes with significant SNPs in our GWAS from the above category sets comprised POU3F2, IL9, CDH13, LAMA1, ALDH1A3, NFKB1, MAP2K4, JUN, IL2, BMPR1B, SMAD3 and SPINK5. GWAS GSEA could be used as a complementary strategy to help selecting SNPs in phase 1 to be genotyped in consecutive replicas.

An integrated high-throughput automated workflow for RNA and DNA extraction from FFPE samples for Second Generation Sequencing. *T. Guettouche[1,2], D. Hedges[1], J. Rantus[1], K. Slosek[2], I. Konidari[1], B. Hulme[1], A. Andersen[1], A.L. Diaz[1], R. Gentry[1], Y. Pasco[1], M. Pericak-Vance[1], J. Gilbert[1].* 1) Hussman Institute for Human Genomics, University of Miami, School of Medicine, Miami, Florida; 2) Oncogenomics Core Facility, Sylvester Comprehensive Cancer Center, University of Miami, School of Medicine, Miami, Florida.

Millions of formalin-fixed, paraffin embedded (FFPE) samples are stored in Biorepositories around the world. These samples contain a vast compendium of phenotypic, histological and pathological data. For genomics studies, such as biomarker discovery, targeted resequencing or gene expression profiling of this resource has been largely unutilized because sample extraction can be challenging and the quality of the extracted nucleic acids is often poor. Currently, RNA and DNA extractions from FFPE samples are commonly performed manually and involve laborious protocols that are not amenable to high throughput processing. In addition there are no standard quality control methods for downstream applications such as second generation sequencing. Here we present a fully automated RNA and DNA extraction method (Tissue Preparation System, Siemens Healthcare Diagnostics; Tarrytown,NY) for IVD and research use that allows simultaneous or separate extraction of DNA and RNA from up to 48 samples in 4h with minimum operator interaction. In contrast to most other FFPE extraction protocols this method uses an innovative de-paraffinization step on the instrument that does not require incubation with Xylene or other solvents. We have extracted DNA and RNA from over 100 Melanoma, Breast and Prostate cancer FFPE samples and are currently processing 350 additional samples from 7 different tumor types including lung, pancreas, bladder and cervix. From adjacent 10uM paraffin sections the automated system, on average, extracts longer nucleic acid fragments as judged by Bioanalyzer traces and similar amounts of RNA and DNA measured by the Qubit method compared to a standard commercially available manual protocol. Matched fresh frozen and FFPE samples are being analyzed by second generation sequencing on a HiSeq2000. We present an integrated FFPE analysis workflow that includes standardized and fully automated nucleic acid extraction and quality controls for high-quality, high-throughput preparation of FFPE samples (96 samples/8 hr workday) for downstream analysis such as resequencing or transcriptome analysis by second generation sequencing. Our integrated workflow should significantly simplify utilization of FFPE samples for downstream genomic analyses such as second generation sequencing and as a consequence unlock a largely untapped source of information.

From “gene desert” to cancer stem cell biomarker: Using public genomic data to take 8q24 from GWAS to the clinic. *A. Hsu, J. Madhusoodanan, J. Su, M. Shekar, I. Kupershmidt.* NextBio, Cupertino, CA.

The SNP rs6983267 and others in the 8q24.21 region have been identified in numerous genome-wide association studies of several different types of cancer. At the time of the original publications, the region was thought to be a “gene desert”, containing only the pseudogene POU5F1B. POU5F1B has since been found to encode a functional isoform of the transcription factor POU5F1, though POU5F1B's roles in cancer and normal development are still not understood. Using the NextBio platform, we performed meta-analyses of curated public genomic data. Strong evidence from multiple independent studies show that 1) POU5F1B is overexpressed in embryonic stem cells (ESCs) compared to differentiated tissues and cells; 2) POU5F1B is up-regulated and/or amplified in several types of cancer; 3) POU5F1B is highly up-regulated when reprogramming differentiated cells into induced pluripotent stem cells via overexpression of a 4-gene cocktail comprising SOX2, KLF4, POU5F1/OCT4, and MYC; and 4) POU5F1B is down-regulated when differentiating ESCs by overexpression of the tumor suppressor INHBA. These multiple lines of evidence—**not discoverable in the biomedical literature**—suggest that POU5F1B may be a useful biomarker for cancer stem cells, as well as a lead in understanding the progression of certain types of cancer.

859W

RNA-sequencing and allele-specific expression analysis identify strong allelic expression imbalance (AEI) for a bladder cancer associated variant rs2294008 within the prostate stem cell antigen (PSCA). *I. Kohaar, A. Mumy, W. Tang, Y-P. Fu, P. Porter-Gill, L. Prokunina-Olsson.* Laboratory of Translational Genomics, DCEG/NCI/NIH.

A recent GWAS identified a SNP rs2294008 within the prostate stem cell antigen (PSCA) at 8q24.3 as a risk factor for bladder cancer, [OR=1.13 (1.09-1.17), p=4E-11, Rothman, 2010]. PSCA encodes a GPI-anchored cell membrane glycoprotein expressed in the prostate, bladder, stomach and pancreas. A transcript with the non-risk C allele of rs2294008 encodes a protein of 114 amino acids, while the risk T allele creates a novel upstream translation start site (acg->aTg) that extends the N-terminal leader peptide by 9 amino acids, to generate a protein of 123 amino acids. A humanized monoclonal anti-PSCA antibody is already used in clinical trials for prostate and pancreatic cancer, but the functional roles of PSCA and its genetic variants in normal and cancer conditions remain unknown. We aimed to explore mRNA expression of PSCA in relation to rs2294008 and bladder cancer risk. RNA-sequencing of 6 bladder tissues (3 tumors and 3 normal adjacent) and one normal prostate tissue detected PSCA expression in all samples. Analysis of three samples heterozygous for rs2294008 (bladder tumor, bladder normal and prostate normal) showed evidence of strong allelic imbalance (AEI) - 90%; of all PSCA transcripts carried the risk T allele, while only 10%; showed the non-risk C allele. A similar pattern was observed for 11 additional transcribed SNPs within the PSCA gene, but not for SNPs located in neighboring genes, Ly6K and JRK, suggesting that the AEI is specific for PSCA and not a result of AEI of the whole region. Analysis of total PSCA expression in 42 tumor and 39 normal bladder tissue samples showed that total PSCA expression was strongly increased in carriers of risk TT and TC genotypes, up to 10-fold compared to carriers of non-risk CC genotypes (p trend=0.00064), even after adjustment for sample status (normal/tumor). By using an allele-specific expression assay that measured allelic ratio of rs2294008 in PSCA transcripts, we also confirmed AEI detected by RNA-seq. We are currently evaluating regulatory potential of SNPs in strong LD with rs2294008 and located upstream of PSCA ansd exploring functional significance of the alternative leader peptide of PSCA created by rs2294008 risk allele. In conclusion, we suggest that either rs2294008 or other variants in LD with it regulate mRNA expression of PSCA and cause strong AEI that leads to almost monoallelic expression of PSCA transcript that carries the bladder cancer associated T allele of rs2294008.

Integrative molecular profiling in serous epithelial ovarian cancer for identification of biomarkers of chemoresistance. *M. Koti[1], R. Vidal[1], P. Nuin[1,2], A. Haslesurst[1], J. Weberpals[3], T. Childs[4], P. Bryson[4], H. Feilotter[1], J. Squire[1], P. Park[1].* 1) Pathology and Molecular Medicine, Queen's University, Kingston, Ontario, Canada; 2) Ontario Cancer Biomarker Network, Toronto, Canada; 3) Division of Gynecologic Oncology, Ottawa Health Research Institute, Ottawa, ON, Canada; 4) Department of Obstetrics and Gynecology, Queen's University, Kingston, ON, Canada.

Development of primary resistance to carboplatin and paclitaxel poses a major challenge in the management of ovarian cancer. To identify the molecular mechanisms underlying this process, we used integrative microarray analyses to profile the 1) copy number alteration and SNP, 2) mRNA, 3) miRNA and 4) methylation signatures in a cohort comprising 11 chemoresistant and 19 sensitive tumour samples, as defined by the RECIST criteria. The profiles were analyzed by Bayes statistics, based on R/Bioconductor packages, and the relevant pathways determined using Ingenuity Pathway Analysis. The data from each array platforms were integrated using bioinformatics tools developed in house to decipher the most critical biological pathways, and to identify the molecular mechanisms driving the pathways. Copy number analysis shows significant alterations in the chemoresistant group (gains on chromosomal regions, 4q, 6q, 8p, 8q, 19q, 7q and 22q; losses on 8p and 10q) compared to the sensitive group. Preliminary mRNA expression analysis identified an enrichment of upregulated genes involved in cellular growth and proliferation, development as well as differential gene expression changes in the, TGFB1, TNF, , ERBB2, CTNNB1, IFNG, LH and FSH networks, in the resistant compared to the sensitive group. The major molecular and cellular functions associated were cell-to-cell signaling, molecular transport and cellular movement. Similarly, the major gene networks by IPA analysis of most significantly downregulated genes were the IFNG, IRF3, IFN alpha, IL-1B. Differences were also seen in the PI3K, TP53, and the TNF networks. Interestingly, these changes were consistent with PTEN loss which has been frequently observed in serous low grade tumours. Additionally, genes involved in activation of NF2B pathway and the TP53 network showed differential expression in the two groups.Analysis is being performed on correlating the gene expression data with miRNA, methylation and copy number alterations. Ongoing comparative analyses and integration of miRNA profiles within this cohort have also identified several differentially expressed transcripts including mir-34b, mir-155, mir-214, mir-200c and mir-143. Some of these miRNAs have been earlier reported to be associated with tumour progression. Further integrated analysis will elucidate the synergistic roles that the genetic and epigenetic alterations in the deregulation of these and other pathways involved in primary chemoresistance.

HUMAN GENETICS. *b. nasasira.* Mbarara university of science and technology, Kampala, Mbarara, Uganda.

Human genetics describes the study of inheritance as it occurs in human beings. This encompasses a variety of overlapping fields including molecular genetics, biochemical genetics, Population genetics, Developmental and clinical genetics among others. The study of human genetics is vital in that it helps us understand the diseases and develop effective disease treatment, as well as helping us understand human life. Genes are the common factor of the qualities of most human-inherited traits. These are carried on the DNA of the individual, each DNA carrying several genes that determine the organism's characteristics. The sum of the entire DNA contained within an organism is its genome. The structural and functional study of which is called genomics. Population genetics deals with investigating processes that cause changes in allele and genotype frequencies in populations based on inheritance. The human karyotype, that is the picture of homologous chromosomes;44 autosomes and 2 sex chromosomes during metaphase 1 arranged according to their length provides a way of diagnosing chromosomal abnormalities in clinical genetics. These anomalies, normally caused by non-disjunction during cell division include, Trisomy21, Down's syndrome and many more. However, allelic disorders also occur; such as albinism, sickle cell anemia among others. Here particular genes are affected. Some traits are sex linked in that the genes determining such are carried on sex chromosomes. These include Hemophilia, muscular dystrophy. Genetic anomalies are often inherited from parent to daughter organisms. This is by autosomal recessive inheritance, autosomal dorminant inheritance or sex linked inheritance. Genetic knowledge of such anomalies provides a basis for their diagnosis and treatment. Genes also have a strong influence on human behavior. IQ is largely heritable. We must not forget that the sex of an organism is also genetically determined so that an individual with XX sex chromosomes is a female, one with XY is a male.

Integrative analysis of whole-genome and transcriptome sequence data for metastatic triple negative breast cancer. *A. Siddiqui[1], O. Sakarya[1], C. Barbacioru[1], J. Aldrich[2], S. Sinari[2], A. Christoforides[2], T. Izatt[2], J. Keifer[2], L. Hoang[1], S. Mousses[2], J.D. Carpten[2], D. Von Hoff[2], D.W. Craig[2].* 1) Life Technologies, Foster City, CA; 2) The Translational Genomics Research Institute (TGen) Phoenix, AZ.

Triple negative breast cancer (TNBC) is characterized by the absence of expression of estrogen receptor, progesterone receptor and Her2-neu, accounting for 15% of all breast cancer diagnosis. Targeted therapies have a reasonable likelihood of improving the cure rate of early stage TNBC, and promising therapies discovered in the metastatic setting are rapidly advancing through clinical trials. We present integrated analysis of matched normal and tumor whole genome data, along with tumor transcriptome sequencing data of multiple individuals with metastatic chemo-resistant TNBC. In each case, two independent 1.5kb Mate-pair libraries were generated for both tumor and germ-line derived genomic DNA and sequenced using SOLiD® version 4.0 paired 50mers to a target of 30x depth. The tumor transcriptome was sequenced on four replicates and compared to transcriptome sequencing from ethnicity-matched population-based control hyperplastic breast tissue. Genome analysis was performed using multiple aligners and variant callers. Transcriptome alignment was performed using Life Technologies Bioscope pipeline, and differential expression analysis was performed using EdgeR and DESeq. We prioritized annotated germline and somatic variants by integrative analysis with differential expression results. Several striking examples of intronic events correlating with either altered splicing or differential expression were observed in genes relevant to cancer treatment, suggesting that transcriptomic data may have high value in interpreting somatic events that fall outside of coding regions. Final integration of data was validated through knowledge mining and convergence of somatic events and expression. For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.

Detecting Neoplasms of Hematopoetic or Lymphatic Tissue as an Incidental Finding of GWAS within the electronic Medical Records and Genomics (eMERGE) Network. *U. Schick[1], A. McDavid[1], N. Weston[2], K. Ehrlich[2], K.N. Newton[2,3], P.K. Crane[4], C. Laurie[5], C. Laurie[5], A.P. Reiner[1,6], R.D. Jackson[7], U. Peters[1], G.P. Jarvik[4,8], E.B. Larson[2,4], C.S. Carlson[1,6].* 1) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Group Health Research Institute, Seattle, WA; 3) School of Public Health, University of Washington, Seattle, WA; 4) Department of Medicine, University of Washington, Seattle, WA; 5) Department of Biostatistics, University of Washington, Seattle, WA; 6) Department of Epidemiology, University of Washington, Seattle, WA; 7) Department of Internal Medicine, Ohio State University, Columbus, OH; 8) Department of Genome Sciences, University of Washington, Seattle, WA.

Collaborators at the Gene, Environment Association Studies Consortium (GENEVA) have developed an algorithm that detects large copy number variants (>50 kb) and mosaic copy-neutral loss of heterozygosity with high sensitivity and specificity from Illumina high-density SNP genotyping data. In this study, the GENEVA detection method was applied to population-based cohort of 2,771 elderly participants enrolled in a study of aging and dementia, where GWAS genotypes were available from the eMERGE consortium. Genotyping was performed on the Illumina Human 660W-Quad1 platform using DNA derived from peripheral blood samples. We hypothesized that karyotypic anomalies detected in DNAs collected at enrollment would be associated with a subsequent occurrence of neoplasms of the lymphatic or hematopoietic tissue and tested this hypothesis using electronic data derived during ongoing care in an integrated delivery system during a median 6 years of follow-up after enrollment samples were collected. Through the application of the GENEVA method, 109 individuals were observed to have at least one chromosomal anomaly greater than 1.5 megabase in length. An association was observed between these large chromosomal anomalies and a subsequent diagnosis of leukemia, lymphoma or multiple myeloma in this cohort (odds ratio, 3.69; 95% Confidence Interval: 2.08-6.27). Odds ratios for each type of neoplasm were consistent, and several of the anomalies observed in participants later diagnosed with neoplasms have previously been reported as recurrent findings in leukemia (e.g. trisomy 12). These findings suggest that this method may have utility in the early detection of neoplasms of hematopoetic or lymphatic origin. Replication efforts are underway to confirm the association of apparently acquired copy number variants with hematopoetic or lymphatic neoplasms in an independent sample of 10,497 individuals from the Women's Health Initiative.

Genetic Architecture of Adiponectin in Hispanic Americans from the IRAS Family Study. *S.S. An[1], N.D. Palmer[1], A. Hanley[2], J.T. Ziegler[1], W.M. Brown[1], S.M. Haffner[3], J.M. Norris[4], J.I. Rotter[5], X. Guo[5], Y.D.I. Chen[5], L.E. Wagenknecht[1], C.D. Langefeld[1], D.W. Bowden[1].* 1) Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC; 2) University of Toronto, Toronto, Ontario; 3) University of Texas Health Sciences, San Antonio, TX; 4) University of Colorado, Denver, CO; 5) Cedars-Sinai Medical Center, Los Angeles, CA.

Adiponectin is a widely studied adipocytokine that has been implicated in glucose, lipid and energy homeostasis. Adiponectin has been found to be inversely correlated with obesity, insulin resistance and diabetes. Plasma adiponectin levels are highly heritable, with heritabilities ranging between 40-70%. Previous studies have suggested the the ADIPOQ locus itself is the major genetic determinant of plasma adiponectin levels. Common variations in the ADIPOQ gene, however, have accounted for less than 10% of the observed variance in adiponectin levels. Previously, we identified a low frequency (1.1%) coding variant, G45R, in Hispanic Americans from the Insulin Resistance Atherosclerosis Family Study (IRASFS) which accounted for an estimated 16.7% of the proportion of variance in plasma adiponectin levels in the Hispanic population. The current study was designed to quantify the variation in adiponectin attributable to clinical traits, low frequency variants, and common variants in ADIPOQ, in a Hispanic sample. Through resequencing and bioinformatic analysis, we identified 45 low frequency (MAF<5%) and common (MAF>5%) SNPs in ADIPOQ which were genotyped in 822 Hispanics in IRASFS in 90 pedigrees. To test for association and estimate contributions to adiponectin variation, a variance components model was computed as implemented in SOLAR. Eight of the 12 low frequency SNPs (MAF 0.01-0.04) were associated with adiponectin levels (p-value 0.013-5.03E-40), with G45R having the strongest association. We postulate that low frequency variants contribute a major component of variance in plasma adiponectin. In addition to genetic contributions to adiponectin variation, we estimated the variation attributable to an extensive list of 14 clinical variables (age, gender, recruitment center, BMI, glucose homeostasis, adiposity, PAI-1, fibrinogen, CRP, and blood pressure). In 822 individuals with complete clinical data, the clinical measures accounted for 31% of the variance in adiponectin. Low frequency genetic variants accounted for 24% of the variance and common variants accounted for only 4% of the variance. Cumulatively, the clinical data, low frequency and common SNPs accounted for an estimated 58% of variance in plasma adiponectin. In conclusion, low frequency variants and clinical characteristics account for the majority of the variance observed and in combination with common SNPs account for a substantial proportion of the variation in adiponectin levels.

In Search of Regulatory Variants in Exfoliation Glaucoma. *M.A. Hauser[1,2], Y. Liu[1], S.E. Williams[3,4], B.T. Whigham[1], J. Wheeler[1], T.R. Carmichael[4], X. Qin[1], R.R. Allingham[2].* 1) Ctr Human Gen, Duke Univ Med Ctr, Durham, NC; 2) Department of Opthalmology, Duke Medical Ctr, Durham, NC; 3) St John Eye Hospital, University of Witwatersrand, Johannesburg, South Africa; 4) University of Witwatersrand, Johannesburg, South Africa.

Exfoliation (pseudoexfoliation) glaucoma (XFG) is the most common identifiable form of open-angle glaucoma in the world. XFG is defined by the inappropriate production and extrusion of fibrillar extracellular protein by multiple tissues within the eye and systemically. Abnormal protein aggregates damage the aqueous humor outflow pathways of the trabecular meshwork, causing elevated intraocular pressure. A recent genome wide association study and several followup studies have found that the non-synonymous coding variant rs3825942 in the lysyl oxidase-like 1 gene (LOXL1) is highly associated with increased risk of XFG. Our analysis of a native South African population of 113 cases and 107 controls has demonstrated that this variant is not causal. It is highly associated ($p=6x10^{-21}$; odds ratio 6.3 (95%CI 3.7-10.8)); however, the risk allele is reversed. The A allele of this SNP is associated with risk rather than the G allele seen in other populations, indicating that the actual functional variants are nearby but remain undiscovered. We hypothesize that causal variants in LOXL1 will contribute to disease risk by regulating the level of expression of LOXL1. In order to identify these risk variants, we have sequenced the full genomic LOXL1 locus in 50 XFG cases and 50 controls from South Africa. The sequence region includes all exons and introns as well as 10kb upstream of the gene (a total of 40kb). Our sequence analysis and followup association studies in this subset of our study population show that the original rs3825942 SNP is highly associated with XFG ($P=10^{-10}$). Eight additional eight sequence variants in the first 5000 bases of intron 1 were also significantly associated with XFG ($P= 10^{-4}$ - 10^{-10}). Interestingly, the risk alleles for these variants were also reversed in comparison to those in our Caucasian XFG dataset. These data suggest possible DNA recombination events around the exon1/intron 1 in the LOXL1 gene. We are currently sequencing additional upstream regions of LOXL1 in both Caucasian and African samples.

Analysis of targeted exome-plus sequencing in a kidney transplantation outcome cohort. *B.M. Herrera[1], S.M. Kurian[2], P. Langfelder[3], S. Horvath[3], T. Mondala[2], P.L.F Tang[1], E.T. Lam[1], D. Solomon[2], P. Kwok[1].* 1) CVRI, UCSF, San Francisco, CA. University of California, San Francisco 555 Mission Bay Blvd South, MC-3118 San Francisco, CA 94158-9001; 2) Molecular and Experimental Medicine (MEM-241) The Scripps Research Institute, La Jolla, CA, 92037; 3) Department of Biostatistics UCLA School of Public Health Los Angeles, CA 90095-1772.

Despite vast efforts in matching kidney donors with recipients and the use of immunosuppressive therapy, only 30% of recipients have a well functioning graft (TX) 10 years after transplantation, while 70% will develop Chronic Allograft Nephropathy (CAN). Furthermore, diagnosis of the degree of graft rejection requires invasive procedures which further contribute to graft injury. Therefore, the identification of genetic markers indicative of risk for developing CAN, is of paramount importance and may eventually assist in donor-recipient matching. To test the hypothesis that rare coding mutations affect the outcome of renal transplantation. We have sequenced the exome (38MB) and regulatory regions of over 2000 genes which were previously implicated in outcome studies through differential expression and as part of a weighted correlation network analysis. Whole exome-plus capture was carried out in a cohort of 100 unrelated renal transplant recipients (CAN= 50 and TX=50) collected as part of the Transplant Genomic Collaborative Group. Sequence capture was performed using the SureSelect kit v1.0 (38Mb+6Mb) and parallel DNA resequencing was carried out on the HiSeq-2000. 2x100bp paired-end sequence reads were aligned to the hg19 reference genome using the Burrows-Wheeler alignment tool (BWA 0.5.7). Duplicate reads, resulting from PCR clonality or optical duplicates and reads mapping to multiple locations were excluded from downstream analysis. The unified genotyper utility from the Genome Analysis Toolkit was used for variant calling and then filtered using rigorous quality controls. In the first 55 exomes sequenced (CAN=28, TX=25), on average, 80.02% of reads were aligned to the genome, of these, 87.13% are on or near target intervals with a mean target coverage for bases is ~ 70.7x. We identified an average of 21,866 variants per individual, of which ~5% are novel. Filtering of variants was done by comparing to dbSNP131 and 1000 Genomes pilot SNP calls and annotated using SeattleSeq. Thus far we have identified up to 18 novel coding variants with different frequencies between the CAN and TX samples suggesting genetic involvement, among these, several variants clustered around the Protocadherin alpha-8 isoform-1 precursor gene (PCDHA8, chr-5q32) and Double-stranded RNA-binding protein Staufen (STAU1, chr-20q13). In addition we will investigate IN/DELS and CNVs and explore the role of these observations in kidney transplant outcome.

Tumor exome sequencing in patients with isolated bilateral Micronodular Adrenocortical Disease identifies pathogenic somatic and germline mutations. *A. Horvath[1], R.B. Alexandre[1], E. Saloustros[1], C. Wassif[1], A. Manning[1], P. Paschou[1], P. Briasoulis[1], S. Sigh[1], J. Epstein[1], I. Levi[1], J. Neimela[2], J.B. Oliveira[2], J.A. Carney[3], F.D. Porter[1], C.A. Stratakis[1].* 1) NICHD, NIH, Bethesda, MD; 2) CC, DLM, Bethesda, MD; 3) Mayo Clinic, Rochester, Minnesota 55905, USA.

Micronodular Adrenocortical Disease (MAD) is a form of bilateral adrenocortical hyperplasia associated with corticotrophin (ACTH)-independent Cushing's syndrome. It has been seen isolated or as a part of multi-neoplasia syndromes, such as Carney complex and McCune-Albright Syndrome. Both isolated MAD (iMAD) and MAD in the context of Carney complex or McCune-Albright Syndrome have been related to molecular defects in cAMP- signaling pathway. Carney complex is caused by germline mutations in regulatory subunit type 1-alpha (*PRKAR1A*) of Protein Kinase A (PKA), while McCune-Albright Syndrome results from early postzygotic mutations of the alpha subunit of the stimulatory G protein gene (*GNAS*). Despite the recent identification of several new genes implicated in the adrenocortical tumors predisposition, including at least two members from the family of the phosphodiesterases (P*DE11A* and *PDE8B*), a subset of iMAD tumors remain with undiscovered genetic cause. The genetic etiology of iMAD is clearly supported by very early onset and invariable bilateral appearance. We applied targeted exome enrichment (Agilent technologies) and subsequent massive parallel sequencing on SOLiD4 platform (Applied Biosystems) on adrenocortical tumors from 5 unrelated patients with bilateral iMAD. An average coverage of 50-fold per targeted base was achieved, and filtering criteria to reduce false positive calls were applied. After filtering against existing mutation databases, and our own clinically unrelated next-generation sequencing datasets, between 298 and 452 novel sequence-altering variants per tumor were identified, these including missense, nonsense, and splice base substitutions (up to 3 bp from the junction), small (up to 9bp) and large indels. The variants were sorted according to their presence in maximum number of patients, expression in the adrenal cortex, functional relevance and pathogenic potential, and a short list of candidate genes was generated. Among the most favored candidates are genes involved in the cAMP-signaling and Wnt-signaling pathways, cell growth and differentiation control, and genes known to have altered expression in related tumor conditions; experiments further confirming selected genetic variants are ongoing.

868W

In search of a new vascular dementia: An exome sequencing approach to a Swedish multi-infarct family. *M. Junna[1], A. Börjesson Hanson[2], C. Sundal[3], O. Andersen[3], M. Baumann[4], H. Kalimo[5], M. Pöyhönen[6,7], M. Viitanen[8,9].* 1) Dept. of Medical Biochemistry and Genetics, University of Turku, Turku, Finland; 2) Dept. of Psychiatry and Neurochemistry, Neuropsychiatry Epidemiology Unit, Institute of Neuroscience and Physiology, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; 3) Dept. of Neurology, Institute of Neuroscience and Physiology, Sahlgrenska Academy at the University of Gothenburg, Gothenburg, Sweden; 4) Protein Chemistry Unit, Institute of Biomedicine/Anatomy, University of Helsinki, Helsinki, Finland; 5) Dept. of Pathology, Haartman Institute, University of Helsinki, Helsinki, Finland; 6) Dept. of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 7) Dept. of Medical Genetics, University of Helsinki, Helsinki, Finland; 8) Dept. of Neurobiology, Care Sciences and Society, Karolinska Institutet, Stockholm, Sweden; 9) Dept. of Geriatrics, University of Turku, Turku, Finland.

In 1977, Sourander and Wålinder described a case of hereditary multi-infarct dementia (MID) in a Swedish family. Later their disease was suggested to be the cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). The clinical picture of recurrent strokes, (but without the frequently seen characteristic migraine) with MRI that shows subcortical white matter degeneration and vascular changes resembles CADASIL, but in our studies we did not detect any pathogenic mutations in the entire 8091 bp reading frame of *NOTCH3* nor found clear evidence for the *NOTCH*3 gene linkage. Neither did we find any evidence of the CADASIL-typical granular osmiophilic material (GOM) in skin biopsies. These multiple approaches suggest that in this Swedish family the hereditary MID suspected to be CADASIL is a different disorder with dissimilar pathological features, and belongs to the growing group of genetically uncharacterized familial small vessel diseases (SVDs).

In order to search for the pathogenic mutation behind the disease, we did a whole-exome sequencing for one healthy and three affected family members. Their genomic DNA was extracted from peripheral blood lymphocytes, the exon targeting was done with NimbleGen's sequence capture (Roche Inc. USA) and the sequencing with Illumina's sequencing platform (Illumina Inc. USA).

After sequencing, the results were filtered against public SNP databases and the data from the Thousand Genomes Project in order to identify the sequence variants that have not been published previously as polymorphisms. Subsequently, we concentrated on the variants that are shared by all the three patients and excluded the variants that are also shared by the healthy control. Since we are searching for a dominant disease we narrowed our search by excluding the variants that are homozygous in all patients. Detailed results of these analyses and the possible pathogenic variation or variations will be presented at the congress.

Genetic contribution to neuronal cell death in hippocampus induced by prolonged seizures in rats. *C. Martin[1], P. Lema[2], L. Carmant[2], P. Cossette[1].* 1) Notre-Dame Hospital, University of Montreal, Montreal, PQ, Canada; 2) Pediatric department, Neurology, Ste Justine Hospital, Montreal, PQ, Canada.

Temporal lobe epilepsy (TLE) is the most common form of epilepsy and is often associated with hippocampal sclerosis. The disease usually evolves in three different stages: 1) the acute phase, associated with an initial insult (brain trauma, status epilepticus, infection); 2) the latent period where the person shows no sign of epilepsy; and 3) the chronic phase, characterised by the apparition of recurrent spontaneous seizures. Rats reproduce the pattern of evolution of TLE after the induction of a prolonged seizure (status epilepticus), making them a good model for the disease. Hippocampal sclerosis (HS) is associated with intractable TLE and has been reproduced in mice models of epilepsy. However, the molecular mechanisms underlying this neuronal death and gliosis in the hippocampus remain to be determined. Our hypothesis is that HS found in TLE occurs in individuals that are genetically predisposed. In a preliminary study, we measured the severity of the HS in 4 consanguineous strains of rats (SHR, Brown-Norway, Dahl, Lewis) after the induction of a status epilepticus (SE) using kainate acid (n=10/strain). Dahl and Lewis showed a similar sensitivity to KA and underwent a comparable SE. Interestingly, only the Dahl rats suffered from severe HS (n=9; 90%). The level of expression of all the glutamatergic receptors was measured, and no significant difference was observed. Galanin is known to have neuroprotective effect in the mice model of TLE. We therefore measured the basal level of expression of Galanin, Galanin receptor 1 (Galr1) and Galanin receptor 2 (Galr2) in the hippocampus of our control rats. The results showed that the level of expression of Galr1 was 4 times higher in the Lewis compared to the Dahl (p=0.02). We sequenced the coding region of Galr1 as well as its promoter in both strains, but no genetic variation was found. Our results suggest that decreased expression of Galr1 is associated with susceptibility to HS induced by SE. The exact genetic variation leading to decreased Galr1 expression remains to be identified.

Genetic variations in matrix metalloproteinases are associated with increased risk of Ulcerative Colitis. *A.R. Morgan[1,4], D.Y. Han[1,4], W.J. Lam[1,4], C.M. Triggs[2,4], A.G. Fraser[3,4], M. Barclay[5,6], R.B. Gearry[5,6], L.R. Ferguson[1,4].* 1) Discipline of Nutrition, FMHS, The University of Auckland, Auckland, New Zealand; 2) Department of Statistics, FoS, The University of Auckland, Auckland, New Zealand; 3) Department of Medicine, FMHS, The University of Auckland, Auckland, New Zealand; 4) Nutrigenomics New Zealand; 5) Departmentof Medicine, University of Otago, Christchurch; 6) Departments of Gastroenterology & Clinical Pharmacology, Christchurch.

Matrix metalloproteinases (MMPs) are believed to play an important role in the pathogenesis of inflammatory bowel disease (IBD), functioning as pro-inflammatory cytokines, chemokines and other immune and inflammation regulators, as well as playing a role in extracellular matrix turnover.

We undertook an extensive candidate gene SNP study of the MMP family and their inhibitors and investigated MMP's -1, -2, -3, -7, -8, -9, -10, -12, -13, -14 and tissue inhibitor of metalloproteinases (TIMPs) -1, -3 and -4 for association with Ulcerative Colitis (UC). We identified tagging SNPs across these genes, and genotyped these SNPs in a Caucasian New Zealand dataset consisting of 419 UC patients and 907 controls.

Analyses showed SNPs in a number of MMP genes to be associated with UC. After correcting for multiple testing using false discovery rate analyses, SNPs in MMP-3, MMP-8, MMP-10 and MMP-14 remained significant in their associations with UC. Data from an international meta-analysis provide confirmatory results.

The data from this study provides preliminary evidence to suggest that genetic variation in the MMPs may explain a significant part of inter-individual differences in IBD susceptibility and clinical outcome, consistent with data from in vitro studies and from animal experiments.

Search for candidate genes that contributes to or protect from diabetic nephropathy in type 1 diabetes through exome sequencing. *M.G. Pezzolesi[1,2], H.A. Keenan[1,2], J.C. Mychaleckyj[3], J.S. Dunn[1], S.S. Rich[3], J.H. Warram[1], G.L. King[1,2], A.S. Krolewski[1,2].* 1) Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, MA; 2) Department of Medicine, Harvard Medical School, Boston, MA; 3) Center for Public Health Genomics, University of Virginia School of Medicine, Charlottesville, VA.

Diabetic nephropathy (DN) is a late complication that affects 30% of all patients with type 1 diabetes (T1D). Only a minority of patients with T1D, approximately 5%, survive without this complication for 50 or more years following the onset of disease. Despite its known familial aggregation and intense effort to determine the genetic components that underlie its risk, no major gene that either contributes to or protects from its susceptibility has been identified. To identify genetic variants that contribute to either risk of or protection from nephropathy in T1D, we initiated a project to resequence approximately 180,000 exons for 18,673 protein-coding genes in 3 individuals who developed DN after a short duration of T1D and 5 individuals who remained free of kidney complications despite 50 or more years of disease. Following in-solution capture using Nimblegen's SeqCap EZ Exome SR, whole exome resequencing was performed on an Illumina GAIIx Genome Analyzer. The resulting data were aligned to the human genome using BWA and processed using Samtools. These data provided a mean on-target read depth of 56-80X and 20X coverage for greater than 80% of the targeted region. Multi-sample variant calling was implemented using GATK. In total, we identified 32,682 non-reference SNPs, including 2,459 (7.5%) novel variants not annotated in dbSNP or present in data available from the 1000 Genomes Project and 14,084 (43%) non-synonymous SNPs that map to 6,939 distinct genes. We identified an average of 6,574 non-synonymous SNPs, including 6,534 and 40 nonsense variants, per exome. Among these non-synonymous SNPs, 1,581 and 4,163 were unique to individuals with and without DN, respectively. Nine-hundred thirteen genes contained non-synonymous SNPs that were exclusively observed in patients with early onset DN, while 2,565 genes contained non-synonymous SNPs that were exclusively observed in patients without kidney complications. Together, these data implicate several potential candidate genes in the pathogenesis of diabetic nephropathy in type 1 diabetes. Efforts to expand this project to included ~20 individuals who developed DN after a short duration of T1D and ~20 individuals who remained free of kidney complications despite 50 or more years of disease are currently underway. We anticipate that these studies will aid in identifying genes that contain functional changes associated with either the risk of or protection against this complication.

872W

Candidate Gene Identification in a Pediatric Patient with Immune Mediated Enteropathy by Whole Genome Sequencing and VAAST Analysis. *P.G. Ridge Jr[1,2,6], R.L. Margraf[1,6], S.L. Guthery[3,6], M. Singleton[4], J.D. Durtschi[1], B. Moore[4], L.B. Jorde[4], M. Yandell[4], A. Kumanovics[1,5], K.V. Voelkerding[1,5].* 1) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Department of Biology, Brigham Young University, Provo, UT; 3) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 5) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 6) Authors contributed equally.

A 4-year-old male presented with persistent severe watery diarrhea and small intestinal total villous atrophy with dense lymphocytic infiltrate. Celiac disease antibody studies were negative and the patient failed to respond to a gluten-free diet. Coexisting hypothyroidism, hyperglycemia, and reduced numbers of FOXP3 positive CD4+ T cells suggested IPEX syndrome, but sequencing of the FOXP3 gene revealed no mutations. Under a clinical research protocol, the genomes of the patient, and asymptomatic parents and male sibling were sequenced.

Whole genome sequencing was performed using the Illumina Hiseq 2000 achieving ~30x coverage for each genome. Reads were aligned to human genome reference hg19 using BWA, with variant and indel detection performed with SAMtools. A recently developed probabilistic disease-causing variant discovery algorithm termed VAAST was used to identify candidate disease genes. VAAST performs a likelihood ratio test on variants within a given feature (gene) to calculate the probability that the target disease genotype differs significantly from the background healthy genotype. VAAST employs the use of mode of inheritance (dominant/recessive) and family pedigree information when calculating the maximum likelihood ratios.

The proband, mother, father, and unaffected sibling each had expected numbers of SNVs and indels (3.5 Million (M)/506,000, 3.6 M /500,000, 3.5 M/506,000, and 3.6 M/536,000, respectively). Each had between 10,000 and 10,500 missense variants. VAAST analysis of missense variants, assuming recessive inheritance, identified 24 candidate genes, two of which, LY9 and MICB, are of particular interest due to their known roles in immunity and previous reports suggesting roles in autoimmune diseases.

The current study, evaluating the VAAST algorithm for candidate gene identification in whole genome analyses has generated several candidate genes, including two with known roles in immunity and autoimmunity. These data provide the foundation for additional genetic and functional studies in this patient with enteropathy. Further studies will investigate other inheritance patterns.

Obesity alters adipose tissue metabolic and endocrine function and leads to an increased release of proinflammatory molecules and adipokines, which have been implicated in the pathogenesis of the chronic inflammation and insulin resistance. In this way, some studies has reported a strong relationship between polymorphisms located in inflammation-related genes, such as Interleukin 6 (IL-6), Tumor Necrosis Factor (TNF( ) and C-Reactive Protein (CRP), and increasing body mass index (BMI). To investigate the possible role of inflammation-related genes, six common SNPs within IL-6, TNF(and CRP were screened in 541 obese cases (BMI>30) and 366 non-obese Mexican controls (BMI<25). Cases and controls were recruited from two tertiary Hospitals in Mexico City. We analyzed the variants rs2069827G/T and rs1554606G/T from IL-6; TNF SNPs rs1800629G/A and rs361525G/A and the variants r1205C/T, rs1130864C/T and rs1417938T/A localized on CRP gene. Genotyping was carried out by 5' exonuclease assay (TaqMan). The association test, Hardy-Weinberg Equilibrium (HWE) and haplotypes were evaluated using EPIDAT, FINETTI and Haploview software, respectively. Genotype distributions of all SNPs were in HWE in both patients and controls. When genotypes and alleles frequencies were compared between cases and controls, no significant differences were observed in any of the variants analyzed. However, when sample was stratified by severity, the CRP rs1130864T and rs1417938A alleles were found to be associated with protection against morbid obesity (allele frequency: p=0.0052, OR=0.635, 95% CI 0.461-0.874, and p= 0.0123, OR=0.665 95% CI 0.483-0.916; and genotype frequency: p=0.0221, OR=0.440 95% CI 0.215-0.900 and p= 0.0221, OR= 0.440 95% CI 0.215-0.900, respectively). Consistently, haplotype analysis reveled a severity obesity protection haplotype (CTA), p= 0.0048, OR=0.70 IC 95% 0.54-0.90 when we campared patients with BMI>35 and controls. In conclusion, polymorphisms within the CRP gene could be severity obesity modifiers in Mexican population, however, in contrast with data previously reported, our results suggest than variants in the IL6R and TNF-(genes are not associated with BMI in Mexican population. These findings reveal a genetic heterogeneity among populations and support the need to determine the behavior of polymorphisms in each population.

A polygenic risk profile for Achilles tendinopathy incorporating components of the extracellular matrix degradation pathway. *A.V. September[1], E. Nell[1], J. Cook[2], C.J. Handley[3], M. Collins[1,4].* 1) MRC/UCT Research Unit for Exercise Science and Sports Medicine, Department of Human Biology, University of Cape Town, South Africa; 2) School of Primary Health Care, Faculty of Medicine, Nursing and Health Sciences, Monash University, Victoria, Australia; 3) School of Human Biosciences and the Musculoskeletal Research Centre, La Trobe University, Melbourne, Australia; 4) MRC/UCT Research Unit for Exercise Science and Sports Medicine, South African Medical Research Council, Cape Town, South Africa.

INTRODUCTION Achilles tendinopathy (AT) is a degenerative condition for which several risk factors have been implicated including components of the extracellular matrix (ECM) degradation pathway. OBJECTIVE The aim was to identify a polygenic risk profile using 6 variants within 5 genes involved in the ECM degradation pathway for AT. METHODS 191 asymptomatic controls (CON) and 110 participants diagnosed with Achilles tendinopathy (TEN) from South Africa and Australia were genotyped for 6 variants within 5 genes (COL5A1, MMP3, GDF5, IL-1beta, PTGER4). Total genotype scores (TGS) were calculated (2=risk, 1=neurtral, 0=protective). A Mann-Mitney test was used to determine differences in TGS distribution between CON and TEN. Median and inter-quartile ranges, sensitivity and specificity were calculated and a receiver operator characteristic (ROC) curve plotted to determine the accuracy of TGS to predict risk of AT. Statistical significance was accepted at $p<0.05$. RESULTS The TGS in CON (56.4±16.2) was significantly lower ($p<0.001$) than in TEN (62.8±13.9). ROC analysis showed a significant discriminating accuracy of risk of AT (AUC=0.62; 95%CI 0.55-0.767; $p<0.001$). CONCLUSION This study demonstrates that a polygenic profile incorporating components of the ECM degradation pathway discriminating between individuals with and without AT is feasible.

875W

A Genome-wide analysis of Copy Number Variations in Dyslexic families reveal Duplications in Language gene *PCDH11X*. *A.M. Veerappa[1], J.S. Marita Priya[2], P. Padakannaya[2], N.B. Ramachandra[1].* 1) Genomics Lab, DOS in Zoology, University of Mysore, Mysore, India; 2) DOS in Psychology, University of Mysore, Mysore, India.

Purpose: Developmental Dyslexia (DD) is a specific learning disability with unexpected difficulty in learning to read and spell despite adequate intelligence, education, environment and normal senses affecting 5-12% of school age children. Recent evidences suggest that structural variation, including copy number variations (CNVs), across the genome is common and likely contributes to human disease. **Methods:** Fifteen certified DD subjects from eight families were subjected to power analysis using standard parameters. Genomic DNA from each member of the family was extracted using Promega Wizard® Genomic DNA purification Kit. Genome-Wide genotyping was performed using an Affymetrix Genome-Wide Human SNP Array 6.0 chip. All SNPs that were called using Birdseed v2 algorithm had a Quality Control (QC) call rate of >97%. Contrast QC across all samples was > 2.5. Eigenstrat method and Bonferroni correction were used to avoid possibility of spurious associations and for multiple testing. **Results:** Testing for dyslexia showed impairment of mapping sound to symbol than mapping symbol to sound in the neurocognitive process. Association testing and CNV analysis revealed a microduplication at Xq21.3 in 5 dyslexic subjects from two families. This duplication varied in size from 113 kb to 212 kb and also the position of duplication site varied from upstream region through coding region to downstream regions. Further analysis revealed the location of the language gene, *PCDH11X* in the Xq21.3 region. Duplication sites in the subjects had a direct impact on the exon structure of the PCDH11X, which is known as protocadherin 11 X-linked. **Discussion:** *PCDH11X* codes for a cell adhesion molecule belonging to the cadherin superfamily. The protein products are expected to play a role in intercellular communication acting as axonal guidance factors and influencing the connectivity of the cerebral cortex. *PCDH11X* phenotypically is associated with verbal ability, language processing and cerebral asymmetry suggesting that this is a major new promising candidate gene involved in reading-spelling deficits in developmental dyslexia. Thus, partial duplications of *PCDH11X* affects the production and function of PCDH11X proteins causing dyslexia.

15q11.2-13.3 chromatin analysis reveals epigenetic regulation of CHRNA7 with deficiencies in Rett and autism brain. *DH. Yasui[1], HA. Scoles[1], S. Horike[2], M. Meguro-Horike[2], KW. Dunaway[1], DI. Schroeder[1], JM. LaSalle[1].* 1) Dept Medical Micro and Immuno, Univ California Davis, Med Sch, Davis, CA. 95616 011-530-754-7906, dhyasui@ucdavis.edu; 2) Kanazawa University, Frontier Science Org. Kanazawa Japan,.

Genomic copy number variants (CNVs) within human 15q11.2-13.3 show reduced penetrance and variable expressivity in a range of neurologic disorders. Therefore, characterizing the epigenetic chromatin organization of 15q11.2-13.3 is important for understanding the structural basis of this locus in normal neuronal development. Deletion of the Prader-Willi imprinting center (PWS-IC) disrupts long range imprinted gene expression resulting in Prader-Willi syndrome. Previous results establish that MeCP2 binds to the PWS-IC and is required for optimal expression of the 15q11.2-13.3 genes GABRB3 and UBE3A. To examine the hypothesis that MeCP2 facilitates 15q11.2-13.3 transcription by linking the PWS-IC to distant loci, chromosome capture conformation on chip (4C) analysis for a 13 Mb region of 15q11.2-13.3 was performed on human SH-SY5Y neuroblastoma cells. Differentiated SH-SY5Y neurons displayed 2.84 fold fewer 15q11.2-13.3 chromatin loops formed by PWS-IC interactions than SH-SY5Y undifferentiated neuroblasts, revealing a developmental increase in chromatin decondensation. Of the total 15q11.2-13.3 PWS-IC interactions identified by 4C and MeCP2 binding sites previously identified, five sites were found to significantly overlap. Remarkably, overlapping PWS-IC and MeCP2 bound loci mapped to 15q13.3 containing CHRNA7 encoding the cholinergic receptor, nicotinic, alpha 7. Consistent with these results, siRNA knockdown of MeCP2 levels abolished PWS-IC interaction with CHRNA7. Subsequent quantitative transcriptional analyses of frontal cortex from Rett syndrome and autism patients with reduced MeCP2 protein revealed significantly reduced CHRNA7 expression compared to control cortices. PWS-IC interaction with CHRNA7 was independently confirmed by FISH analysis of SH-SY5Y neuroblasts and neurons. Together, these results suggest that transcription of CHRNA7 is modulated by chromatin interactions with the PWS-IC. Loss of long-range chromatin interactions within 15q11.2-13.3 may contribute to multiple human neurodevelopmental disorders.

Functional characterization of DcR3 in EBV transformed cell lines from IBD patients of different allelic background and role in disease pathogenesis. *R. Pandey, C. Cardinale, S. Panossian, F. Wang, E. Frackelton, C. Kim, M. Frank, R. Chiavacci, K. Kachelries, S. Grant, R. Baldassano, H. Hakonarson.* Centre for Applied Genomics, Children's Hospital Of Philadelphia, Philadelphia, PA., Select a Country.

Aim: Decoy receptor3 (DcR3), a soluble receptor for FasL, plays significant role in immune suppression and tumor progression by neutralizing the FasL mediated apoptosis signal. Here we investigate the possible immuno-modulation mediated by DcR3 in EBV transformed control and patient derived cell lines with and without risk variants in the TNF Receptor Superfamily 6B gene, TNFRSF6B captured by the tagging SNP, rs2315008). Methods: Expression of DcR3 and its kinetics were examined by immunoblot analysis in whole cell lysates from EBV transformed control and patient derived cell lines of different genotype background for rs2315008 (AA, AT, TT). DcR3 induced rapid activation of nuclear factor 2B (NF-2B) monitored by immnunoblot analysis of IkB(. DcR3 knockdown was performed using specific DcR3 siRNA. Cell proliferation and cell death was measured by MMT assay. Caspase8, caspase9, caspase3, and Bcl2 expression were analyzed by western blots. Results: EBV transformed cell lines derived from IBD patients harboring risk variants in TNFRSF6B (A allele) exhibit differential pattern of DcR3 expression and NF-2B kinetics in comparison with wild type. siRNA mediated knockdown post 24hrs of nucleofection results in decreased DcR3 expression, increased cell death and decreased cell proliferation, effects that were also genotype-dependent. Conclusion: EBV cell lines from IBD patients harboring risk variants in the TNFRSF6B gene exhibit differential pattern of DcR3 expression and NF-2B activation and promote inflammation in Crohn's disease by inhibiting FasL-induced apoptosis.

Detection of the 16p11.2 chromosomal rearrangements in two patients with global developmental delay and dysmorphism. *E. Shin[1], c. Jung[1], k. lee[1], h. yeun[1], h. jung[2].* 1) Genome Res Ctr, NeoDin Med Inst, Seoul, seoul, Korea; 2) Dept. of Pediatrics, NHIC Ilsan Hospital.

Recurrent microdeletion and microduplication of approximately 550 kb at 16p11.2 was reported to occur in developmental delay, cognitive impairment, autism spectrum disorder, seizures, minor dysmorphic features without a consistent pattern and abnormal head size. Recently, many new diagnoses of 16p11.2 microdeletions and microduplications have been made by array CGH (comparative genomic hybridization) and congenital anomalies and abnormal brain findings were frequently observed in patients with these rearrangements. We report two patients identified by microarray analysis with copy number variation (CNV) of 16p11.2 (one deletion and one duplication) using Roche NimbleGen 135K (Roche NimbleGen Inc., USA). Case 1 is a 1 year old boy with dysmorphic features and mild Rt/Lt ventriculomegaly with brain MRI and has deletion in 16p11.2. And, case 2 is a 3 year old boy with developmental delay, hypotonia, failure to thrive and low set ear and has duplication in 16p11.2. Two all patients have a heterozygous loss or gain corresponding to chromosomal coordinates (chr16:26,594,890-30,100,123) with a minimal size of 535.23 kb. Recurrent reciprocal 16p11.2 deletion and duplication are charaterised by a spectrum of primarily neurocognitive phenotype that are subject to incomplete penetrance and variable expressivity. Two of our cases indicates that recurrent 16p11.2 deletions and duplications are associated with variable clinical outcome, most likely arising from haploinsufficiency of one or more genes.

Strategies for analyzing allele specificity in ChIP-seq data. *V. Vacic[1], N. Dewal[1], T. LaFramboise[2], M.L. Freedman[3,4], I. Pe'er[1].* 1) Department of Computer Science, Columbia University, New York, NY; 2) Department of Genetics, School of Medicine, Case Western Reserve University, Cleveland, OH; 3) Department of Medicine, Harvard Medical School, Boston, MA; 4) Medical Oncology Service, Dana-Farber Cancer Institute, Boston, MA.

Allele specificity can be used as a powerful tool for interrogating the relationship between genetic and functional variation. It opens the possibility for novel discoveries, such as identifying distal promoters or associating regulatory elements to genes, by probing functional variation at heterozygous sites in a single sample. In addition, analysis of allele specific effects is appealing because it eliminates the influence of environment and minimizes potential noise from otherwise variable factors across multiple experiments. We examine single nucleotide variants and how they influence distributions of histone modification marks and binding sites of DNA binding proteins. Unfortunately, it has been demonstrated that naïve analysis of allele specificity performed via aligning ChIP-seq reads against a default human reference introduces subtle biases which hamper discovery. We devise a pipeline to facilitate unbiased analysis of allele specificity in functional sequencing. When genetic variation is known upfront, biases can be mitigated by aligning reads against a “personalized” set of two haploid reference copies, modified with appropriate variants. We demonstrate that this removes bias. Under the same quality measurements we align about 0.75 to 1% more reads which span het SNPs. The unbiased ascertainment of such reads is essential for identifying sites of allelic imbalance and estimating their significance. In addition we evaluate the power to call het SNPs within deeply-sequenced transcription factor-binding peaks or histone modification domains -- which are the sites of interest in functional sequencing -- using ChIP-seq reads only. We tested this approach on HapMap sample NA12878, for which a complete catalogue of variation is known due to the 1000 Genomes Project. Using the publicly available single-end ChIP-seq data from ENCODE project the power was in the 16-26% range while on our previously unpublished paired-end ChIP-seq data the power was 84-90%. These results underscore the benefits of deep paired-end sequencing in allele specificity studies. Our results open a possibility of using allelic imbalance in ChIP-seq disease studies of samples which did not have their whole DNA sequenced and are directly applicable to studies of regulatory perturbations in cancer.

MitoDx and MitoNucleomeDx: Next Generation (NextGen) Sequencing of the Mitochondrial Genome and Nuclear Genes Synergistically Enhances the Diagnosis of Mitochondrial Disease. *N. Neckelmann[1], C. Buzin[1], W. Scaringe[1], A. Zare[1], C. Boysen[1], M. Pold[1], R. Boles[2], S. Sommer[1].* 1) MEDomics, LLC, Azusa, CA., Select a Country; 2) Los Angeles Childrens Hospital.

90+ percent of the cellular energy is derived from oxidative phosphorylation (OXPHOS) within mitochondria. The human mitochondrial DNA (mtDNA) contains only 37 genes (13 proteins required for OXPHOS, 2 ribosomal RNA genes, and 22 tRNA genes), but these genes mutate rapidly because of (i) high exposure to free radicals and other mutagenic agents, and (ii) only rudimentary mechanism are known to exist for the repair of DNA damage. However, the vast majority of genes required for oxidative phosphorylation are found within the nuclear genome. Evidence from more limited previous technology suggests that most mitochondrial disease mutations in children result from nuclear gene mutations, while most mitochondrial disease in adults arises from mitochondrial genome mutations. The revolutionary power of NextGen sequencing enables the comprehensive analysis of mtDNA mutations at ultra-low heteroplasmy levels, via ultra-deep sequencing, and the analysis of the many mitochondrial nuclear genes listed in OMIM as OXPHOS-associated diseases, as well as 120+ additional genes involved in OXPHOS and related biochemical pathways. Synergistic NextGen Sequencing of both the mitochondrial genome and OXPHOS nuclear genes allows analysis of patients suspected of having mitochondrial diseases with unprecedented rigor. In addition, sequencing of both the mitochondrial genome and the mitonucleome facilitates the analysis of interactions between mtDNA and nuclear gene variants which may affect the penetrance and/or severity of the disease. Three illustrative cases will be presented. It is hoped that coordinated NextGen sequence-based testing of DNA derived from blood samples will send most muscle biopsies to hell, where they belong.

A Comprehensive Next-Generation Sequencing Panel for Molecular Testing of Primary Ciliary Dyskinesia (PCD) and PCD-like Ciliopathies. *S. Lee, S. Mexal, W. Guo, A. Kammesheidt.* Ambry Genetics, Aliso Viejo, CA.

Primary Ciliary Dyskinesia (PCD) is a genetically heterogeneous, usually autosomal recessive disorder with impaired ciliary function leading to progressive sinopulmonary disease. Upper and lower respiratory tract manifestations are key features of PCD and are often present at birth. Upper respiratory tract features include chronic nasal drainage, sinusitis, and otitis media. Lower respiratory features include neonatal respiratory distress, chronic productive cough, chronic bronchitis, recurrent pneumonia, and bronchiectasis. Approximately half of the PCD patients have situs inversus (also known as Kartagener's syndrome) and at least ~6% have situs ambiguous (heterotaxy). Fetal cerebral ventriculomegaly and hydrocephalus can also occur due to impaired circulation of the cerebrospinal fluid. In adults with PCD, male infertility and female sub-fertility are also common features. Prompt diagnosis of PCD is critical for the prevention of secondary respiratory complications, such as bronchiectasis, pneumonia and/or progressive loss of lung function. Diagnosis of PCD has relied on identification of ciliary dysmotility and specific ciliary ultrastructural defects. Most PCD patients (80-90%) have defective outer dynein arms (ODA), and/or inner dynein arms (IDA). A few patients have defective radial spokes (RS) or central apparatus (CA). Because ultrastructural studies are challenging and not readily available, the diagnosis is often delayed or missed or made incorrectly. In some patients, PCD is confirmed by genetic studies despite normal ciliary ultrastructure. Thus far, disease-causing mutations have been identified in eleven genes coding for ODA proteins (DNAI1, DNAI2, DNAH5, DNAH11, TXNDC3), RS proteins (RSPH4A, RSPH9), cytoplasmic proteins involved in DA assembly (C14orf104/KTU, LRRC50) and in RPGR and OFD1. Full gene sequence analysis in molecular testing of PCD is costly and time-consuming due to the relatively large size of many of the disease genes and the extensive locus heterogeneity. Targeted resequencing offers an alternative, more cost-effective approach for enrichment and next-generation sequencing (NGS) of all exons of candidate genes in parallel. RainDance targeted amplification of exons and exon/intron boundaries of eleven genes associated with PCD was carried out followed by Illumina's NGS. This study presents performance data of the Ambry panel for Primary Ciliary Dyskinesia (PCD) and PCD-like ciliopathies.

Detection of copy-number changes in Bardet-Biedl syndrome by targeted array CGH. *A. Lindstrand[1], C. Carvalho[2], J.R. Lupski[2,3], N. Katsanis[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham NC, USA; 2) Department of Molecular and Human Genetics and Department of Pediatrics, Baylor College of Medicine, Houston TX, USA; 3) Texas Childrens Hospital, Houston TX, USA.

Bardet-Biedl syndrome (BBS: MIM209900) is a multisystemic developmental disorder characterized by retinal degeneration, obesity, polydactyly, mental retardation, renal dysfunction, and hypogonadism. Extensive in vitro and in vivo studies have highlighted BBS as a model ciliopathy, with at least 16 causal genes. In addition, cis and trans modifier alleles contribute to variable expressivity and reduced penetrance both in BBS and across the ciliopathy spectrum, supporting the hypothesis that the mutational load in the ciliary proteome plays a critical role in defining disease presentation. As part of our systematic analysis of the ciliary proteome in BBS families irrespective of their primary genetic lesion, we have initiated a systematic examination of CNV in disease burden. To establish the genetic contribution of CNVs in the known BBS loci and to identify new BBS genes, we tested 102 BBS patients by a targeted custom array CGH with 180,000-60mer oligos/array and 4 arrays/slide focusing on 772 `ciliary proteome'-genes. On average, coding sequences had a probe density on 1/100bp and non-coding sequences 1/500bp. Target genes were selected based on known association with ciliopathies, known association with in vivo ciliary dysfunctions and genes from the ciliary proteome. The results showed the presence of multiple CNVs in known BBS genes including either single or multiple exons (for example ARL6, BBS4, BBS5 and BBS12), as well as in other ciliopathy genes (such as NPHP1); indicating that this mutational mechanism contributes significantly to the disease burden. In addition, we found new candidate BBS loci that are presently undergoing in vivo and in vitro validations. Functional studies will also demonstrate whether more common copy number changes might be causal and/or represent modifiers in BBS.

ChIP-Enrich: An application for improved gene set enrichment testing of ChIP-Seq results. *C. Lee[1], R.A Smith[2], R. Welch[1], L. Scott[3], M.A. Sartor[1,3].* 1) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Human Genetics, University of Michigan, Ann Arbor, MI; 3) Biostatistics, University of Michigan, Ann Arbor, MI.

Gene set enrichment testing is used to identify predefined biologically related sets of genes that are over- or under-represented in data from a biological experiment. ChIP-Seq experiments allow assessment of genome-wide protein-DNA interactions. Microarray based gene set enrichment testing methods have been used to analyze ChIP-Seq peaks, but direct use of these methods can create false positives and negatives. Unlike microarray data each ChIP-Seq peak has to be assigned to a gene. Genes with greater distance to their nearest neighbors are more likely to contain a peak and biological categories such as nervous system, development, cell adhesion, and transcription are enriched for such genes. Furthermore, some gene loci are more mappable than others, and peaks are more likely to be identified in highly mappable loci. Existing methods do not take mapability into account; this can affect the results, because as we show, mapability is also associated with functional gene categories. We developed an empirical approach to correct for potential biases introduced by differing locus lengths and mapabilities. We estimated weights for each gene based on the relationship between the mappable locus length and presence of a peak in the overall data using a binomial smoothing spline. We perform a modified version of the random sets method, weighing genes to correct for peak bias due to locus length and mapability. Our method is available in the application, ChIP-Enrich. We tested our method on simulated and experimental ChIP-Seq data. For example, we simulated ChIP-Seq peaks such that a specified percent were false positives (randomly assigned to the genome), and a randomly chosen Gene Ontology (GO) term, e.g. reproduction, was purposely enriched. We used Fisher's exact test and ChIP-Enrich to test for enrichment. Fisher's exact test identified nervous system development and other GO terms with longer loci lengths as most significantly enriched, whereas ChIP-Enrich correctly identified reproduction and related GO terms. Simulating data under the null hypothesis, ChIP-Enrich showed the expected uniform distribution of p-values. With experimental data, we show that ChIP-Enrich provides expected results, as opposed to Fisher's Exact test, which resulted in nervous system development as the top enriched GO term. Our results suggest that our method corrects for bias due to gene locus length and mapability, thus allowing for discovery of biologically enriched gene sets.

Computational Genomics for genome sequencing: development of a pipeline graphical workflow environment. *F. Macciardi[2,3], F. Torri[2,3], P. Petrosyan[1], Z. Liu[1], A. Zamanyan[1], P. Eggert[1,4], J. Pierce[1], A. Genco[1], J.A. Knowles[5], A.P. Clark[5], J.D. Van Horn[1], J. Ames[2], C. Kesselman[2], A.W. Toga[1,2], S.G. Potkin[2,3], I. Dinov[1,2].* 1) Laboratory of Neuro Imaging (LONI), UCLA, Los Angeles, CA; 2) Biomedical Informatics Research Network (BIRN), Information Sciences Institute (ISI-USC), Los Angeles, CA; 3) Department of Psychiatry and Human Behavior, UCI School of Medicine, Irvine, CA; 4) Department of Computer Science,UCLA, Los Angeles, CA; 5) Zilkha Neurogenetic Institute, USC Keck School of Medicine, Los Angeles, CA.

Background and rationale Whole-genome and exome sequencing in simple traits have already proven to be powerful methods to identify genes responsible for several disorders. These methods are also beginning to be applied to complex traits as well, other than being adopted as the current mainstream approach in population genetics. These achievements have been possible mostly thanks to next generation sequencing technologies; however, a substantial bioinformatics work is needed to analyze sequence data. Within the framework of a joint collaboration between LONI (Laboratory of Neuro Imaging) at UCLA and BIRN (Biomedical Informatics Research Network) at UCI, ISI and USC, we have developed a pipeline environment for genomics computations that may enable genetic investigators to simplify and speed-up their approaches to real genome sequencing projects. **Methods: Implementation of Genomics and Informatics Pipeline Protocols** To develop a complete Pipeline biomedical solution to a well-defined genomic computational challenge as analyzing sequencing data, there are essential steps to follow: protocol design, tool installation, module definition, workflow implementation, and workflow validation. Implementing these steps for specific sequencing issues and using the framework of the already existing LONI pipeline environment originally created for neuroimaging analyses[1,2], we have developed modules for basic sequence alignment and search, sequence data quality control, SNPs and CNVs identification, molecular annotation and visualization of results, These represent the essential basic steps of any genome sequencing task. **Results** We developed the Graphical Pipeline for Computational Genomics and Visual Informatics (GPCG) with a flexible graphical infrastructure for efficient biomedical computing and distributed informatics research. The GPCG is intended to satisfy needs of geneticists and computational scientists who are interested in whole genome sequence projects. Our aim is to allow advanced sequence data processing, integrate diverse arrays of computational tools and services, promote community-based protocol validation, and openly share and disseminate knowledge, tools and resources. The current version of the pipeline is available for interested researchers at both http://www.birncommunity.org/ and http://pipeline.loni.ucla.edu [1] Rex DE et al 2003-Neuroimage doi:10.1016/S1053-8119(03)00185-X [2] Dinov I et al 2010-PLoS ONE doi:10.1371/journal.pone.0013070.

Molecular characterization of mutations in CYP21A2 gene from indian congenital adrenal hyperplasia patients. *N. Rehal[1], A. Bhansali[2], R. Walia[2], D. Dayal[3], G. Kaur[4], R. Prasad[1].* 1) Biochemistry, PGIMER, Chandigarh, India; 2) Endocrinology, PGIMER, Chandigarh; 3) Pediatrics , PGIMER, Chandigarh; 4) Physiology, GMCH, Chandigarh.

The congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder that occurs due to presence of mutations in CYP21A2 gene, which expresses 21-hydroxylase enzyme. It catalyzes the conversion of progesterone to deoxycortisone. More than 90% of cases are caused by 21-hydroxylase deficiency, and the severity of the resulting clinical symptoms varies according to the level of 21-hydroxylase activity. The CAH is associated with different phenotypes, viz simple virilizing, salt wasting and nonclassical CAH. It is noteworthy that there are only few reports available on spectrum of mutations in CYP21A2 gene from Indian CAH population. In view of this fact, the present study was conducted to establish spectrum of mutation in CYP21A2 gene from Indian patients. In this study 35 CAH patients and their families were included. Out of the 35 patients, 43% were males and 57% were females. The serum 17OHP levels were found to be several folds higher than the normal in CAH patients. Additionally, hyponatremia and hyperkalemia were also observed in the patients. In salt wasting cases, minimum and maximum ages of onset were found to be at birth and 26 days of life respectively. In simple virilizing cases, the minimum and maximum ages of onset were found to be at birth and 16yrs respectively. In nonclassical CAH cases, the minimum and maximum ages of onset were found to be at 13 yrs and 19 yrs respectively. Out of 35 patients 50% were of simple virilizing, 29% were of salt wasting and 21% were of nonclassical CAH. Further, the studies were carried out to establish the spectrum of mutations in CYP21A2 gene from CAH patients. At first instance, most common mutations present in other populations were analysed using RFLP, further these mutations were molecularly characterized by subsequent DNA sequencing. The genetic analysis study revealed that maximum patients were heterozygous for R356W mutation, followed by gene deletion. It was ascertained that P30L and V281L, I172N and i2g , R356W, E6 cluster, Q318X, and gene deletion are associated with non classical, simple virilizing and salt wasting forms of CAH respectively. In conclusion the most common mutation (R356W) was found with 54% frequency. Our results have shown a good genotype/phenotype correlation in the case of most common mutations.

886W

***De novo* transcriptome assembly by pooling samples in case-control studies identifies novel events missed by alignment-based approaches.** *M.W. Snyder[1], R.P. Nair[2], L.C. Tsoi[1], T. Tejasvi[2], P.E. Stuart[2], B. Li[1], H.M. Kang[1], J.T. Elder[2,3], G.R. Abecasis[1].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Dermatology, University of Michigan, Ann Arbor, MI; 3) Ann Arbor Veterans Affairs Hospital, Ann Arbor, MI.

Next-generation shotgun sequencing technologies allow the characterization of the transcriptomes of individual tissues. Typically, many short sequence reads are generated from a cDNA library, which provides a snapshot of gene expression in a particular sample. These short sequence reads can either be mapped to known transcript sequences (or the reference genome) or can be assembled *de novo*. While technically more challenging, *de novo* transcriptome assembly has enhanced ability to detect completely novel transcripts, including variation not present in the reference genome that might be missed by alignment-based analyses.

Here, we used next generation sequencing technologies to characterize gene expression in punch biopsy samples of lesional skin from 92 psoriasis patients and site-matched samples of normal skin from 82 controls. We generated an average of 38 million 80-bp reads per sample. We first pooled reads across individuals and assembled potential transcripts using the software ABySS. After assembly, contigs were filtered by length and number of supporting reads, and compared against known transcript and EST collections to identify candidate novel events. At the time of abstract submission, we identified 18,919 known transcripts representing 14,335 genes present in both cases and controls, along with smaller numbers of transcripts unique to each set (1,084 in cases 1,864 in controls). We further assembled 8,585 and 13,076 contigs 100bp or longer in cases and controls, respectively, which were unmapped to reference collections and potentially represent previously unannotated transcripts or portions of transcripts. We then searched for evidence of differential gene expression between cases and controls and identified 2,049 differentially expressed genes. The set of highly differentially expressed genes included IL17D, IL20RA and IL20RB, and IFNGR2, consistent with previous reference-based analyses, but also identified differential expression of previously unidentified transcripts such as an extended 3' UTR in DSC1.

Our results show that *de novo* transcriptome assembly in case-control samples can yield insights into the genetic architecture of complex diseases.

Complex structural polymorphisms predispose to 15q13.3 deletion syndrome. *F. Antonacci[1], PH. Sudmant[1], JA. Rosenfeld[2], L. Vives[1], A. Stuart[3], TA. Graves[4], RK. Wilson[4], LG. Shaffer[2], CT. Amemiya[3], EE. Eichler[1].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Signature Genomic Laboratories, LLC, Spokane, WA 99207, USA; 3) Benaroya Research Institute at Virginia Mason, 1201 9th Avenue, Seattle, WA 98101, USA; 4) The Genome Institute at Washington University, Washington University School of Medicine, St Louis, MO 63108, USA.

The human genome is a highly dynamic structure that shows a wide range of genetic variation ranging from SNPs to a variable number of tandem repeats and structural alterations such as deletions, duplications and inversions. Complex structural polymorphisms are significantly enriched in regions of segmental duplications but most of this diversity has yet to be characterized at the sequence level. Different duplication architectures have been shown to predispose and protect specific haplotypes as well as different population groups to microdeletions associated with genomic disorders. The 1.5 Mbp microdeletion at chromosome 15q13.3 is one of the most common recurrent mutations associated with intellectual disability, schizophrenia and epilepsy. We developed next-generation sequencing coupled with cytogenetic-based assays to characterize the organization, orientation and segmental duplication architecture of this region in multiple individuals from different ethnicities. Using fluorescence in situ cohybridization experiments, we identified a total of four alternate structural configurations of the 15q13.3 region ranging in size from 2.2 to 2.8 Mbp. In particular, the inverted haplotype shows a significantly smaller and less complex organization than the directly oriented haplotypes. Our preliminary analysis of 809 human genomes suggests an inversion allele frequency of 6% in individuals from different populations. Analyzing multiple individuals from two outgroup species of great apes (chimpanzee and orangutan), we show that the large inversion polymorphism is specific to the human lineage. To resolve the complex segmental duplication organization of the 15q13.3 region, we are creating a BAC library resource from 16 human genomes. Complete sequencing of a contiguous set of 17 BAC clones from one haplotype corresponding to this 2.8 Mbp region on 15q13.3 has discovered a smaller inversion of a 150 kbp region not detectable by cytogenetic assays. This inversion places pairs of highly identical segmental duplications, flanking the disease-critical region, in direct orientation creating a configuration predisposing to 15q13.3 microdeletion. Using high density and targeted array-based comparative genomic hybridization (CGH) experiments, we examined 13 microdeletion samples and mapped the breakpoints of the disease-critical region to these large blocks of segmental duplications, which we posited might mediate the recurrent rearrangement associated with disease.

Hydroxyurea induces de novo copy number variants in human cells. *M.F. Arlt[1], A.C. Ozdemir[1], S.R. Birkeland[2], T.E. Wilson[2], T.W. Glover[1].* 1) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 2) Department of Pathology, University of Michigan, Ann Arbor, MI.

Copy number variants (CNVs), defined as deletions or duplications of a few kilobases to over a megabase, are widely distributed throughout the human genome, where they contribute to genetic variation and phenotypic diversity. Spontaneous CNVs are also a major cause of genetic and developmental disorders, including intellectual disability, neuropsychiatric disorders and structural birth defects, and arise frequently in cancer cells. As with all mutation classes, genetic and environmental factors almost certainly increase the risk for new and deleterious CNVs. However, despite the importance of CNVs, there is limited understanding of these precipitating risk factors and the mechanisms responsible for a large percentage of CNVs. Here we report that low doses of hydroxyurea, an inhibitor of ribonucleotide reductase and an important drug in the treatment of sickle cell and other diseases induces a high frequency of de novo CNVs in cultured human cells that resemble pathogenic and aphidicolin-induced CNVs in size and breakpoint structure. We exposed normal human fibroblasts to HU-mediated replication stress and generated clonal cell populations, which were analyzed for CNVs using high-resolution SNP arrays. We found that treatment with low doses of HU, equivalent to patient serum levels, resulted in de novo CNVs at a frequency of 1.8-2.4 CNVs/clone, a significant increase over the 0.7 CNVs/clone seen in untreated cells ($p<0.001$). These CNVs are distributed throughout the genome, and several hotspots of de novo CNV formation were found, including 3q13.31 at the LSAMP gene and 7q11.22 at AUTS2. Sequencing revealed that CNV breakpoint junctions are characterized by short microhomologies, blunt ends, and short insertions, consistent with the hypothesis that these rearrangements are the result of nonhomologous repair processes and not homologous recombination repair. These data provide direct experimental support for models of replication-error origins of CNVs and further suggest that any agent or condition that leads to replication stress has the potential to induce deleterious CNVs. In addition, they point specifically to a need for further study of the genomic consequences of the therapeutic use of hydroxyurea.

A Genome-Wide Investigation of Copy Number Variation in Patients with Sporadic Brain Arteriovenous Malformation. *N. Bendjilali[1], H. Kim[1], S. Weinsheimer[1], P.Y. Kwok[1], J.G. Zaroff[2], S. Sidney[2], C.E. McCulloch[1], W.L. Young[1], L. Pawlikowska[1].* 1) University of California , San Francisco, CA; 2) Kaiser Permanente Division of Research, Oakland, CA.

Background: Brain arteriovenous malformations (BAVM) are a tangle of poorly formed blood vessels with abnormal connections between arteries and veins. AVMs often occur in patients with hereditary hemorrhagic telangiectasia, an autosomal dominant disease with mutations in TGF-beta pathway genes, but most are sporadic. Copy number variation (CNV) has been reported in TGF-beta pathway genes and in other brain vascular malformations. We hypothesized that CNVs (defined as deletions or duplications of a DNA segment >1kb in size) may be associated with sporadic BAVM. **Methods:** 338 BAVM cases and 510 healthy controls of Caucasian ethnicity were genotyped on the Affymetrix 6.0 SNP array. We used PennCNV to identify deletions and duplications on the 22 autosomes, adjusting for genomic waves. We used standard quality control (QC) filters, excluded outliers, and further restricted analysis to CNVs called based on >10 markers. CNVs passing QC were merged into CNV regions (CNVR) using a reciprocal overlap threshold of >70%. We performed both a CNVR-based analysis and a gene-based analysis to assess for association with BAVM compared to controls using one-sided Fisher's exact tests. A Bonferroni correction was used to adjust for multiple testing. To validate our findings, we repeated the above analyses using CNVs called by the Birdsuite algorithm. **Results:** After QC, we observed a total of 34,253 CNV calls in 270 cases and 457 controls using PennCNV. 5119 CNVRs were constructed and tested for association with BAVM; 2 CNVRs (duplications) on 1p36.13 and 4p16.3 were significantly enriched in cases compared to controls using PennCNV and Birdsuite. From the gene-based analysis, 28 genes showed statistically significant enrichment of duplications in cases versus controls. Of those, 13 genes were replicated using Birdsuite. 4 of these 13 genes map to the associated CNVRs on 1p36.13 (NBPF1 and NBPF10) and 4p16.3 (ZNF595 and ZNF718). **Conclusions:** We conducted the first genome-wide study of CNVs in sporadic brain AVM, and have identified two CNVR loci that significantly differ between cases and controls. These CNV loci overlap NBPF genes known as candidate tumor suppressor genes linked to neuroblastoma, where ZNF595 and ZNF718 genes may be involved in transcriptional regulation. These results need to be validated experimentally and replicated in an independent brain AVM cohort.

CNV load in recessive carrier status - preliminary findings from exon-targeted array comparative genomic hybridization (aCGH). *P.M. Boone[1], C. Shaw[1,2], S.W. Cheung[1,2], A.L. Beaudet[1,2,3,4,5], P. Stankiewicz[1,2,6], A. Patel[1,2], J.R. Lupski[1,2,4,5].* 1) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Medical Genetics Laboratories, Baylor College of Medicine, Houston, TX; 3) Dept. of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX; 4) Dept. of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Texas Children's Hospital, Houston, TX; 6) Dept. of Medical Genetics, Institute of Mother and Child, Warsaw, Poland.

We previously reported that exon-focused clinical aCGH, in which array probes are concentrated in exons of disease genes, enables the detection of small copy-number variations (CNVs) affecting single genes or even single exons. We now show that, in addition to detecting intragenic CNVs associated with specific dominant clinical phenotypes, exon-targeted aCGH unveils heterozygous single-gene mutations in recessive disease genes (i.e. establishing carrier status) and in disease genes for late onset dominant disorders (i.e. potentially predicting disease susceptibility). DNA from 9,005 anonymized clinical patients was analyzed by exon-targeted aCGH. Computational analyses revealed CNVs in 3,946 individuals, 1,295 of whom exhibited a single CNV affecting a single gene. Eighty-six of these CNVs encompassed or disrupted one of 242 genes implicated in severe, pediatric, recessive disease [Bell et al. Sci Transl Med 3:65ra4 (2011)] and for which at least one exon had enhanced probe coverage on our array. In total, 39 unique genes were affected, including *AHI1* (Joubert syndrome, type 3), *ATR* (Seckel syndrome, type 1), *BCKDHB* (classic maple syrup urine disease, type 1B), and *CRTAP* (osteogenesis imperfecta, type IIB). For 77/86 individuals, a brief (1-10 words) clinical indication was available; 6 of these descriptions suggested the possibility of recessive disease corresponding to the affected gene [e.g. “dysmorphic features” and *VPS13B* (Cohen syndrome)], though no indications were pathognomonic for any disorder. Our cohort also includes examples of potentially damaging single-gene CNVs in genes associated with susceptibility to dominant late onset disease, for example *SPAST* (autosomal dominant hereditary spastic paraplegia, type 4) and *EXT2* (multiple exostoses, type 2). Previous investigation of carrier status and genetic load, whether population-based or grounded in recently acquired personal genome sequences, has focused on simple nucleotide variation (SNV). Our findings demonstrate that assessing CNV using clinical exon-targeted aCGH is an effective means not only for diagnosing genetic illnesses, but also for identifying CNV resulting in recessive carrier states and potential predisposition to late onset dominant disease. Which of these many variants are likely medically actionable and reportable to clinicians is an evolving question, made particularly challenging when the mutation is novel and has not been functionally or epidemiologically assessed.

Copy Number and Allelic Variation of Immunoglobulin Variable Gene IGHV1-69 and HIV Progression. *F. Breden[1], C. Watson[1], J. Willsey[1], M. Brockman[2], F. Pererya[3], B. Walker[3].* 1) Biological Sciences, Simon Fraser University, Burnaby, British Columbia, Canada; 2) Molecular Biology and Biochemistry and Faculty of Health Sciences, Simon Fraser University, Burnaby, British Columbia, Canada; 3) Ragon Institute of MGH, MIT and Harvard, Charlestown, Massachusetts, USA.

The immunoglobulin Variable (V) gene IGHV1-69 is used in at least one neutralizing antibody against HIV, and is greatly enriched in the antibody responses to HIV and influenza. This gene is also elevated in several autoimmune diseases and is characteristic of CLL (chronic lymphocytic leukemia). Human IGH haplotypes exhibit extensive copy number (CNV) and allelic variation for IGHV1-69, although how this variation is distributed among geographical populations is unknown. Also, it is not clear how well human SNP assays can determine these IGHV1-69 haplotypes, and therefore possible associations between germline variation and human diseases remains untested by conventional genome-wide association studies (GWAS). To test for such associations, we have developed a TaqMan assay to measure copy number and allelic variation in order to rigorously genotype individuals at IGHV1-69. We validated this approach by comparing CNV and allelic state of several human HapMap samples by cloning and sequencing and by our new TaqMan assay. The results agreed in all cases. We then compared spontaneous controllers of HIV infection to normal HIV+ progressors, and observed an increase in copy number for alleles with a distinctive hydrophobic amino acid in CDR-H2 in the spontaneous controllers. This allele is known to be associated with anti-HIV and anti-flu antibodies.

Hutterite genome sequencing identifies potential asthma genetic susceptibility variants. *C.D. Campbell[1], M. Malig[1], A. Ko[1], L. Vives[1], B.J. O'Roak[1], C. Alkan[1], P.H. Sudmant[1], L. Han[2], M. Abney[2], M.J. Rieder[1], C. Ober[2], E.E. Eichler[1,3].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Howard Hughes Medical Institute.

Copy number variants (CNVs) may be important in the development of asthma: many associations between common CNVs and disease were with immune-related phenotypes, and immune genes are overrepresented in CNV regions. We hypothesized that CNVs, including recurrent CNVs, are a source of genetic risk for asthma. To test this hypothesis, we studied individuals from an extended 13 generation Hutterite pedigree who have reduced genetic heterogeneity due to a small founding gene pool and reduced environmental heterogeneity as a result of a communal lifestyle. We selected six individuals for whole-genome sequencing: three had asthma and were from asthma-enriched families and three did not have asthma and were from asthma-poor families. All six individuals are related to each other within four to ten generations. We generated 10-15X effective sequence coverage of the genome for each of these six individuals using the Illumina HiSeq2000 platform. Using sequencing read-depth, we have genotyped 7,550 known CNVs. Of these CNVs, 3,456 (46%) were copy number variable in these six individuals; 97 CNVs were enriched in the asthmatics or had an asthmatic individual as an outlier compared to the controls and to 45 CEU individuals (1000 Genomes Project). We tested 31 of these CNVs using microarray comparative genomic hybridization in an additional 74 Hutterites with asthma and 201 Hutterite controls and found three (9.7%) that showed a nominally significant difference between asthmatics and controls. Of particular interest was the *beta-defensin* cluster of genes on chromosome 8, where we found that the median copy number of asthmatic individuals was significantly lower than controls ($p = 0.019$). Defensins are antimicrobial peptides, and copy number of this locus has been implicated in other immune-related diseases. In addition, we have identified previously unreported genetic variants, including 750 deletions from pair-end mapping (including 44 that affect coding sequence), 56 frame-shifting indels, 25 nonsense mutations, 34 splice-site mutations, and 1,302 missense mutations. We are integrating both CNV and other disruptive mutations into the haplotype structure of these six individuals to identify regions of identity-by-descent that may help to explain the enrichment of asthma in some families and paucity of asthma in other families of this large pedigree.

893W

dbVar: A database of genomic structural variation. *D. Church, T. Hefferon, J. Lopez, J. Garner, N. Husain, M. DiCuccio, J. Paschall, M. Feolo, S. Sherry, D. Maglott.* Natl Ctr Biotech Infor/NIH, Bldg 45 Rm 5AS43, Bethesda, MD.

As part of NCBI's comprehensive approach to facilitate research into the discovery and understanding of human variation, we have developed an archive of large-scale variation called dbVar. In collaboration with our sister archive DGVa, we currently hold over 50 human studies, including those assessing individuals with no determined phenotype, such as 1000 Genomes, as well as studies looking at complex structural variation in phenotyped individuals, such as data from the ISCA consortium and data from a tumor and matched normal set. This collection consists of a diverse set of variants ranging from deletions, insertions, inversions and more complex events. One of the challenges of capturing such data is that discovery methods often do not define the precise breakpoints of the events being assayed. Additionally, different analytic methods can produce multiple interpretations of the same underlying data. Thus, we have developed a data model that attempts to capture the evidence for a particular variant call, as well as validation information when available. Additionally, we store and display ambiguity when breakpoint resolution has not been obtained. Each variant region is assigned a unique identifier of the type SV (nsv|esv) and each variant instance (or example) is given a unique identifier of the type SSV (nssv|essv). NCBI has taken an integrated approach to managing human variation data. Information from individuals that have not consented to have their DNA sequence made publicly available can submit controlled access data to dbGaP. Genotype information can be deconstructed, after which summary data can be submitted to dbVar. This approach has been used to make summary data from several studies, including data from the ISCA consortium, widely available. While dbVar serves a primary role in defining molecular events, integration with the ClinVar database allows for clinically important information to be layered on the variants in dbVar. We also make use of other NCBI resources such as Gene, PubMed, dbSNP and our assembly alignment and analysis tools to provide a comprehensive resource that allows for both the molecular definition of large-scale variation and integration with other biological information to aid in the interpretation of this data.

Genome-wide copy number detection and analysis in a large diabetes cohort implicates rare yet recurrent imbalances in *INS*, *ABCC8* and *KCNJ11*. *L. Davis[1], J. Below[1], A. Konkashbaev[1], K. Aquino-Michaels[1], V. Paz[1], E. Cook[2], G. Bell[1], N. Cox[1].* 1) Section Genetic Medicine, The University of Chicago, Chicago, IL; 2) Department of Psychiatry, The University of Illinois, Chicago, IL.

Type 1 diabetes mellitus (T1DM) is a chronic disease resulting from autoimmunological destruction of the insulin-secreting cells in the pancreas. Complications of T1DM can be serious and include nephropathy retinopathy, neuropathy and peripheral vascular disease. The Genetics of Kidneys in Diabetes (GoKinD) cohort was collected to study these complications. Our study sought to investigate the role of copy number variation (CNV) in T1DM and diabetic complications in the GoKinD data set. DNA samples from patients and unaffected parents (2,726 individuals with T1DM with and without diabetic complications) were tested for CNV using the Affymetrix Genome-Wide Human SNP Array 5.0. Signal intensity values generated from the SNPs and copy number probes present on the array were then analyzed with PennCNV which utilizes a Hidden Markov Model to detect deviations in signal intensity indicative of CNVs. After sample-based and CNV-based quality control measures were implemented, a complete set of 66,719 CNVs was generated consisting of CNVs detected in patients (N= 1930) and unaffected parents (N=956). We identified a number of rare yet recurrent CNVs in patients including known candidate genes for diabetes and nephropathy. Mutations in these genes are associated with hypo- and hyperglycemia. These CNVs have are currently undergoing validation with real time PCR methods and are exceedingly rare as evidenced by their absence from the comprehensive Database of Genomic Variants (DGV). Additionally, we have identified a small number of deletions and duplications indicating monogenic forms of diabetes (MODY) masquerading as T1DM in this large cohort (e.g. *HNF1B* and *HNF4A* deletions). The results are consistent with the hypothesis that copy number variation plays a role in the development of T1DM and its complications.

Comparative Analysis of High Resolution Array Platforms Reveals Diverse Genome-wide Copy Number Variation Detection in Humans. *R.R. Haraksingh[1,2], A. Abyzov[3,4], M. Gerstein[4,5], A.E. Urban[1,6], M. Snyder[1].* 1) Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT 06520; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA 94305; 3) Program in Computational Biology & Bioinformatics, Yale University, New Haven, CT 06520; 4) Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT 06520; 5) Department of Computer Science, Yale University, New Haven CT 06520; 6) Department of Psychiatry and Behavioral Sciences, School of Medicine, Stanford University, Stanford, California 94305.

Accurate and efficient genome-wide detection of copy number variants (CNVs) is essential for understanding human genomic variation, genome-wide CNV association type studies, cytogenetics research and diagnostics, and independent validation of CNVs identified from sequencing based technologies. Numerous, array-based platforms for CNV detection exist utilizing array Comparative Genome Hybridization (aCGH), Single Nucleotide Polymorphism (SNP) genotyping or both. We have quantitatively assessed the abilities of eight leading genome-wide CNV detection platforms to accurately detect Gold Standard sets of CNVs in the genome of HapMap CEU sample NA12878, and found significant differences in performance. The technologies analyzed were the NimbleGen 2.1M and 3x720K Whole Genome and CNV focused arrays, the Agilent 2x400K CNV and SNP+CGH arrays, the Illumina Human Omni1Quad array and the Affymetrix SNP 6.0 array. The Gold Standards used were a 1000 Genomes Project sequencing-based set of 3997 validated CNVs and an ultra high-resolution aCGH-based set of 756 validated CNVs. We found that sensitivity, total number, size range and breakpoint resolution of CNV calls were highest for CNV focused arrays. Our results are important for cost effective CNV detection and validation for both basic and clinical applications.

Longevity has a strong genetic component evidenced by family-based studies. Lipoprotein metabolism, FOXO proteins, and insulin/IGF-1 signaling pathways in model systems have shown polygenic variations predisposing to shorter lifespan. To test the hypothesis that rare variants could predispose individuals to shorter lifespan, we compared the rates of CNVs in healthy children (0-18 years of age) with individuals 67 years or older. CNVs at a significantl higher frequency in the young cohort were considered risk variants impacting lifespan, while those in the old cohort were considered longevity protective variants. We performed a whole-genome CNV analysis on 7,313 children and 2,701 adults of European ancestry genotyped with 302,108 SNP probes. Positive finding were evaluated in an independent cohort of 2,079 young and 4,692 old subjects. We detected 8 deletions and 10 duplications that were enriched in the young group (P=3.33x10-8 1.6x10-2 unadjusted), while only one duplication was enriched in the old cohort (P=6.3x10-4) These CNVs replicated in the independent cohort (combined P=2.33x10-16-1.8x10-4) and were experimentally validated, using qPCR. Evaluation of these genes for pathway enrichment demonstrated one-half involved in alternative splicing (P=0.0077 Benjamini and Hochberg corrected). We conclude that genetic variations disrupting RNA splicing could have long-term biological effect impacting lifespan.

Copy number variation and transcription levels of the PXE-gene ABCC6 and its pseudogenes. *M.K. Kringen [1], C. Stormo [2], R.M. Grimholt [2], J.P. Berg [2], A.P. Piehler [2].* 1) Department of Pharmacology, Oslo University Hospital, Ullevål, Oslo, Norway; 2) Department of Medical Biochemistry, Oslo University Hospital, Ullevål, Oslo, Norway.

Background: The ATP-binding cassette transporter ABCC6 is located on chromosome 16 along with its two pseudogenes (ABCC6P1 and ABCC6P2). Mutations in ABCC6 cause pseudoxanthoma elasticum. Previously, we have shown that ABCC6P1 is transcribed and affect ABCC6 at the transcriptional level. The aim of this study was to determine copy number variations in ABCC6, ABCC6P1 and ABCC6P2. Moreover, we sought to study the transcription pattern of ABCC6P2 in 39 differen human tissues. Methods: Genomic DNA from fiv populations (Chinese (n=24), Middle East (n=20), Mexicans (n=24), Caucasians (n=50) and Africans (n=24), were examined for copy number variation of ABCC6 and its pseudogenes. Due to the high sequence similarities of the three genes, relative copy numbers were determined by pyrosequencing. Previously, we determined the expression pattern of ABCC6 and ABCC6P1 in 39 human tissues by RT-qPCR. By pyrosequencing, we were now able to quantify the relative transcription of ABCC6P2 to ABCC6 and ABCC6P1 in the same tissues, and thereby to deduce the relative expression of ABCC6P2 from the previous expressional data of ABCC6 and ABCC6P1. Results: Copy number variation of ABCC6 was very rare (2/142). However, deviation in copy number was more frequent for ABCC6 pseudogenes. In Africans, no deviation from the normal copy number of two was found for ABCC6 pseudogenes. In Chinese, deletions or duplications of ABCC6P1 were more frequent than in any other population (9/24). Furthermore, in the total population (n=142), 1 or 3 copies of ABCC6P1 was relatively common (3% and 8%, respectively). Only one person had 1 copy of ABCC6P2 while none had 3 copies. The transcription pattern of ABCC6P2 was highly similar to ABCC6 and ABCC6P1, with highest transcription in liver and kidney. Interestingly, the total transcription of pseudogenes, ABCCP1 + ABCC6P2 was higher than ABCC6 in most tissues, including liver and kidney. Conclusions: By pyrosequencing, we were able to quantify copy number variation of ABCC6 pseudogenes. Having less or more copies of ABCC6 pseudogenes is quite common, especially in populations of Chinese ancestry. The expression pattern of ABCC6P2 in 39 human tissues was highly similar to that of ABCC6 and ABCC6P1 suggesting similar regulatory mechanisms for ABCC6 and its pseudogenes. Furthermore, the findin of a higher expression of ABCC6 pseudogenes than ABCC6 in many tissues, strongly support that they may have an important biological function.

898W

Genome-wide analysis of rare CNVs in control populations. *L.-P. Lemieux Perreault [1, 2], E. Giannoulatou [1], M.-P. Dubé [2], C. Spencer [1], P. Donnelly [1,3], The Wellcome Trust Case Control Consortium 2.* 1) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Montreal Heart Institute, Université de Montréal, Montréal, Québec, Canada; 3) Department of Statistics, University of Oxford, Oxford, United Kingdom.

Recently, a number of genome-wide associations studies have been conducted using rare copy number variations (CNVs) typed on SNP arrays. The power to detect associations relies on the accuracy of CNV detection (SNP density, algorithm, etc.) and on appropriate quality control filters. To minimize the false positive rate, researchers tend to filte calls based on fixe criteria such as size, number of probes, confidenc measure and presence of rearrangement-prone regions. There are also differen ways to specify CNV regions (such as reciprocal overlap) in the presence of imperfect CNV detection. Differen criteria, thresholds, or definition will result in substantially differen calls, due to a change in both false positive and false negative rates. For associations with rare CNVs false negative calls (failure to detect the CNV in individuals) can lead to spurious associations. To study the impact of differen detection methods and quality control procedures in association studies, control samples from three sources genotyped on both Affymetri 6.0 and Illumina custom array Human 1.2M-Duo have been used. The control samples consisted of approximately 9,000 healthy individuals from the National Blood Service, the 1958 Birth Cohort and the Wellcome Trust funded People of the British Isles study. Technical replicates of the HapMap sample NA12878 were also genotyped on Affymetri 6.0 (n=345) and Illumina Human660W (n=68). The firs phase was to perform an evaluation of concordance of CNV calls in between NA12878 replicates, as well as in between platforms and calling algorithms. A comparison of these calls with a well-characterized data set (1000 Genomes Project) using differen overlap definitio and thresholds has been performed, showing a high variability. The second phase was to compare the CNV burden between control groups, as previous studies have found an increase in genome-wide CNV burden in cases compared to controls. Fold change between control groups for the mean number of calls, the mean size of calls, the mean total size of calls and the mean number of overlapped genes have been compared between control groups. The third and last phase was to test for association, treating one control group as cases and another as controls, using a gene-centric approach consisting offi nding how many calls overlaps a given gene for each group. This study highlights difficulti underlying rare CNV calling, filterin and association analyses.

Identification of a novel locus associated with the common birth defect spina bifida. *L. Muthuswamy[1], AG. Bassuk[2], R. Boland[3], M. Hakeman[3], J. Dierdorf[3], A. Hulstrand[3], G. Bonde[4], R. Cornell[4], DW. Houston[3], JR. Manak[2,3,5].* 1) Ontario Institute for cancer Research, Toronto, Canada; 2) Department of Pediatrics, University of Iowa, College of Medicine; 3) Department of Biology, University of Iowa, Iowa City, IA; 4) Department of Anat and Cell Biology; 5) Carver Center for Genomics, University of Iowa, Iowa City, IA.

Neural Tube Defects (NTDs) such as spina bifida are common birth defects of complex etiology. Family and population studies have confirmed a genetic component underlying NTDs. However, despite more than three decades of research, the genes involved in human NTDs remain largely unknown. We used array-based comparative genomic hybridization (aCGH) to identify copy number variants (CNVs) in 122 spina bifida cases, including 20 trios. We performed two types of analyses: one looking for rare spontaneous copy number variations (SCNVs), and one looking for rare genes enriched in the disease population compared to unaffected parents and the publically available database of genomic variants. We identified 28 de novo copy number variants (SCNVs) comprising 105 genes and approximately 480 genes within rare regions of duplications and deletions in the disease population. One de novo heterozygous deletion removed Pax3, a previously identified candidate gene for spina bifida, among several other genes. Another smaller de novo heterozygous deletion removed glypican 5 (GPC5) and part of glypican 6 (GPC6). Glypicans act by modulating the activity of morphogens such as Wnts, which themselves are candidate genes for spina bifida. However, up to now, glypicans have not been considered to be candidate genes for this disorder. To determine whether GPC5 or 6 has a role in neural tube closure, we used antisense morpholino oligonucleotides to inhibit their function in both the frog, Xenopus tropicalis, and the fish, Danio rerio. We show that knockdown of GPC5/6 results in neural tube closure defects in both vertebrate model systems, providing strong evidence that loss of glypican function is etiologic for human spina bifida.

Copy number variations are associated with osteoporotic fracture: The Framingham Osteoporosis Study. *K. Nandakumar[1], C.L. Cheung[1], H. Zhou[1], Y. Zhou[2], C.T. Liu[2], S. Demissie[2], D. Karasik[1], A. Cupples[2], D.P. Kiel[1], Y.H. Hsu[1].* 1) Institute for Aging Research, Boston, MA; 2) Boston University, Boston, MA.

Osteoporosis is a skeletal disorder characterized by low bone mineral density (BMD) and the deterioration of bone tissue, predisposing to an increased risk of fracture. Though vertebral fractures are the most common type of osteoporotic fractures, non-vertebral fractures, are associated with high levels of morbidity and mortality. Although, GWAS have successfully discovered novel SNPs associated with osteoporosis related skeletal phenotypes, these common variants explain only 10% of BMD variance in Caucasians. Furthermore, there have been no GWAS for fractures. To discover additional genetic determinants of bone phenotypes, we conducted a genome-wide CNV association analysis of osteoporotic fractures in 8,700 adult men and women from the Framingham Osteoporosis Study. The CNVs were called from the Affymetrix 500K chip using the PennCNV package, and then confirmed by the Golden Helix SVS CNV module. The PennCNV software uses Hidden Markov Models to predict CNV events, whereas Golden Helix uses the optimal segmenting algorithm. A total of 112,745 CNV events were estimated in the Framingham population. Non-vertebral osteoporotic fractures (Non-vt O-Frx) (excluding fractures resulting from high-impact trauma, skull, spine, finger and toe fractures) were ascertained by medical records/X-ray images in most cases or were self-reported. There were 1,671 men and 2,160 women with at least one Non-vt O-Frx. Association analysis was performed by using a burden test for rare/low frequency CNV regions. The PLINK software was used to perform the burden test by chromosomes (http://pngu.mgh.harvard.edu/~purcell/plink/). From the burden test we found chromosomes 8, 9 and 15 to be significantly associated with non vertebral fracture based on the number of segments (or CNV events) and proportion of samples with one or more segments. To further identify rare events, regional tests were performed for CNV regions on each chromosome. One of the regions on 15q11.2 was shown to be significantly (adjusted P=0.02) associated with Non-vt O-Frx This is the first study showing the contribution of CNVs to the susceptibility to osteoporotic fracture for which replication will be sought in other cohorts.

High resolution map of canine copy number variation. *E. Nevalainen[1,2,3], J. Berglund[6], C. Hitte[4,5], A. Nyström[6], C. André[4,5], M. Webster[6], H. Lohi[1,2,3], K. Lindblad-Toh[6,7], LUPA Consortium.* 1) Veterinary Biosciences, Univ Helsinki, Helsinki, Finland; 2) Department of Medical genetics, University of Helsinki, Finland; 3) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Finland; 4) CNRS, UMR6061, Institut de Génétique et Développement de Rennes, F-35000 Rennes, France; 5) Université de Rennes 1, IFR 140, F-35000 Rennes, France; 6) Department of Medical Biochemistry and Microbiology, Uppsala University, Sweden; 7) Broad Institute of Harvard and Massachusetts Institute of Technology.

Copy number variations (CNVs) are an important form of structural variation in mammalian genomes. Substantial amount of phenotypic differences between healthy individuals have been attributed to CNVs and they also contribute to disease risk in several human disorders including autism spectrum disorders, schizophrenia and epilepsy. Dog breeds as genetic isolates have recently emerged as a new model for human inherited diseases. Hundreds of genetic diseases have been identified in dogs, many of which are similar to human diseases and are likely to have a similar genetic background. CNVs are expected to play a role in several disease conditions in dogs and contribute to breed-specific characters. This study aims to map and catalogue CNVs in 50 dogs from 17 breeds (2-10 dogs/breed) and 3 wolves by comparative genome hybridization (aCGH) using Nimblegen's arrays with 2.1 million probes giving a high resolution of approximately 1 kb median probe spacing across the canine genome. This density gives considerably higher resolution than previously published studies. A Finnish Boxer DNA was used as a reference for other breeds. The results of this high resolution analysis of the CNVs in a large number of breeds provide important discoveries likely to contribute to several phenotypes in dogs and are being followed up in many cohorts available in the European canine genomics effort, LUPA consortium. Furthermore, findings associated with genetic diseases can be tested on human cohorts and eventually this will improve the health of both species. The new CNV data will be discussed in the meeting.

903W

Detection of copy number variations (CNVs) in PARK2 and SNCA in Parkinson disease patients using NanoString® technology. *K. Nuytemans[1,2], G. Bademci[1,2], L. Wang[1,2], S. Zuchner[1,2], F. Nahab[3], C. Singer[3], T. Guettouche[1,2], J.M. Vance[1,2].* 1) John P. Hussman institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL.

CNVs are recognized as a prevalent form of structural variation in the genome, contributing to genetic variability and susceptibility for complex diseases such as Parkinson disease (PD). Disease causing CNVs have been reported in four out of five major PD genes. Therefore, detection of CNVs is of major research and clinical interest. Interestingly, whole gene multiplication of *SNCA* is more common than missense mutations, while up to 50 percent of mutations identified in *PARK2* represent CNVs of one or more exons of the gene. CNVs in other PD genes appear to be far less common. Current CNV detection technologies can lead to high false-positive rates, can be expensive and labor intensive when screening in a large set of samples for many genomic regions. We employed a novel direct digital detection method developed by NanoString to screen for exonic CNVs in *SNCA* and *PARK2*. Multiplexed, fluorescent barcoded probes bind directly to genomic DNA without any amplification step, avoiding biased overrepresentation of specific genomic regions. This digital method allows high-throughput detection of multiple CNVs in a single reaction. In a total of 125 individuals, we included both positive and negative controls, previously screened with SNP and CGH arrays. Family members of the positive controls were also included to investigate segregation. Presence or absence of CNVs was confirmed in 13/13 positive and 64/64 negative controls, indicating that the NanoString technology provides accurate results. Additionally, segregation of *PARK2* CNVs with disease was shown in six out of nine families. Interestingly, the three instances of non-segregation to other affected relatives involved isolated deletions or duplications of *PARK2* exon 2. In summary, we are able to utilize this high-throughput technique that circumvents many of the previous technology-based issues to detect CNVs in PD related genes. Our results indicate that the NanoString technology is very reliable and user-friendly. We expect this analysis system will be a promising alternative for current CNV detection methods. The reason for non-segregation of the *PARK2* exon 2 CNVs is not clear. These CNVs might not be the causal PD mutations in these families. Currently, we are sequencing these families for other potential *PARK2* mutations. However, these results emphasize the importance of determining CNV segregation when evaluating pathogenicity.

Detection of novel copy number variation in individuals with autism spectrum disorder using a comparative genomic hybridization array. *A. Prasad[1], C.R. Marshall[1,2], B. Thiruv[1], J. Wei[1], J.L. Howe[1], D. Pinto[1], J. Rickaby[1], Q. Tran[1], S.W. Scherer[1,2].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON., Canada; 2) McLaughlin Centre, Faculty of Medicine, University of Toronto, ON., Canada.

Autism spectrum disorder (ASD) is a neurodevelopmental condition with a strong genetic component. Previous studies have reported rare copy number variations (CNVs) to be associated with autism and implicated several contributing risk loci/genes. There are a variety of platforms available to detect CNVs including comparative genomic hybridization (CGH) and single nucleotide polymorphism (SNP) arrays. Each platform has its own advantages and disadvantages and can be complementary. In the present study, we used the Agilent 1M CGH array to detect novel rare CNVs in more than 700 unrelated ASD probands which have been previously run on other SNP microarrays. The high-resolution Agilent 1M CGH array has a total of 974,016 probes providing uniform whole genome coverage. The ASD cases were competitively hybridized to a pool of fifty sex-matched Caucasian controls as a reference. The CNV calling was performed using Aberration Detection Module 2 (ADM2) algorithm of DNA Analytics 4.0.85 and a circular binary segmentation (CBS) algorithm implemented in the DNAcopy package. The CNVs detected by both algorithms were defined as stringent and were utilized for further analyses. The calls were compared with the CNV data from Illumina 1M single and duo, Affymetrix 500K, Affymetrix 6.0 & Illumina 2.5M arrays. For example, 350 samples in our dataset were run previously on Illumina 1M single array which was analyzed using two algorithms-iPattern and QuantiSNP. The average number of stringent calls generated for Agilent 1M and Illumina 1M is 36 and 18, respectively. We found that only 27% of the total Agilent 1M call set was detected using the Illumina 1M platform. Conversely, 46% of the Illumina 1M calls were not detected using the Agilent 1M platform. The difference in the CNVs detected using multiple platforms is mainly due to the differences in probe distribution and sensitivity of the detection algorithms used. In addition, we have detected several novel rare CNVs using Agilent 1M array which were missed by other SNP genotyping platforms. Some of the novel CNVs encompasses genes that are known to play a potential role in neurodevelopment e.g. *NF1*, *CTNNA2*, *DPYD*, *YWHAE*, *NRXN1*, *DMD* and have been experimentally validated. Our data suggests that use of multiple platforms is advantageous for both maximizing CNV discovery and validation rates in case-cohorts.

Discovery of Pseudoautosomal region 3 redefines the structure and function of Human X and Y chromosomes. *N.B. Ramachandra[1], A.M. Veerappa[1], J.S. Marita Priya[2], P. Padakannaya[2].* 1) Genomics Lab, DOS in Zoology, University of Mysore, Mysore, India; 2) DOS in Psychology, University of Mysore, Mysore, India.

Purpose: Recombination is restricted to the tips of the short and long arms of the X and Y chromosomes, which contain pseudoautosomal region 1 (PAR1) and pseudoautosomal region 2 (PAR2). Beside the PARs, homology also exists in the X-transposed region (XTR), which is at Xq21.3 and Yp11.2.When the PAR2 block and XTR block were both created by duplication and have a high level of sequence homology, then the question arises as to why recombination would be limited only to the PARs? **Methods:** DNA of fifteen dyslexic subjects, their parents and unaffected siblings, from eight families were subjected to whole genome genotyping using an Affymetrix Genome-Wide Human SNP Array 6.0 chip. All SNPs and CNVs had a Quality Control (QC) call rate of >97% across all subjects and controls. Contrast QC across all samples was > 2.5. Genomic DNA of these subjects was amplified by PCR using X and Y specific primers for validation. **Results:** A mother of a dyslexic subject from one of the families revealed two transposed blocks of 144 kb and 102 kb of Yp11.2 in the Xq21.3 region of one of her X chromosomes. The presence of these transposed blocks was validated by using Y- and X-specific primers for PCR. A further analysis of the blocks revealed the presence of *PCDH11Y* exons of the Yp11.2 region. These transposition sites had a direct impact on the exon structure of *PCDH11X*. The subject had a total of 6 exon transpositions, from the 1st to the 6th exon, which truncated the gene arrangement from the sixth exon. **Discussion:** Xq21.3 region has a history of duplication and transposition activity by means of a duplicated and later transposed block of 3.5 Mb from the X to Y chromosome approximately 5-6 MYA. This process is very similar to the origination of the PAR2. Like the PARs, XTR has 98.78% identity, and *PCDH11X* in the XTR has a 99.1% identity with its PCDH11Y allelic homolog. A few genes in PAR1 and PAR2 are known to escape inactivation in the inactivated chromosome. Likewise, a few genes in Xq21.3/*PCDH11X* escape inactivation. PAR2 and XTR (PAR3) share similar type of origin and creation. PAR2 is found to exhibit a much lower frequency of pairing and recombination than PAR1. Thus, one can expect varied frequency of recombination in each of these PAR regions, which could be due to the differential structural dynamics of the X and Y chromosomes. Therefore, this recombination event in the XTR can be regarded as a PAR3 region.

CNV detection Using Uncertainty of Read Mapping. *z. wang[1], f. hormozdiari[1], w. yang[2], e. eskin[1].* 1) Computer Science Department, University of California, Los Angeles, Los Angeles, CA; 2) Bioinformatics Program, University of California, Los Angeles, Los Angeles, CA.

Copy number variation (CNV) has widely been known as a genetic risk factor for disease. The development of high-throughput sequencing (HTS) technologies has provided great opportunities to detect CNV regions in mammalian genome. Millions of short reads generated from donor genome using HTS are mapped back to the reference genome. Then depth-of-coverage information can be used for identification of copy variation regions. However, a large fraction of the reads can be mapped to more than one position. Most existing methods only consider reads that can be uniquely mapped to the reference genome, and therefore have low power in detecting CNV, especially those located within repeat sequences. We proposed a probabilistic model that utilizes the uncertainty of read mapping. We use maximum likelihood to estimate locations and copy number of copied regions, and implemented an expectation-maximization (E-M) algorithm to update the mapping posterior probabilities of each read. One important contribution of our model is that we can distinguish between regions in the reference genome that slightly differ from each other. We can also predict the CNV with high resolution. Previous methods either divide the genome into small windows or use paired-end reads to find a rough boundary. These strategies make the resolution of predicted copy regions low. Our method takes each single nucleotide as the basic unit, and thus can predict the breakpoints precisely. We applied our method to simulation datasets and achieved higher accuracy.

Characterizing copy number variation at the human immunoglobulin heavy chain locus. *C.T. Watson[1], K.M. Steinberg[2], R.L. Warren[3], F. Hach[4], J.B. Joy[1], T. Graves[5], R.K. Wilson[5], C. Sahinalp[4], R.A. Holt[3], E.E. Eichler[2], F. Breden[1].* 1) Department of Biological Sciences, Simon Fraser University, Burnaby, British Columbia, Canada; 2) Department of Genome Sciences, University of Washington, Seattle, Washington, USA; 3) Genome Sciences Centre, BC Cancer Agency, Vancouver, British Columbia, Canada; 4) School of Computing Science, Simon Fraser University, Burnaby, British Columbia, Canada; 5) The Genome Institute, Washington University, St. Louis, Missouri, USA.

The human immunoglobulin heavy chain (IgH) locus spans approximately 1 MB of chromosome 14, and consists of 120-130 functional and nonfunctional variable (V) gene segments that reside adjacent to ~27 diversity (D), 9 joining (J), and 11 constant (C) functional and non-functional gene segments. Each of these groups of gene segments is the result of duplication and divergence, making the IgH locus one of the most segmentally duplicated regions of the human genome. As in many parts of the genome, segmental duplication in IgH has lead to extensive copy number variation (CNV), the extent and distribution of which are not fully known. For example, upwards of 15 expressed V genes remain uncharacterized at the genomic level, and are not included in the current human reference sequence. Large insert clones, such as bacterial artificial chromosomes (BACs) and fosmids provide a useful resource for characterizing CNV-containing haplotypes in human populations. As part of a larger project seeking to describe polymorphisms across immunoglobulin loci that are relevant to human disease, we analyzed complete sequences of 30 fosmid and BAC clones mapping to the IgH region from multiple human populations, including the first complete haploid sequence for IgH from a single human chromosome constructed using a hydatidiform mole BAC library. BAC and fosmid sequences allowed for the characterization and mapping of many previously undescribed insertions and deletions within IgH, including multiple V genes with known roles in infectious and autoimmune diseases. These data are now being used to (1) assess the mutational mechanisms directing CNV in Ig loci, (2) design genotyping assays to assess the frequency of these polymorphisms across human populations as well as test for associations with infectious and autoimmune disease susceptibility, and (3) assess the efficacy of next-generation short-read sequence mapping approaches and tag SNPs to interrogate these polymorphisms.

dbSNP: Database of Short Genetic Variations. *R. Maiti, H. Zhang, M. Kholodov, D. Shao, E. Shekhtman, D. Rudnev, K. Sirotkin, M. Ward, D. Maglott, M. Feolo, S. Sherry, L. Phan.* National Center for Biotechnology Information (NCBI), National Library of Medicine (NLM), National Institutes of Health (NIH), Bethesda, MD.

The National Center for Biotechnology Information (NCBI) develops and maintains dbSNP as an open source centralized database of short genetic variations. There are three major functionalities in this resource: 1) archiving submitted variants, 2) integrating the variant information with relevant NCBI resources, and 3) disseminating variant information in a biological context to the scientific community worldwide. dbSNP not only catalogs millions of variations from large projects such as The SNP project, The International HapMap Consortium, and 1000 Genomes, but also catalogs thousands of variations with clinical properties from Locus Specific Databases (LSDB) and clinical sources. Both neutral and clinically significant variations are accessioned in a standard process for publication, and are accessible for search and download. dbSNP archives submissions, and assigns a unique identifier to each variant for citing in manuscripts and providing the appropriate acknowledgement to the submitter. Data submitted as changes relative to a reference sequence, e.g., an HGVS expression, are validated against that reference and returned to the submitter if any discrepancy is identified. The original data provider is given access to a specific link to maintain their own submissions. Data are integrated with other NCBI resources such as Sequence Viewer, RefSeqGene, Gene, PubMed, ClinVar, and OMIM®, for interpreting the variants in a variety of biological contexts as such as positions on the genome, genes or proteins, functional implications, clinical relevance, and scholarly publications. Variant records can be accessed through NCBI's web search system using different parameters and filters, such as type of variation, clinical significance, somatic allele origin, minor allele frequency (MAF), location on the genome, or suspected artifact. For example, users wanting to retrieve only single nucleotide polymorphisms can ask for variations of type `single nucleotide variation' with MAF > 0.01. Complete variation datasets can be downloaded from the dbSNP FTP site in such formats as FASTA, XML, and ASN.1, and VCF. Data from clinical sources are displayed in the gene-centric Variation Viewer, where clinical significance and testing status are reported. LSDB and other clinical researchers may continue to submit via the specialized data submission system (http://www.ncbi.nlm.nih.gov/SNP/tranSNP/VarBatchSub.cgi); data will be integrated into ClinVar.

Determination of *RET* sequence variation in an MEN2 unaffected cohort using multiple-sample pooling and massively parallel sequencing. *R. Margraf[1], J. Durtschi[1], J. Stephens[1], M. Perez[1], K. Voelkerding[1,2].* 1) Research & Development, ARUP Institute for Clinical & Experimental Pathology®, Salt Lake City, UT; 2) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT.

Determination of sequence variation within a genetic locus is essential for developing clinically relevant databases, designing molecular assays and clinical test interpretation. In this study, multi-sample, non-indexed pooling combined with Illumina Genome Analyzer (GA) sequencing was used to discover sequence variation within the *RET* proto-oncogene for a cohort known to be unaffected by Multiple Endocrine Neoplasia type 2 (MEN2). Known unaffected DNA samples (113 Caucasians and 23 of other ethnicities) were amplified for the *RET* gene (from intron 9 to intron 16, ~9Kb amplicon). Amplicon concentrations were normalized using Sequalprep and quantified by Picogreen. Between 27 and 29 Caucasian samples' amplicons were pooled before Illumina library prep and GA sequencing (4 pools total). The ethnic cohort was sequenced in a separate pool. Two controls were also included in this study (previously GA sequenced for the 9Kb *RET* amplicon and Sanger sequenced for *RET* exons): a single sample and also a pool of 50 samples. The single sample control was used for the subtraction correction method on the pools. All 59 variants previously detected in the 50 pool were present. Of the 57 variants detected in the unaffected cohort, 6 and 10 variants of low variant frequency were unique to the 113 Caucasian sample set and ethnic pool, respectively. A total of 20 variants were novel changes, not seen in the 50 pool control or in dbSNP132. Several variants within the unaffected cohort were validated by high-resolution melting analysis and Sanger sequencing, and the expected allele frequencies correlated with the GA sequencing frequencies determined for the pools. The variant results from the unaffected cohort will be added to the *RET* MEN2 database and also used for comparison in case reports. These methods can be applied to other pooled samples (such as genetic locations for GWAS follow up) and natural pools (such as mitochondrial heteroplasmy or mixed tumor populations).

ALFRED: A resource for research and teaching. *H. Rajeevan[1,2], U. Soundararajan[1], A.J. Pakstis[1], J.R. Kidd[1], K.K. Kidd[1].* 1) Genetics, Yale University, New Haven, CT; 2) Center for Medical Informatics, School of Medicine, Yale University School of Medicine, New Haven, CT.

ALFRED (http://alfred.med.yale.edu) is a unique resource of allele frequency data on human population samples available for use by the scientific and educational communities. A five-fold increase in allele frequency tables over the past year (663,410 polymorphisms, 710 populations and 35,227,249 frequency tables (one population typed for one site)) has necessitated creation of efficient search and summary functions. Though not all polymorphisms have been studied on all populations, there are over 150 different polymorphisms (including SNPs, InDels, and STRPs) with data on over 100 different populations and over 6,000 on more than 52 populations. The Illumina ~650K marker set have data on 50 populations (HGDP-CEPH panel and the Kidd Lab Korean population). We highlight developments to facilitate effective use of ALFRED: one to use the available search options to search and identify a gene, polymorphism or population and another to use the various summary tables to identify polymorphisms that can be explored further within ALFRED and the databases to which active links exist. In response to user feedback we have revised the `homepage' to make it easier for first-time users (especially students) to learn how to search and navigate within ALFRED. Other new additions include highlighting interesting examples in ALFRED as part of increased effort to make ALFRED a better didactic tool through empiric human population genetics. Some such highlighted SNPs include those for earwax type (rs17822931 at ABC11), hair thickness (rs3827760 at EDAR), skin color (rs16891982 at SLC45A2), and bitter taste (haplotypes of rs713598, rs1726866, and rs1024639 at TAS2R38). The textual materials in the `Educational Material' section under the `Documentation tab' also provide suggestions and starting points to help with possible classroom projects. ALFRED is supported by US NSF BCS0938633.

Tracing experimental process flow to the original biologics in genomic relational databases. *S. Saccone, J. Quan.* Department of Psychiatry, Washington University, St Louis, MO.

There is growing evidence that the results of genetic association studies are enriched for certain kinds of genomic data such as eQTLs and biochemical pathways. The integration of genetic association studies with genomic databases may therefore provide new insights into these studies and further their impact on public health. In order to viably integrate genome-wide genetic association results with today's exciting, diverse and ever-expanding genomic databases, we need new methods and tools for assessing credibility by systematically tracing genomic data through the experiments that generated it back to the original biologics. Our solution to this challenge is the introduction of the new biologic-experiment-result (BERT) relational database model. The BERT model viably captures the sequence of experiments that produced the data in a genomic database. Its implementation will enable investigators to assess credibility by tracing key information back through these experiments to, whenever possible, the original biologics and samples. We have implemented the BERT model in an interactive web application for graphically visualizing experimental process flow. The web application allows investigators to explore the data from all parts of the experimental process in high detail using methods based on our dbSNP-Q application (http://cgsmd.isi.edu/dbsnpq). One example that we have incorporated with particularly high detail is the HapMap relational database. Because of its ubiquity in designing commercial genotyping arrays and guiding disease association studies, there is a substantial need to assess the credibility and reliability of HapMap data. For all 11 populations in the HapMap Phase III Release 3 and Public Release 28 databases, the web application enables investigators to trace experimental results, such as allele frequency and linkage disequilibrium estimates, back through processes such as statistical analysis, genotyping and quality control assessment to detailed information on DNA extraction for the original subjects. Public genomic databases rarely provide a systematic means of tracing the data back to its experimental origins. The BERT model and its implementation in a web application represents a key step in overcoming this major obstacle to the viable integration of diverse genomic databases for studying the genetics of human disease.

dbGaP: genotype data processing and QC. *N. Sharopova, J. Paschall, Z. Wang, L. Hao, Y. Jin, M. Kimura, S. Stefanov, S. Pretel, A. Sturcke, M. Feolo, S. Sherry*. NCBI/NLM/NIH, Bethesda, MD.

Data sharing in human genetics benefits the community by reducing research costs, time and by providing opportunities for data verification. However the necessity of combining genomic datasets generated by more than one independent research team and/or across various technologies raises concerns about standards of data sharing, accessibility of proper data annotation/quality metrics, as well as availability of standard methods and tools for routine data merging and evaluation. In addressing these concerns, NCBI's dbGaP (http://www.ncbi.nlm.nih.gov/gap) has implemented submission and quality control processing steps necessary for the deployment of community accepted quality standards. Today, dbGap stores and provides access to genotype data for more than 350,000 subjects. The dbGaP's genotype curators are actively involved with investigators in the curation of submitted genotype datasets. Based on recommendations from NIH and UW investigators, genotype processing pipelines were developed to ensure internal and cross-dataset consistency in annotation, quality control, and representation of genotype data. Considering the size of genomic datasets, the dbGap team constantly searches for more flexible ways of serving genotype data to the community. Data flow for genotype data processing, quality control, and accepted quality standards will be presented.

913W

A relational database for next-generation sequencing data. *C. Xu, Q. Tian, J. Li, H.W. DENG*. Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, School of Public Health & Tropical Medicine, Tulane University, New Orleans, LA 70112.

Rapid advances in high-throughput DNA sequencing technologies, along with dramatically reduced cost, have allowed increased scales in whole-genome sequencing of multiple individuals. Management and analyses of the huge amount of data generated from whole-genome sequencing studies demand dedicated and efficient software. To satisfy such increasing needs, we have designed and implemented a relational database, with a focus on the sequencing data generated on the Complete Genomics, Inc. platform. Our software is easy to use and provides multiple functionalities such as integrated management of sequencing data from multiple individuals, variant extraction based on types and/or from pre-selected genomic regions, and annotation information extraction and comparison across multiple sequences. Incorporated comparison and analyses of different forms of genomic data, such as SNP, DNA sequence, RNA sequence, from the same individual can also be easily performed. In addition, similar operation on sequencing data from other platforms is also under development. Our database is a sophisticated tool and can provide excellent help for next-generation sequencing based research.

914W

An automated workflow for library preparation, target enrichment, and bioinformatics processing for large-scale 2nd Generation resequencing studies. *D. Hedges[1], T. Guettouche[1, 2], C. Siebert[1], A. Griswold[1], C. Kroner[1], S. Slifer[1], M. Schmidt[1], P. Whitehead[1], I. Konidari[1], W. Hulme[1], A. Andersen[1], A. Lekas-Diaz[1], R. Gentry[1], Y. Pasco[1], A. Aviram[1], G. Beecham[1], M.A. Pericak-Vance[1], J.R. Gilbert[1].* 1) Center for Genome Technology, Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, Florida; 2) Oncogenomics Core Facility, Sylvester Comprehensive Cancer Center, University of Miami Miller School of Medicine, Miami, Florida.

Second Generation sequencing in the context of large population-based genetic studies has necessitated the development of automated workflows that minimize human intervention. Manual execution of protocols in high-throughput scenarios is laborious and presents numerous opportunities for the introduction of human error. To improve throughput for a large-scale 2000 sample autism targeted resequencing study covering 17Mb (corresponding to the exons of 689 genes), we have developed an automated library and target enrichment workflow. The laboratory automation operates in tandem with a downstream informatics processing pipeline that navigates samples through alignment, quality control, genotype calling, and genomic annotation. The laboratory component of our workflow automates the Illumina library preparation and Agilent SureSelect capture protocol using the Sciclone G3 and Zephyr Liquid Handling Workstations (Caliper). We divided our workflow into pre-PCR (Sciclone G3) and post-PCR (Zephyr) components. Library preparation and target enrichment included optimization of purification to maximize sample recovery. Our approach includes methods for quality control (QC), post-shearing quantitation and normalization, and post-hybridization amplification. The hybridization set up is carried out within an open deck layout and includes an innovative liquid handling step to account for temperature differences and evaporation. In contrast to manual protocols, our workflow currently has a maximum throughput of 384 samples per five day work week, and the resulting sequencing metrics are comparable to manual protocol performance. Following Illumina HiSeq2000 sequencing, an informatics pipeline was developed to automate the processing of samples through BWA alignment, quality control, genotype calling (via GATK Unified Genotyper), and genomic annotation. Results are then archived in VCF format for downstream statistical analysis. Our bioinformatics pipeline targets the LSF load distribution system for parallelization on a 5000 core Linux cluster (PEGASUS). The pipeline allows for complete informatics processing of a HiSeq2000 flow cell (56 multiplexed samples) in approximately 5 hours, enabling downstream data process to provide rapid feedback to the laboratory. Our performance data indicate that the workflow is an efficient and robust solution for large-scale genetic studies requiring targeted resequencing.

915W

Flexible Desktop Software for Genome Assembly and Variation Analysis. *M. Keyser[1], T. Durfee[1], T. Schwei[1], S. Baldwin[1], R. Nelson[1], D. Nash[1], D. Jurzcak[1], C. Stern[1], J. Stieren[1], A. Pollack-Berti[1], K. Maxfield[1], E. Ma[1], A. Niffenegger[1], K. Dullea[1], P. Pinkas[1], R. Solberg[1], G. Plunkett III[1,3], F. Blattner[1,2,3].* 1) DNASTAR, Inc., Madison, WI; 2) Scarab Genomics LLC; 3) University of Wisconsin.

The new biotechnology and biomedical frontiers opened up by next generation sequencing (NGS) also pose significant hurdles in terms of data management, assembly and analysis. Most available software solutions require cobbling together disparate programs that typically require substantial computing resources and bioinformatics expertise. In addition, these systems may be fine tuned to a particular sequencing platform. At DNASTAR, we have developed an integrated suite of software programs for assembling and analyzing NGS data from all of the major platforms and supporting the key workflows on a desktop computer. At the core of the suite is the SeqMan NGen assembler, which runs on Windows, Macintosh and Linux operating systems, and assembles single and paired end data from all the major NGS technologies: Illumina, Roche 454, Ion Torrent, Helicos and SOLiD. The assembler shows excellent performance on modestly priced desktop computers. For example, whole human genome assemblies of deep Illumina data (35x) take less than 24 hours on a $2500 desktop computer with 16GB of RAM while human exome assemblies (~150x coverage) take about three hours on the same computer. Probabilistic SNPs/small indels and genotype calls are included in the output with known variants identified by their dbSNP IDs. The new assembler version expands on this foundation in two crucial areas. First, a structural variation report is included for identification of large indels, inversions and translocations. Second, multiplexed (e.g. MID-tagged) samples can be processed and assembled either as individual data sets or as one or more groups. These capabilities make SeqMan NGen a truly fully functional, high performance desktop assembler for discovering genetic variation from NGS data sets of any size or configuration. Interactive alignment and strategy views within SeqMan Pro, together with tables for SNPs, structural variation, coverage, and features, allow for efficient navigation through even large projects such as human genome assemblies. New multi-sample views and tables provide for analysis of MID-tagged or indexed samples in a single project. For large multi-sample projects composed of hundreds of individual data sets, SeqMan NGen generated variation tables can now be exported to ArrayStar, which has tools for filtering, set comparison and clustering that support a number of different workflows, such as identifying candidate polymorphisms in a NGS-based association study.

Droplet Digital PCR™ as a Powerful Microscope to Explore and Optimize Genomic Assay Designs. *R.T. Koehler, S. Saxonov, N. Heredia, J. Regan.* QuantaLife , Pleasanton, CA.

Droplet Digital PCR (ddPCR) is a new molecular detection system whereby samples are first partitioned into thousands of nanoliter droplets, a PCR reaction is run to completion, then each droplet is read as either positive or negative. With these counts, statistics are used to estimate the concentration of the target DNA/RNA present in the original sample. Compared with real-time PCR, ddPCR takes PCR from a measure of relative quantification to one of digital absolute quantification. This high precision enables DNA detection applications well beyond real-time PCR. For example, ddPCR can readily differentiate copy number variants (CNV) of five from six copies, discern gene expression differences as small as 10% among samples, and detect rare mutant alleles in a high background of normal sequences.

We find that most published and commercial PCR assays work well in our ddPCR format without any modifications to either sequence or experimental conditions. This holds true across the board for applications including CNV and SNP genotyping, RNA quantification, and rare event detection, as well as for target characteristics like genomic complexity and GC content. However, given the unprecedented precision afforded by our system, it is clear that some assays perform better than others. With the goal of optimizing assay design, we ask: Why do some assays perform better than others and can we learn to predict this?

Here we show how ddPCR can illuminate subtle aspects of assay performance that would be impossible to detect with other systems. Using well-characterized TaqMan assays as reference points, we quantitatively explore the affects of perturbing sequence and experimental conditions in several assay-relevant dimensions. Sequence changes include shifting primer and probe position, switching target strand, altering oligo length and predicted melting temperature, and introduction of mismatches at different positions. Experimental variations include PCR conditions such as annealing temperature, choice of polymerase and restriction enzymes, and effects of buffer additives. Our results quantitatively illustrate how different aspects of assay design influence performance and robustness, helping to optimize genomic assay design rules not only for ddPCR but for PCR systems in general.

The CIDR Infinium WebLIMS: A Modular, Multi-Product Laboratory Information Management System for Illumina Infinium Genotyping Platforms. *D. Leary, M. Barnhart, J. Goldstein, B. Craig, J. Romm, K. Doheny, L. Watkins, Jr.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research provides high quality next-gen sequencing, genotyping, and statistical genetics consultation to investigators working to discover genes that contribute to common disease. CIDR began using Illumina® Infinium™ genotyping arrays in 2005, with the Infinium 100K (Human-1) product. A LIMS was unavailable from Illumina at the time, so we developed our own using a Java Swing front end and a MySQL relational database back end. This required approximately 500 person-hours over 2 1/2 months by a three-person software development team. The HumanHap300 product was released in 2006; leveraging the existing codebase, we developed a similar LIMS for the HumanHap300 product in about 30 person-hours over a one-month period. This was followed by a LIMS for the HumanHap550 product. As new Infinium arrays followed every few months, it became obvious that we needed an "all-inclusive" Infinium LIMS that would be flexible enough to allow us to add new products while preserving the workflows for existing products. For this new LIMS, we abandoned Swing in favor of a Web-based front end coded in HTML, CSS, and JavaScript, using Java Servlet technology in the application layer. Building the second-generation LIMS took about 1225 person-hours over 9 months. External to the LIMS, but integrated with the back end, are: a utility for uploading plated sample information from a designated robot, an automated QC pipeline, and an extensive collection of reports. The LIMS can also generate worklists for "cherry-picking" individual samples from plates. This is especially helpful for re-dos of failed assays. Adding a LIMS module for a new genotyping array involves duplicating the codebase and database lookup tables for a product with a similar workflow, then modifying source files as necessary. This results in some redundancy and code bloat but preserves the integrity of existing modules. Portions of the module creation process have been automated, reducing the time required to add a module for a product whose workflow is similar to that of an existing product to as little as eight hours, including testing. The advent of next-generation sequencing has brought additional challenges; sample pre-testing is performed with Infinium genotyping arrays, but the need to accommodate differences between sequencing projects and genotyping projects has led to a proliferation of LIMS modules. To date, the LIMS comprises 30 modules (10 of them now obsolete).

AnnTools -Genome annotation toolkit for SNP and CNV data from whole exome and whole genome sequencing data and microarrays. *V. Makarov[1,2], T. O'Grady[6], G. Cai[1,2], J. Lihm[1,2,7], J. Buxbaum[1,2,3,4,5], S. Yoon[1,2].* 1) Seaver Autism Center, Mount Sinai School of Medicine; 2) Department of Psychiatry, Mount Sinai School of Medicine; 3) Neuroscience, Mount Sinai School of Medicine; 4) Genetics and Genomic Sciences, Mount Sinai School of Medicine; 5) Friedman Brain Institute, Mount Sinai School of Medicine; 6) Levy Library, Mount Sinai School of Medicine; 7) Department of Applied Mathematics and Statistics, Stony Brook University.

As massively parallel sequencing is becoming technically and economically feasible, the amount of sequence data grows exponentially. Dramatic increase in the detection of novel sequence variants requires reliable and comprehensive annotation. To meet this need, we developed a fast and robust bioinformatics tool set for annotation of the genomic variants generated from the sequencing and microarray data. For each Single Nucleotide Variant (SNV) and Copy Number Variant (CNV) we specify gene name and chromosomal location. The tool allows to indicate whether SNV is in a promoter region, exon, intron, UTR, or intergenic. Using pre-calculated data tables, we specify coding changes and type of mutation for both known and novel SNV. For the exonic variants we provide the exon number and the total number of exons in the gene. Optionally, the tool can indicate an overlap with the conserved transcription factor binding sites, known regions of segmental duplications, artifact prone regions such as parts of antibodies (abParts), immunoglobulin (IG), T-cell receptor regions, and disease/trait associated CNV regions. If the gene has several isoforms, annotation is provided for each isoform. Finally, we generate a short summary report to indicate the number of variants in each location. AnnTools can accept custom tracks in a BED format downloaded from UCSC or generated by the user to meet the specific user's needs. Our genome annotator mines data from several reliable and constantly updated sources, such as dbSNP (NCBI) and UCSC Genome Browser tables. AnnTools accepts input files in the VCF or pileup formats, but user specified formats are also possible. Output is in the VCF 4.0 format used by the 1000 Genomes project, which will facilitate data exchange between working groups. High annotation speed (over 1000 lines per min) makes our application suitable for high throughput genomic facilities. The Python source code can easily be parallelized, making it suitable for high-performance computer clusters. On the other hand, a low memory footprint and CPU requirements allow the application to run even on a personal computer. We provide installation scripts, demos and a useful set of extra tools, such as pileup-to-VCF, Tab-to-VCF and VCF-to-BED conversion tools. Availability: AnnTools is freely available for academic and non-commercial use from http://anntools.sourceforge.net/.

Generating Large Scale pedigree drawings for Genetic Studies. *R. Mayani[1], G. Mehta[1], E. Deelman[1], K. Seth[1], J. Vöckler[1], F. Wang[2].* 1) Information Sciences Institute, University Of Southern California, Marina Del Rey, CA; 2) Department of Psychiatry, Washington University, St Louis, MO.

Pedigree diagrams are common and useful tool in documenting the genetic history of a family over several generations. Most large-scale studies done by NIH and NIMH to determine disease linkages to genes include these charts including the full genotypic and phenotypic data. There are several software solutions for drawing these charts but most of them tend to have drag-and-drop or click-based user interface to draw pedigree charts for one family at a time.Curating and drawing pedigrees for large-scale data across several different studies of the same disease consisting of 1000's of families can be a cumbersome, long, tiring, and error prone job. Also currently most pedigree software have very basic error checking and reporting functionality to check mistakes in the pedigree drawing in terms of relationships, age, or other parameters.

We have created a Pedigree plotting service for the Center For Collaborative Genetic Studies on Mental Disorders funded by NIMH at https://www.nimhgenetics.org/pedigree that allows users to quickly generate large-scale pedigrees in a matter of minutes instead of months of manual work. The pedigree service allows users to upload a CSV file consisting of hundreds of families, totaling thousands of individuals. Several quality control steps check age, gender, and relationships as well as other aspects. It also provides the user options to select different shading patterns for each affected status. In matters of seconds to minutes the service generates large, high-quality pedigree graphs in PDF format, and makes it available for download. The PDF contains a well-documented legend page and an index page organized by family identifiers. The table of contents is hyper-linked for an improved online viewing experience. This service is free for use and is also freely available as a source to download.

The CGSMD pedigree plotting service is based on an open source software Madeline 2.0 Pedigree Drawing Engine developed at University of Michigan Kellogg Eye Center [1].

[1] Madeline 2.0 PDE: A new program for local and web-based pedigree drawing, E. Trager; R. Khanna; A. Marrs; L. Siden; K. Branham; A. Swaroop; J. Richards. Bioinformatics 2007; doi: 10.1093/bioinformatics/btm242.

Automated high-throughput analysis of personal genome sequences: towards clinical interpretation. *A. Russell[1], S. Chervitz[1], M. Yandell[2], E. Kiruluta[1], M. Reese[1], F.M. De La Vega[1,3].* 1) Omicia Inc, Emeryville, CA, USA; 2) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah and School of Medicine, Salt Lake City, Utah, USA; 3) Department of Genetics, Stanford School of Medicine, Stanford, CA, USA.

Recent advances in high-throughput genome sequencing and the ensuing outpouring of genomic information have accelerated the convergence of discovery science and clinical medicine. Cheap genome sequencing is now producing analysis bottlenecks, especially as regards the clinical interpretation of genetic variants. The ability to automatically annotate variants, to combine data from multiple projects, and to prioritize subsets of variants for downstream analyses is becoming a critical step in the adoption of genomics in personalized medicine. Here we present an new automated and integrated analysis system, the Omicia Genome Analysis System (GAS), a comprehensive pipeline for the clinical interpretation of personal genomes data integrating medical relevant annotations from such diverse data sources and algorithms such as OMIM, HGMD, LSDB, PharmGKB, dbSNP, 1000Genomes, Harrison's anchored disease ontologies, drug sets and clinically actionable gene set and algorithms such as PolyPhen, SIFT and VAAST. GAS includes a web-based application for genome-enabled clinical decision support that allows users to drill down from genome-wide views of variant data to individual genes and their variants; allows users to generate customized subsets of variants germane to particular clinical analyses, and provides a unique disease-gene ontology that ties variants and genes to clinically relevant disease literature. This functionality speeds the clinical decision-making process - from weeks to hours - and enables innovative meta-analyses of personal genomic data from gene panels, exomes and whole-genomes. GAS also integrates a newly developed tool called VAAST, the Variant Annotation, Analysis and Selection Tool. VAAST provides simple means to identify disease genes and causative variants within sets of genomes, making possible case-control style studies of personal genome sequences. We present here several genome analyses and show how GAS can be used to identify variation hotspots both along the chromosome, and within gene ontologies, disease classes and metabolic pathways. Special emphasis is placed upon the impact of data quality and ethnicity, and their consequences for further downstream analyses. We also show how variant calling procedures, pseudogenes and gene families all combine to complicate clinically-oriented analyses of personal genome sequences in ways that only become apparent when cohorts of genomes are analyzed.

SNP genotyping using the Affymetrix® Axiom® Genome-Wide Yoruba (YRI) Array Set. *M. Shapero, Y. Lu, M. Purdy, M. Shen, J. Gollub, Y. Zhan, T. Webster.* Affymetrix, 3420 Central Expressway, Santa Clara, CA 95051.

Genome-wide association studies (GWAS) in African populations pose unique challenges, given the extensive genetic heterogeneity that has been observed. The landscape of human genetic variation is rapidly changing as next-generation sequencing is used to survey an increasing number of populations, enabling the continued identification of common and rare SNPs across diverse sample sets. Thus, sufficiently powered GWAS can be designed using array-based SNP panels that provide high genetic coverage of populations of interest. To this end, the Axiom® Genome-Wide YRI Array Set has been designed to maximize coverage of common and rare variants in populations of Yoruba (YRI) ancestry and admixed populations. This array set contains ~2.2 million markers (SNPs and insertions/deletions) obtained from HapMap, dbSNP, the 1000 Genomes Project, and the Southern African Genomes Project. In addition to high genome-wide coverage, these markers were also selected for coverage of the following categories: chromosomes X and Y, mitochondria, coding regions, recombination hotspots, ADME, miRNA, and disease-associated regions. The array set has been tested using manual and automated workflows with multiple sample types such as cell line, saliva, and blood-derived DNA. Assay performance was evaluated and shown to have an average sample call rate greater than 99.0%; trio concordance and average sample concordance to independent DNA genotype information (HapMap) were greater than 99.5%, and intra- and inter-run reproducibility were greater than 99.8%. Genetic coverage estimates for Yoruba, Asian (Chinese and Japanese), European, African-American, Luhya, and Maasai populations will be presented, as well as a discussion of how the array set can be applied to genome-wide association, disease association, and replication studies.

922W

Statistical approach to predicting functional effects of allelic variants from comparative sequence analysis. *S. Sunyaev[1], I. Adzhubey[1], D. Jordan[1,2].* 1) Div Gen, Dept Med, Brigham & Women's Hosp, Boston, MA; 2) Biophysics, Harvard University, Cambridge, MA.

Rapid advances in DNA sequencing technology enabled massive identification and cataloging of human allelic variation in research and clinical setting. A key challenge for human genetics today is to identify, among the myriad of alleles, those variants that have an effect on molecular function and phenotypes. Discovery of allelic variants of functional significance can be facilitated by computational predictions based on comparative sequence analysis. Specifically, massive exome sequencing projects aiming at identifying genes that harbor rare coding variants involved in human phenotypes require highly accurate, easy to use and fast methods for annotating large numbers of sequence variants. Although a number of computational methods for predicting the functional effect of human missense mutations and SNPs exist, limited prediction accuracy remains the major bottleneck in applications of these methods. We propose a new statistical approach that benefits from the newly available comparative genomics dataset of 46 vertebrates and the large size of training set based on over 60,000 missense disease mutations reported at HGMD. For positions with zero or one substitution per site in vertebrates, we directly estimate the probability that a given amino acid change at a site with a given phylogenetic pattern would be pathogenic. For variable positions we represent the observed phylogenetic pattern by a set of features and use a machine learning approach. Using a set of cross-validation experiments, we demonstrate that this approach benefiting from rich phylogenetic and training data substantially improves prediction accuracy over existing methods.

Building an infrastructure for 21st century research: VIVO. *M.R. Tennant[1,2], K.L. Holmes[3,4], M. Conlon[5], VIVO Collaboration.* 1) Health Science Center Libraries, University of Florida, Gainesville, FL; 2) UF Genetics Institute, University of Florida, Gainesville, FL; 3) Bernard Becker Medical Library, Washington University School of Medicine in St. Louis, St. Louis, MO; 4) Department of Genetics, Washington University School of Medicine in St. Louis, St. Louis, MO; 5) Clinical and Translational Science Institute, University of Florida, Gainesville, FL.

VIVO is an open source semantic web discovery tool that enables exploration of research and scholarship across and among institutions. Discovery is facilitated across disciplinary and administrative boundaries through interlinked profiles of people and other research-related information. VIVO allows scholars to visualize academic and social networks and display information related to their activities and expertise, such as research interests, publications, grants, teaching, service, awards and more. Researcher information can be automatically ingested from authoritative data sources such as institutional human resources, bibliographic and grant databases. VIVO allows students and others to showcase their research - essential when applying for fellowships and postdoctoral and faculty positions. VIVO does more than provide current profiles. Through VIVO, researchers can keep abreast of the literature in their areas of expertise as well as in peripheral areas of interest. VIVO can help identify potential collaborators, events, seminars, programs, facilities and resources on the local campus and beyond. VIVO's linked set of structured data provides a foundation for search, navigation and additional tools for research discovery. One can begin with a search for a term, locating grants, papers, and people associated with the term. Click on a grant, then click on its principal investigator or other key personnel, click on the investigator's department, program or college, click on additional grants from those units, traversing the works. In each case, details are discovered, revealing the connections between each concept. VIVO supports learning and searching across domains. For example, linking researchers and clinicians to the genes they work on provides a capability to search for efforts based on the human diseases linked to those genes. These types of powerful linkages enable discovery of interdisciplinary activity as well as potential gaps and opportunities. Adoption, ontology usage, data provision, application development, and data consumption are all ways in which institutions and individuals can become involved with VIVO. The VIVO community enjoys a robust open source space on SourceForge, and the software and ontology are publicly available at http://vivo.sourceforge.net along with content that supports implementation, adoption, and development efforts.

High-throughput annotation of genomic variants using a relational database system. *L. Wiley, W. Bush.* Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN.

With waves of new data arriving from next-generation sequencing studies, there is a growing need for computational tools to annotate and characterize both common and rare genetic variants. Ideally, genomic annotations could be stored in a centralized relational database system established specifically for this purpose. Relational databases have many advantages over standalone software, most notably that information is stored and processed on disk rather than in memory. However, even after appropriate optimizations, retrieval time for interval-based queries (i.e. Does this position fall within any known genomic intervals/annotations?) is not trivial. In 2007, Alekseyenko and Lee presented a nested containment list (NCList) data structure which queried ranges 5-500 fold faster than current database indexing methods. This algorithm has been implemented successfully in many tools including JBrowse, a popular genome browser, and PeakAnalyzer, a utility that processes ChIP-seq and ChIP-chip data, however the authors note that for optimal incorporation into existing workflows and pipelines, the algorithm should be implemented within a relational database system. Here we present an implementation of the NCList algorithm in the popular database software MySQL, with the goal of providing an easily extendible collection of genomic annotations for rapid querying of next-generation sequence data. Our implementation consists of a pre-processing Perl script that establishes the initial database structure, and stored procedures for single position query, batch query, and batch update of the data structure. This collection currently contains over 500,000 annotations and can query 150 positions in approximately ten seconds. All tools accept genomic annotations from the widely used bed-file format.

Biases in coverage and mutation detection of human coding exome by next generation sequencing. *G. Wu[1], M. Edmonson[2], L. Wei[1], M. Rusch[1], J. Easton[1], X. Chen[1], C. Mullighan[1], M. Dyer[1], T. Le[1], D. Alford[1], D. Zhao[1], A. Ulyanov[1], J. Downing[1], J. Zhang[1].* 1) Department of Computational Biology, St Jude Children's Research Hospital, Memphis, TN; 2) National Cancer Institute, Bethesda, MD.

Advances in next-generation sequencing (NGS) technology has made it possible to sequence a human genome with an average of 20-30x haploid coverage, enabling discovery of somatic alterations and genetic variations for biomedical research. Although poorly-covered exons in known human cancer genes have been noted, the extent and the impact of the coverage bias of the entire human coding exome has not been comprehensively analyzed. In this study, we evaluated coding exon coverage of two major cancer genome sequencing projects: The Cancer Genome Atlas (TCGA) and the St Jude Children's Research Hospital - Washington University Pediatric Cancer Genome Project (PCGP). Our analysis included matching normal samples of 58 patients of 5 different cancers sequenced by three NGS platforms of either whole-genome or exome. Approximately 2.1%-14% coding exons are poorly covered with an average coverage below 10x. They are highly enriched in GC-rich exons (e.g. exons with >60% GC content) as 26-90% of the GC-rich exons are poorly covered. 12-58% of the genes in Cancer Gene Census have at least one poorly-covered coding exon. This observation is universal regardless of platforms, data types (exomes or WGS), sequencing centers and diseases. To evaluate the impact of NGS coverage bias on mutation detection, we compared the distribution of somatic mutations deposited in the COSMIC database (http://www.sanger.ac.uk/genetics/CGP/cosmic/) in 12 large-scale candidate gene sequencing projects with those detected by NGS. 22% of the somatic mutations detected by Sanger sequencing are in GC-rich exons compared with 15% by NGS, indicating that poor coverage in GC-rich exons by NGS may cause the reduction of somatic mutations identified in these regions. For PCGP project, we explored possible solutions for improving coverage in GC-rich exons and found both RNA-seq and custom exon capture targeting poorly-covered exons can “re-cover” approximately 80% of the poorly-covered exons.

A novel algorithm for detecting low frequency variants and somatic mutations at 1% frequency in hundreds of genes from heterogeneous research samples using the 5500 Genetic Analyzer. *X. Xu, M. Storm, S. Mangul, Y. Sun, J. Ichikawa, R. Padilla, D. Hom, M. Rhodes, F. Hyland.* Biological Information System, Applied Biosystems, part of Life Technologies, Foster City, CA.

The identification of low frequency variants resulting from sub-populations is important to elucidate the underlying biology of cancer. Here we describe the reliable detection of low frequency variants in hundreds of genes from heterogeneous research samples by utilizing the accuracy of the 5500 Genetic Analyzer. We developed a new algorithm to detect low frequency variants in whole exome or other targeted resequencing research applications. We leveraged the error correcting capability of the 5500 Genetic Analyzer to generate highly accurate data and detect extremely rare variations, down to an allele ratio of 1%. To test the performance of the algorithm, we diluted a known PCR enriched HapMap sample (NA12878) with a background of HuRef DNA of the same enriched 2 MB regions to create a series of concentration ratios, and applied our algorithms to the targeted resequencing data mapped with LifeScope Genomic Analysis Software, with an average coverage of 1400x. We measured the true positive, false positive and false negative rate for rare variants based on the known genotypes of these two samples. We demonstrated the ability to identify somatic mutations to a frequency of 5% with high sensitivity and high specificity and to a frequency of 1% and below with some loss of sensitivity. *For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.*.

927W

Accurate and Sensitive Somatic Mutation Detection in Heterogeneous Cancer Research Specimens by castPCR Technology. *I. Casuga[1], D. Merrill[1], B. Ching[1], Y. Bao[1], D. Deng[1], D. Le Corre[2], S. Desai[1], R. P. Petraroli[1], T. Hartshorne[1], H. Blons[2], P. Laurent-Puig[2], C. Chen[1].* 1) Life Technologies, 850 Lincoln Centre Drive, Foster City, CA; 2) UMR-S775, INSERM, Paris, France.

The discovery of pivotal genetic alterations and the understanding of their role in cancer is leading to remarkable successes in therapeutics and patient care. Molecular diagnosis methods such as DNA sequencing and conventional genotyping of tumor biopsies have advanced research in this field, but are limited in sensitivity due to stromal contamination and by genetic heterogeneity in cancer. We have recently developed competitive allele specific TaqMan® PCR (castPCR) assays for detecting cancer-associated sequence variations. The technology has demonstrated detection of as little as 1 mutant allele molecule in 10,000,000 wild type molecules. We report here sensitive and accurate detection of cancer-associated KRAS mutations within formalin-fixed paraffin-embedded (FFPE) heterogeneous cancer specimens. Eight FFPE model cell lines were initially used to investigate the assay capabilities (NCI-H2009:p.G12A; SW1463:p.G12C; PANC-1:p.G12D; PSN-1: p.G12R; A549:p.G12S; SW480:p.G12V; DLD-1:p.G13D; Jurkat:-Wild Type). Mutant FFPE cell line DNAs were titrated into the FFPE wild type cell line DNAs from 100% to 0.1%. Mutations were unambiguously identified and clearly distinguished from background signal at the level of 0.1% with high reproducibility. In a follow up set of experiments, 21 anonymous tumor tissues and 12 non-tumor tissues from FFPE specimens were evaluated for somatic mutations. Seven different KRAS gene mutations in each of the tumor derived samples were examined by castPCR assays. No mutations were detected in non-tumor tissues. The results obtained by castPCR for the 21 tumor tissues were concordant to those previously reported by three different methods (Taqman® PCR, Taqman® PCR + PNA and Sequencing). Our results demonstrate that castPCR, as a new rare mutation detection technology, has greater sensitivity, specificity and can thereby facilitate accurate mutation detection of heterogeneous cancer specimens.

A New Sequencing Workflow Increases Accuracy and 5' Resolution for Capillary Electrophoresis Resequencing Applications. *C. Davidson[1], P. Ma[1], S.-C. Hung[1], S. Berosik[1], S. Schneider[1], V. Bourdon[2], T. Noguchi[2], H. Sobol[2], M. Wenz[1].* 1) Life Technologies, Foster City, CA; 2) Institute Paoli Calmette, Marseille, France.

The MLH1 and MSH2 are mismatch repair genes that play an essential role in DNA repair. Variants in MLH1 and MSH2 are highly heterogeneous and contribute to genome instability, and for this reason are associated with increased risks of cancer including Lynch syndrome or hereditary nonpolyposis colorectal cancer (HNPCC). MLH1 and MSH2 are large with more than 200 unique variants characterized for each gene. The size of the MLH1 and MSH2 genes and the sheer number of sequence variations requiring confirmation across a large genetic region makes interrogation by Sanger sequencing the preferred technique. To enable the identification of MSH2 variants, we have employed an improved capillary electrophoresis Sanger sequencing workflow that offers substantial time savings compared to previous workflows. The sequencing-based mutation detection methodology described here improved the resolution of fragments at the 5' end of all amplicons investigated in the MSH2 gene. 40% of the new method reads have⁄ 25 bases with QV20+ scores when compared to the same amplicons sequenced using a standard cycle sequencing workflow. Electrophoresis migration time was improved from 145 minutes to 75 minutes while maintaining read length and preserving excellent resolution starting at the first base after the gene-specific primer sequence. Further, the modified chemistry employed in the workflow resolved the peak compression problems that can occur when sequencing with conventional chemistries. All steps in the workflow, from the PCR reaction to loading on the capillary, were performed in the same reaction tube without the need to transfer material. As a consequence of workflow enhancements, the amount of hands-on time was reduced by 40% with the new method requiring 4 steps taking approximately 5 hours compared to 5 processing steps and up to 8 hours for a conventional cycle sequencing workflow. By minimizing the number of manual handling steps and eliminating the possibility of transfer errors, the likelihood of experimental variability is reduced compared to standard sequencing workflows. A unique one-step PCR purification-cycle sequencing reaction was also employed, further enabling a rapid sample to sequence turn-around time and improving the rate of variant detection in the MSH2 gene. Taken together, the workflow described here is a simple, streamlined procedure that increases throughput, and improves the accuracy of MSH2 genetic variant identification.

Development of SureSelect Target Capture Methods for Sequencing on the Ion Torrent PGM System. *A.C. Giuffre[1], J. Ong[1], M. Guadalupe[1], S. Joshi[1], H. Ravi[1], M. Visitacion[2], C. Pábon-Peña[2], E. Lin[2], B. Novak[2], M. Hamady[2], F. Useche[2], D. Roberts[2], E. LeProust[2], S. Happe[1].* 1) Agilent Technologies, Cedar Creek, TX; 2) Agilent Technolgies, Santa Clara, CA.

New powerful methods for massively-parallel sequencing have emerged, allowing for enhanced ease-of-use, faster turnaround times, and focused analyses. However, limited read output still requires that samples be enriched for targets of interest prior to sequencing. To determine the efficacy of the Agilent SureSelect Target Enrichment System as a method for targeted resequencing on the Ion Torrent Personal Genome Machine (PGM), we developed methods to prepare genomic DNA libraries and perform hybrid capture, followed by analysis of sequencing performance. For PGM library construction, we utilized the Ion Fragment Library kit to append specific adapters. Hybrid capture was performed with specially-designed blocking reagents to prevent cross-hybridization of adapters. Following sequencing on the PGM, we demonstrated high specificity for capturing targets of interest, excellent uniformity, and even coverage across the targeted regions. The method was ideally suited for targeting regions < 1Mb, but higher coverage of larger regions could be achieved by sequencing across multiple chips. High performance was achieved across different sample types captured with SureSelect libraries of varying complexity and content. Data obtained was used to efficiently identify non-reference variants, and showed high correlation with previously-determined HapMap genotypes. These findings illustrate the utility of the SureSelect method for target enrichment on the Ion Torrent PGM, and provide a path forward for variation discovery in small targeted regions , validation of hits from other platforms, and profiling variation within large sample sets in minimal time.

Genomic Structural Rearrangement Detection in Highly Aneuploid cancers using Long Fragment Read Technology. *B.A. Peters[1], B.G. Kermani[1], O. Alferov[1], J. Haas[1], R. Drmanac[1], T.D. Barber[2].* 1) Research Department, Complete Genomics, Inc., 2071 Stierlin Court, Mountain View, CA 94043; 2) Translational Science, Eli Lilly and Company, Lilly Corporate Center/DC 0428, Indianapolis, IN 46285.

Detection of genomic structural rearrangements in cancer is currently limited by the read length and mate pair gap length of next generation sequencing (NGS) technologies. The typical NGS read length of 35-200 base pairs with a mate pair gap of 200-2000 base pairs can make translocations difficult to detect. Using a library preprocessing method called Long Fragment Read (LFR) technology, which generates data similar to single molecule sequencing of 50kb fragments, we generated approximately 2 TB of data on 2 matched tumor and normal hepatocellular carcinoma samples. We show that complicated genomic rearrangements can be easily mapped using standard NGS library construction and sequencing when LFR is employed. Further, by using the long fragments to phase variants in tumor samples we demonstrate that potential false positive somatic mutations, which are inconsistent with assembled haplotypes, can be effectively identified and removed from further analysis. Importantly this work was performed using ~130 pg of DNA an amount equivalent to what is contained within 20 human cells. This technological breakthrough will enable similar analyses to be performed on circulating tumor cells, cancer stem cells, fine needle aspirates, and other DNA samples extracted from extremely low abundance tissue sources.

931W

5500 GATM System in Combination with Enhanced Call Chemistry (ECC) Enables the Detection of Low Frequency Genetic Variation in Heterogeneous Samples. *C. Storm, J. Ichikawa, R. Padilla, D. Hom, G. Meridith, C. Adams, X. Xu, YM. Sun, F. Hyland, M. Rhodes.* Applications, Life Technologies, San Francisco, CA.

The propagation of next generation sequencing has opened up many new and exciting avenues for cancer research. One such area is to actively search for and determine the clinical relevance of genetic sub populations in circulating tumor samples. There are two main considerations that have to be accounted for when undertaking this type study. First the sequencing throughput has to be adequate to detect the variation at low frequencies; for example, theoretical calculations show that low frequency variants occurring at 1% may require as much as 1000 fold coverage to maximize the ratio between true positives and false negatives. Secondly, the accuracy of the sequencing will determine the ability to ascertain with any level of confidence that novel variation is actually true and not an artifact of the sequencing process. Accuracy of the sequencing chemistry is paramount to address both these issues. The difference between an accuracy of 99.95 and 99.99 for a minor allele that occurs at 1% translates in to an additional 100 fold coverage. And at a certain point there is no benefit to additional sequencing, since the number of false positive variants will soon vastly outnumber the number of true variants. Further higher accuracy and a lower number of false positive variation calls will significantly reduce the amount and complexity of the downstream validation work that has to be done. In this poster we describe how the addition of Enhanced Call Chemistry (ECC) to the already highly accurate two base encoding of the SOLiDTM platform in combination with a new set of computational algorithms designed specifically to take advantage of this chemistry shows a significant improvement to current abilities to detect variation occurring at an exceedingly low frequency in a background of “normal” material. For this proof of concept we have looked at two different enrichment methods, one PCR based and one based on hybridization of complimentary probes. For both methods we targeted a number of genes commonly associated with cancer. Further, we chose to simulate the frequency of circulating tumor cells in a normal background by pooling samples at predetermined levels, down to 0.1%. In this poster we demonstrate feasibility to detect these variants down to the lowest level as well as describing the pros and cons of each type of enrichment for this type of study.

Microsatellite Instability & Immunohistochemistry Testing of Colorectal Tumors among U.S. Cancer Programs & Follow-up of Abnormal Results. *L.C. Beamer[1], D.J. MacDonald[1], C. Huizenga[1], H. Hampel[2], K.R. Blazer[1], M. Grant[3], J.N. Weitzel[1].* 1) Clinical Cancer Genetics, City of Hope, Duarte, CA; 2) Division of Human Genetics, The Ohio State University, Columbus, OH; 3) Nursing Research & Education, City of Hope, Duarte, CA.

PURPOSE: Reflex microsatellite instability (MSI) and immunohistochemistry (IHC) testing of CRC tumors to screen for Lynch syndrome, a hereditary cancer predisposition syndrome, is an emerging practice in the U.S. To date, no formal studies described this practice. We sought to explore the practice of MSI/IHC testing by type of cancer program and number of CRC cases, and patient follow-up of abnormal results. DESIGN: A 12 item survey was developed following input from expert panels and pilot testing in 22 cancer programs (99.5% return rate). METHODS: The study sample included 39 NCI-designated Comprehensive Cancer Centers (NCI-CCCs), 50 randomly-selected Community Hospital Comprehensive Cancer Programs (CHCCPs) and 50 randomly-selected Community Hospital Cancer Programs (CHCPs). An invitation letter, survey, and online-survey option was emailed to a contact at each cancer program. Data were merged into one SPSS file. Program characteristics and MSI/IHC data were summarized using frequencies and percentages. The association between cancer program type and current reflex testing practice was measured using a chi-square test of independence. Multinomial logistic regression was implemented to create a model to predict reflex testing. RESULTS: The overall response rate was 50% (63% for NCI-CCCs, 50% for CHCCPs, and 40% for CHCPs). Seventy-one percent of the NCI-CCCs, 36% of the CHCCPs, and 15% of the CHCPs were using a reflex MSI and/or IHC test. Only 30% of the programs used a pre-surgical information packet, consent, or opt-out option. Nearly one-half of the programs had patients who did not engage in a recommended genetics clinic visit. A significant association was found between the type of cancer program and current reflex testing practice ($X^2(2, n=69),=14.543, p=.001$). NCI-CCCs were significantly more likely to currently engage in reflex testing than the CHCCPs and CHCPs. Number of CRC cases predicted current practice of using reflex MSI/IHC testing (p= .049). Similarly, NCI-CCC status predicted current reflex MSI/IHC testing (p=.013); CHCCP status did not predict current reflex MSI/IHC testing. CONCLUSIONS: Most NCI-CCCs use MSI/IHC whereas most CHCPs do not; nearly two-thirds of CHCCPs currently or plan to use this testing. Clinic follow-up is suboptimal. CLINICAL RELEVANCE: Findings will guide the creation a toolkit to enhance MSI/IHC testing and follow-up of abnormal results.

A Single SNP Surrogate for HLA-Cw6 Genotyping in Diverse Populations. *R.P. Nair[1], P.E. Stuart[1], T. Tejasvi[1], P.A. Shaiq[4,5], R. Qamar[4], G.K. Raja[5], P. Kullavanijaya[3], J. Ding[2], Y. Li[2], J.J. Voorhees[1], G.R. Abecasis[2], J.T. Elder[1].* 1) Dept Dermatology, Univ Michigan, Ann Arbor, MI; 2) Dept of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI; 3) Institute of Dermatology, Bangkok, Thailand; 4) COMSATS Institute of Information Technology, Islamabad, Pakistan; 5) PMASAA University, Rawalpindi, Pakistan.

Psoriasis is an autoimmune disease of the skin affecting ~2% of the Caucasian population. Several studies have conclusively established the Cw6 allele of HLA-C, a highly polymorphic MHC Class I gene, as the most strongly associated among 24 known psoriasis susceptibility loci. Because of the high degree of polymorphism, direct assay of HLA-Cw6 requires sequencing, serological assays or highly temperamental allele-specific PCR, and a reliable surrogate marker for Cw6 has not been available. We have previously established a 7-SNP typing system to identify the Cw6 allele with a high degree of accuracy [Nair et al., AJHG 78:827, 2006]. Here we report a single SNP that can predict HLA-Cw6 status with 99% accuracy. In attempting to further delineate the MHC psoriasis locus, which appears to harbor multiple susceptibility genes, we genotyped a dense set of 1332 markers spanning the MHC. The most significantly psoriasis-associated markers that emerged from this analysis are rs12191877 ($p = 1.2 \times 10^{-35}$, OR = 2.67) and rs4406273 (1.2×10^{-34}, OR = 2.94). Comparison with 2332 samples typed for HLA-Cw6 showed that the A allele of rs4406273 tagged HLA-Cw6 with high specificity (genotype concordance 0.989, LD $r^2 = 0.983$, Pearson correlation = 0.991). We developed a single base extension assay (Snapshot, Applied Biosystems) for rs4406273 and genotyped 4995 North American Caucasian samples, 308 from Thailand and 837 from Pakistan, and compared the results with HLA-Cw6 types assayed using our previously reported method. The concordance rates were 99.1% for Caucasians, 98.7% for Thai and 99.5% for the Pakistani samples. Our results show that the A allele of rs4406273, located 26.5 kb centromeric of HLA-C and 55.3 kb telomeric of HLA-B can serve as a highly accurate surrogate for HLA-Cw6.

A novel proteomics approach for identification of protein-RNA complex associated with specific gene loci using a human artificial chromosome (HAC). *T. Seko[1], S. Yamaguchi[1,2], Y. Yoshimura[1,2], Y. Nakayama[3], M. Kato[4], T. Obayashi[2], M. Oshimura[1,5], H. Kugoh[1,5].* 1) Dept. of Biomed. Sci., Inst. of Regenerative Med., Tottori Univ.,Tottori,Japan; 2) Div. of Laboratory Animal Sci., Res. Ctr. for Biosci. and Technology, Tottori Univ. Tottori,Japan; 3) Div. of Functional Genomics, Ctr. for Biosci. and Technology., Tottori Univ.,Tottori,Japan; 4) Div. of Human Genomic Sci., Dept. of Mol. and Cellular Biology, Sch. of Life Sci., Faculty of Med., Tottori Univ., Tottori,Japan; 5) Chromo. Eng. Res. Ctr., Tottori Univ.Tottori,Japan.

Functional analysis of DNA, RNA and protein-protein interaction has progressed rapidly in recent years. Numerous protein-complex on chromatin are involved in the gene regulation. Therefore, identification of molecular complex of specific genome loci is critical to understanding genomic network. Here, we propose a novel method using HAC, termed chromosome immunoprecipitation (ChrIP), which allows for efficient purification of protein complex on targeted gene loci. ChrIP assay consist of the following three steps to purify proteins on specific genome loci. 1. The introduction of targeted genomic region and tag marker to HAC. 2. Recover of the HAC by chromatin immunoprecipitation. 3. Identification of proteins that specifically bind to targeted genomic region. In this study, we introduced a direct repeats of the lac operator (lacO) into chinese hamster ovary (CHO) chromosome to confirm whether it is able to recover genomic DNA equivalent to the DNA size of HAC. The lacO was produced by gene amplification using a dihydrofolate reductase (DHFR) expression vector with methorexarte selection. To identify the CHO cells that carry the lacO in the CHO chromosome, we performed fluorescence in situ hybridization (FISH). As a result, one of 23 clones was introduced lacO sequence to the CHO chromosome. Next, we introduced the LacI-GFP vector that produce LacI-GFP protein complex into one of the lacO positive clones. We report here that a large size of CHO chromosome was recovered by anti-GFP antibody. These results suggest the possibility of recovery of the HAC by chromatin immunoprecipitation. Furthermore, our colleague has developed a new HAC vector with multi-integrase recombination sites.[1] MI-HAC enables to introduce various large genes or genomic loci. Further studies to introduce MI-HAC that contains the lacO repeat sequences and targeted gene loci are still in progress. [1] A method for Producing Transgenic Cells Using a Multi-Integrase System on a Human Artificial Chromosome Vector. PLoS one February 2011 vol.6.

Efficient computing of genotype calling for GWAS. *S. Leo[1], I. Zara[1], M. Valentini[1], S. Sanna[2], G. Zanetti[1].* 1) CRS4, Pula, CA, Italy; 2) IRGB, CNR, Monserrato, CA, Italy.

Genotype Calling (GC) represents an important challenge for Genome-Wide Association Studies (GWAS), given the noise associated with high-throughput genotyping and batch effects when performing plate-by-plate processing. Confounding can be drastically serious for certain genotyping platforms, and in order to reduce batch effects and other error sources, it is mandatory that all available samples are processed in one run. However, as the number of samples grows, job running time and computational resource usage increase dramatically, making it difficult to scale efficiently to thousands of samples. Even partitioning data into probeset subsets, thus allowing a certain level of parallelization, does not solve the problem, since the core of currently available algorithms requires accessing all data samples at once. For instance, a GC run performed at our site using the Affymetrix Power Tools (APT), took two weeks for processing 6863 samples by using 18 nodes with 8 CPUs and 16 GB of RAM for each job (one node for each probeset subset). Moreover, these computational costs make it cumbersome to perform a systematic analysis of the robustness of results with respect to changes in the dataset used. We developed a new distributed GC application that scales efficiently with the number of samples, harnessing the full power of a large computational cluster. For example, we were able to perform GC on the aforementioned 6863 samples in about 16 hours using 30 nodes with 8 CPUs each. Results obtained with our tool are comparable with those of the Birdseed v2 algorithm included in the APT. Specifically, the average call rate, 94.983%, was slightly higher than the one obtained with the APT Birdseed v2 implementation (94.794%), which resulted in calling about 12 million additional genotypes over all 6863 samples. The average allelic discordance rate with respect to the original run was 3.6×10^{-4}, with a standard deviation of 0.1×10^{-4}; 6838 out of 6863 samples (99.6%) had an allelic mismatch rate $\leq 7 \times 10^{-4}$. The new tool is implemented as a Hadoop MapReduce application that uses the Pydoop Python API (http://pydoop.sourceforge.net) to interact with Hadoop, and Numpy plus Boost.Python extension modules for APT for core computation and Affymetrix-specific data I/O. The software will be available as open source in the near future.

Pegasus WMS: Enabling Bioinformatics using Workflow Technologies. *G. Mehta[1], E. Deelman[1], K. Vahi[1], Y. Wang[2,4], A. Clark[3], R. Mayani[1], T. Chen[4], J. Knowles[3].* 1) Information Sciences Institute, University of Southern California, Marina Del Rey, CA; 2) Department of Automation, Xiamen University, China; 3) Department of Psychiatry, USC Keck School of Medicine, Los Angeles, CA; 4) Department of Biological Sciences, University of Southern California, Los Angeles, CA.

Recent advances in bioinformatics from genome sequencing techniques, to protein analysis to bacterial RNA studies have resulted in large amounts of raw data being generated. This data needs to be analyzed, mapped to genomes as well as handled in a robust, efficient and secure manner. Generally most laboratories lack the tools or the manpower to create complex pipelines to analyze these datasets and run these pipelines on the computing infrastructure present either in the laboratories or on campus or the commercial cloud environments.

To enable scientists to run their bioinformatics analyses on large-scale computational resources we use Pegasus WMS, a Workflow Management System that can manage large-scale scientific workflows across local, Grid, and Cloud resources simultaneously. Pegasus WMS provides a means for representing the application as a workflow in an abstract XML form, agnostic of the resources available to run it on and the location of the input data and executables. It then, compiles these workflows into executable workflows by querying catalogs and farming computations across local and distributed computing resources, as well as emerging commercial and community cloud environments in an easy and reliable manner. Pegasus WMS optimizes the execution as well as data movement by leveraging existing Grid and cloud technologies via flexible pluggable interfaces and provides advanced features like data reuse, automatic cleanup of generated data, and hierarchal workflows with deferred compilation. It also captures all the provenance of the workflow from the compilation stage to the execution of the generated data, helping scientists accurately measure performance metrics of their workflow as well as tackle data reproducibility issues.

Pegasus WMS has also been packaged in an easy to use Virtual Machine that can be used on local machines or clusters to run RNA Sequencing Workflows using different Genome mapping tools and expression calculators for the NIMH Transcriptional Atlas of Human Brain Development project. It was recently used to compute more then 200 samples of human RNA samples on a campus cluster. Pegasus WMS was initially developed to support large-scale high-energy physics and astrophysics experiments and supports a wide variety of applications from earthquake simulation, bacterial RNA studies, helioseismology to bioinformatics.

Handling the data management needs of high-throughput sequencing data and GWAS: SpeedGene, a C++ library for the fast and efficient storage of genetic data. *D. Qiao, W. Yip, C. Lange.* Department of Biostatistics, Harvard School of Public Health, Boston, MA.

The pedigree file-format is one of the most commonly used input formats for genetic data analysis software, e.g. FBAT, PBAT, PLINK. For high-throughput sequencing data and data from genome-wide association studies, the sizes of these pedigree files can reach several tetra-bytes of disk space. Unnecessarily large files result in waste of disk space and loading time during analysis. We introduce here the SpeedGene-library that includes an optimized "storage-and-load" algorithm for genetic data. Depending on the minor allele frequency, the SpeedGene algorithm chooses among three different compression-methods to minimize the disk and memory space for storage. The SpeedGene-format does not require any CPU-time for decompression. The library provides functions for loading of the compressed files and retrieving any part of the original data. Our new algorithm performs better than currently available compression formats for pedigree files by several magnitudes. The compression factor of the algorithm depends on the genotype frequency distribution of the markers and the number of subjects in the dataset. The compression factor ranges from 16 to several hundreds. Furthermore, it takes only few seconds/minutes to load an entire file with the library, and our implementation supports parallel processing of the dataset, i.e. loading of subsets of markers. This greatly decreases the loading time when parallel jobs are dispatched in clusters. The library provides direct-data-retrieving functions, which allows the compressed dataset to be accessed by any other C++ programs. In conclusion, the SpeedGene library enables the storage and the analysis of next generation sequencing data in existing hardware environment, making system upgrades unnecessary.

Software library and tools for efficient and flexible processing of sequence reads and variant calls. *M. Trost, G.R. Abecasis, H.M. Kang.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI.

As the volume of large scale next-generation sequence data increases from terabytes to petabytes, the need for high quality, high performance analytic tools is becoming crucial. The Sequence Alignment/Map (SAM) format and its binary counterpart (BAM) are the most widely used formats for storing alignment information. The Variant Call Format (VCF) is commonly used for storing genetic variations discovered from sequence reads. We developed an object-oriented C++ library that allows us to efficiently and flexibly process these files and built a set of useful tools to automate common tasks for the manipulation and analysis of these files.

Our generic C++ library for robustly and interchangeably handling SAM or BAM files provides a rapid, validated, and modularized interface to access aligned sequence read information without the detailed knowledge of the data format. The library is designed to provide a clear and convenient interface to SAM/BAM files in order to facilitate the development of sequence data processing software. In addition, by handling VCF files, our C++ library allows us to flexibly perform various types of data manipulation and association analysis from variant calls identified from the sequence data.

A number of tools for handling SAM/BAM/VCF files have been built using our library. The bam diff tool compares a pair of SAM/BAM files produced by different analytic pipelines outputting discordant records. The bam revert tool allows us to undo realignment or recalibration operations by recovering original alignment information from ancillary information stored in info tags. To reduce the size of a BAM file, the squeeze bam tool drops unessential fields and duplicate reads and edits the representation of base sequences to reduce file size. This saves on storage space and facilitates storage and long-term archiving. The VcfCooker tool allows data manipulation and the filtering of variants. The verifyBamID tool detects contamination in the sequence data using known genotypes or allele frequency information.

Our software tools and library are publicly available at http://genome.sph.umich.edu/wiki/Software.

Improving mate-paired sequencing for submicrogram human samples. *Z. Chen, M. Wei, T. Biorac, B. Li, X. Xu, G. Marnellos, R. Bennett.* Life Technologies, 5791 Van Allen Way, Carlsbad, CA 92008.

Mate paired sequencing is critical for shotgun based whole genome sequencing and structural variation study using next generation massively parallel sequencing technologies. Recent published studies showed that mate paired sequencing detected 69% more structural variation by average in the primary breast cancer samples than paired end sequencing method and over 2-fold more in the breast cancer cell lines. To construct long mate-paired (LMP) library with high complexity it usually requires tens of micrograms of input DNA, which is rarely the case for primary tumor samples. The least efficient step in the LMP protocol is a circularization step, which joins two ends of a molecule together to an internal adaptor to form a mate pair. We have developed a new intramolecular circularization (NIC) method, which improves efficiency of this circularization step dramatically. We used the nick translation method in SOLiD™ 4 LMP protocol to generate even-sized mate-paired tags with defined average length, and further optimized the protocol to generate longer mate tags and tighter tag size distribution for 2x60 mate-paired sequencing. Using the NIC method and improved procedure to construct LMP libraries with HuRef genomic DNA, we demonstrate 3 to 10 fold improvement on yield of LMP library over SOLiD™ 4 LMP method for 1-3kb insert LMP libraries, and a reduced number of false positive mate reads. Furthermore, we develop a unique mate paired barcoding strategy so that submicrogram starting material can be used and 8 to 12 samples can be pooled after barcoded mate paired adaptor ligation in the early library construction workflow to simplify the library preparation for processing 8 to 12 LMP libraries parallel. This approach enables us to increase LMP library throughput and improve the library complexity for sequencing. This low input mate-paired library construction method will further broaden the application of mate paired sequencing in human genome research. For Research Use Only. Not intended for any animal or human therapeutic or diagnostic use.

Methods for systematically reducing the uncertainty in calling copy number variations by combining information from multiple sources and technologies. *D.S. Greer, D. Malhotra, W. Wu, J. Sebat, Psychiatric GWAS Consortium.* Psychiatry, University of California, San Diego, La Jolla, CA.

We address the general computational problem of more accurately determining copy number variations (CNVs) by consolidating data gathered from multiple experiments and diverse technologies. While the underlying duplication or deletion of a genetic region has theoretically well-defined breakpoints, at present, common methods for ascertaining these locations produce results that are only rough approximations. Many algorithms, which operate on high-throughput sequencing or microarray data, implicitly overstate their actual accuracy by reporting only the estimated breakpoints. Consequently, CNV calls made on the same subject by various analysis software vary significantly, and the differences are difficult to evaluate.

We are developing algorithms that can accept information from heterogeneous technologies and from multiple experiments to progressively refine the estimates of the CNV regions with increasing certainty and accuracy. Rather than producing a final set of calls, a data structure is retained which is continually updated by incorporating additional results from additional tests. This facilitates not only the detection of CNVs, but also the evaluation of different calling methods.

In order to systematically represent and analyze the uncertainty, CNV calls from a single individual are used to divide the genome into disjoint segments. The segments can vary in length from a single base-pair to very long regions which do not contain structural variations. As calls are added to an existing segment table, segments are split where they span one of the endpoints. For each segment, a feature vector is extracted from the multiple data sources. The features may be derived from sequence matching, average microarray intensity values, or estimated probability functions. Since the segment data structure contains at most a few thousand regions (compared to one that explicitly represents all three billion base-pairs) it can be used in complex computations that would otherwise be intractable. These include signal processing and machine learning algorithms that attempt to make the optimal use of all the available information. By extracting the abstract mathematical properties of CNVs, the segment table structure is extensible, flexible, independent of specific measurement techniques, and capable of representing the results of many repeated and diverse experiments.

Chromosome Copy Number Variation by Digital PCR. *J.T. Wang, J.T. Kuykendall, J.F. Stevens.* qPCR R&D, Life Technologies, Foster City, CA.

Chromosomal rearrangement is a common feature in transformed tumor derived cell lines. The number of chromosomes (karyotype) of different tumor cell lines can be unique and may be used for identification of the cell line lineage. The number of duplicate chromosomes in transformed cells can be quite high. At these high copy numbers small differences can be difficult to detect using traditional qPCR (quantitative real-time Polymerase Chain Reaction) methods as the measuring method is base on logarithmic scale. Digital PCR is an advanced utilization of PCR technology where the number of nucleic acid template is accurately counted. This technology relies on diluting the nucleic acid template to the Poisson distribution limit where each PCR reaction contains at least a single copy of template or none. The 1 and 0 scoring of the reactions gives the digital nature of this PCR application. The average number of copies per reaction can then be calculated using Poisson statistics. Digital PCR technology's linear scale measurement offers the precision and accuracy required to discriminate variations in higher copy number. Here we describe an approach using Digital PCR to detect chromosomal aberration in tumor cell lines. We use 48 TaqMan® Copy Number Assays (2 assays for 24 chromosomes - 22 autosomes and 2 sex chromosomes) to count the copy number of chromosomes. We characterized genomic DNA extracted from 6 different human derived transformed cancer cell lines as well as 3 normal cell lines. We found the digital method provides advantage in accuracy of copy number is that the linear scale of the quantification method allows discrimination between two high copy numbers. The digital PCR technique allows precise copy determination of chromosome locus assayed.

Evaluation of Recruitment Strategies for Web-based Genetic Studies. *E.M. Drabant, K.E. Barnholt, C. Dijamco, J.Y. Tung, A.K. Kiefer, J.L. Mountain, A. Wojcicki.* 23andMe, Mountain View, CA.

Many of the hundreds of web-based genetic studies conducted by 23andMe's research arm rely solely on organic recruitment through 23andMe's personal genome service. For a few studies, however, 23andMe actively recruits individuals who meet particular inclusion criteria. Two examples are 23andMe's Parkinson's disease and sarcoma studies. Recruitment of participants for these studies is conducted via a number of strategies. We evaluated our recruitment strategies by reviewing the changes in enrollment rate in response to each type of effort. The recruitment strategies that have been most successful include paper-based mailings from advocacy organizations such as the Michael J. Fox Foundation and the Parkinson's Institute, and email and website campaigns conducted by advocacy organizations. Grass-roots efforts led by 23andMe members affected with the disease in question have been a significant source of recruitment through online support groups and blog posts. Both studies have garnered attention in the press, which has enhanced enrollment to some extent. The strategies that have been least successful include attending and sponsoring disease-focused events, listing the study on www.clinicaltrials.gov, and speaking to disease-focused support groups. Together these efforts have resulted in rapid recruitment for both studies. In the two months after the Parkinson's study was launched, more than 2,000 patients enrolled. Two years later, the study includes 5,100 patients, the largest single cohort of Parkinson's patients to date. Since the sarcoma study was launched in April 2010, 23andMe has enrolled 519 patients with sarcoma, again, the largest cohort of its kind. Web-based genetic studies allow for global recruitment and require no participant travel. However, such studies do require participants to have Internet access and to navigate the Internet. These requirements are likely correlated with the relative success rates of the recruiting strategies in that individuals who learn of the study via the Internet or email are likely to successfully navigate the recruitment and participation process. Understanding which strategies are most effective for recruitment of web-based genetic research will inform future efforts to engage patients and develop large cohorts for research in a variety of diseases and conditions.

Scalable data management and computable framework for large scale longitudinal studies. *L. Lianas[1], G. Cuccuru[1], S. Leo[1], I. Zara[1], M. Pitzalis[2], M. Zoledziewska[2], F. Deidda[2], S. Sanna[3], G. Zanetti[1].* 1) CRS4, Pula, Italy; 2) Dipartimento di Scienze Biomediche, Università di Sassari, 07100 SS, Italy; 3) CNR-IRGB, Monserrato, CA, Italy.

The increasing rate of data production and decrease of experimental cost of the latest generation of high throughput technologies facilitates large scale high resolution studies even in medium size laboratories. However, once the pure experimental data acquisition hurdle has been overcome, success will depend on the ability to properly manage and process the high-dimensional data sets that are generated, which in turn requires to adopt advances in informatics. Apart from the computational problems connected to the data analysis proper, one key issue is the increasing number of items that need to be tracked, for instance the network of connections and dependencies from the same biological sample to different experiments. Moreover, for clinically motivated studies, the amount of related information, from diagnosis to laboratory results, starts to be comparable to what is handled by a Clinical Information System of a small hospital. We have implemented a computable biobank (CB) in support of two large scale longitudinal studies (~10,000 individuals) on autoimmune diseases and longevity conducted in Sardinia. The CB is designed to represent, using a uniform computational formalism, the information on all the relevant objects (e.g., physical samples, experimental and derived data, clinical data) and the network of actions, performed during the experiments and the computational analysis, that relate one to the other. The system supports type introspection on all its objects and reflects OpenEHR archetypes, an open standard specification in health informatics that describes the management storage, retrieval and exchange of health data in electronic health records (EHRs). The latter choice guarantees a robust, computable, uniform and implementation independent description of the clinical data. The results of computation, e.g., genotype calling data, is held in specialized data structures that directly support further parallel processing and analysis. The current implementation of CB is built upon the core services of OME Remote Objects (OMERO), an open source software platform that includes a number of storage mechanisms, remoting middleware, an API, and client applications for biological data management developed by the Open Microscopy Environment. Currently available CB aware external programs include suites of map-reduce programs for GWAS and sequencing applications, as well as basic chain-of-custody inspection tools and tools for clinical data import.

The clinical and molecular genetic characteristics of Korean patients with Argininosuccinate Synthetase (ASS1) deficiency. *B.W. Jeon[1], B.H. Lee[1,2,3], G.H. Kim[1,2], J.M. Kim[1,2], J.H. Choi[1,3], H.W. Yoo[1,2,3].* 1) Genome Research Center for Birth Defects and Genetic Disorders, Asan Medical Center, Seoul, Korea; 2) Medical Genetics Center, Asan Medical Center, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center Children's Hospital, University of Ulsan College of Medicine.

The urea cycle, consisting of a series of six enzymatic reactions, plays key roles to prevent the accumulation of toxic nitrogenous compound and synthesize arginine. Argininosuccinate synthetase (ASS1) deficiency is a urea-cycle disorder characterized by a defect in ammonium elimination in liver, leading to hyperammonemia.Citrullinemia type I (CTLN1). This study was undertaken to investigate the clinical and molecular genetic characteristics of Korean patients with CTLN1. A total of 21 patients from 20 unrelated Korean families have been diagnosed with CTLN1. Presenting manifestations were hyperammonemic encephalopathy (14pts, 73.7%) and vomiting and irritability (3 pts, 15.8%). The remaining two patients (2 pts, 10.6%) were identified in asymptomatic period, one by neonatal screening test and another patient by family member screening test. Fifteen patients (71.4%) were identified in neonatal period, 2 pts (9.5%) in infantile period, and 4 pts (19%) in adulthood period. The *ASS1* gene analysis revealed 11 different mutations in 39 of 40 alleles (97.5%).p.G230A, p.E298K, and p.I394N were novel mutations. These mutations were located on highly-conserved residues of ASS1, and In silico analysis predicted these variants as pathogenic. Notably, three variants.c.421-2A>G (12/40, 30.0%), G324S (10/40, 25.0%), and c.1127-9_1185dup67 (8/40, 20.0%), were common mutations in Korean CTLN1 patients. The mutation spectrum of the ASS1 gene in Korean population was different from those in other populations, even from those in other East Asian countries. Our report supports wide spectrum of genetic heterogeneity in CTLN1. Further study for the functional characterizations of novel variant is needed.

Investigation of ECM1 mutation in lipoid proteinosis (LP). *F. mahjoubi[1], s. samanian[1], f. izadi[2], mm. tavakoli[2], m. farhadi[2].* 1) National Institute of Genetic Engineering and Biot, tehran, Iran; 2) HAZRAT Rasool Hospital, Tehran University of Medical Sciences and Health Care Services,.

Purpose: Lipoid proteinosis is a rare autosomal recessive disorder (OMIM 247100) that results from mutations in extracellular matrix protein 1 (ECM1), a glycoprotein that is expressed in several tissues. Lipoid proteinosis is a clinically heterogeneous disease. Affected individuals show differing degrees of skin scarring, variable signs of hoarseness and respiratory distress, neurological abnormalities such as temporal lobe epilepsy, hyperkeratosis in knee and elbow and shortening of tongue. Methods used: In this study DNA was extracted from peripheral blood samples taken from affected individuals and their parents, exons were amplified using PCR and then sequenced the PCR product. The project was approved by the local ethical committee of National Institute for Genetic Engineering and Biotechnology (NIGEB) and written informed consent was obtained from all cases. Specimens (peripheral blood) were collected from Hazrat Rasool hospital. Results: One of the patients was a 21-year-old Iranian female who had hoarseness, skin scarring on the face and keratosis in knee and elbow. To best of our knowledge a new homozygous missense mutation C269Y in exon 7 was observed, parents were both heterozygous for this mutation. Conclusion: Our results suggest that this mutation is responsible for LP disease in this patient.

Proteinuria in Infantile-Onset Spinocerebellar Ataxia, Type 2. *R.K. Brar[1], C. Moore[2], L. Eviatar[3], R. Smith[3], C. Sethna[4], M.G. Bialer[2].* 1) Dept. of Pediatrics, Nassau University Medical Center, East Meadow, NY; 2) Div. of Medical Genetics, North Shore LIJ Health System, New Hyde Park, NY; 3) Div. of Pediatric Neurology, North Shore LIJ Health System, New Hyde Park, NY; 4) Div. of Pediatric Nephrology, North Shore LIJ Health system, New Hyde Park, NY.

Spinocerebellar ataxia, type2 (SCA2) is an autosomal dominant progressive neurodegenerative disorder. It typically presents during adulthood in the 4th decade as gait ataxia and incoordination. Other symptoms include hyporeflexia, dysarthria, dysphagia and oculomotor dysfunction. Paternal transmission instability of the causative CAG repeat can, in some cases, lead to extreme repeat expansion, resulting in earlier onset of disease. Infantile-onset of SCA2 is characterized by hypotonia, dysphagia, infantile spasms, myoclonus, dystonia, myokymia, pigmentary retinopathy and abnormal eye movements. There is often rapid progression of disease with early death. We saw a 7 month old girl with axial hypotonia, appendicular hypertonia, microcephaly and global developmental delay. Delays had initially been noted at 5 months with poor head control and lack of tracking. Ophthalmology evaluation revealed cortical visual impairment. EEG showed hypsarrhythmia. CT scan of the head showed parenchymal volume loss. A strong family history of SCA2 exists across 3 generations. The father had onset in his 20's and had a CAG expansion of 44 in the ATXN2 gene. The paternal grandfather had onset in his 30's. Our patient had a heterogeneous expanded repeat allele of 300-350 repeats. At about 12 months she developed nephrotic range proteinuria (protein:creatinine ratio 4-7, normal <0.2). DNA sequencing of known nephrotic syndrome genes (NPHS2, WT1, LAMB2, PLCE1 and NPHS1) did not reveal any definitive pathogenic mutations. Of note, the patient's brother presented similarly as an infant with blindness, developmental delay, seizures, and respiratory and feeding problems. He also developed nephrotic syndrome. A brain CT scan showed cerebral atrophy with a small cerebellum. He died at 2.5 years without a definitive diagnosis. SCA2 gene analysis was never performed. Our case demonstrates considerable molecular instability and, surprisingly, it appears to have occurred twice in the same family. A number of infantile-onset SCA2 cases have been reported in the medical literature, but to the best of our knowledge, this is the first clinically reported case with an expansion significantly more than 200 CAG repeats. To our knowledge, renal involvement has not previously been reported in SCA2. SCA2 should be seriously considered in the differential diagnosis of infants with non-specific neurodevelopmental delay and a family history of cerebellar ataxia.

Investigation of triplet repeat nucleotide in ATXN8OS Gene in one SCA8 suspected patient. *Z. Ghaderi Ardekani[1, 2], M. Houshmand[1, 3], O. Aryani[1], N. Chaparzadeh[2].* 1) Genetic Lab.,Special Medical Center, Tehran, Iran; 2) Depatment of Biology, Azarbaijan University of Tarbiat Moallem; 3) National Institute of Genetic Engineering and Biotechnology Depatment of Medical Biotechnology.

ABSTRACT Introduction: SCAs are progressive neurodegenerative disease that produced from three nucleotide repeat expansion in special region in specific Genes. In SCA8, CTG triplet repeats in untranslated region in ATXN8OS Gene on 13q21 choromosome, are increased above 80 units. Normal range has 15-50 repeats. Intermediate range are Alleles of questionable significance. Materials and Methods : Sample was one patient with clinical features similar to SCA symptoms that had refered to Special Medical Center. DNA was extracted from blood and ATXN8OS Gene was amplified, PCR product ran in polyacrylamide gel. by this formula, Number of repeats measured (N - 231)/3) that N is the PCR product length. Results: The patient was similar to his mother that had 55 repeats in ATXN8OS Gene in one allele and both of them had another allele in normal range, his father had two alleles in normal range. Discussion: By considaration of dominant inheritance manner in this disease, exist of one allele in intermediate range, can be justifier of seen clinical features. By attention to intermediate alleles in correlation to penetrance percentage, personal qualifications and some undefined parameters can or can't illustrate disease, therefore it can clarify that his mother despite of one allele in intermediate range due to uncomplete penetrance didn't show clinical features but the child by inheritance of this allele was patient.

CHARGE SYNDROME; REPORT A NEW CASE. *E. Hernandez Gomez[1], L. Hernández Gómez[2], S.G. Juárez García[3], D.O. Gómez Torres[4].* 1) Biology, Facultad de Estudios Superiores Iztacala, Mexico, Mexico; 2) Instituto Nacional de Rehabilitación, Audiología. Universidad del Valle de México, Campus Coyoacan; 3) Instituto Nacional de Rehabilitación. Patología de Lenguaje; 4) Instituto Nacional de Rehabilitación.

CHARGE syndrome is a recognizable (genetic) pattern of birth defects which occurs in about one in every 9-10,000 births worldwide. It is an extremely complex syndrome, involving extensive medical and physical difficulties that differ from child to child. The vast majority of the time, there is no history of CHARGE syndrome or any other similar conditions in the family. Caused by a change (mutation) in a single gene, most often CHD7. In August, 2004, the first major gene for CHARGE syndrome was reported by a group of researchers in the Netherlands. Newborn with CHARGE syndrome are often born with life-threatening birth defects, including complex heart defects and breathing problems. They spend many months in the hospital and undergo many surgeries and other treatments. Most have hearing loss, vision loss, and balance problems which delay their development and communication. : coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness. The clinical diagnosis is made using a combination of Major and Minor features. Major features are characteristics that are quite common in CHARGE syndrome but relatively rare in other conditions, and are, for the most part, diagnosable in the newborn period We present a new case: female Mexican child at 4 years old: product of the first gestation no consanguineous young parents; present circular umbilical cord in utero, with growth arrest and malnutrition. she. born at 42 weeks by cesarean section, low weight, course with cyanosis, the diagnosis of congenital hypothyroidism, membranous choanal atresia, and ventricular septal defect. Hearing loss was detected at one year of age, language delay. Used hearing aids. Physical examination: Female to conduct hearing, normal, language impairment. hypertelorism, facial asymmetry, ear hypoplasia helix bilaterally, tortuous ear canals, tympanic membranes opaque. Rhinoscopy was normal. High palate, uvula bifida. Audiometric test showed sensorineural severe hearing loss. Speech audiometric test showed sensorineural deficit. Timpanogram: curves As of Jerger bilateral Stapedial reflex absent bilaterally. ABR wave V to 100 dB bilateral, elongated latency, low amplitude waves. Psychological assessment: normal IQ. . Computed tomography of the temporal bones normal.

OTOFACIOCERVICAL SYNDROME, IN A MEXICAN FAMILY. *L. Hernandez-Gomez[1], E. Hernández Gómez[3], S.G. Juárez García[2], D.O. Gómez Torres[4].* 1) Instituto Nacional de Rehabilitación Audiología. Universidad del Valle de México, Campus Coyoacan; 2) Instituto Nacional de Rehabilitación. Patología de Lenguaje; 3) Facultad de Estudios Superiores Iztacala. Biología; 4) Instituto Nacional de Rehabilitación.

Otofaciocervical syndrome may be caused by a contiguous gene deletion involving the EYA1 gene or by mutation in the EYA1 gene (Gene map locus: 8q13.3). The otologic features were conductive hearing loss and prominent auricles with large conchae and preauricular fistulas just in front of the helix. Distinguishing features were a long face with narrow nose, high arched palate, prominent and dysmorphic ears, long neck, sloping shoulders and clavicles, winged, low and laterally set scapulae, tetralogy of Fallot, and deafness secondary to cochlea malformation. The absence of preauricular tags, lacrimal duct stenosis, and renal malformations, and the presence of distinct facial and radiographic findings and markedly downward sloping shoulders in their patient led Dallapiccola and Mingarelli (1995) to suggest that the syndrome is a unique, clinically recognizable entity. We report a Mexican family with 3 affected members with hearing loss in 2 generations, In which father, his daughter and his son are affected. CASE 1: male patient 47-year-old, propositus father,hearing loss onset at 8-year-old, tinnitus at 44 year old. Physical exploration: male with auditory conduct hearing loss, voice and language with alterations. Ears: malformations of helix and antihelix, ducts, external auditory permeable, left with hypoplasia, tympanic membrane opaque with myringosclerosis. Cleft palate, micrognathia. CASE 2: female 17 year old, hearing loss onset at 15-year-old. Physical exploration: female with auditory conduct hearing loss, voice and language with alterations. Ears: Prominent auricles, malformations of helix, preauricular fistulas, ducts, external auditory permeable. Tympanic membrane opaque, long face, narrow nose, cleft palate, micrognathia, long neck, sloping shoulders, low-set clavicles. CASE 3 male 9 year old, left microtia, language impairment l hearing loss onset at 7-year-old Physical exploration: male with auditory conduct hearing loss, voice and language with alterations. Ears: Prominent auricles, malformations of helix and antihelix, preauricular and lateral cervical fistulas, ducts, external auditory permeable. Tympanic membrane normal, long face, eyelid left coloboma, narrow nose, cleft palate, micrognathia, long neck. At 3 patients were performed audiometry, speech audiometry, tympanometry and stapedial reflex, at 2 pediatric patients were also carried out nasal endoscopy, urinalysis, renal ultrasound, computed tomography of temporal bone.

950W

Velocardiofacial syndrome: report of case. *S. Juarez-Garcia[1], L. Hernández Gómez[2], E. Hernández Gómez[3], F. Castillo Lorca[4], D.O. Gómez Torres[5].* 1) INSTITUTO NACIONAL DE REHABILITACION. NEUROPSICOLOGIA; 2) INSTITUTO NACIONAL DE REHABILITACION. AUDIOLOGIA. UVM; 3) FACULTAD DE ESTUDIOS SUPERIORES IZTACALA; 4) S.S.A. TABASCO; 5) INSTITUTO NACIONAL DE REHABILITACION.

Velocardiofacial syndrome are caused by a 1.5 to 3.0-Mb hemizygous deletion of chromosome 22q11.2. The del22q11 syndrome is associated with a highly variable phenotype despite the un-iformity of the chromosomal deletion, characterized by the following frequent features: cleft palate, cardiac anomalies most commonly tetralogy of Fallot, and learning disabilities. Ophthalmologic abnormalities, including tortuous retinal vessels, small optic discs, or bilateral cataracts. In some case presence of progressive sensorineural deafness, whereas in del22q11 the hearing loss was mostly conductive due to palate deformities and velopharyngeal insufficiency. The subjects showed higher verbal than nonverbal IQ scores, assets in verbal memory, and deficits in the areas of attention, story memory, visuospatial memory, arithmetic performance relative to other areas of achievement, and psychosocial functioning. We present a caso: female mexican, child 3 year old, is the child of non consanguineous parents, pregnancy without adversities prenatal. She present tetralogy of Fallot, submucosal cleft palate, bilateral cataracts, hearing loss sensorineural and language disabilities. Normal IQ. ABR with V wave at 100dB. FISH with 22q deletion.

951W

Novel Locus Identified for Branchio-Oto-Renal Syndrome. *A. Sun, K. Taylor, N. Kramer, JM. Graham.* Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA.

Branchio-Oto-Renal (BOR) syndrome is an autosomal dominant disorder characterized by branchial arch anomalies, ear malformations, hearing loss, and renal abnormalities. It has a prevalence of 1 in 40,000 and accounts for 2% of children with profound hearing loss. To date, 3 genes have been identified to cause BOR syndrome. *EYA1* is implicated in 40% of cases, and *SIX1* and *SIX5* together account for approximately 5% of cases. The remaining 55% of individuals with BOR syndrome have an unknown etiology. The EYA1 protein is expressed in renal mesenchyme, cochlear and vestibular neuroepithelia, and other parts of the ear. EYA1 directly interacts with members of the SIX gene family as part of the Six-Eya-Dach regulatory network. Once EYA1 binds SIX1 or SIX5, the complex translocates into the nucleus where the phosphatase activity of EYA1 de-represses target genes. Mutations in *EYA1* can either result in haploinsufficiency of the protein or reduced phosphatase activity. Mutations in *SIX1* and *SIX5* decrease the ability of the proteins to bind EYA1 or DNA. Aberrant gene activation ultimately results in abnormal morphogenesis of the branchial arches, ears, and kidneys. We present a 5 generation family with BOR syndrome. Sequence analysis of *EYA1* did not identify any mutations. A SNP chromosomal microarray showed no significant genomic deletions or duplications. Linkage analysis demonstrated an area on the short arm of chromosome 8 with a LOD score of 3.02. This region does not overlap with any of the existing genes known to cause BOR syndrome and likely represents a novel locus for this disorder. Further association analysis will be done to narrow down the area of interest followed by high throughput sequencing to screen candidate genes. The causative gene may be another member of the SIX or EYA gene families or encode a cofactor that participates in this regulatory network. Once the gene has been identified, we plan to screen other families with BOR syndrome in whom a genetic change has yet to be found.

952W

Inherited systemic hyalinosis: a novel mutation and association with marked alpha-ketoglutaric aciduria. *F. Al Murshedi[1], S. Al Sinani[2], R. Abdwani[2].* 1) Dept of Genetics; 2) Dept of Child Health, Sultan Qaboos University Hospital, Muscat, Oman.

Inherited Systemic Hyalinosis (ISH) is an autosomal recessive condition characterized by progressive hyaline deposition in the papillary dermis and other tissues, namely gastrointestinal mucosa. The infantile form typically presents at birth with reduced spontaneous movements secondary to severe pain and progressive joint contractures. Progressive thickening of skin and appearance of hyperpigmented patches over bony prominences of the joints is a hallmark. Protein-losing enteropathy is the main life threatening complication. ANXR2 gene is the only gene known to be associated with ISH. We hereby report a classic case of infantile ISH. Sequencing of ANTXR2 gene revealed a novel homozygous 79 bp deletion of the entire exon 11 (c.867_945del). Work-up also revealed persistent and marked ketoglutaric aciduria. Association of ketoglutaric aciduria with ISH is not previously documented. A female baby was born at full term with birth weight of 3.3 kg. She was noticed at day one of life to have reduced spontaneous movements and pain with handling. Clinical findings at age of 8 months included tense shining skin marked over bony prominences, joint contractures affecting small joints of hands and knees with overlying skin thickening, hyperpigmentation and nodules. Development, other than gross-motor, was age-appropriate. Other features included gum hypertrophy and perianal tags. Parents are first-cousins and three siblings (2 males, one female), undiagnosed, died with a similar presentation in infancy. Work-up revealed osteopenia and bilateral femur green-stick fractures on skeletal X rays. Biochemically, alkaline phosphatase and parathyroid hormone were elevated with low phosphate consistent with rickets. Urine organic acids done at age of four, six and eight months respectively revealed large increase of alpha-ketoglutaric acid (>500 umol/mmol creatinine). Baby had normal cognitive development and normal plasma and urine lactate excluding the possibility of concurrent alpha-ketoglutarate dehydrogenase deficiency. Diarrhea started at around the age of 6 months, progressively worsened despite dietary modifications and a trial of Octreotide. Patient passed away at age of 15 months with intractable diarrhea. Although mild ketoglutaric aciduria is a common non-specific finding, this consistently profound elevation of the Krebs cycle intermediate may reflect disturbance in mitochondrial function as a contributing factor into the pathogenesis of ISH.

A Report of Three Patients with MMP2 Associated Hereditary Osteolysis. *M.S. Aglan[1, 2], S.A Temtamy[1, 3], S. Ismail[1], A.M. Ashour[1], L.A. Hosni[1], T.H. El-Badry[4], E.H.A. Aboul-Ezz[4, 2], K. Amr[5], E. Fateen[6, 2], T. Maguire[7], K. Ungerer[7], A. Zankl[8].* 1) Clinical Genetics Dept, National Research Centre(NRC), Cairo, Egypt; 2) Board member of the National Society of Human Genetics (NSHG), NRC, Egypt; 3) Head of NSHG, NRC, Egypt; 4) Orodental Genetics Dept, NRC, Egypt; 5) Medical Molecular Genetics Dept, NRC, Egypt; 6) Biochemical Genetics Dept, NRC, Egypt; 7) Queensland Health Pathology Services, Brisbane, Australia; 8) UQ Centre for Clinical Research, The University of Queensland, Brisbane, Australia.

Osteolysis disorders are a group of inherited diseases characterized by rheumatoid like destruction and resorption of affected small joints with associated swelling and pain. Historically, the existence of three autosomal recessive osteolysis syndromes was suspected: Torg syndrome, Winchester syndrome and Nodulosis-Arthropathy-Osteolysis syndrome or Multicentric Osteolysis, Nodulosis and arthropathy. As they are all caused by MMP2 mutations, they were grouped under the nomenclature of Torg-Winchester syndrome (TWS). The current study reports three new patients from two unrelated Egyptian families with TWS. Clinical examination, radiological, biochemical and molecular studies were conducted. Clinical and radiological findings suggested the diagnosis of TWS. The three affected patients were homozygous for novel missense MMP2 gene mutations which confirmed the diagnosis. In both our families, based on the amino acid position, the mutation seems to be far from the catalytic domain with subcutaneous nodules as a prominent clinical feature. The patients reported here further define the clinical spectrum of TWS. They are the first to be reported from Egypt thus, supporting the pan ethnic nature of the disease.

Chronic Tibial Nonunion in a Rothmund-Thomson Syndrome Patient. *A.M. Carlson[1], S. Kirmani[2], K.B. Thomas[3], N.M. Lindor[2].* 1) Mayo Medical School, Mayo Clinic College of Medicine, Rochester, MN; 2) Department of Medical Genetics, Mayo Clinic, Rochester, MN; 3) Department of Radiology, Mayo Clinic, Rochester, MN.

Background: Rothmund-Thomson Syndrome (RTS) is a rare disorder caused by biallelic mutations in RECQL4, a DNA helicase involved in chromosomal stability and DNA excision repair. Patients with RTS present with a characteristic phenotype of diffuse poikilodermatous rash, sparse hair, skeletal abnormalities, short stature, photosensitivity, and a predilection to developing osteosarcoma and cutaneous malignancies. Known skeletal abnormalities include osteopenia, radial ray defects, and congenital dislocations. **Purpose:** To present an adult with RTS who had chronic nonunion of the proximal tibias bilaterally due to minor trauma and later developed generalized lower extremity osteopenia with normal calcium homeostasis and calcitriol levels. **Methods:** Medical records from July 7, 1998 to January 27, 2011 were reviewed and abstracted; radiographs were correlated with clinical course. A comprehensive literature search was performed to identify previously reported skeletal abnormalities and rates of occurrence. **Results:** Despite 400 U of vitamin D daily and calcium supplementation, the patient's osteopenia progressed and nonunion of the proximal tibias bilaterally continued without resolution over nine years of observation. Additional fractures such as an ununited intra-articular fracture of the proximal right ulna and stress fractures in multiple metatarsals were also noted. Bony abnormalities are quite common in RTS patients, as Mehollin-Ray et al. found in 2008 that 75% of their cohort had at least one bony abnormality. However, this literature review showed chronic bony nonunion was a novel and unexplained finding in RTS. **Conclusions:** As treatments for osteosarcoma improve and RTS patients survive into later decades of adulthood, osteopenia and congenital malformations present a source of morbidity. Treatment options for osteopenia are limited by RTS patient's predilection for osteosarcoma. Further work is needed to determine the mechanism for osteopenia and nonunion of fractures in this patient and whether or not this is a common event in individuals with RTS.

De-novo microdeletion of chromosome region 1p36.12: unmasking a rare autosomal recessive form of spondyloepimetaphyseal dysplasia. *L. Dupuis[1], A. Guerin[1], E. Goh[1], A. Chaudhry[1], M. Shago[2], R. Zeller[3], D.J. Stavropoulos[2], R. Mendoza-Londono[1].* 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Canada; 2) Department of Paediatric Laboratory Medicine, Hospital for Sick Children, Toronto, Canada; 3) Department of Orthopedic Surgery, Hospital for Sick Children, Toronto, Canada.

Classically, microdeletions are not associated with autosomal recessive phenotypes. However, here we report clinical, radiologic and molecular cytogenetic findings in a female of Portuguese descent with a de-novo microdeletion of chromosome region 1p36.12 involving HSPG2. The patient was born at 38 weeks gestation with a birth weight of 2.6 kg (5-10th centile) and length of 48 cm (25th centile). She was diagnosed postnatally with a form of spondyloepimetaphyseal dysplasia (SEMD). She developed progressive limitation of the range of motion of multiple joints and became wheelchair-bound by 4 years of age. At age 14, she was significantly short at 122 cm (50th centile for a 7 year old). Her bone mineral density was low (Z score -3.8). Her intellectual development has been normal. Skeletal survey at 12 years of age showed irregularities of the endplates of the cervical spine with fusion of the bodies of C2 and C3 and kyphoscoliosis of the thoracolumbar spine. She had severe deformities of the pelvis with small iliac wings and shortening of the pelvic bones bilaterally. The femoral heads were irregular and showed sclerosis. In addition, there was broadening of the femoral neck. The epiphyses of the distal femur and tibia were enlarged and there was generalized shortening of the long bones. Her elbow joints were dislocated bilaterally and there was radio-ulnar dislocation. Array CGH identified a deletion of chromosome region 1p36.12 with an estimated size of 1.357 Mb. This deletion results in the loss of 17 UCSC RefSeq genes, which include OMIM gene HSPG2. Mutation analysis of HSPG2 revealed a base pair deletion in the other allele, c. 9326delA. This mutation has been previously described as a pathogenic mutation. The mutation was identified in a family of Brazilian origin making it likely that it arose in Portugal. Mutations in HSPG2 have been implicated in a rare autosomal recessive form of SEMD: Schwartz-Jampel syndrome type 1 (SJ) and Silverman-Handmaker type of dyssegmental dysplasia (SHDD). Although this patient was deficient in both copies of HSPG2, her skeletal findings were different from those typically seen in SJ or SHDD, thus expanding the phenotype of HSPG-related disorders. This case highlights the importance of considering the unmasking of a recessive phenotype when a microdeletion is identified.

Vitamin D Status & Decreased Muscle Function in Children with Neurofibromatosis Type 1. *S.M. Huson[1], C.W. Hockett[1,2,6], J. Eelloo[1], S. Roberts[3], J. Berry[4], C. Chaloner[5], Z. Mughal[6].* 1) Neurofibromatosis Centre, Genetic Medicine, Manchester Biomedical Research Centre, Manchester Academic Health Sciences Centre, University of Manchester and Central Manchester University Hospitals Foundation Trust, M13 9WL UK; 2) Department of Biology, South Dakota State University, Brookings, SD; 3) Biostatistics Group, School of Epidemiology & Health Sciences, University of Manchester; 4) Vitamin D Research Group, Medicine, Manchester Royal Infirmary; 5) Department of Clinical Biochemistry,, Royal Manchester Children's Hospital, Manchester, UK; 6) Department of Paediatric Endocrinology, Royal Manchester Children's Hospital, Manchester, UK.

Background - Recent studies have reported significantly lower mean serum 25-hydroxyvitamin D (25OHD) concentration in adults with NF1. Vitamin D deficiency not only has a negative effect on bone, but is also important in muscle function. One of the main factors influencing bone formation and size is the mechanical load that is placed on bone. If there is decreased muscle function, loading forces on bone may be reduced leading to increased bone resorption and low BMD. Therefore, muscles play a key role in the sculpting of bone size and maintenance of bone integrity. Previous studies have shown that NF1 patients have slender long bones, which may be due to decreased muscle strength. Objective - The aim of this cross-sectional pilot study was to assess the vitamin D status and muscle function in children with NF1 compared with unaffected siblings. Methods - We identified NF1 children between 5 to 18 years of age and who had at least one unaffected sibling from the NF1 clinic records. Along with 25OHD serum concentration, we also measured serum concentrations of calcium, inorganic phosphate alkaline phosphatase activity, parathyroid hormone and 1,25-dihydroxyvitamin D concentrations in the study subjects. The Leonardo Mechanography Ground Reaction Force Platform was used to measure peak jumping power, peak jumping force and peak jump height. Results - The mean serum 25OHD concentration between NF1 children and their non-affected sibling was not different. There was no significant relationship between vitamin D status and muscle function. After controlling for weight and height, the least squares means for non-NF1 and NF1 children for peak jumping power was 1.64 (1.53, 1.75), 1.40 (1.29, 1.51) respectively, force 1.05 (0.99,1.10), 0.91 (0.85,0.96) respectively, and height 0.35 (0.27, 0.44), 0.31 (0.22, 0.39). From the least squares means, we found that NF1 children had significantly lower maximum jump power (p=0.004) and force (p=0.001) than non-NF1 children. Conclusions - We did not find low levels of vitamin D in children with NF1. Lammert et al (2006) showed a correlation between vitamin D and neurofibroma number, as significant numbers of these lesions are only present in adults with NF1 this is one possible explanation.NF1 children have impaired jumping power and jumping force, when compared to a child not affected by NF1.Decreased muscle function may contribute to the osseous abnormalities observed in NF1 children.

Association study of common polymorphisms in human lysyl oxidase genes with adolescent idiopathic scoliosis. *T.L. McGregor[1,8], C.A. Gurnett[2,3], M.B. Dobbs[3,4], C.A. Wise[5,6], J.A. Morcuende[7], T.M. Morgan[1,8], R. Menon[9,10], L.J. Muglia[1,11].* 1) Dept of Pediatrics, Vanderbilt University Medical Center, Nashville, TN; 2) Depts of Neurology and Pediatrics, Washington University School of Medicine, St. Louis, MO; 3) Dept of Orthopedic Surg, Washington University School of Medicine, St. Louis, MO; 4) Saint Louis Shriners Hospital for Children, Saint Louis, MO; 5) Sarah M. and Charles E. Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, Dallas, TX; 6) Dept of Orthopaedic Surgery and McDermott Center for Human Growth and Development, University of Texas Southwestern Medical Center, Dallas, TX; 7) Dept of Orthopedic Surgery and Rehabilitation, University of Iowa, Iowa City, IA; 8) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 9) Perinatal Research Center, Nashville, TN; 10) Dept of Epidemiology, Rollins School of Public Health, Emory University, Atlanta, GA; 11) Dept of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, and Vanderbilt Kennedy Center for Human Development, Vanderbilt University, Nashville, TN.

Background: Although adolescent idiopathic scoliosis affects approximately 3% of adolescents, the genetic contributions have proven difficult to identify. Work in model organisms, including zebrafish, chickens, and mice, has implicated the lysyl oxidase family of enzymes in the development of scoliosis. We hypothesized that common polymorphisms in the five human lysyl oxidase genes (*LOX, LOXL1, LOXL2, LOXL3,* and *LOXL4*) may be associated with the phenotype of adolescent idiopathic scoliosis. Methods: This was a case-control genetic association study. A total of 112 coding and tag SNPs in *LOX, LOXL1, LOXL2, LOXL3*, and *LOXL4* were genotyped in a discovery cohort of 138 cases and 411 population controls. Genotypes were tested for association with adolescent idiopathic scoliosis by logistic regression with a two degree of freedom genotypic model and gender as a covariate. Fourteen SNPs with $p < 0.1$ in the discovery phase were genotyped in an independent replication cohort of 400 cases and 506 controls. Results: No significant associations were found between coding or tag SNPs in *LOX, LOXL1, LOXL2, LOXL3,* and *LOXL4* and the phenotype of adolescent idiopathic scoliosis. Conclusions: Despite suggestive evidence in model organisms, common variants and known coding SNPs in the five human lysyl oxidase genes do not confer increased genotypic risk for adolescent idiopathic scoliosis. The above methodology does not address rare variants or individually private mutations in these genes, and future research may focus on this area.

Expanding the Phenotype of the Novel Ehlers-Danlos caused by mutations in the *CHST14* gene. *R. Mendoza-Londono[1,2], D. Chitayat[1], W. Kahr[1], A. Hinek[2], S. Blaser[1], L. Dupuis[1,2], E. Goh[1], A. Howard[2], L. Mittaz[3], A. Superti-Furga[3], S. Unger[3], G. Nishimura[4], L. Bonafe[3].* 1) Div Clinical & Metabolic Gen, Hosp Sick Children and University of Toronto, Toronto, ON, Canada; 2) The Bone Health Centre, The Hospital for Sick Children, Toronto, ON, Canada; 3) Division of Molecular Pediatrics, CHUV, Laussanne, Switzerland; 4) Department of Radiology, Tokya Metropolitan Kiyose Children's Hospital, Kiyose, Japan.

Ehlers-Danlos Syndrome (EDS) is a heterogenous group of disorders characterized by varying degrees of connective tissue hyperextensibility. In 2010 a new type of EDS was described in patients of Japanese and of Turkish descent presenting with craniofacial characteristics, contractures and joint and skin laxity. All patients had mutations in the *CHST14* gene coding for the enzyme dermatan 4-O-sulfotransferase. We present the detailed clinical findings in 2 sisters of Afghani descent born to consanguineous parents and 1 male patient of Somali descent. All patients presented with multiple contractures, progressive joint and skin laxity and hemorrhagic diathesis following minor trauma. Prenatal evaluation of patient 2 identified possible Dandy-Walker variant, prominent amnion-chorionic separation, bilateral club feet and clenched hands.In addition to the findings above patient 3 has significant ocular defects and microphthalmia. Platelet aggregometry and electron microscopy revealed normal function and ultrastructure. Cultured fibroblasts produced normal amounts of fibronectin and elastin but demonstrated lack of collagen III production, lack of extracellular deposition of collagen I fibers and a peculiar intracellular retention of Collagen I. All patients were found to be homozygous for novel missense mutations in the *CHST14* gene. The identification of three additional patients with this disorder raises awareness of the pan-ethnicity of the condition and expands our knowledge regarding the clinical manifestations. Our studies show that the condition has to be considered in cases presenting prenatally with clenched fists and amnion-chorion separation, that the facial features are characteristic regardless of ethnicity and the bleeding diathesis in these patients is not the result of thrombocytopathy. We also expand the knowledge regarding the collagen abnormalities in this condition.

959W

Cherubism: clinical, radiological and familial aspects in a large French family. *G. Morin[1], S. Demachy[2], E. Cadet[3], B. Demeer[1], S. Testelin[2], S. De Broca[2], J. Rochette[3], B. Devauchelle[2], M. Mathieu[1].* 1) Clinical Genetic Unit, Amiens University Hospital, Amiens, France; 2) Maxillofacial Surgery and Stomatology Service, Amiens University Hospital, France; 3) Molecular Biology Laboratory, Amiens University Hospital, France.

Cherubism is a rare genetic osseous dysplasia responsible of oligodontia, giant cysts of maxillaries, and deformations of the lower part of the face. The mode of inheritance is autosomal dominant and the expressivity very variable. The maxillary involvement is generally asymmetric and the teeth disorganization often spectacular, associated with malocclusion, gum hypertrophy, and mastication problems. Some extra-maxillary involvements are possible: exophthalmia, ptosis, retraction of the lower eyelids, cervical lymphadenopathies, skin's café-au-lait spots, other skeletal lesions. The clinical features generally appear during the first five years of life and progress until the late teens. However, a regression of the cysts is often observed during the third decade. The genetic nature of the disease was quickly suggested, and a linkage to the chromosome 4p16.3 region was discovered in 1999. Mutations of the SH3BP2 gene were reported in 2001. They all concern the exon 9 and modify only 3 amino acids located 31 to 36 amino acids upstream of the SH2 domain and 205 to 210 amino acids downstream of the SH3-binding domain. This gene plays a critical role in regulation of myeloid cell responses and mutations are probably responsible of a gain of function. We report a large family affected by cherubism on at least 3 generations with at least 8 affected persons including 2 monozygotic twins. A mutation was found in the exon 9 of SH3BP2 gene (c.1253C>A / p.418H). This mutation was already reported in affected patients (Ueki et al 2001). We describe the clinical, radiological and familial aspects of the disease in this large French family. The outcome of the affected family members is also considered.

960W

Ischiospinal dysostosis results from mutations in BMPER and is allelic with diaphanospondylodysostosis. *L. Nevarez[1], S. Nampoothirii[2], O. Kim[3], A. Superti-Furga[4], D.H. Cohn[1].* 1) MCDB, UCLA, Los Angeles, CA; 2) Amrita Institute of Medical Sciences and Research Centre, Cochin, Kerala, India; 3) Department of Radiology, Ajou University Hospital, Suwon, Korea; 4) Department of Pediatrics, Univ. of Lausanne, Switzerland.

Ischiospinal dysostosis (ISD) is a non-lethal skeletal dysplasia named for the severe hypoplasia of the vertebral bodies and the hypoplastic ischia that characterize the disorder. Delayed ossification and hypoplasia of the vertebral bodies can lead to a short trunk phenotype and to significant kyphoscoliosis. In some patients, ossification defects of the ribs, termed rib gaps, have also been observed. In addition to the dysostosis, defects in the kidneys, ranging from a single cystic kidney to enlarged kidneys with nephroblastomatosis, have been seen in several cases. The combination of defects in vertebral segmentation and nephroblastomatosis is also seen in diaphanospondylodysostosis (DSD), a perinatal lethal skeletal dysplasia recently found to result from recessively-inherited, inactivating mutations in BMPER. BMPER encodes the BMP-binding endothelial cell precursor-derived regulator, a pro-BMP signaling molecule, implying that defective BMP signaling underlies the phenotype. To determine whether DSD and ISD are allelic, mutation analysis of BMPER was carried out in two ISD cases. One of the affected individuals was a compound heterozygote for two stop codon mutations, similar to the types of mutations observed in DSD. The newborn phenotype of this individual resembled DSD but over time evolved into the characteristic ISD phenotype, indicating that factors other than the BMPER genotype may determine clinical outcome. The second affected individual studied, who was the offspring of consanguineous parents, was homozygous for a F375S missense mutation in the gene. The phenotype was milder, with ossification defects in the lumbar vertebrae and mildly hypoplastic ischia, but there was still significant shortening of the trunk. The mutation altered a highly evolutionarily conserved residue within the von Willebrand D domain of BMPER, which appears to tether the molecule to the cell surface to facilitate its signaling role. These findings thus demonstrate that DSD and ISD are allelic recessive disorders.

PARRY ROMBER SYNDROME. MULTIDISCIPLINARY EVALUATION OF SIX PATIENTS BY ORTHODONTICS AND GENETICS. HOSPITAL PARA EL NINO POBLANO, MEXICO. *S. Ochoa[1], J. Aparicio[2,3], E. Huitzil[3].* 1) Orthodontics; 2) Genetics, Hospital para el Nino Poblano, Puebla, Puebla, Mexico; 3) Estomatology, Benemerita Universidad Autonoma de Puebla.

Hemifacial atrphy or Romberg disease, Parry Romberg syndrome and facial trophoneurosis are a rare clinical entity. It is characterized due to facial lipid tissue, skin, bones and cartilaginosous tissue atrophy. The early diagnosis in pediatrics is sometime difficult due to be a rare event. Actual orthodontics is a medical discipline that must be treated by a multidisciplinary medical team in estomatology and pediatrics. Some of the dentofacial malocclusions and deformities have a familiar distribution that makes necessary that ortodonthics and genetics work together including lift and palate deformities. Pediatric cases are analyzed in this study, where hemifacial hemiatrophy are observed more frequently in female than males, and on the left facial side according to the literature. Six pediatrics cases are studied where four (Males) and two (females) were observed. 3 males and a one female patient had a left facial side affected and two male and one female patient on the right side. All of the patients had a multidisciplinary attention both at the departments of orthodontics and genetics.

Skeletal anomalies and severe language disorder with submicroscopic deletion in 12q13 including HOXC cluster. *N. Okamoto[1], K. Shimojima[2], T. Yamamoto[2].* 1) Dept Medical Genetics, Osaka Med Ctr/Res Inst, Osaka, Japan; 2) Tokyo Women's Medical University Institute for Integrated Medical Sciences, Tokyo, Japan.

HOX genes have an important role in the initial formation of the body. We report a patient with severe kyphoscoliosis and digital abnormalities with a submicroscopic deletion of 12q13. He also exhibited cardiac anomalies and a severe delay in language development. The deletion was detected by array-CGH and confirmed by FISH. The patient was haploinsufficient for the HOXC gene cluster. No human genetic disorders due to HOXC abnormalities are yet known. A haploinsufficiency of the HOXC gene cluster may result in severe kyphoscoliosis and digital abnormalities. Radiologic features of the fingers had some similarities with those for multiple synostosis syndrome. Deformation of the spine seen may be partially explained by a haploinsufficiency HOXC-4. The flexion contracture and other digital abnormalities in our patient may have some association with a HOXC-8 haploinsufficiency. A haploinsufficiency of other genes may contribute to the cause of language disorder.

963W

Hereditary Disorders of Connective Tissue in Patients with Intracranial Hypotension Syndrome. *E. Reinstein[1], W. Schievink[2], M. Pariani[1], D. Rimoin[1].* 1) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 2) Dept. of Neurosurgery, Cedars-Sinai Medical Center, Los Angeles, CA.

Introduction: Intracranial hypotension syndrome (ICH) is a rare and understudied condition with an estimated prevalence of 1:50,000. It is an under diagnosed and frequently misdiagnosed condition, even by experienced clinicians. Consequently, the diagnosis and treatment are often significantly delayed. This has major consequences on the quality of life of the patients and their families, as well as on the medical system in terms of excessive financial and time expense, unnecessary investigations, incorrect therapies, and preventable deterioration of the disease state. The clinical presentation of patients with ICH is a postural headache that worsens in the upright position. The most common cause of ICH is spontaneous cerebrospinal fluid leak and an underlying weakness of the spinal dura is generally suspected. Hereditary disorders of connective tissue comprise a clinically and genetically heterogeneous group of disorders, characterized by generalized fragility of connective tissues with an incidence of 1:5000. Several case reports and small studies suggested a link between hereditary disorders of connective tissue and spontaneous cerebrospinal fluid leaks but it is not clear what the exact prevalence is. Objective: To determine the prevalence of hereditary disorders of connective tissue among patients with ICH in a prospective study using a large cohort of patients. Methods: We enrolled a consecutive group of 45 patients presenting with ICH. All patients have been carefully examined for clinical features of hereditary disorders of connective tissue, and based on findings patients underwent genetic testing. Ancillary diagnostic testing included echocardiography and histopathological examinations of skin and dura biopsies in selected patients. Results: Preliminary results based on 45 patients indicate that hereditary disorders of connective tissue, including Marfan syndrome, Ehlers-Danlos syndrome and other unclassified hereditary disorders of connective tissue are significantly more prevalent in patients with ICH compare to the general population (20% as opposed to .0002%; P<.001). Conclusion: Hereditary disorders of connective tissue are common among patients with ICH syndrome, and cerebrospinal fluid leak may be the first clinical presentation of the disorder.

964W

The Singleton-Merten Syndrome Calcification Paradox is Potentially Associated with Decreased *TGFBRII* Expression. *F. Rutsch[1], Y. Nitschke[1], I. Buers[1], O. Mamaeva[2], J. Dong[2], C. Müller[1], HG. Kehl[3], J. Kleinheinz[4], P. Barth[5], M. Daudon[6], D. Bazin[7], R. Hennekam[8], M. MacDougall[2].* 1) Dept. of General Pediatrics, University Children's Hospital, Muenster, Germany; 2) Institute of Oral Health Research, School of Dentistry, University of Alabama, Birmingham, AL, USA; 3) Dept. of Pediatric Cardiology, Muenster University Children's Hospital, Muenster, Germany; 4) Dept. of Cranio-Maxillofacial Surgery, Muenster University Children's Hospital, Muenster, Germany; 5) Institute of Pathology, Muenster University Hospital, Muenster, Germany; 6) Service de Biochimie A, AP-HP, Hopital Necker, Paris, France; 7) Laboratoire de Physique des Solides, Universite Paris Sud, Orsay, France; 8) Dept. of Pediatrics, Academic Medical Center, University of Amsterdam, The Netherlands.

Ectopic artery calcification is frequently associated with decreased bone mineral density or disturbed bone-turnover. This contradictory association, referred to as the calcification paradox might be due to opposite regulation of the OPG-RANK-RANKL system in bone and vasculature by TGF-beta. Extensive calcification of the ascending aorta and cardiac valves and early loss of rootless secondary teeth is characteristic of Singleton-Merten syndrome (SMS), a rare inborn disorder of autosomal dominant inheritance. We report on the first three European patients with SMS (two siblings of both sexes and one unrelated girl), who presented with delayed eruption of their deciduous teeth, loss of secondary dentition during adolescence, widened medullary cavities of the phalanges and calcifications of the ascending aorta and heart valves, requiring cardiac valve replacement in two of the patients before 25 years of age. Explanted calcified cardiac valves from one patient were subjected to HE staining, FTIR spectroscopy and scanning electron microscopy. Primary dental cells (Pulp and enamel organ epithelial, EOE) from a Singleton-Merten tooth were established and analyzed for mineralization potential by in situ alkaline phosphatase histochemistry and XO staining for calcium deposition. Quantitative RT-PCR and gene array analysis was performed to compare gene expression profiles to normal age- and sex-matched controls. Histologically the cardiac valves showed an effacement of their normal structure by extensive fibrosis of all layers and amorphous calcifications without significant inflammation. The calcifications contained mainly hydroxyapatite crystals. Dental pulp cells showed decreased mineralization potential under osteogenic media conditions. Of 72 genes of an osteogenesis array panel, 40 genes (47.6%) were down-regulated in the EOE cells while 39 (46.2%) were down regulated in pulp cells. TGFBRII receptor was dramatically down-regulated in both cell types (-4,627 and -785, respectively). Singleton-Merten syndrome is a model disease for the calcification paradox. Decreased TGF-beta signaling is potentially a good candidate for the driving force of decreased bone and tooth mineralization and increased arterial calcification in this syndrome.

Crommelin-type symmetrical tetramelic reduction deformity; Report of a case with review of prenatal and postnatal findings, differential diagnosis and etiology. *S. Sawyer[1], O. Caluseriu[1], J. Kohlhase[2], A.M. Innes[1].* 1) Department of Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Institute for Human Genetics and Anthropology, University of Freiburg, Freiburg, Germany.

We report on a 3 year old girl with upper limb amelia and lower limb phocomelia. Her features are in keeping with the Crommelin-type symmetrical tetramelic reduction syndrome[1]. This case report contributes to our knowledge of the long term prognosis for this rare condition. The limb deformities were first noted on a 22 week fetal ultrasound. Post-natal X-rays confirmed complete absence of the arms with normal scapulae and clavicles. In the lower limbs the acetabulae were poorly formed and femurs were absent bilaterally. There was a single bone bilaterally in the legs and 4 rays in the feet with soft tissue syndactyly of the lateral two rays. X-rays a year later suggested a femoral ossification centre on the right lower limb, and an unusual appearance of the calcaneus and talus bilaterally. There were no other abnormalities on fetal ultrasound or fetal echocardiogram. There was no exposure to Thalidomide during pregnancy. Amniocentesis confirmed a normal karyotype without evidence of centromeric `puffing'. At age 3 she has normal cognitive development and despite her striking limb anomalies is currently learning to walk. Genetic investigations, including karyotype and array CGH, were normal. As WNT3 and WNT7A have been implicated in syndromes with limb malformations [2] they were both sequenced in our patient. No point mutations or deletions were found. The differential diagnosis for this condition includes Fibula-Femur-Ulna complex, however the striking symmetry in Crommelin-type tetramelic reduction appears to set this condition apart. To date there has been no underlying genetic etiology described that causes Crommelin-type symmetical tetramelic reduction. Further cases are being identified in preparation for possible next generation sequencing studies. References 1. Head and Neck Pain in EDS: Significant Co-Morbidity. *B. Tinkle.* Div Human Gen, Cincinnati Children's Hosp, Cincinnati, OH.

Ehlers Danlos Syndrome (EDS) is a group of heritable connective tissue disorders characterized largely by joint laxity and skin/soft tissue fragility. While chronic joint pain or even widespread pain are features of EDS (Sacheti, 1997), it is underappreciated that the craniocervical junction is one of the most mobile joints and also susceptible to joint instability and pain. A significant portion of EDS patients complain of chronic or recurrent head pain. Head pain could have several sources from headache, sinus pain, temporomandibular dysfunction (TMD; including myofascial pain), and neck pain. Chronic headaches are estimated to affect about half of EDS patients (Sacheti 1997; Jacome, 1999; Castori, 2010) with majority suffering from migraine (Bendik, 2011). Estimates for the prevalence of neck pain in EDS range from 37% to 67% (Hudson, 1995; Sacheti, 1997). The Brief Pain Inventory results show that 67% of 118 EDS patients experience head and neck pain of some kind (our data). Fifty percent of the patients complained of neck pain, 19.5% complained of posterior cranial pain, and 33.1% complained of facial pain. TMD can also be associated with face pain and headache. It was seen in 67% (20/30; our data) of EDS patients which was comparable to previous reports (Castori, 2010). Further, the mean TMD Disability Index of 48 EDS patients demonstrated moderate disability (our data). Of 52 EDS patients, the mean Northwick Park Neck Pain score was 36.9% revealing a moderate disability; however, several patients had no pain but 17 had severe and 10 had crippling disability. Similarly, the Neck Pain Disability Index of another group of 30 EDS patients had a group mean of 18.8% consistent with moderate disability with the clear majority of patients (16/30) also scoring in this category. Common symptoms that these patients complained of in clinic included: numbness and tingling in the upper extremities; frequent spells of dizziness; nausea; fatigue; muscle spasms; tinnitus; jaw “popping”, “clicking”, or locking; sleep difficulty; history of dropping things; palpitations; unusual visual impairment (e.g. blurriness, double vision, or tunnel vision); and difficulty swallowing. These symptoms, along with the head and neck pain, significantly decreased the quality of life of these patients. Recognition and acknowledgment of the patient's symptoms will focus management and have a better chance of improving the quality of life of those suffering with EDS.

Candidate gene analysis of nonsyndromic sagittal craniosynostosis.

X. Ye[1], A. Guilmatre[1], E. Jabs[1], Y. Heuzé[2], J. Richtsmeier[2], D. Fox[3,4], C. Druschel[3,4], R. Goedken[5], P. Romitti[5]. 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, NY; 2) Department of Anthropology, Pennsylvania State University, University Park, Pennsylvania, PA, USA; 3) Department of Epidemiology and Biostatistics, School of Public Health, University at Albany State University of New York, Albany, NY, USA; 4) Congenital Malformations Registry, New York State Department of Health, Troy, New York, NY, USA; 5) Department of Epidemiology, The University of Iowa College of Public Health, Iowa City, Iowa, IA, USA.

Craniosynostosis, the premature fusion of one or more cranial sutures, occurs in approximately 1 in 2,500 live births. Among various forms, midline sagittal nonsyndromic craniosynostosis represents the most prevalent type. In syndromic craniosynostosis, causative mutations are known on fibroblast growth factor receptors (FGFRs), TWIST1, RAB23, and other genes. However, the etiology of nonsyndromic craniosynostosis is largely unknown. We used data from an ongoing, population-based case-control study in Iowa and New York State to identify novel candidate genes for nonsyndromic sagittal craniosynostosis. Diagnosis was confirmed by radiographic images. Family history data are being collected from mothers, and saliva samples are being collected from the index child and birth parents in case and unaffected control families. In our initial analyses, we evaluated 96 nonsyndromic sagittal synostosis cases and performed extensive candidate gene analysis by direct sequencing. Two isoforms of FGFR1, FGFR2, TWIST1 and RAB23 were selected based on their expression patterns, animal models, and/or roles in human craniosynostosis syndromes such as Carpenter syndrome, which is associated with midline craniosynostosis and RAB23 mutations. We identified three novel variants among different patients. In case 1, we found a frameshift variant in exon 6 of FGFR1 isoform 6 (c.732_733insG) which was predicted to abolish the entire immunoglobin III domain, including the ligand binding region. In case 2, a variant in TWIST1 exon 1 (c.439C>G) was observed at the highly conserved loop domain and may affect the DNA binding ability; the mother of the case reported to have had jaw surgery and was also confirmed to harbor the same variant. In case 3, we identified a variant in exon 6 in RAB23 (c.546A>C) that led to the amino acid substitution from glutamic acid to aspartic acid and was inherited from the mother. These variants detected in our study were unique and did not occur in 116 alleles from healthy control children from the same population or in more than 200 alleles previously screened in controls or in the NCBI dbSNP and CHIP Bioinformatics databases. Our data suggest that mutations in these candidate genes may contribute to nonsyndromic sagittal craniosynostosis, although they would account for a small proportion of total cases, and add to the perception of craniosynostosis as a complex developmental anomaly under potential polygenic control.

Rasmussen encephalitis associated with other autoimmune disorders.

F. Andermann[1,4,5,6,9], D. Amrom[2,4,5,9], D. Kinay[10], M. Guduk[10], D. Atakli[10], B. Arpaci[10], S. Berkovic[11], Y. Hart[12], E. Andermann[2,4,5,7,9], A. Bar-Or[3,4,5,8,9]. 1) Epilepsy Service and Seizure Clinic; 2) Neurogenetics Unit; 3) Neuroimmunology Unit; 4) Department of Neurology, Montreal Neurological Hospital & Institute; 5) Departments of Neurology & Neurosurgery; 6) Pediatrics; 7) Human Genetics; 8) Microbiology & Immunology; 9) McGill University, Montreal, Quebec, Canada; 10) Bakirkoy State Hospital for Research and Training in Neurology, Neurosurgery, and Psychiatry, Istanbul, Turkey; 11) Epilepsy Research Center, Department of Medicine (Neurology), University of Melbourne; Austin Health, Heidelberg West, Melbourne, Australia; 12) Department of Neurology, Royal Victoria Infirmary, Newcastle upon Tyne, UK.

Background: Rasmussen's encephalitis (RE) is a rare chronic inflammatory disease characterized by intractable focal epilepsy, often epilepsia partialis continua, progressing to hemiparesis, cognitive impairment, and unilateral cerebral atrophy. The etiology of RE remains unknown. We have previously reported the occurrence of two rare autoimmune disorders, Behcet's disease and RE, in a father and son respectively, and suggested that they might be genetically susceptible to developing autoimmune conditions which have been precipitated by separate environmental triggers. Purpose: To report four individuals with a dual diagnosis of RE and other autoimmune disorders (AID), and to discuss the possible mechanisms of this association. Results: The diagnosis of RE in all four patients was based on previously reported criteria, and was pathologically confirmed in patients 2, 3 and 4. In family 1, a patient with RE onset at 2y 8mo developed Hashimoto's thyroiditis at 15 years; he also had a brother with Type 1 (autoimmune) diabetes mellitus. In family 2, the patient had RE onset at 3y 9mo, and developed ulcerative colitis at 10y 9mo. In family 3, the patient had RE at the age of 6 y, and developed Crohn's disease at age 14y. In family 4, the patient had RE onset at 14y and onset of systemic lupus erythematosus at 31y. In these four families, the second AID appeared a number of years after the onset of RE, with a mean interval of 11 years (median 10 years). Discussion: We suggest that the occurrence of a second autoimmune disease in RE patients may be higher than by chance; however, the true frequency and relative risk are unknown. The delay between the appearance of RE and the second autoimmune disease might seem long, but in fact the mean age of onset of these other AID is younger than average. Although the role of the immune system in RE, causing or merely reacting to the disease, is still unclear, our observations suggest that there may be a common predisposing factor for the development of RE and other AID. One hypothesis could be a common underlying genetic susceptibility to developing autoimmune conditions; these may then be precipitated by exposure to two different hits, e.g. separate environmental triggers or other susceptibility genes. Further study of the long term evolution of RE patients, as well as detailed family histories, and use of newer molecular techniques such as CGH microarray and whole exome sequencing, are warranted to clarify this.

969W

Action Myoclonus-Renal Failure Syndrome (AMRF): Founder Effect in French Canadians. *E. Andermann[1], D. Amrom[2], J. Mulley[3], M. Bayly[4], M. Jomphe[5], S. Berkovic[6], F. Andermann[7], L. Dibbens[4].* 1) Neurogenetics Unit, Montreal Neurological Hospital and Institute; Depts of Neurology & Neurosurgery and Human Genetics, McGill University, Montreal, Canada; 2) Neurogenetics Unit, Montreal Neurological Hospital and Institute; Dept of Neurology & Neurosurgery, McGill University, Montreal, Canada; 3) Department of Genetic Medicine, Women's and Children's Hospital, North Adelaide, Australia; 4) School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, Australia; 5) BALSAC Project, Université de Chicoutimi, Quebec, Canada; 6) Epilepsy Research Center, Department of Medicine (Neurology), University of Melbourne; Austin Health, Heidelberg West, Melbourne, Australia; 7) Epilepsy Service and Seizure Clinic, Montreal Neurological Hospital and Institute; Depts of Neurology & Neurosugery and Pediatrics, McGill University, Montreal, Canada.

BACKGROUND: AMRF, an autosomal recessive form of progressive myoclonus epilepsy with renal failure, was initially described in three French Canadian families in 1986. Additional families were reported in the USA, Cuba, Germany, Portugal and Australia. The gene for this disease was recently found to be SCARB2/Limp2, encoding a lysosomal-membrane protein. A nonsense mutation c.862C>T (Q288X) in exon 7 of SCARB2 was identified in one of the original French-Canadian families. PURPOSE: To characterize the SCARB2 mutations in French Canadian patients with AMRF, and to determine whether these mutations can be explained by a founder effect. DESIGN/METHODS: DNA was obtained on 105 family members in 7 families, and exon 7 of SCARB2 was sequenced for the Q288X mutation. Genealogies of the AMRF families sharing this mutation were analyzed employing the BALSAC population register. Haplotype analysis using highly heterozygous markers was also performed. RESULTS: Four new patients in three families were homozygous for the Q288X mutation. Thirty-three unaffected individuals in five families who were not obligate carriers were found to be heterozygous for the Q288X mutation. In a sixth family, the mother was found to carry another SCARB2 mutation, suggesting allelic heterogeneity. One patient of French-Canadian extraction living in New England was found to be a compound heterozygote for both mutations. Genealogies of the 5 families sharing the Q288X mutation demonstrated three links 6 generations back, and one 9 generations back. The mean kinship coefficient was significantly higher than in control French Canadian genealogies. Haplotype analysis resulted in a shared haplotype of over 7.2 Mb involving 6 heterozygous markers, strongly suggesting identity by descent. CONCLUSIONS: By combining genealogical and molecular data, we have established that six French Canadian families share the same SCARB2 mutation that can be explained by a founder effect. Carrier screening for the founder mutation in this population can be carried out without sequencing the entire SCARB2 gene. This has important implications for genetic counseling, prenatal and preclinical diagnosis, and prevention of this debilitating disease.

Brain Abnormalities in Individuals with Beckwith-Wiedemann Syndrome. *D. Chitayat[1, 3, 8], K. Gardiner[2], S. Choufani[3], C. Shuman[4, 8], S. Blaser[5, 8], D. Terespolsky[6], P. Ray[7, 8], B. Baskin[7, 8], R. Weksberg[3, 4, 8].* 1) Prenatal Diag & Med Gen, Mount Sinai Hosp, Toronto, ON, Canada; 2) Sarah Lawrence College, Bronxville, NY; 3) Genetics and Genome Biology, Research Institute, The Hospital for Sick Childrenm Toronto, On; 4) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, On; 5) Diagnostic Imaging, The Hospital for Sick Children, Toronto, On; 6) Genetics Department, Credit Valley Hospital, Mississauga, On; 7) Molecular Genetics Division, Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, On; 8) Faculty of Medicine, University of Toronto, Toronto, On.

Beckwith-Wiedemann syndrome (BWS) is an overgrowth disorder with variability in clinical manifestations and molecular etiology. Developmental issues identified in patients with BWS can, in most cases, be ascribed to neonatal hypoglycaemia or chromosome abnormalities involving copy number variation for genes beyond the critical BWS region on chromosome 11p15.5. Brain malformations are not known to be part of the BWS phenotypic spectrum. A retrospective review of 450 BWS patients included in our registry detected 7 cases with brain abnormalities including 2 with Blake's pouch cyst, 2 with Dandy-Walker variant (hypoplasia of the inferior part of the vermis), 1 with Dandy-Walker malformation and 1 with DWM, dysgenesis of the corpus callosum and brain stem abnormality. Molecular analysis showed loss of methylation at imprinting center (IC2) in 3, CDKN1C mutations in 2, and 11p14-15 microdeletion in 1. One had no detectable mutation/methylation abnormalities. These data suggest that genes in imprinted domain 2 are involved in normal midline and posterior fossa brain development. Brain ultrasound/MRI should be considered for BWS patients with developmental delay, especially if they have molecular alterations in imprinted domain 2 of chromosome 11p15.5.

971W

Glut1 deficiency syndrome with a SLC2A1 splice site mutation and normal erythrocyte glucose uptake. *N. Ishihara[1], Y. Azuma[1,2,3], K. Yanagihara[4], S. Yokoi[1], T. Nakata[1,2], K. Aso[3], K. Ohno[2], J. Natsume[1].* 1) Dept Pediatrics, Nagoya Univ Graduate Sch Medicine, Nagoya, Japan; 2) Div Neurogenetics and Bioinformatics, Nagoya Univ Graduate Sch Medicine, Nagoya, Japan; 3) Dept Pediatrics, Aichiken Aoitori Medical and Welfare Center, Nagoya, Japan; 4) Dept Developmental Medicine, Osaka Medical Center Res Inst for Maternal and Child Health, Osaka, Japan.

Glucose transporter type 1 deficiency syndrome (Glut1-DS) is characterized by infantile seizures, acquired microcephaly, developmental delay, hypoglycorrhachia, and decreased erythrocyte glucose uptake. These are caused by a mutation of the Glut1 gene (SLC2A1) leading to brain energy failure. Since Glut1 protein is highly expressed on the erythrocyte membranes, the state of Glut1-deficiency usually can be revealed by erythrocytes glucose transport assays. Here we report a 5-year-old boy, who had typical symptom of Glut1-DS and hypoglycorrhachia, but normal erythrocytes glucose uptake caused by new mutation of SLC2A1. He was born to non-consanguineous parents with moderate mental retardation. His motor development was delayed; head was controlled at 8 months of age, and he walked with support at 18 months. He had loss of consciousness during febrile illnesses several times since 16 months of age, and his first afebrile seizure occurred at 28 months of age. Treatment with phenobarbital caused unsteady standing and diziness. Head MRI was normal. EEG revealed diffuse irregular spike-waves during fasting period. The CSF glucose level was 27 mg/dl and blood-glucose level was 75 mg/dl, thus a CSF/blood glucose ratio was decreased to 0.36. He was suspected to have Glut1-DS, but his erythrocyte glucose uptake was normal. Mutational analysis of SLC2A1 was performed with genomic DNA extracted from white blood cells, and we found heterozygous mutation at intron 9, c1279-1G>A. Next we performed RT-PCR with mRNA extracted from white blood cells, and found 2 different splice variants which were not seen in healthy controls. Glut1 protein is expressed in vascular endothelial cells comprising blood-brain barrier. As SLC2A1 is also expressed in erythrocytes, the diagnosis of Glut1-DS is confirmed by a decreased uptake of 3-O-methylglucose into erythrocytes. In our case, in spite of the clinical features which strongly suggested Glut1-DS, erythrocyte glucose uptake revealed normal. Wang et al. reported two patients with a Glut1-DS phenotype associated with a heterozygous Glut1 T295M mutation and normal erythrocyte glucose uptake. The T295 places intracellular loop 6-7 and it co-operated with intracellular C-terminal of Glut1. As both of our splice variants make truncation of C-terminal of Glut1, we speculated that our mutation could also lead to decreased uptake of glucose into blood-brain barrier without decreasing erythrocyte uptake.

Distinct de novo deletions in a brother-sister pair with RTT: A case report. *K. Mittal[1], N. Gupta[2], M. Kabra[2], R. Juyal[3], B.K. Thelma[4].* 1) Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) All India Institute of Medical Sciences, New Delhi, India; 3) National Institute of Immunology, New Delhi, India; 4) University of Delhi South campus, University of Delhi South campus.

Rett syndrome (RTT), a neurodevelopmental disorder caused by mutations in the X-linked gene encoding methyl-CpG-binding protein2 (MeCP2), is a leading cause of mental retardation in females. Majority of cases are sporadic (99%) but some familial cases have also been observed. We describe a familial study with a brother-sister pair with symptoms of RTT and exhibiting distinct deletions in the MECP2; with the sister exhibiting deletion in exon3 (MBD domain)and the brother with deletion in exon4 (TRD and DPR domains). The non-shared de novo deletion in the two sibs provides important insights into the disease etiology, especially for male sibs showing varied phenotypes as compared to the classical ones seen in the females.

973W

Identification of a novel recurrent microdeletion at 2q11.2 associated with speech delay and ADHD. *A. Patel[1], P. Hixson[1], P. Stankiewicz[1], S.W. Cheung[1], P.I. Bader[2].* 1) Dept Molecular and Human Gen, Baylor Col Medicine, Houston, TX; 2) Parkview Health Systems,Fort Wayne, IN.

A rare recurrent microdeletion involving chromosome 2q11.2 of approximately 900 kb in size was detected by a custom-designed exon-targeted clinical microarray in four individuals from approximately 15,000 cases evaluated by our laboratory. The deleted segment is flanked by low copy repeats suggesting nonallelic homologous recombination is the mechanism of origin. The common clinical features observed include speech delay and attention-deficit/hyperactivity disorder (ADHD). The deletion is de novo in one individual and was inherited from an affected mother of a sibling pair. Copy number variation in this region has not been reported in any normal individuals (Database of Genomic Variants). There are at least 21 genes mapped in this interval, including 13 OMIM genes. Of the genes whose function is known, the most intriguing gene in this region with respect to the phenotype observed in these individuals is the ADRA2B (adrenergic, alpha-2B receptor) gene. This gene belongs to a family of receptors which play a critical role in regulating neurotransmitter release from sympathetic nerves and from adrenergic neurons in the central nervous system. A functional deletion variant of this gene that consists of an inframe deletion of 3 acidic residues in the third intracellular loop of the receptor, acts as a loss of function polymorphism in regulation of emotional memory. Carriers of this deletion exhibit increased activation of the amygdala and inferior frontal gyrus in response to acute stress. Interestingly, the prefrontal cortex is one of the brain structures implicated in mood disorders and ADHD. In summary, we describe the molecular and clinical features of a novel recurrent microdeletion at 2q11.2 associated with speech delay and ADHD further supporting that deletion of the ADRA2B gene is likely responsible for the observed ADHD phenotype.

974W

Neonatal Epilepsy as a Presenting symptom of Infantile Cerebral and Cerebellar Atrophy in a Caucasus Jewish Child. *A. Singer[1], A. Shaag[2], D. Lev[3,4], C. Vinkler[3,4].* 1) Dept Clinical Gen Unit, Barzilai Med Ctr, Ashkelon, Israel; 2) The Department of Genetic and Metabolic Diseases, Hadassah, Hebrew University Medical Center, Jerusalem, Israel; 3) Institute of Medical Genetics, Wolfson Medical Center, Holon, Israel; 4) Metbolic Neurogenetic Clinic, Wolfson Medical Center, Holon, Israel.

Infantile cerebral and cerebellar atrophy is a new syndrome recently described. Five patients have been described so far. They all presented with swallowing difficulties at the age of 1-2 month leading to failure to thrive, poor visual fixation and lack of tracking, jitteriness and truncal arching. At a few months of age they started with overt seizures. Progressive microcephaly is observed with a head circumference of -6 SD at about 9 months of age. They did not show any acquisition of developmental milestones and any dysmorphic features. Brain MRI revealed severe diffuse cerebral and cerebellar atrophy already evident at few months of age with poor myelination. All five patients were of Caucasus Jewish origin. Using homozygosity mapping, a common mutation- L371P, in the MED 17 gene was found. We describe a 4y old patient with a severe clinical presentation of intractable epilepsy right after birth. He is the first child of young unrelated parents of Caucasus Jewish origin born at term following an uneventful pregnancy. Initially, extensive evaluation, including brain ultrasound and CT, were normal. EEG was abnormal with epileptogenic foci especially remarkable in the right temporal area. At first, he responded well to phenobarbital treatment. His head circumference at birth was 35 cm. At 4 months he was reevaluated because his seizures recurred and could not be controlled by drugs, he had roving eye movement and developmental delay . At the age of one year, his head circumference was -4 SD and brain MRI showed sever diffuse cerebral and cerebellar atrophy with poor myelination. At 3.5 y, he had profound mental retardation, overt epilepsy and dysmorphic features. Molecular analysis of the MED17 gene revealed the common mutation L371P. The underlying genetic etiologies of neonatal seizures are diverse. Some of the known mutated genes cause channelopathies. Others are related to metabolic diseases. Another group of genes relate to syndromes involved with brain structural anomalies. The mechanism by which a mutation in the MED17 gene causes neonatal onset epilepsy is not clear. Our patient presented with neonatal epilepsy. Microcephally, abnormal MRI of the brain and dysmorphic features were apparent only at a later stage. We would like to suggest that mutation in the MED17 gene should be included in the differential diagnosis of neonatal seizures in patients of Caucasus Jewish origin.

975W

46, XY Pure Gonadal Dysgenesis and Pontocerebellar Hypoplasia. *K. Siriwardena[1], A. Guerin[1], S. Blaser[2], D. Chitayat[1].* 1) Division of Clinical & Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Radiology, Hospital for Sick Children, Toronto, Ontario, Canada.

We present an infant with XY pure gondal dysgenesis, developmental delay, spasticity, and ponto-cerebellar hypoplasia. This is only the second patient with this unique combination as described by Huq and Nigro, Pediatr Neurol 23(4):357-60. The phenotypically female infant was seen at 10 months of age for severe global developmental delay and cerebellar hypoplasia. She was born to non-consanguineous Caucasian parents at term after an uneventful pregnancy and vaginal delivery with a birth weight of 3.75kg. Family history was unremarkable. She required nasogastric tube feeds until 2 weeks of age. Developmental milestones were delayed with patient smiling at 4 months, holding objects at 8 months and rolling but not sitting at 10 months. Episodes of back arching were noted at 4 months but an EEG showed no evidence of epileptiform activity. Audiology, eye examination and VEP testing were normal. On examination she had minor craniofacial dysmorphic features with a flat occiput, prominent glabellar with nevus flammeus, broad nasal root and tip. External genitalia were unambiguously female with a clitoris and labia minora with posterior labial agglutination. At 10 months, she had significant head lag and truncal hypotonia associated with increased distal tone and brisk deep tendon reflexes but no clonus. She was able to fix and follow well but bilateral intermittent esotropia was noted. A thorough metabolic screen including isoelectric focusing was normal. A microarray analysis showed a 46 XY complementation with maternally inherited 2q12.3 duplication. While this region contains known genes- GCC2, SULT1C3, SULT1C4, SULT1C2 and SLC5A7- it is considered to be a variant. FISH for SRY was positive. Molecular testing for ATRX and DHCR7 was negative. Repeat MRI at 17 months showed reduced periventricular white matter and size of corpus callosum, thalami and pons in addition to cerebellar hypoplasia. MRI imaging of the pelvis followed by examination under anesthesia showed the presence of a blind ended vagina and bilateral “gonadal” structures noted to be Fallopian tubes on pathological examination. FSH was elevated at 85 IU/L with low androgens levels. Our patient continues to gain milestone: was crawling by 17 months. Our patient and the patient described by Huq and Nigro appear to have the same rare disorder of sexual differentiation with as yet unknown genetic etiology.

976W

Mutation in *MKI-67* in a family with intellectual disability and microphthalmia. *M. Srour, M.E. Samuels, J.L. Michaud.* Human Genetics, University of Montreal, Montreal, Quebec, Canada.

Microphthalmia is a heterogeneous condition, whose genetic basis remains poorly characterized. We recently observed a new form of syndromic microphthalmia in a consanguineous Lebanese family. The proband was a girl with severe intellectual disability, central hypotonia, peripheral spasticity and severe anterior chamber eye defects consisting of aphakia and sclerocornea. Brain MRI and array genomic hybridization were normal. To our knowledge, this association of severe intellectual disability and microphthalmia has never been reported. The mother of the proband subsequently became pregnant of a fetus with evidence of bilateral microphthalmia on ultrasound and MRI. The pregnancy was terminated. Autopsy demonstrated similar ocular defects.

To study the molecular basis of this new phenotype, we performed whole genome SNP genotyping of the proband and the fetus using the Illumina 610 Quad panel. We identified 7 regions of homozygosity (RH) larger than 1 Mb shared by the proband and the fetus. The largest RHs (>3 Mb) were: 1) chr1:43,071,708-53,738,134 (10.7 Mb); 2) chr10:77,586,965-131,072,928 (53.5Mb). With the exception of *FOXE3*, which maps to the chromosome 1 interval, none of the known microphthalmia genes (*PAX6, RAX, SIX3, SIX6, OTX2, SOX2, CHX10,GDF6, MITF*) lie in the candidate RHs and we did not find any rare variants in *FOXE3*. Whole-exome sequencing was performed in the affected child using an Agilent SureSelect biotinylated RNA library and the Illumina Genome Analyzer II (GAII) system. After filtering out common variants, we identified a homozygous nonsense mutation in *MKI-67* (Antigen identified by monoclonal antibody Ki-67) (c.7402C>T, p.2468Q>X) in the largest interval of homozygosity. The mutation is predicted to abolish the distal third of the protein. Sanger sequencing confirmed that both affecteds are homozygous and their parents heterozygous for this mutation. This mutation was not found in 152 Middle-Eastern control chromosomes, nor was it identified in the 1000 genome project. *MKI-67* encodes a ubiquitous nuclear protein whose exact function is unknown, though it is widely used as a marker of cellular proliferation. Knock-down experiments in the zebrafish are currently underway. The implication of this gene in neural and ophthalmologic development is novel and suggests new avenues for research.

977W

Description of a patient with characteristic dysmorphic features and mental retardation associated with FGF12 gene deletion. *L. Telvi[1], A. Rouen[1], A. Coussement[1], J.M. Dupont[1], I. Desguerre[2], M.C. Leroux[2].* 1) Cytogenetics Department, Hospital Cochin-St Vincent de Paul, Paris, France; 2) Department of Genetics, Hospital Necker, Paris, France.

We describe a 21 years-old patient with characteristic dysmorphic traits as large forehead, hypothelorism, long nose, broad nasal base, short philtrum and macrognathia associated to a mild mental retardation. The patient showed a normal caryotype after RHG banding. The oligonucleotide array analysis using Nimblegen whole genome tiling CGX 135K HG18 demonstrate that the patient carry an 112 kb deletion localized at 3q28, which include FGF12 gene. The RP11-466I16 probe was used for FISH analysis and confirms this deletion. The phenotypically normal father was found carrying the same deletion after using oligonucleotide array and FISH analysis. The phenotypical differences between the patient and his father could be explained by a haploinsufficency. The patient had phenotypically normal two sisters. The patient's mother and one of the sisters showed no deletion at this chromosomal site after FISH analysis with the same probe. The fibroblast growth factors are referred as fibroblast homologous factors (FHFs) and comprise a family of related polypeptides with broad mitogenic and cell survival activities. Smallwood et al. (1996) showed that FHFs are expressed principally in the nervous system and are therefore likely to play a role in nervous system development and/or function. Nie X (2006) was described the FGF12 gene as having function in the developing mouse cranial base, and showed that the FGF12 was transitorily expressed at early chondrocranium. We discuss the possible relationship between the deletion of the FGF12 gene and phenotypical abnormalities of the patient.

978W

Ramon Syndrome in a 38 years old male. *S.B. Turyk, M. Sakurai, C. Galliuss, E. Maloberti.* Servicio de Genetica, Hospital Britanico de Buenos Aires, Buenos Aires, Buenos Aires, Argentina.

Ramon Síndrome (RS) was initially described by Ramon et al. (Oral Surg. 24:436-48,1967). Since that time there have been few patients reported in the literature with this rare, presumed autosomal recessive syndrome. Described patients were mostly children. We report a new case of RS, a rare disorder, characterized primarily by gingival overgrowth, congenital generalized hypertrichosis, mental retardation and epilepsy. Our proband was a caucasian 38 year old male. Third son of non consanguineous parents and his older brothers of whom were unaffected. He was born full-term by normal vaginal delivery and his birth weight was 2 kg. Developmental milestones were delayed. Reportendly, he attended regular school up to the 9th grade. Our patient had mental deficiency, epilepsy, gingival fibromatosis, cherubism due to the fibrous dysplasia of the maxillae, hypertrichosis and pigmentary changes in the retina. Chromosomal study of peripheral blood lymphocytes confirmed the 46,XY karyotype. Ocular features were not described in the original report on this syndrome. Recent reports of other families with R.S. describe pigmentary retinopathy and optic disc pallor. It may be concluded that ocular abnormalities are another feature of Ramon syndrome and are developing later.

979W

Cutaneous manifestations in 9 patients with biallelic germline MUTYH mutations. *F. Caux[1], A. Lévy[2], P.O. Schischmanoff[3], F. Coulet[4], F. Soubrier[4], Y. Parc[5], L. Laroche[1], C. Colas[4].* 1) Reference Center for Genetic Skin Diseases & Dpt of Dermatology, Avicenne Hospital, Bobigny, France; 2) Dpt of Pathology, Avicenne Hospital, Bobigny, France; 3) Laboratory of Biochemistry, Avicenne Hospital, Bobigny, France; 4) Laboratory of Oncogenetics, Pitié Salpétrière Hospital, Paris, France; 5) Dpt of Digestive Surgery, Saint Antoine Hospital, Paris, France.

Biallelic germline MUTYH mutations (M-/-) are associated with autosomal recessive adenomatous polyposis and colorectal cancer. Skin lesions such as sebaceous adenomas, hyperplasia or carcinomas may occur in association. Prevalence of these lesions is unknown since only case reports have been described. In order to assess prevalence and describe histologically these lesions, we performed a systematic clinical examination of 9 individuals M-/-. A dermatological examination has been proposed to all patients M-/- seen in oncogenetic counseling (n=36). Nine patients were examined including 8 by the same dermatologist. Six skin biopsies were performed in 4 patients. Colonic manifestations were gathered in order to search for phenotype-genotype correlation. There were 5 males and 4 females with a mean age of 49.3 years (range 26-65). Six out of 9 patients had skin lesions with a mean age of beginning of 43 years (range 33-54). These lesions were yellowish papules in a variable number occurring on the face (forehead, cheeks). Analysis of 6 lesions always demonstrated sebaceous hyperplasia, none showing microsatellite instability (n=3). Colonic polyposis was present in 8 patients with a mean beginning age of 40.6 years (range 30-49) and a variable number of polyps (range 5-150). A colorectal cancer was associated in 6 patients. MUTYH analysis demonstrated homozygous mutations in 7 patients (p.Gln337Ter, p.Gly382Asp, p.Tyr165Cys, p.Glu396GlyfsX43) and compound heterozygous mutations in 2 patients (p.Tyr165Cys and p.Glu466del; p.Gly382Asp and p.Pro391Leu). No phenotype-genotype correlation was detected. Treatment with isotretinoin completely cleared skin lesions (n=3). Prevalence of sebaceous lesions is high (66%) in our patients M-/-. These lesions constantly were hyperplasia while 14 sebaceous tumors (8 adenomas, 4 hyperplasia, 2 carcinomas) have been described in the literature. Dermatological appearance of these patients may evoke Muir-Torre syndrome. However Muir-Torre syndrome is autosomal dominant and characterized by sebaceous adenomas. Skin findings also share similarities with multiple sebaceous hyperplasia seen in transplant recipients under immunosuppressive therapies. Finally we observed a high prevalence of sebaceous hyperplasia in patients M-/-. Dermatologists have to be aware that multiple facial yellowish papules in a young individual is not specific of Muir-Torre syndrome but may also lead to search for MUTYH mutations and to perform colonoscopy.

980W

A new case of Gorlin Syndrome in Mexican female. *N. DAVALOS, A. RINCON, C. ISLAS, R. LOPEZ, J. ONTIVEROS, D. GARCIA, S. RAMIREZ, J. OLMOS, S. ALONSO, Genetic variation group.* Inst Human Genetics, Univ Guadalajara, Guadalajara, Mexico.

Gorlin Syndrome also know as Nevoid Basal Cell Carcinoma (NBCCS) present a pattern hereditary autosomical dominant. Cases is caused by a novo mutation, was reported clinical variability in populations and ethnic groups.The prevalence is 1/57000 to 1/256000 among.The pourpouse of the new case in Mexican famele, with age 39-year-old,product of the fourth pregnancy ,of non consanguineous parents,family history revealed by the maternal breast and thyroid, was operated on 13 times for removal of keratocysts and nevus mainly from the frontal and thorax. Grandmother and two maternal aunts showed breast cancer and sister thyroid cancer.Psychomotor development was normal,dermatologist reported more than twenty nevi with different body distribution which have removed many times,beginning with dental anomalies ten years keratocysts detected, and the date has since been operated on 13 times this reason, also present history abortions reported two three wings near and ten weeks of gestation, asocited with bicornuate uterus. Proband present attention deficit within the average IQ bordering. Other findings in proband is magraine, a quiet cooperative patient with face feature characteristics for macrocephaly,hypertelorism,frontal bossing, any more palmoplantar pits,more than twenty nevi on the face and neck,high-class,dermatology has surgically resected nevi in at least thirteen occasions where pathology reports type basal cell carcinoma, pigmented and superficial multifocal micronodular variant, micro surgical side edges and free of neoplasia, hands and feet has many pits. TAC of nervious system showed calcification falx cerebri and microcalcifications in the frontal zone,through grooved maxillofacial,reported poor dental occlusion sclerotic radiolucent edge of the branch at the left maxillary and images supported by multiple scar lesion was excised by keratocysts, gynecology. We conclude than this is the first case which shows the association between abortion-Gorlin syndrome repetitions for bicornuate uterus and multiple microcalcifications in the central nervous system.

981W

Pulmonary anomalies in a novel syndrome of macrocephaly, nephromegaly, and Wilms tumor reveals mechanistic etiologies for overgrowth syndromes. *J.A. Martinez-Agosto.* Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA.

The molecular basis for several overgrowth syndromes, including Beckwith-Wiedemann (BWS) and Sotos, has been identified. However, the etiology for many others remains unknown. Here we describe a novel overgrowth syndrome characterized by macrocephaly, congenital pulmonary cysts, nephromegaly, and Wilms tumor predisposition. The presence of multicytsic lung disease in these cases prompted a search of the literature and patient database records for the presence of pulmonary malformations in other overgrowth conditions. An exhaustive search did not identify any overgrowth syndrome cases with pulmonary anomalies. The unique association of these findings with cystic lung disease suggests that they represent a novel overgrowth syndrome. In contrast, bullous pulmonary lesions have been described in a subset of patients with Proteus syndrome. We compare the Proteus lung phenotype to our patients and have identified unique similarities that support a distinct common molecular etiology. Birt-Hogg-Dube syndrome includes multiple lung cysts as well as renal tumors and is due to mutations in FLCN, which regulates PTEN/Akt/mTor signaling. As mutations in PTEN have been identified in hamartoma syndromes that share many findings with Proteus, dysregulation of PTEN/Akt/mTor signaling likely underlies the somatic overgrowth and lung defects in these syndromes. This is supported by the pulmonary phenotype in tuberous sclerosis, which presents with lung cysts prior to development of lymphangiolyomyomatosis. In addition, mouse knockouts for the TAZ gene, a transcriptional coactivator and downstream target of the Hippo pathway, develop pulmonary cysts. TAZ is required for lung alveolarization, where it regulates expression of connective tissue growth factor. We propose that dysregulation of the Hippo and PTEN/Akt/mTor pathways cause anomalies that lead to somatic overgrowth and cystic lung changes in this subset of overgrowth syndromes. The advent of massively parallel/whole exome sequencing technologies has allowed the genetic characterization of these sporadic disorders and we are currently using this approach to identify the causative gene for this syndrome.

982W

Gorlin Syndrome: A familial case. *I.M. Salazar-Dávalos[1], M.A. Aceves-Aceves[1], D. García-Cruz[2], N.O. Dávalos[2], M.G. González-Mercado[2,3], J.A. Cruz-Ramos[2,3], A. González-Mercado[2,3], S.A. Alonso-Barragán[1,2], C. Roa[4], I.P. Dávalos[2,3].* 1) Facultad de Medicina, CUCS, Universidad de Guadalajara; 2) Instituto de Genética Humana, Doctorado en Genética Humana, CUCS, Universidad de Guadalajara; 3) División de Genética, CIBO, Instituto Mexicano del Seguro Social; 4) UMAE, Hospital de Pediatría, CMNO, Instituto Mexicano del Seguro Social. Guadalajara, Jalisco, México.

Introduction: The Gorlin syndrome, also known as Gorlin-Goltz syndrome, Nevoid Basal Cell Carcinoma Syndrome (NBCCS) and Basal Cell Nevus Syndrome (BCNS), is an infrequent multisystemic disease, inherited as an autosomal dominant disorder, with complete penetrance and variable expressivity. It is characterized by odontogenic keratocysts of jaws, multiple basal cell nevi and skeletal abnormalities, other features include palmar and plantar epidermal pits, facial dysmorphism including broad facies, frontal and biparietal bossing, ocular anomalies, cleft lip/palate, medulloblastoma as well as intracranial ectopic calcifications. BCNS is caused by mutations in the PTCH1 gene (601309.0001) on chromosome 9q22, the PTCH2 gene (603673.0003) on chromosome 1p32, or the SUFU gene (607035) on chromosome10q24-q25. Case report: We studied a 16 year-old male, product of the 1st pregnancy, mother of 36 and father 38 years old, a brother of 10 years and a sister of 5 years old. His father had a previous history of an odontocyst. In the present case at 13 years old were detected multiple odontogenic cysts in mandible and maxillary regions by orthopantomography, the cysts were surgically removed and histopathological analysis reported keratocystic odontogenic tumors (KCOTs). Physical examination showed height of 163 cm, weight of 53 and head circumference of 56 cm, frontal bossing, moderate hypertelorism, pits of the palms and soles. Radiological studies showed bridging in sella turcica. At 15 year-old presented a mass in the left lumbar region and in inframaleolar dorsal region, both masses were surgically removed and histopatologically diagnosed as benign lipomatous tumor of skin and subcutaneous tissue. The father with a previous odontogenic keratocyst was clinically examinated showing palmar/plantar pits and multiple nevi. These datae led us to consider a familial BCNS. Conclusion: Several studies include KCOTs, basal cell nevi and skeletal anomalies as major clinical features of BCNS. The diagnosis criteria of BCNS require the presence of two major criteria or one major and two minor criteria (Kimonis et al, 1997). The aim of this work is to present a familial case of BCNS, reaffirming early diagnosis and clinical evaluation are necessary in Gorlin syndrome patients and relatives, as well as to reduce exposure to UV radiation to prevent BCC (Basal Cell Carcinoma).

983W

Association between rs642961 and cleft lip and palate in Patagonia (ECLAMC) population. *F.M. de Carvalho[1], A.R. Vieira[2,3,4], F. Poletta[5,6], J.C. Mereb[7], R.F. Fonseca[1], J.L. Camelo[5,6,8], E.E. Castilla[5,6,9], I.M. Orioli[1].* 1) ECLAMC and INAGEMP at Genetics Department, Federal University of Rio de Janeiro, RJ, Brazill; 2) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 3) Pediatric Dentistry Department, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 4) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 5) ECLAMC and INAGEMP at CEMIC (Center for Medical Education and Clinical Research), Buenos Aires, Argentina; 6) CONICET (National Research Council of Argentina), Buenos Aires, Argentina; 7) ECLAMC and INAGEMP at Hospital Zonal El Bolson, El Bolson, Rio Negro, Argentina; 8) ECLAMC at IMBICE /CONICET, La Plata, Argentina; 9) ECLAMC and INAGEMP at Epidemiology Laboratory of Congenital Malformations, Oswaldo Cruz Institute, Rio de Janeiro, Brazil.

Cleft lip with or without cleft palate (CL/P) birth prevalence is about 1/1,000 live births. In South America four CL/P high prevalence regions was detected, one of them being the Patagonia (Argentina). Significant association between the ancestral allele of the single nucleotide polymorphisms (SNPs) rs2235371(C>T) in the IRF6 gene and CL/P was inconsistently shown in multiple populations. Recently it was proposed that the ancestral allele of rs2235371(C>T) does not have an association with clefting independently of the mutated allele of the SNP rs642961(G>A) near the IRF6 region. We tested for association between these SNPs in IRF6 region (rs2235371C>T and rs642961G>A) and the risk of CL/P, using case-parent trio design in a high frequency CL/P population from Patagonia (Argentina). Five-hundred and twenty-six individuals from 129 families were selected through the Latin-American Collaborative Study of Congenital Malformations (ECLAMC). Genotyping was carried out by using TaqMan®SNP genotyping assays on the ABI Prism 7900HT. Haplotype and transmission distortion analyzes were performed with the Family Based Association Test (FBAT). We found an association between rs642961(G>A) around the IRF6 gene and CL/P with over transmission of the ancestral allele (f (G)=0.70, Z=2.042, p=0.04) in this population. This association remained when we analyzed a subgroup of 52 families (217 individuals) from El Bolsón and neighborhood villages (Lago Puelo, Ñorquincó, El Maitén, El Mallín Ahogado, Los Menucos, Maquinchao, Ingeniero Jacobacci) (f(G)=0.69, Z=2.616, p=0.009) and disappeared when we excluded this subgroup from the analysis (f(G)=0.71, Z=0.533, p=0.60), suggesting some kind of heterogeneity in this population. The variant rs2235371 is not associated with CL/P in this population. The association between the rs642961 (G>A) and CL/P, through the ancestral allele in some populations and through the mutated allele in other suggests that this SNP is not causal to CL/P.

984W

IRF6, SNAP91, PRSS35 and CRISPLD2 contribute to the etiology of oral clefts in a Latin American population (ECLAMC). *R.F. Fonseca[1], F. Poletta[2,3], F.M. Carvalho[1], E.E. Castilla[2,3,4], A.R. Vieira[5,6,7], I.M. Orioli[1].* 1) ECLAMC and INAGEMP at Department of Genetics, Federal University of Rio de Janeiro, RJ, Brazil; 2) ECLAMC and INAGEMP at CEMIC, Buenos Aires, Argentina; 3) CONICET (National Research Council of Argentina), Buenos Aires, Argentina; 4) ECLAMC and INAGEMP at Epidemiology Laboratory of Congenital Malformations, Oswaldo Cruz Institute, Rio de Janeiro, Brazil; 5) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 6) Pediatric Dentistry Department, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 7) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

The aetiology of oral clefts is complex and very heterogeneous, with multiple genetic and environmental factors playing a role. The most recent estimative suggest that from 3 to 14 genes contribute to oral clefts. The aim of this study was to test if 26 single nucleotide polymorphisms (SNPs) distributed in in seven loci previously associated with oral clefts [MTHFR (2 SNPs), IRF6 (7 SNPs), TGFA (5 SNPs), 6q (six SNPs), FOXE1 (2 SNPs), CRISPLD2 (2 SNPs), and PVR (2 SNPs)] were associated with oral clefts. Genotypes were generated using TaqMan chemistry and real time PCR equipment. From years 2003-2006, DNA samples were collected from 304 triads through the Latin-American Collaborative Study of Congenital Malformations (ECLAMC) for this case-parent trio association study. These triads were from hospitals in: Argentina (103), Bolivia (14), Brazil (16), Chile (87), Ecuador (50), Colombia (13) and Venezuela (19). Analyses of association were performed by FBAT (Family Based Association Test) and TRIMM (Triad Multi-Marker) in total sample and in groups according to type of cleft diagnosed: 76 associated cases, 43 isolated cleft lip, 50 isolated cleft palate, 133 isolated cleft lip with cleft palate and 176 cleft lip with or without cleft palate. We found a statistically significant association between IRF6 (rs2235371:G>A, P=0.0001), and genes located in 6q [PRSS35 (rs7753918:A>G, P=0.004) and SNAP91 (rs217325:C>G, P = 0.04)] and oral clefts. For cleft palate only we found association with IRF6 (rs2013162:A>C, P=0.003; rs861019:A>G, P=0.01 and rs2073487:C>T, P= 0.048) and CRISPLD2 (rs1546124:C>G, P=0.02). The TRIMM analysis confirmed the FBAT results and did not shown any association with the maternal genotype. The results of this study support the hypothesis that IRF6 contributes to the aetiology of oral clefts and suggest SNAP91, PRSS35 and CRISPLD2 as candidates for these defects in a Latin American population.

985W

Phenotype characterization of a sibship with *SDCCAG8*-related disease. *E. Héon[1, 2], C. Deveault[2], G. Billingsley[2].* 1) Ophthalmology, Vision Science; 2) Genetics and Genome Biology Program, The Hosp For Sick Children, Toronto, ON, Canada.

Mutations in *SDCCAG8* were recently identified to cause a retinal-renal ciliopathy which included patients with the clinical diagnosis of Senior-Loken syndrome (SLSN) as well as Bardet-Biedl syndrome (BBS). The full clinical phenotype has yet to be defined. We assessed a subgroup of patients with the clinical diagnosis of BBS, for which no mutation was identified, and identified a *SDCCAG8*-mutation positive sibship that we thoroughly phenotyped. A sibship of East Indian origin carried the putative clinical diagnosis of BBS and previously published *SDCCAG8*(NM_006642.3) compound heterozygous mutations in exon12 (c.1444delA, p.Thr482LysfsX12) and exon14 (c.1627-1630delATAG, p.Asp543AlafsX24) which segregated with the disease phenotype. Revision of comprehensive systemic and ocular assessments was performed. No digit anomaly was observed. The kidney disease was early onset and required kidney transplant at the ages of 9 and 11 years old. Other features such as increased insulin, transaminases, parathyroid hormone and cholesterol levels were observed in both sisters. Both sibs had abnormal echogenicity of the kidneys, liver and pancreas by age 7y. BMI at the age of 10 was 25.5 and 27.1, respectively. Both sibs also have high blood pressure, asthma and are growth hormone deficient. The patients have been followed for 10 years. Unlike what is most commonly seen in BBS, the central visual acuity was preserved in the teenage years with a recordable electroretinogram despite a constricted visual field. Optical coherence tomography showed a preservation of the retinal lamination as seen in other forms of BBS. However, the rate of vision loss was less than that usually seen in BBS. Brain MRI, hearing, smell and cardiac function assessment were normal. No neurological anomalies were documented. The only variability observed in this sibship was at the level of weight gain and cognitive ability. Distinctive features of this *SDCCAG8* genetic variant appear to be severe renal disease combined with lack of digit anomaly and slower rate of vision loss when compared to patients with *BBS* gene mutations. This is the first comprehensive phenotyping of this genetic variant.

986W

Mutation screening of the *LPP* gene in patients with esophageal atresia, tracheoesophageal fistula, and VACTERL association. *A. Hernandez-Garcia[1], E. Brosens[2,3], H. Zaveri[1], Z. Yu[1], C. Fernandes[4], A. Johnson[1,5,6], S. Lalani[1], D. Tibboel[3], A. de Klein[2], D.A. Scott[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, the Netherlands; 3) Department of Paediatric Surgery, Erasmus Medical Center, Rotterdam, the Netherlands; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 5) Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 6) Department of Pediatric Surgery, Baylor College of Medicine, Houston, TX.

Esophageal atresia (EA) and tracheoesophageal fistula (TEF) are life threatening birth defects that affect ~1 in 3,500 newborns. Approximately 50% of cases occur in association with additional anomalies while VACTERL (Vertebral, Anal, Cardiac, TracheoEsophageal fistula, Renal, Limb) association is found in ~10% of infants with EA/TEF. The genes responsible for most cases of EA/TEF and VACTERL have yet to be identified. Recently, Arrington et al. described a 451 kb interstitial deletion involving only the LIM domain containing preferred translocation partner in lipoma (*LPP*) gene in an individual diagnosed with VACTERL association. This diagnosis was based on cardiac defects—tetralogy of Fallot (TOF) with a right aortic arch and left superior vena cava draining to the coronary sinus—EA/TEF, and small kidneys. They also described an intronic deletion in *LPP* that segregated with TOF in a small nuclear family and was associated with reduced *LPP* expression in a qPCR assay. To determine if alterations in *LPP* are a common cause of EA/TEF or VACTERL association, we screened 170 patients with these diagnoses for *LPP* deletions by microarray and a smaller cohort of 42 patients for sequence changes. No deletions involving *LPP* were identified. However, we found a missense change (c.1162C>T) in an African American male diagnosed with VACTERL association. He presented with a persistent left superior vena cava draining to a mildly dilated coronary sinus, a mildly dilated ascending aorta, vertebral anomalies, unilateral renal agenesis, hypoplastic ribs, polydactyly, and a bladder diverticulum. This sequence change results in an R388C substitution that affects a highly conserved region upstream of the first LIM domain and was predicted to be probably damaging by Polyphen2. Although this change was not reported in the SNP database, subsequent testing revealed the same change in the patient's apparently unaffected mother and in 1 out of 78 African American control samples. This suggests that this change is unlikely to be the sole cause of our patient's phenotype. No other novel sequence changes were identified in our cohort. We conclude that alterations in the *LPP* gene are not a common cause of EA/TEF or VACTERL association. If changes in *LPP* contribute to the development of VACTERL-related phenotypes they likely do so in combination with other genetic and/or environmental factors.

Case-parent trio genome-wide association study identifies several candidate loci for nonsyndromic sagittal craniosynostosis. *C.M. Justice[1], Y. Kim[1], G. Yagnik[2], I.A. McMullen[3], H. Ling[3], P.A. Sanchez-Lara[4], V. Kimonis[5], J. Stoler[6], M. Cunningham[7], A.F. Wilson[2], S.A. Boyadjiev[1].* 1) Genometrics Section, Inherited Disease Research Branch, NHGRI, NIH, Baltimore, MD 21224; 2) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA 95817; 3) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD 21224; 4) Division of Genetics, Department of Pediatrics, University of South California, Los Angeles, CA 90027; 5) Division of Genetics, Department of Pediatrics, University of California Irvine, Irvine, CA 92697; 6) Division of Genetics, Children Hospital Boston, Harvard University, Boston, MA 02115; 7) University of Washington Department of Pediatrics, Division of Craniofacial Medicine and Seattle Children's Craniofacial Center, Seattle, WA 98101.

Craniosynostosis is a common malformation in which one or more of the cranial sutures in an infant skull (metopic suture, coronal sutures, sagittal suture and lambdoid sutures) fuse prematurely. Sagittal craniosynostosis is the most common type of craniosynostosis, accounting for 40 to 58% of all cases, with an estimated prevalence of 1.9-2.3 per 10,000 live births. The International Craniosynostosis Consortium (genetics.ucdmc.ucdavis.edu/icc.cfm) has been established with the aim of identifying the genetic causes of nonsyndromic craniosynostosis and more than 720 families with at least one affected individual have been recruited. In an attempt to identify genetic variants associated with nonsyndromic sagittal craniosynostosis, we performed a genome-wide association analysis of 201 case-parent trios and 13 nuclear families with two affected siblings. A total of 662 individuals in 214 families (70% Caucasian families, 30% mixed ethnicity families) were genotyped on the Illumina 1M Human Omni1-Quad array. Quality control measures reduced the number of SNPs available for analysis from 1,140,419 to 914,402 markers. Association between sagittal craniosynostosis and each SNP was measured using the transmission disequilibrium test (TDT) as implemented by PLINK v1.0.7. The strongest association was with rs1884302 ($p = 3.79 \times 10^{-14}$) in the flanking 3' UTR of BMP2 on chromosome 20. BMP2 belongs to the transforming growth factor-beta (TGFB) gene family and is involved in bone and cartilage formation. Genome-wide significant ($p \leq 5 \times 10^{-8}$) associations were also detected for SNPs intronic to BBS9 (rs1420154, $p=3.51 \times 10^{-13}$) on chromosome 7, which is thought to be involved in parathyroid hormone action in bones. Additionally, we have strong but not genome-wide significant signals on DLG1 (rs12152266, $p= 1.44 \times 10^{-7}$) on chromosome 3, RPS12 (rs9493468, $p=2.8 \times 10^{-7}$) on chromosome 6 and LOC643631 (rs1948330, $p=4.78 \times 10^{-7}$) on chromosome 5. Loss of heterozygosity mapping identified several chromosomal regions which are in process of further analysis.

Oral-facial clefts (OFC) have a multigenic etiology that involves many different signaling pathways. We recently reported that families segregating OFCs present an increased history of cancer when compared to control families, and that AXIN2 is associated with OFCs in a US population. Since Axin2 is an important negative regulator of the Wnt pathway, and the Wnt pathway is integral to craniofacial development, we expanded our initial study to explore the association of AXIN2 markers with OFCs in 724 cleft families from North America, Europe, Asia, and Latin America. Thirteen AXIN2 SNPs were genotyped using TaqMan chemistry and tested for association with OFC using the Family-Based Association Test (FBAT). An association between SNP rs7224837 and OFC was identified in the pooled populations ($P=0.001$), while SNP rs3923086 showed association with Chinese families from Beijing and Shanghai presenting cleft lip and palate individuals only ($P=0.004$). We found statistical evidence of interaction between these AXIN2 SNPs and IRF6 SNPs rs2235371 and rs642961 ($P<0.05$). We assessed mouse Axin2 expression during mouse palatogenesis, and also detected co-localization of Axin2 and IRF6 proteins in the palate, oral and molar tooth epithelia. Taken together, our results support an important role for AXIN2 during craniofacial and palatal development. Further, these results provide insights into potentially etiologic AXIN2-IRF6 interactions that may contribute to the etiology of OFCs in humans.

989W

Refining the 2p15-p16 Microdeletion Syndrome. *R. Lozano, W. Wilcox.* Lozano, Reymundo. Cedars Sinai, Los Angeles, CA.

In 2007 Rajcan et al., reported the clinical and molecular cytogenetic findings of two individuals with a similar microdeletion at 2p15p16. Additional 4 more patients have been reported. We report here the youngest case that represents the earliest development phenotype, with one of the smallest 2p15-16.1 microdeletions, that helps to narrow the critical region previously suggested by Felix et al. to 0.08KB (Ch:2:61.24-61.32) containing 4 genes. CLINICAL REPORT: The patient is 2 year-old Mexican-boy born to non-consanguineou parents. He is developmentally delayed sitting at 1.2 years, does not walk unsupported, and has only a few spoken words. At 25 months old, his height is 85cm (25th percentile), weight of 10.3kg (below 5th percentile), head circumference of 45cm (5 standard deviations below the mean for age). He is microcephalic and has bitemporal narrowing, low anterior hairline, a wide and prominent nasal bridge, thick-bushy eyebrows, long eyelashes, epicanthal folds and ptosis. CYTOGENETIC AND FISH ANALYSIS: Array CGH was performed and showed a 1.11 MB deletion includes four OMIN genes (BCL11A, REL, PUS10, and PEX13) and 7 other genes (PAPOLG, FLJ16341, KIAA1841, LOC339803, C2orf74, AHSA2 and USP34). DISCUSSION: This is the sixth report of a patient with 2p15-16.1 microdeletion syndrome. The child described here has a clinical history, facial features and associated malformations similar to the cases reported (table 1). The 1.1 Mb loss detected in our patient falls within the critical region previously suggested by Felix et al. (2010) and overlaps only a small region of the case with the smallest deletion reported by E. Chabchoub et al; The deletion of the present report is the first that excludes XPO1 and SNORA70B, refining the critical region and leading us to hypothesized that the genes contain in this small region are causative of the typical dysmorphic features and cognitive impartment. The genes contain in the critical region are KIAA1841, C2orf74, AHSA2 and USP34. Only deletions In the C2orf74 gene have been describe as a normal variants of unknown clinical significance. Little information is known about these genes and their functions. The KIAA1841 gene has significant higher expression in brain. We suggest KIAA1841gene as a good candidate gene not only for the neurodevelopment condition, but also the dysmorphic features, since it is expressed in human fetal brain, adult whole brain, the hippocampus and amygdala.

990W

Microduplication on chromosome 17q23.1q23.2 involving TBX4 is not a common cause of nonsyndromic clubfoot. *W. Lu[1], C.A. Bacino[2], S. Richards[3], J.T. Hecht[1].* 1) University of Texas Medical School, Houston, TX; 2) Baylor College of Medicine, Houston, TX; 3) Texas Scottish Rite, Dallas, TX.

Clubfoot is a common birth defect characterized by inward posturing and rigid downward displacement of one or both feet. It occurs as an isolated birth defect in 1/700-1000 newborns in the US each year or as an associated anomaly in more than 200 syndromes. The etiology of syndromic forms of clubfoot is varied and the causes of isolated clubfoot are not well understood. A microduplication of 2.2 Mb on chromosome 17q23.1q23.2 and including TBX4, a hind limb-specific gene and 16 other genes was recently identified in 3 of 66 families with reported nonsyndromic clubfoot. While other malformations were identified in some of the family members who also had this microduplication, other family members with the microduplication reportedly had no malformations suggesting that there was nonpenetrance. To determine whether this microduplication was a common cause of nonsyndromic clubfoot, 609 probands (from multiplex and simplex families) with nonsyndromic clubfoot where evaluated by copy number and oligonucleotide array CGH testing. Only one multiplex family with 12 affected individuals had a 350kb microduplication, which included the complete duplication of TBX4 and NACA2 and partial duplication of BRIP1. The microduplication was transmitted in an autosomal dominant pattern of inheritance and all those with the microduplication had either severe clubfoot or short wide feet and short toes. Hands and stature were normal. These results suggest that there is variable expressivity associated with this microduplication and that modifier genes may be affecting whether there is a clubfoot or milder foot phenotype. The 17q23.1q23.2 microduplication occurred in only 0.16% of our isolated nonsyndromic clubfoot probands indicating that this microduplication is not a frequent cause of this common orthopedic birth defect.

991W

Association Analysis of *MSX1*, *AXIN2*, and *PAX9* with Palatally Displaced Canines in Subjects Exhibiting No Lateral Incisor Agenesis . *L.A. Morford[1, 2], D.L. Kujak[3], G. Falcão-Alencar[2], D.W. Fardo[4], J.V. Macri[5], J.K. Hartsfield, Jr.[2, 3].* 1) Deptartment of Oral Health Practice, Univ of Kentucky College of Dentistry, Lexington, KY USA; 2) Center for Oral Health Research, Univ of Kentucky College of Dentistry, Hereditary Genomics Laboratory, Lexington, KY USA; 3) Division of Orthodontics, Univ of Kentucky College of Dentistry,Lexington, KY USA; 4) Department of Biostatistics, Univ of Kentucky, College of Public Health, Lexington, KY USA; 5) Department of Orthodontics and Oral Facial Genetics, Indiana University School of Dentistry, Indianapolis, IN USA.

Objective: Palatal displaced canines (PDCs) are maxillary canines that are developmentally displaced to the palate, frequently resulting in impaction. PDCs can occur concurrently with several other tooth anomalies including: small or peg-shaped lateral incisor(s) and lateral incisor agenesis. This simultaneous occurrence of PDCs with multiple incisor anomalies suggests that incisor development may influence canine eruption patterns. This study investigated the hypothesis that genetic variation in tooth development genes such as *MSX1*, *AXIN2,* and *PAX9* could influence the formation of PDCs when lateral incisors were present. **Methods:** DNA was isolated from the buccal swabs of 136 Caucasian subjects undergoing orthodontic treatment (29 subjects with unilateral PDCs, 10 with bilateral PDCs and 97 controls). TaqMan-based® SNP genotyping of *MSX1* (rs12532), *AXIN2* (rs7591, rs2240308, rs3923086), and *PAX9* (rs10141087, rs17176643) was completed on the Roche LightCycler480®. PDC phenotypes were determined by treatment records and radiographs. Hardy-Weinberg Equilibrium (HWE) and Chi-Square analysis for association were performed assuming a co-dominant mode of inheritance with significance at ($p<0.05$). **Results:** PDCs were identified more often in women than men (1.8-to-1). All genotypes tested maintained HWE within the control population. *MSX1* rs12532 was analyzed in 38 PDC subjects (18AA/17GA/3GG) and 96 controls (43AA/44GA/9GG) with no association identified ($p=0.95$). *AXIN2* rs7591 was analyzed in 38 PDC subjects (10TT/19TA/9AA) and 96 controls (37TT/47TA/12AA) with no significant association ($p=0.19$). Association analyses for the *AXIN2* SNPs, rs3929086 and rs2240308, were also not significant ($p=0.55$ and 0.72, respectively). *PAX9* rs17176643 was analyzed in 36 PDC subjects (18CC/17CA/1AA) and 89 controls (37CC/39CA/13AA) with no association ($p=0.16$). Similarly, no association was observed for *PAX9* rs10141087 ($p=0.98$). **Conclusions:** This study presents no evidence that *MSX1*, *AXIN2* and *PAX9* play a role in PDC formation in the presence of intact lateral incisors. A minimal number of DNA markers were tested, however, and portions of the genes tested cannot be excluded from involvement as they are not in linkage disequilibrium blocks represented by the markers tested. **This study was supported by the Indiana University Bixler Fund for Research in Genetics, the Southern Association of Orthodontics and the UK College of Dentistry E. Preston Hicks Endowed Chair (JKH).**.

992W

Comparison of neoplastic phenotypes in Cowden/Cowden-like syndrome characterized by germline *SDHx* variants, *PTEN* mutations versus *KLLN* epimutations. *Y. Ni[1,2], MH. Tan[1], K. Bennett[1], J. Mester[1], J. Chen[1], J. Moline[1], M. Orloff[1], C. Eng[1,2,3].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, OH; 2) Department of Molecular Medicine, Cleveland Clinic Lerner College of Medicine, Cleveland, OH; 3) Taussig Cancer Institute, Cleveland Clinic, Cleveland, OH.

Cowden syndrome (CS), a Mendelian autosomal-dominant disorder, predisposes to breast, thyroid, and other cancers. As a heterogenous disease, many patients have some features of CS but do not meet diagnostic criteria (CS-like). Therefore, identifying and characterizing susceptibility genes are important for diagnosis, risk assessment, predictive testing and medical management. In addition to germline *PTEN* mutation, variations in mitochondrial complex II succinate dehydrogenase genes (*SDHx*), and germline epimutation in *KLLN* have also been associated with CS/CS-like. In this study, we sought to compare the frequencies and clinical characters of *SDHx* variants to the alterations in *PTEN* and *KLLN* in CS/CS-like patients. We analyzed *SDHB/C/D* genes in 598 *PTEN* mutation negative adult CS/CS-like patients and identified 47 (7.9%) with *SDHx* germline mutations/variants: 15 in *SDHB* [A3G (n=1), R27G (1), H57R (1), N120S (1), and S163P (11)], 1 in *SDHC* [A66V], and 31 in *SDHD* [G12S (18), H50R (12), and H145N (1)]. Among these variant carriers, 27 (57.4%) presented with breast carcinoma, 24 (51.1%) with thyroid cancer, and 4 (6.4%) with renal cancer. Compared to *PTEN* mutation carriers, *SDHx*-related CS/CS-like individuals have increased prevalence of breast cancer (57.4% vs 32.4%, p=0.003) and thyroid cancer (51.1% vs 25.7%, p=0.002). Interestingly, *SDHx*-associated thyroid cancers are papillary (22/24, 91.7%) compared to follicular in *PTEN* mutation carriers (33%, p<0.001). The prevalence of renal cancer in *SDHx* variant carriers is similar to *PTEN* mutation carriers. *KLLN* epimutation were found in 45/123 (36.6%) *PTEN* mutation-negative patients (Bennett et al., JAMA2010). While breast cancer prevalence is much higher compared to *PTEN* mutation carriers (80% vs 32.4%, p<0.001), *KLLN* epimutation positive patients had similar frequencies of thyroid cancer but overrepresentation of renal cancer compared to *PTEN* mutation carriers (4/45 vs 6/155, p= 0.004). In conclusion, *PTEN*, *SDHx*, and *KLLN* germline alterations together account for >50% of CS/CS-like individuals but with different neoplasia risks. In contrast to *PTEN* mutations, *SDHx* variants confer higher breast cancer and papillary thyroid cancer risks, while *KLLN* germline methylation associates with higher breast and renal cancer risks. Therefore, genetic testing for these genes should be prioritized based on patients' specific clinical presentations. Gene-specific surveillance and management should be considered in the future.

993W

Analyzing the contribution of GTF2IRD1 to Williams-Beuren syndrome: mouse knockout phenotypes and molecular mechanisms. *S.J. Palmer[1], J. Widagdo[1], K.M. Taylor[1], S. Bontempo[2], M. Howard[3], A.C. Wong[4], G.D. Housley[4], A.J. Hannan[5], P.W. Gunning[5], E.C. Hardeman[1].* 1) School of Medical Sciences, Neuromuscular and Regenerative Medicine Unit, University of New South Wales, Sydney, Australia; 2) Muscle Development Unit, Children's Medical Research Institute, Sydney, Australia; 3) Howard Florey Institute, University of Melbourne, Melbourne, Australia; 4) School of Medical Sciences, Translational Neuroscience Facility, University of New South Wales, Sydney, Australia; 5) School of Medical Sciences, Oncology Research Unit, University of New South Wales, Sydney, Australia.

Williams-Beuren syndrome (WBS) results from a hemizygous microdeletion within chromosome 7q11.23 involving 28 genes. Its features typically involve characteristic physical abnormalities and a set of cognitive and behavioural symptoms that are collectively called the Williams syndrome cognitive profile (WSCP). The WSCP includes reduced IQ, a severe visuospatial construction deficit, decreased social anxiety, increased non-social anxiety and defects in motor coordination. The high accordance of these features in WBS, irrespective of social or ethnic background, indicates the existence of a consistent biological defect in brain function with an identifiable genetic origin. Genotype/phenotype correlations in patients with atypical deletions have mapped the characteristic craniofacial dysmorphology and the WSCP to a pair of genes that encode the evolutionarily-related transcriptional regulators GTF2IRD1 and GTF2I. We have generated *Gtf2ird1* knockout mouse lines that show some striking similarities to aspects of the human disease, including craniofacial abnormalities, loss of motor coordination, hearing defects and behavioural disturbances. To understand the cellular origin and the molecular basis of these defects, we have conducted detailed studies of *Gtf2ird1* gene expression and analysed the biochemical properties of the GTF2IRD1 protein with respect to its evolutionary conservation, DNA binding properties and its interactions with other nuclear proteins. We have demonstrated that GTF2IRD1 interacts directly with a protein that belongs to a histone deacetylase complex and undergoes post-translational modification through attachment of SUMO via interactions with PIASX and UBC9. These data have begun to reveal a complex interplay between nuclear proteins that explain the observed gene silencing effects of recombinant GTF2IRD1 in vivo. Evidence also suggests that the GTF2IRD1 protein is subject to exquisitely tight control by auto-regulation of gene transcription, SUMOylation and degradation via ubiquitin-mediated proteasomal degradation. Therefore, it is predicted that haploinsufficiency of GTF2IRD1 due to hemizygous loss of one GTF2IRD1 allele would result in unintended increases of transcription from GTF2IRD1 target genes. These data strongly support the genotype/phenotype mapping correlations from human patients and indicate that GTF2IRD1 is a major contributor to the features of WBS.

994W

HoxA9 regulatory SNP is associated with clubfoot and alters gene expression. *T. Powell[1], K.S. Weymouth[1], S. Richards[2], C.V. Patel[3], S.H. Blanton[4], J.T. Hecht[1].* 1) University of Texas Medical School, Houston, TX; 2) Texas Scottish Rite Hospital, Dallas, TX; 3) University of South Carolina School of Medicine, Columbia, SC; 4) University of Miami Miller School of Medicine, Miami, FL.

Clubfoot, a common orthopedic birth defect, is characterized by inward and rigid downward displacement of one or both feet. It occurs in 1/700-1000 newborns and affects 135,000 worldwide each year. Calf musculature is underdeveloped at birth and remains hypoplastic even after corrective treatment. Clubfoot is a complex disease involving both genetic and environmental factors. Despite many studies, the genetic causes of this birth defect are just now being defined. Previously, we found positive associations with multiple SNPs in the HoxA and HoxD gene families. The HoxA family of genes play important roles in limb and muscle development suggesting an etiologic role in clubfoot. One SNP, rs3801776, located in the basal promoter of HoxA9 was significantly overtransmitted in family-based discovery (p= 0.002) and validation (p=0.03) datasets. In silico analysis predicted that the alternate allele of rs3801776 was in a DNA binding site. Since myogenesis occurs in two stages, in undifferentiated and differentiated muscle cells, all expression studies are being performed in these cell types. EMSA analysis in undifferentiated and differentiated mouse muscle nuclear extracts showed that the ancestral allele and not the alternate allele, as suggested by in silico analysis, creates a binding site. Higher gene expression was observed with the ancestral allele in undifferentiated C1C12 mouse muscle cells. These results suggest that variation in HOXA9 may confer differential gene expression during limb and muscle development, which in concert with variants in other genes, may perturb limb and muscle development and contribute to clubfoot. Moreover, these findings suggest that gene dysregulation of limb and muscle-specific genes is a potential common mechanism for clubfoot.

995W

Investigation of molecular basis of X-linked mandibulofacial dysostosis with cleft palate. *N. Sobreira[1], A. Telegrafi[1], L. Cirulli[2], P. Pichurin[3], D. Avramopoulos[1], M. Gunay-Aygun[1], A. Hamosh[1], D. Valle[1].* 1) McKusick Nathans Institute of Genetic Medicine, Johns Hopkins Univ, Baltimore, MD; 2) Center for Human Genome Variation, Duke University School of Medicine, Durham, NC; 3) University of Texas Southwestern Medical Center, Dallas, TX.

Clefts of the lip and/or palate (CLP) are common congenital malformations with complex inheritance and affect approximately 1 in 700 live births. Approximately 50% of cleft palate only (CLO) are considered to be non-syndromic and most cases appear to be sporadic. The remaining cases include Mendelian syndromes, chromosomal abnormalities and teratogenic effects. Among the Mendelian syndromes with CPO a few are X-linked with known molecular basis. On the other hand, most of the mandibulofacial dysostosis (MFD) patients present with CLP, but there is no description of an X-linked example. Here we describe a 4 generation X-linked pedigree with 7 males affected with MFD with micrognathia, CPO, malar hypoplasia, and, in some cases, microtia and ear abnormalities. The proband and an affected cousin had normal skeletal survey, echocardiogram, head ultrasonography, karyotype, and SNP genotyping. Despite the X-linked pattern, we sequenced *TCOF1* and found it normal. Using Agilent Sure Select X exome capture and next-generation sequencing, we performed the X chromosome exome sequencing in the proband. Library preparation was performed using SPRIWorks system. We performed a 75 bp paired-end sequencing of the captured fragments in one flowcell lane of an Illumina Genome Analyzer IIx. We aligned sequence reads to the 1000 genomes NCBI36/hg18 human reference using BWA software (version 0.4.9). We found no variants of obvious functional significance (missense, nonsense, splice-site or indels) in the genes associated to X-linked syndromes associated to CLP (*PHF8, BCOR, EFNB1, FLNA, PQBP1, TBX22, and RBM10*). We also identified no functional variants in 3 X-linked genes encoding proteins known to interact to *TCOF1 (OFD1, TBL1X*, and *DCX*). We identified a total of 10 candidate missense variants in 9 other X-linked genes, we determined the segregation of these variants in the family and their frequency in 600 controls. Only one variant segregated with the phenotype and was not present in homozygosity or hemizygosity among the controls. We performed a linkage study (MINX) for this variant in the family (2 affected and 10 unaffected individuals) and found the maximum possible LOD score of 1.93 confirming the complete segregation of this variant with the phenotype. Sequencing of this gene in other families with a similar phenotype and utilization of animal model will confirm if mutations in this gene are responsible for this X-linked MFD with cleft palate.

996W

Increased need for medical intervention in children with 22q11.2 deletion (velocardiofacial) syndrome. *E. King[1], K. Stanford[5], B.J. Leech[1,3], H.M. Saal[1,3], J. James[2], S.R. Callahan[4], S. Geraghty[4], I. Sageser[1], R.J. Hopkin[1,3].* 1) Human Genetics, Cincinnati Children's Hospital, Cincinnati, OH., USA; 2) Cardiology, Cincinnati Children's Hospital, Cincinnati OH, USA; 3) 22q11.2 VCFS Center, Cincinnati Children's Hospital, Cincinnati OH., USA; 4) General and Community Pediatrics, Cincinnati Children's Hospital, Cincinnati, OH., USA; 5) Biostats, Cincinnati Children's Hospital, Cincinnati, OH., USA.

Deletion 22q11.2 or velocardiofacial syndrome causes congenital heart defects, palate abnormalities, learning disabilities and many other medical and developmental problems. Medical interventions in infants and young children with VCFS have been documented, but there is little information on these issues in school age children. **Objective**: to compare the number of surgical procedures and hospitalizations required by children with VCFS to children with isolated congenital heart defects (CHD), isolated cleft palate (CP), and children from the local community (LC) with no evidence of genetic syndromes or birth defects. **Methods**: We conducted a retrospective medical record review of 77 children with VCFS, 35 children with CHD, 30 children with CP, and 32 LC followed in our center from ages 5-10 years. Numbers and types of surgical procedures and hospitalizations were compared among the groups using analysis of variance methods. **Results**: 52 of 77 (68%) with VCFS had a congenital heart defect. 53 of 77 (69%) had a structural or functional palate defect. Children with VCFS required a significantly greater number of surgical procedures than children with CHD, CP, and the LC (adjusted $p<0.0001$ each comparison). Overall, 81% of the VCFS cohort required at least one surgical procedure. There was no difference in cardiac procedures between those with VCFS and CHD. More children with VCFS had palate surgery than children with isolated CP ($p=0.009$). Other (non-palate) ENT surgeries were performed on 47% of the VCFS population compared to 27% with CP, 6% with CHD and 0 from LC ($p <.0001$). The number of hospitalizations in the VCFS cohort was significantly greater than for the CHD, CP, and LC cohorts (adjusted $p<0.0001$ each comparison). Children with VCFS spent an average of 3.10 days hospitalized which was significantly longer than children in the other cohorts. The results of this study document that children with VCFS have an increased need for medical interventions between the ages of 5-10 years compared to children with non-syndromic CP and CHD. The most frequent indications for intervention were palate dysfunction or other ENT problems rather than cardiac defects. Increased medical needs continue to be a major burden for children with VCFS at least through middle childhood.

997W

A complex cardiac abnormality associated with deletion of the NOTCH1 gene. *D. Myles-Reid[1], L. Nield[2], P. Shannon[3], R. Teitelbaum[1], M. Thompson[3], D. Chitayat[1, 4].* 1) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynecology, Mount Sinai Hospital, Toronto, Ontario, Canada; 2) Division of Cardiology, Department of Pediatrics, The Hospital for Sick Children. Toronto, Ontario, Canada; 3) Department of Pathology and Laboratory Medicine, Mount Sinai Hospital. Toronto, Ontario, Canada; 4) Division of Clinical and Metabolic Genetics, Department of Pediatrics,The Hospital for Sick Children. Toronto, Ontario, Canada.

Mutations in the NOTCH1 gene, coding for a receptor in a developmentally important signaling pathway, are known to be associated with left ventricular outflow tract (LVOT) defects including aortic valve stenosis, coarctation of the aorta and hypoplastic left heart syndrome (HLHS). We report a case with a de novo 614.3 Kb interstitial deletion of 9q34.3 including the NOTCH1 gene among others associated with complex cardiac abnormality including LVOT defects. A stillborn male fetus was born at 26 weeks gestation to 30 years old non-consanguineous and healthy parents following fetal echocardiography findings of complex cardiac abnormality including HLHS. The autopsy showed preductal aortic coarctation, anomalous origin of the right pulmonary artery from the right brachiocephalic artery, perimembranous VSD, dysplastic tricuspid valve leaflets, bicuspid and dysplastic pulmonary and aortic valves. The brain showed periventricuar leukomalacia and the placenta showed areas of chronic villous hydrops with cluster of avascular villi. aCGH showed 614.3Kb interstitial de novo deletion of 9q34.3 with haploinsufficiency of the OMIM Morbid Map genes SEC16A, NOTCH1, EGFL7, MIR126, AGPAT2, LCN10, LCN6, LCN8, C9orf86, PHPT1, EDF1, TRAF2, FBXW5, C8G, LCN12, PTGDS, CLIC3, ABCA2, FUT7, NPDC1, ENTPD2, C9orf140 and MAN1B1genes. Mutations in the NOTCH1 gene have been detected in a few families and in sporadic cases with LVOT defects including bicuspid aortic valve, mitral valve atresia and hypoplastic left ventricle as well as double outlet right ventricle. To our best knowledge, this is the first case with a de novo deletion of the NOTCH1 gene associated with a complex cardiac abnormality as well as brain and placental changes. NOTCH1 mutations were observed in leukemia and have been shown to be associated with gain-of-function mutations. In contrast, where ligand dependent activation is reduced, as in our case, a congenital abnormality develops. These findings are typical of developmentally important genes such as NOTCH1.

998W

R179H mutation in ACTA2 expanding the phenotype to include Prune-Belly sequence and skin manifestations. *J. Richer[1], D.M. Milewicz[2], R. Gow[3], J. de Nanassy[4], G. Maharajh[5], E. Miller[6], L. Oppenheimer[7], M. O'Connor[8].* 1) Med Gen, CHEO, Ottawa, Ontario, Canada; 2) Division of Medical Genetics, Department of Internal Medicine, the University of Texas Health Science Center at Houston, Houston, Tex; 3) Department of Cardiology, CHEO, Ottawa, Ontario, Canada; 4) Department of Pathology, CHEO; 5) Department of Cardiovascular Surgery, CHEO; 6) Department of Diagnostic Imaging, CHEO; 7) Division of Maternal Fetal Medicine, University of Ottawa and the Ottawa Hospital Ottawa,; 8) Ophthalmology Department, CHEO.

Prune-Belly is a rare congenital malformation sequence characterized by loose abdominal musculature, urinary abnormalities and undescended testes. The prognosis is highly variable. The incidence is reported to range between 1 in 35,000 to 1 in 50,000 births; only 3-5% of affected patients are female. The proportion of patients with urethral obstruction remains unclear, and while a small proportion of patients have been diagnosed with rare syndromes such as megacystitis-microcolon, the underlying etiology in a number of patients without an identified mechanical obstruction remains unclear. Mutations in ACTA2 (smooth muscle cell - specific isoform of (-actin) lead to a predisposition for thoracic aortic aneurysms and other vascular diseases. The (-actin isoform is primarily expressed in smooth muscle, but is also expressed in myofibroblasts and patients with this mutation have been described to have bladder dysfunction. We report on a patient heterozygous for the ACTA2 R179H mutation who presented with megacystis at 13 weeks gestational age and, at birth, with Prune-Belly sequence. He also had deep skin dimples and creases on his palms and soles, a finding not previously described but may be related to ACTA2. Moreover, he had pulmonary hypertension, a neonatal aneurysm and areas of hyperintensities in the frontal lobes on MRI. To our knowledge, this is the first report of the R179H mutation in ACTA2 in a child with Prune-Belly sequence and we believe that our patient's Prune Belly sequence is caused by very severe smooth muscle dysfunction with multisystemic involvement. We recommend that molecular testing for this mutation be considered in fetuses presenting with fetal megacystis and a normal karyotype.

999W

Congenital diaphragmatic hernia syndromes and involvement of 1q41. *J. Shieh, A. Slavotinek.* Division of Medical Genetics, Department of Pediatrics, University of California San Francisco, CA.

Congenital diaphragmatic hernia (CDH) is often associated with severe co-morbidities and genetic abnormalities that affect diagnosis and management. Alterations in the 1q41 region have been found in individuals with CDH, and deletions and genes in that region have received recent attention. We found an association of congenital diaphragmatic hernia with an expanded set of anomalies and with new molecular findings that may aid in understanding disease.

We identified a case of Morgagni hernia associated with pericardial absence and bilateral cataracts with severe ophthalmologic complications. The patient also had gallbladder agenesis, an association that appears to be novel. To examine a potential genetic basis for disease, we isolated genomic DNA from peripheral blood and performed 102K CGH microarray analysis (ISCA v2 clinical design) and compared this to pooled reference. Regions of copy number variation were compared with annotated copy number variation to determine polymorphic versus potentially unique variation.

CGH analysis revealed a rare duplication of 1q41 that has not been previously reported with this phenotype to our knowledge. We compare these findings to other individuals with CDH to help refine a critical region. These findings and clinical presentation add further support for the involvement 1q41 and add a unique genomic change. We have identified an area that should be targeted in future studies that focus on disease basis and implications for management.

FIVE CASES REPORT WITH OPITZ G/B.B.B SYNDROME. TWO PATIENTS WITH CHROMOSOMAL ABNORMALITIES; X CHROMOSOME DUPLICATION (47, XXY) AND TRANSLOCATION 46XX t(3q;4q), IN THE HOSPITAL PARA EL NIÑO POBLANO. *J. Aparicio[1,6], M.D.L. Hurtado[2], I. Marroquin[2], G.A. Rojas[2], p. Sanchez[3], S. Rodriguez[4], R. Zamudio[5], no.* 1) Dept Gen; 2) Cytogenetics; 3) Haematology; 4) Neurosurgery; 5) Cardiology, Hosp para el Nino Poblano, Puebla, Mexico; 6) Estomatology, Benemerita Universidad Autonoma de Puebla, Mexico.

Opitz G/BBB syndrome is a genetic condition that affects several structures along the midline of the body. The most common features of this condition are wide-spaced eyes (hypertelorism) with structural defects of the larynx, trachea, and/or esophagus causing breathing problems and difficulty swallowing (dysphagia). Some times in males shows, the urethra opening on the underside of the penis (hypospadias). Mild intellectual disability occurs in 30 percent approximately of patients with Opitz G/BBB syndrome (GBBBS), most likely caused by structural defects in the brain. About half of affected individuals also have cleft lip with or without a cleft palate as in this study. Some have cleft palate alone. Heart defects, an obstruction of the anal opening (imperforate anus), and brain defects such as an absence of the corpus callosum. Facial abnormalities that may be seen in this disorder include a flat nasal bridge, thin upper lip, and low set ears. There are two forms of Opitz G/BBB syndrome, which are distinguished by their genetic causes and patterns of inheritance. The X-linked form of Opitz G/BBB syndrome is caused by a mutation in a specific gene, MID1, on the X chromosome. Autosomal dominant Opitz G/BBB syndrome is caused by a mutation in an as-yet unidentified gene on chromosome 22. Two chromosomal aberrations in this study were observed in two patients, with chromosome duplication 47,XXY and translocation 46,XX t(3;4). However one patient with normal karyotype 46,XY had an oral encephalocele.

1001W

MECP2 duplication (453 Kb) clinical manifestations in a four generation family. *J. Bartley[1], P. Park[2].* 1) Loma Linda University Children's Hospital, Loma Linda CA; 2) Inland Regional Center, San Bernardino CA.

MECP2 duplication was first identified by SNP micorarray in a two year old child with developmental delay. His brother, mother, grandmother and 75 year old great-grandmother also had the same duplication. All but the great-grandmother were consumers of the Inland Regional Center because of a developmental delay or mental retardation of less than 70. All five of the great-grandmothers boys were mentally retarded and had spastic cerebral palsy. Two died at 18 months of age, one died at 10 years of age, and two died at 15 years of age. One of the great-grandmother's daughters died several years ago prior to MECP2 SNP microararry testing but she must have had the duplication since her daughter has the MECP2 duplication. Another daughter of the great-grandmother also has the duplication since heher son has the duplication and is severely mentaly retarded. Each of the females with the MECP2 duplication were mildly mentally retarded, but enough so that the qualified for becoming a consumer of regional center.

Genetic Medicine: The NIH Undiagnosed Diseases Program Model. *C.F. Boerkoel III, D. Adams, T. Markello, C. Toro, C.J. Tifft, W.A. Gahl.* Undiagnosed Diseases Program and NHGRI, National Institutes of Health, Bethesda, MD.

In classical evolutionary theory, human disease arises by maladaptation of humans to their ecological niche. By definition common diseases arise in response to abrupt changes in the ecological niche exposing genetic variants underlying susceptibility and resistance to the ecological change. Modifying the environment therefore likely best treats common diseases. In contrast, rare diseases, which affect ~8% of the population, frequently arise from strong genetic and epigenetic mutations causing maladaptation within a stable niche. Therapy for rare diseases therefore targets modification of the dysfunctional physiological pathway. Within this context, a precise diagnosis is the first step to understanding illness and defining appropriate therapies. Focusing on ill individuals without diagnoses, the NIH Undiagnosed Diseases Program (UDP) models a synthetic approach to diagnosis involving participatory care, transdisciplinary clinical evaluations, and integration of basic science tools into the clinical diagnostic paradigm. As a consequence of this “research is care” approach, the UDP has been able to provide diagnoses to 15-20% of the patients seen. As a prelude for export of this model to the wider community, we have defined factors most influencing diagnostic ability, mechanisms allowing efficient integration of basic science tools into clinical care, and possible conceptual constructs for effective therapy in the future. In summary, we find that the infrastructure needed for personalized medicine is achievable despite several remaining conceptual hurdles.

***Orbicularis Oris* Muscle thickness and area in Cleft Lip with or without Cleft Palate Families versus Controls.** *C.A. Brandon, T. Parsons, J. Joseph, M.E. Cooper, R. DeSensi, S.M. Weinberg, K. Neiswanger, K. Schmidt, J.M. Resick, K. Bardi, M.L. Marazita.* Dept Oral Biology, Center for Craniofacial & Dental Gen, Univ Pittsburgh, Pittsburgh, PA.

Cleft lip with or without cleft palate (CL/P), the most common craniofacial birth defect, is characterized by a wide range of phenotypic variability, and often requires ongoing medical, dental, and speech treatment. Our group has shown that in addition to overt CL/P phenotypes, there are also non-visible discontinuities in the upper lip portion of the *orbicularis oris* muscle (OOM) that are found at a higher rate in unaffected relatives of individuals with CL/P than in controls with no known family history of CL/P. In this study we investigated whether thinning of the OOM should also be considered a subclinical phenotype. Subjects for this study were drawn from a large international consortium (the University of Pittsburgh Orofacial Cleft Study) and comprised 16 “cases” - unaffected parents of individuals with CL/P from multiplex families, and 23 controls with no known family history of CL/P. For each study subject, the OOM was visualized using high-resolution ultrasound, then an area including 1 cm on each side of the mid-line (i.e. the philtrum) was outlined by a blinded assessor using a polygon selection tool in ImageJ. In addition, the thickness of each OOM was measured at every mm across the 2cm span using ImageJ, and the resulting 22 thickness measures were averaged. The mean total area for cases was $0.16cm^2 \pm 0.04$ (range 0.07-0.22), and for controls $0.16cm^2 \pm 0.06$ (range 0.06-0.33). The mean average thickness for cases was 0.09cm±0.02 (range 0.04-0.12) and for controls 0.09cm±0.03 (range 0.04-0.17). No significant differences were found between cases and controls for either area or average thickness for the whole OOM. We also compared the case/control OOM areas and thicknesses separately by left and right sides, and by whether or not the case parents had an additional relative with CL/P. No significant differences were found for any of the comparisons (all p-values>0.50). Therefore although we have previously established that discontinuities in the OOM are part of the phenotypic expression of CL/P risk factors, there is no evidence to add thinning of the OOM as an additional sub-clinical phenotype. Support: DE016148.

***CYP1B1* mutations in Spanish families with primary congenital glaucoma: identification of six novel mutations and association with early diagnosis.** *J. Escribano[1,2], M.P. Lopez-Garrido[1,2], L. Morales[2,3], J.M. Martinez-de-la-Casa[2,3], M.T Garcia-Anton[2,3], J. Garcia-Feijoo[2,3].* 1) Laboratorio de Genética Molecular Humana, Facultad de Medicina/Instituto de Investigación en Discapacidades Neurológicas, Universidad de Castilla-La Mancha, Albacete, SPAIN; 2) Cooperative Research Network on Age-Related Ocular Pathology, Visual and Life Quality, Instituto de Salud Carlos III, Madrid, SPAIN; 3) Servicio de Oftalmología, Hospital Clínico San Carlos, Madrid, SPAIN.

Primary congenital glaucoma (PCG; MIM# 231300) is usually transmitted as an autosomal-recessive trait with incomplete penetrance and is produced by developmental defects of the trabecular meshwork and the anterior chamber angle of the eye, which leads to aqueous outflow obstruction, elevated intraocular pressure and optic nerve damage. PCG is the most common childhood glaucoma and is a significant cause of visual loss in children. Three loci linked to PCG have been identified, named GLC3A (2p21), GLC3B (1p36) and GLC3C (14q24.3). Mutations in gene *CYP1B1* (MIM# 601771) are the main known genetic cause of this type of glaucoma in different worldwide populations. In a previous study we have shown that approximately 1/3 of Spanish PCG patients carry loss-of-function *CYP1B1* mutations. Here we have extended our initial work to determine the contribution and spectrum of CYP1B1 gene mutations to primary congenital glaucoma (PCG) in Spanish patients and to analyze the genotype-phenotype correlation. We analyzed by PCR DNA sequencing the presence of promoter (-1 to -867) and exon *CYP1B1* mutations in a total of 147 unrelated Spanish families affected by PCG, of which 38 probands were previously reported. The patients were recruited in the Ophthalmology Department of the “Hospital Clínico San Carlos”, Madrid, Spain. A total of 29 different mutations were identified in 52 (35.3%) index cases, most of which were compound heterozygotes (28 probands) and 13 were homozygotes. Interestingly, 8 probands were heterozygotes, suggesting that other genetic or environmental factors determine the disease in these patients. The identified mutations included 16 missense and 4 non-sense nucleotide changes, 9 micro insertions or deletions. To the best of our knowledge, six of the identified mutations were novel. Mutations T404fsX30, E387K, R355fsX69 and A179fsX18 were the most prevalent among index cases, and collectively were present in nearly 90% of patients. Patients carrying 2 mutant alleles showed severe bilateral phenotypes featured by very early PCG onset, usually at birth. Our data corroborate that *CYP1B1* mutations are responsible for approximately one third of PCG cases in Spanish patients. *CYP1B1* associated congenital glaucoma usually presents a severe bilateral phenotype, featured by its frequent diagnosis at birth.

1005W

De novo 5q14.3 deletion in a child with developmental delay, microcephaly, venous malformation and seizures. *A. Guerin[1], R. Babul-Hirji[1], S. Al-Zaidy[2], E. Donner[2], M. Shago[3], D. Chitayat[1,4].* 1) Division of Clinical Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Neurology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynaecology, Mount Sinai Hospital; Toronto, ON, Canada.

Microarray technology has been used increasingly in the investigation of cases with unexplained developmental delay, autism spectrum disorders and multiple congenital anomalies and provides a diagnosis in 15-20% of the patients in this group, compared to 3%, using routine chromosome analysis. We present a patient with multiple abnormalities who has been investigated thoroughly since birth and was recently found to have a de novo deletion of 5q14.3. The patient is a 14-year-old girl with developmental delay, microcephaly, venous malformation on the dorsum of the nose, and seizures. She was born to a non-consanguineous couple from Pakistan. Pregnancy history was unremarkable. There were no significant issues in early life with early motor milestones being normal. Delay in milestones became apparent around the age of one, with significant delays in fine motor and speech. Currently, she is unable to read or write. Ophthalmology exam and hearing tests are normal. At the age of 12 seizures were noted and her EEG was suggestive of idiopathic generalized epilepsy and is currently on oral anticonvulsant therapy. She is mildly dysmorphic on examination. Microarray analysis showed a 2.559Mb deletion encompassing the RASA1, CCNH, TMEM161B, and COX7C genes. Many of the genes contained within this regions have an unknown function. RASA1 has previously been described in Parkes-Weber Syndrome and Vein of Galen aneurysm; however, it has not been described in association with developmental delay and seizures. This case highlights the difficulties in providing anticipatory guidance and counseling regarding microarray findings, especially when the patient is developmentally challenged.

1006W

A longitudinal analysis of clinical features in patients labeled cerebral palsy and global developmental delay, define Chronic Complex Disorder syndrome: an undefined clinical entity or genetic disorder? *J. Kapalanga[1,2,3,4], Y. Said[2,6], D. Wong[1,2], A. Gandy[1,2], M. Moyo[4,5], N. Nwebube[3], A. Singh[2].* 1) Dalhousie University, Department of Pediatrics, Halifax, NS, Canada; 2) Summerside Medical Centre, Summerside, PE, Canada; 3) Dept Pediatrics, Genetics, Grey Bruce Health Services, Owen Sound, ON, Canada; 4) Cambridge Memorial Hospital, Cambridge, ON, Canada; 5) Department of Pediatrics, McMaster University, Hamilton, ON, Canada,; 6) Allergy and Pediatric Pulmonology, King Fahad Specialist Hospital, Dammam,Saudi Arabia.

A group of patients commonly given the diagnosis of cerebral palsy and global developmental delay present with a constellation of clinical features which are not due to an identifiable disorder or syndrome. This group of patients also does not share the cardinal features of the developmental encephalopathies. This constellation of clinical features in a group of patients has not been reported previously. We report on a consistent constellation of clinical features in a group of patients identified through a multicenter interdisciplinary collaboration. Patients with multiple medical problems who initially were given the diagnosis of cerebral palsy and global developmental delay were identified through an analysis of clinical records from birth to age10. A total of 38 patients were initially identified. The entire spectrum of clinical features found in each patient over this period was analyzed and clinical features that have been persistent or recurrent beyond the first 3 years of life were recorded. A group of 15 patients aged 5 to 10 years were found to have a consistent constellation of clinical features that included; onset of symptoms and signs during infancy, no identifiable perinatal or prenatal insult, delivery after 35 weeks of gestation, developmental delay, mental retardation, feeding difficulties, gastroesophageal reflux disease, seizures, neurological deficit, no specific brain imaging findings, behavioral difficulties, absence of dysmorphic features, and normal routine clinical laboratory tests, chromosome studies and biochemical studies. Infrequent clinical features include recurrent respiratory difficulties, growth retardation, chronic constipation, sleep difficulties and musculoskeletal problems. We propose that this constellation of clinical features is unique and represent a distinct disorder caused by a mutation in a specific gene or genes at different loci. Patients with these clinical features are suitable for whole genome analysis. We further propose that patients with this constellation of clinical features should be given the diagnosis of Chronic Complex Disorder (CCD) syndrome. We suspect that certain infants who are often given multiple diagnoses that include cerebral palsy and or developmental delay, have CCD syndrome and suggest a systematic analysis of their clinical features for rendering the diagnosis of CCD syndrome.

1007W

Consanguinity as a means to identify pathogenic recessive mutations. *P. Makrythanasis[1], M. Nelis[1], M. Guipponi[2], F. Béna[2], S. Gimelli[2], S. Temtamy[3], A. Megarbane[4], M. Aglan[3], M. Zaki[5], S. Fokstuen[2], L. Gwanmesia[2], A. Masri[6], S. Psoni[7], S. Kitsiou[7], H. Frissyra[7], E. Kanavakis[7], N. Al-Allawi[8], N. Akarsu[9], S. AlHait[10], S. Al-Arrayed[11], I. Al Rashdi[12], H. Hamamy[1], S.E. Antonarakis[1,2].* 1) Dept Genetic Medicine & Dev, University of Geneva, Geneva, Switzerland; 2) Service of Genetic Medicine, University Hospitals of Geneva, Geneva, Switzerland; 3) National Society of Human Genetics , Cairo, Egypt; 4) Université Saint Joseph Campus des Sciences Médicales Unité de génétique médicale , Beirut, Lebanon; 5) Human Genetics and Genome Research Division, National Research Centre, Cairo, Egypt; 6) Pediatric Department. Jordan University Hospital, Amman, Jordan; 7) Laboratory of Medical Genetics, University of Athens Medical School, Athens, Greece; 8) Hematology, Dohuk Faculty of Medicine, Dohuk, Iraq; 9) Genetics, Hacettepe University Medical Faculty, Turkey; 10) Medical Genetics, Al-Amal Hospital, Amman, Jordan; 11) Medical Genetics, Salmaniya Hospital, Bahrain; 12) Clinical Genetics Service, The Royal Hospital, Sultanate of Oman.

Study aim: To define a strategy for the identification of pathogenic variants in patients of consanguineous families. Patient Collection: We have initiated a project to collect samples from families with seemingly recessive phenotypes in consanguinity families. 22 families of different ethnic background (mainly from countries where consanguineous marriages are common) are already participating in the study. From each family, DNA from the patient(s), all their unaffected siblings, and the parents is extracted from blood samples. Any phenotype and family history compatible with autosomal recessive disorder is candidate for participation in the study, which has been approved by the local ethics committee and all participants or their legal representatives have signed an appropriate consent form. Strategy for the detection of the pathological mutation(s): Samples from one or more of the affected individuals per family are examined by aCGH 244K chips for the identification of homozygous deletions and/or pathogenic heterozygote deletions/insertions. All samples per family are genotyped with a dense SNP array (720K) in order to identify the Runs of Homozygosity (ROH), follow the chromosomal haplotypes and define chromosomal regions likely to contain the responsible genes. Exome sequencing (96% of CCDS) is performed in one of the affected individuals. Variants are called genome wide but particularly in the ROH regions and filtered according to polymorphic SNVs deposited in public databases; variants' pathogenicity is also scored using several publicly available software. A step-wise approach has been selected in order to diminish the total number of probable variants. ROH found only in the patients and no other family member are screened first, followed by different comparisons of ROH between the affected individuals and the other family members. Results: The causative variation has been identified in one family (VLDLDR gene, causing disequilibrium syndrome). More likely pathogenic variants will be presented. Consanguineous families provide an opportunity to identify genes responsible for recessive phenotypes and rapidly fill in the space of genotype-phenotype links.

Transient neonatal diabetes: case report of a long term follow-up. *M.C. Moreira[1], C.R.D.C Quaio[1], I. Gomy[1], A. Ino[2], M.E. Ceccon[2], T. Della Manna[3], A.V. Morgante[4], D.R. Bertola[1], C.A. Kim[1].* 1) Genetics Unit - Pediatrics, Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, SP, Brazil; 2) UCINE - Pediatrics, Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, SP, Brazil; 3) Endocrinology Unit - Pediatrics, Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, SP, Brazil; 4) Biology Department, Universidade de São Paulo.

Transient neonatal diabetes (TND) is a rare condition affecting neonates within the first weeks of life, with an estimated incidence of 1 in 400,000 neonates. Evidence has suggested that overexpression of imprinted and paternally inherited genes within the TND critical region at 6q24 may develop TND, as well as other imprinting defects, duplication of this region and mutations in genes as *KCNJ11* and *ABCC8*. We report on long term follow-up of a case presenting TND with documented paternal uniparental disomy (pUPD) of chromosome 6. The Caucasian male patient was born at gestational age of 36 weeks, weighting 2060g and with unremarkable family history for diabetes mellitus (DM). At initial evaluation, he did not present any sign of perinatal asphyxia, demonstrated good suck, normal tonus and had no dysmorphic facial features except for macroglossia. After six hours from birth, he presented an isolated episode of hypoglycemia, thus glucose infusion was started. Following this, he developed hyperglycemia refractory to the suspension of glucose infusion and plasma glucose levels remained high (range: 302-558 mg/dl) for the next 15 days. Normal glycemic control was only achieved by insulin therapy. The treatment was based on a mixed regimen with NPH insulin (0.2-0.7 U/Kg) plus Lispro (0.08 U/Kg), which was needed for the subsequent three months. Thereafter, glycemic control normalized and insulin was discontinued. Nowadays, the patient, a healthy eleven-year-old boy with normal anthropometric measurements and development, has no signs of hyperglycemia or macroglossia. Molecular analysis demonstrated homozygosity in all of the paternally inherited markers of chromosome 6, confirming pUPD. Progress has been made in establishing the etiology of TND, accounting for 50% of neonatal DM. The 6q24 region, that harbors genes enrolled in regulating the secretion of insulin by) -cell, plays a key role in approximately 70% of cases with TND. Suspicion of TND must be raised when growth restriction and hyperglycemia are present. Rehydration and insulin therapy are usually required at the time of diagnosis. Although remission may occur spontaneously after some months of life, as described here, there is a tendency for the child to develop diabetes afterward. Therefore, in spite of our patient has not presented any signs of recrudescence of diabetes after eleven years of follow-up, close surveillance will be maintained.

1009W

Fetal Akinesia in Metatropic Dysplasia: Combination between Chondrodysplasia and Neuropathy? *S. Unger[1], E. Lausch[2], F. Stanzial[3], G. Gillesen-Kaesbach[4], C. Di Stefano[5], E. Bertini[6], C. Dionisi-Vici[7], B. Nilius[8], B. Zabel[2], A. Superti-Furga[9].* 1) Service de Génétique Médicale, CHUV, Lausanne, Switzerland; 2) Centre for Pediatrics and Adolescent Medicine, Freiburg University Hospital, Freiburg, Germany; 3) Servizio Multizonale di Consulenza Genetica, Bolsano, Italy; 4) Institut für Humangenetik, Lübeck, Germany; 5) Ospedale Umberto I Nocera Inferiore, Salerno, Italy; 6) Molecular Medicine, Institute from Hospital Care to Science (IRCCS), Rome, Italy; 7) Division of Metabolism, Bambino Gesù Children's Hospital, Rome, Italy; 8) Department of Molecular Cell Biology, Leuven, Belgium; 9) Department of Pediatrics, Lausanne, Switzerland.

Heterozygous mutations in the TRPV4 gene have been associated with a family of skeletal dysplasias (metatropic dysplasia, Pseudomorquio type 2, SMD Kozlowski, and brachyolmia) as well as with dominantly inherited neuropathies (hereditary motor and sensory neuropathy 2C,scapuloperoneal spinal muscular atrophy (SMA), and congenital distal SMA). While there is phenotypic overlap between the various members of each group, the two groups were considered to be separate with the former being strictly a structural skeletal condition and the latter group being confined to the nervous system. We report here on fetal akinesia as the presenting feature of severe metatropic dysplasia,suggesting that certain TRPV4 mutations can cause both a skeletal and a neuropathic phenotype. Case 1 was diagnosed at week 20 with short limbs, absence of limb movements, elbow pterygia, and finger contractures. Cases 2 and 3 (twins) were observed to have short limbs with arthrogryposis and akinesia at week 20. Both pregnancies were interrupted and fetal radiographs suggested metatropic dysplasia. Case 4 presented with joint contractures and absent limb movements at birth; skeletal survey showed typical features of metatropic dysplasia. The baby died of respiratory complications at age 4 months. Sequencing of the TRPV4 gene confirmed the presence of de novo heterozygous mutations predicting G78W (case 1), T740I (cases 2 and 3), and K276E (case 4). Although some degree of restriction of movements is not uncommon in fetuses with skeletal dysplasia, akinesia as leading sign is unusual and may indicate that certain TRPV4 mutations produce a severe “combinatorial” phenotype.

1010W

A novel SHH missense mutation causing variable phenotypes in familial holoprosencephaly. *D. Wang, M. Huggins, P. Mohide, C. Li.* McMaster University Medical Center, Hamilton, Canada.

Holoprosencephaly (HPE) is incomplete separation of the forebrain during early embryogenesis, resulting in craniofacial anomalies, midline defects, and neurocognitive delay. Clinical phenotypes vary from very mild to embryonic lethal. The underlying etiologies for HPE include chromosomal anomalies, teratogens and monogenic disorders. One of the genes associated with monogenic HPE is the Sonic hedgehog (SHH) gene whose protein product has been shown to play a crucial role in CNS development. Here we report a novel missense mutation in the SHH gene in a family with strikingly variable phenotypes. The proband was a 38-year-old gravida 4 at 19 weeks of gestation with a pair of fraternal twins. Her first pregnancy resulted in a live born female who became an adult and accompanied the proband to this visit. The second baby was a male with facial clefting, hypotelorism and holoprosencephaly. He expired at 11 months of age. The third pregnancy was terminated after ultrasound detected alobar holoprosencephaly in a female fetus at 13 weeks of gestation. On inspection, the proband and her 20 year-old daughter were of short stature (149.86cm and 139.7cm, respectively). Both appeared to be borderline hypoteloric. The proband also had questionable single central incisor although the daughter did have two incisors and the central frenulum. Genetic testing was discussed but they elected not to proceed as the proband's presenting twin pregnancy had normal ultrasound findings at 19 weeks of gestation. The daughter subsequently became pregnant, and ultrasound revealed semilobar holoprosencephaly and midline facial cleft at 19 weeks of gestation. Following pregnancy termination, genetic testing was undertaken. A novel missense mutation [c.494C>A, A165E] in the SHH gene was found in the fetus. This missense mutation represents amino acid substitution of a large glutamic acid residue for a smaller alanine residue at a position in the SHH protein that is highly conserved across species, and is therefore very likely to be the disease causing mutation. Subsequent testing of the proband, her fetus and the daughter proved that the mutation tracked with HPE phenotype. Our report draws attention to this novel mutation and highlights the extremely variable phenotypes associated with this mutation, from the very mild subclinical to lethal alobar HPE.

1011W

Clinical and molecular characteristics of Noonan syndrome among Arabs. *D.M. AlJeaid, J.Y. Al-Aama.* Department of Genetic Medicine, King Abdulaziz University, Jeddah, Saudi Arabia.

Noonan syndrome is a clinically and genetically heterogeneous multisystem autosomal dominant disorder. It is relatively common with a prevalence of 1 in 1000 to 1 in 2500 live births. It is characterized by short stature, distinctive facial dysmorphism, congenital heart defects, most commonly pulmonary stenosis and cardiomyopathy, and developmental delay of variable degrees. Other findings can include broad or webbed neck, chest deformity, cryptorchidism, varied coagulation defects, lymphatic dysplasias, and ocular abnormalities. So far, heterozygous mutations in nine genes (PTPN11, SOS1, RAF1 KRAS, NRAS, BRAF, MEK1, MEK2, HRAS and SHOC2) have been documented to underlie this disorder or clinically related phenotypes. We believe that Noonan syndrome is somewhat unrecognized and under diagnosed in Saudi Arabia. Also,almost nothing is published about the characteristics of Noonan syndrome in Arabs. Although the majority of patients with Noonan syndrome have an autosomal dominant mode of inheritance, there is thought to be a sub group of patients with the so-called type II Noonan syndrome that is believed to be autosomal recessive. The high rate of consanguinity in the Arab world makes it plausible that the second type of Noonan syndrome may actually be more common. Here, we provide an overview of clinical and molecular aspects of this disorder among Arab patients and major genotype-phenotype correlations. In this study, we aim to characterize the phenotype in Arab patients with Noonan syndrome and identify the most common mutations causing Noonan syndrome and compare it with the world literature. Also, to search for candidate gene for those in which no mutation is found.

1012W

Autoimmune diseases and multiple autoantibodies in a cohort of 43 molecularly proven RASopathy patients. *D.R. Bertola[1], C.R.D.C. Quaio[1], J.F. Carvalho[2], C.A.A. Silva[2, 3], C. Bueno[2], A.S. Brasil[1], A.C. Pereira[4], A.L.L. Jorge[5], A.C. Malaquias[5], C.A. Kim[1].* 1) Pediatrics, Instituto da Criança da Universidade de São Paulo, São Paulo, SP, Brazil; 2) Rheumatology Division - Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, Brazil; 3) Pediatric Rheumatology Unit, Instituto da Criança - Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, Brazil; 4) Incor - Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, Brazil; 5) Endocrinology-Genetics Unit - LIM/25, Discipline of Endocrinology - Faculdade de Medicina da Universidade de São Paulo, São Paulo - SP, Brazil.

Association of RASopathies (Noonan syndrome and Noonan-related syndromes) and autoimmune disorders was sporadically reported. However the concomitant evaluations of autoimmunity diseases and assessment of multiple autoantibodies in a large population of RASopathy with proven mutations were not performed. Clinical and laboratorial features were analyzed in a cohort of 43 RASopathy patients. The following autoantibodies were measured: anti-nuclear antibodies, anti-double stranded DNA, anti-SS-A/Ro, anti-SS-B/La, anti-Sm, anti-RNP, anti-Scl-70, anti-Jo-1, anti-ribosomal P, IgG and IgM anticardiolipin, anti-b2GPI, thyroid, anti-smooth muscle, anti-endomysial, anti-liver cytosolic protein type 1, anti-parietal cell, anti-mitochondrial antibodies and anti-liver-kidney microsome type 1 antibodies, and lupus anticoagulant. At least one autoimmune disease complaint was found in 35 (81%) patients, with 14% of autoimmune diseases (systemic lupus erythematous, polyendocrinopathy - autoimmune thyroiditis and celiac disease, primary antiphospholipid syndrome, autoimmune hepatitis, vitiligo and autoimmune thyroiditis). Autoimmune antibodies were observed in 51%. Remarkably, 3 (7%) of them had specific gastrointestinal and liver autoantibodies without clinical findings. Autoimmune diseases and autoantibodies were frequent in Noonan and Noonan-related syndromes. The careful anamnesis and physical examinations for rheumatic symptoms should be seriously considered and followed with proper laboratory investigations. Importantly, the presence of gastric and liver antibodies in RASopathy may predict the occurrence of future autoimmune gastritis and hepatitis, thus requiring a closer surveillance. Supported by FAPESP (08/50184-2), CNPQ (300248/2008-3 and 300665/2009-1) and Federico Foundation.

1013W

Atypical 7q11.23 deletion in a boy with the facies and behavioral phenotype of Williams syndrome but typical overall cognitive ability: phenotype-genotype correlation. *R.D. Clark[1], B. Haas[2], A.L. Reiss[2].* 1) Division of Medical Genetics, Department of Pediatrics, Loma Linda University School of Medicine, Loma Linda, CA; 2) Center for Interdisciplinary Brain Sciences Research, Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, Palo Alto, CA.

Williams syndrome (WS) is a microdeletion syndrome characterized by deletion of about 28 genes on 7q11.23 (WSCR) including the elastin gene (*ELN*), which is responsible for the vascular and connective tissue abnormalities in this syndrome. The molecular basis of the facial, behavioral and neurocognitive phenotypes in WS is less clear. One of two recurrent deletions (1.5 and 1.8 Mb) are seen in ~98% of WS patients. Atypical deletions are present in 2-3% of WS patients. In 2007, a 21 month-old male of Indonesian descent presented with fevers, absolute neutropenia, chronic Staph infections, short stature and developmental delay. He walked at 17 months and said his first words between 17 and 21 months. He had a wide mouth, elfin facies, poor dental enamel, small widely spaced teeth, hoarse voice and a friendly disposition. Echocardiogram and calcium were normal. He had microcytic anemia and a low MCV (68). He and his father have) thalassemia trait with a heterozygous mutation for Hemoglobin Malay. At age 6 years, his height is above the 25th percentile. He reads, writes sentences and draws integrated figures. He speaks 2 languages well. His neutropenia persists but he has had no infections for 3 years. Both FISH for the WSCR and gene analysis for *NCF1*, also at 7q11.23 and responsible for autosomal recessive chronic granulomatous disease, were normal. An oligo-SNP microarray revealed a 963 Kb deletion (73,568,190-74,531,569, hg 19) at the telomeric end of 7q11.23. The deleted segment lies within the WSCR and includes *GTF2I*, *GTF2IRD1*, *NCF1* and *CLIP2*. Among reports of patients with atypical deletions in the WSCR, this patient is unique as his deletion is telomeric and excludes the *ELN* gene. His facial features, dental anomalies, hoarse voice and sociable personality are typical for WS but other characteristic features, including significant overall intellectual disability are absent. His features and gene deletion segment will be compared to others with atypical WSCR deletions reported in the literature. Brain MRI and neurocognitive studies on this patient will be presented and compared to children with typical WS deletions as well as healthy controls. The few patients with WS whose deletions do not span the entire WSCR provide a valuable opportunity to advance the current state of knowledge of the genetic map for the clinical, bahavioral and neurocognitive phenotypes in WS.

1014W

POLR1D and POLR1C sequencing in a series of 33 patients without TCOF1 mutations and study of their profile expression during human development. *C. Collet[1], M. Vincent[2], S. Thomas[3], S. Marlin[4], E. Sanchez[2], A. Harroche[3], K. Dahan[5], T. Attie[3], C. Herlin[6], Y. Chabbi[1], G. Captier[6], C. Blanchet[7], A. Ermakov[8], M. Bigorre[6], M. Mondain[7], M. Willems[2], B. Doray[9], P. Sarda[2], F. Djouad[8], D. Geneviève[2,8].* 1) Service de Biochimie et de Biologie Moleculaire, H, Paris, France; 2) Departement de Genetique Medicale, CHRU Montpellier, Université Montpellier 1, Centre de reference anomalies du developpement et syndromes malformatifs, Montpellier, France; 3) Unite Inserm U781, Departement de Genetique, Hopital Necker-Enfants Malades, France; 4) Centre de Reference des Surdites Genetiques, Service de Genetique, Hopital d'Enfants Armand Trousseau, Paris, France; 5) Universite Catholique de Louvain, Genetique clinique, Bruxelles, Belgique; 6) Chirurgie plastique infantile, CHRU Montpellier, Universite Montpellier 1, Montpellier, France; 7) Service d'ORL, CHRU Montpellier, Universite Montpellier 1, Montpellier, France; 8) Unite Inserm U844, Institut des Neurosciences de Montpellier, France; 9) Service de genetique medicale, Hopital Hautepierre, Strasbourg, France.

Treacher-Collins/Franceschetti syndrome (TCFS, MIM 154500) is a disorder of craniofacial development characterized by a facial gestalt including micrognathia, microtia, hypoplastic zygomatic arches with antimongoloid slant of the palpebral fissures and coloboma of the lower lid. TCFS is genetically heterogeneous with heterozygous mutation in the TCOF1 gene in approximately 70% of the patients. An array-CGH strategy recently identified POLR1D and POLR1C as others disease-causing genes in about 4% of the TCFS patients negative for the TCOF1 gene. POLR1D mutations are associated with an autosomal dominant of inheritance in TCFS patients whereas an autosomal recessive mode of inheritance is described in TCFS patients with POLR1C mutations. Here we report the identification of new POLR1D mutations in 4/33 patients without TCOF1 mutations. The clinical features of the patients are consistent with the TCFS criteria. Among the patients, 2 were sporadic and 2 were familial cases. Interestingly, we identified homozygous POLR1D mutation in one patient and heterozygous status in the healthy parents suggesting an unexpected autosomal recessive mode of inheritance in this family. In addition we studied the TCOF1 mRNA expression in blood sample from patients from our series. We also studied the expression of SOX9, TCOF1, POLR1D and POLR1C in craniofacial structures during human development. In conclusion, we identified mutations in the POLR1D in a series of 33 TCFS patients negative for the TCOF1 gene and study the expression of the SOX9, TCOF1, PORL1D and POLR1C in human craniofacial development.

1015W

A further case of Coffin-Siris syndrome with additional findings: Acanthosis nigricans and obesity. *B. Durmaz[1], E. Karaca[1], O. Cogulu[2], F. Ozkinay[2].* 1) Department of Medical Genetics, Ege Univ, Izmir, Turkey; 2) Department of Pediartic Genetics, Ege Univ, Izmir, Turkey.

Coffin-Siris syndrome is a rare congenital disorder also known as `fifth digit syndrome'. The disorder is characterized by mental retardation and developmental delay, a coarse facial appearance, short fifth digits and hypoplastic or absent nails. The underlying cause of Coffin-Siris syndrome is unknown and most cases are sporadic. Familial cases have also been reported that suggest autosomal dominant or autosomal recessive inheritance. Here we report a 11 year-old girl, the first child of non-consanguineous parents. She was referred to the Pediatric Genetics Department with multiple congenital anomalies and developmental delay. On physical examination, she was seen to have a coarse face, puffy eyes and a depressed nasal bridge. She also had a short stature (<3p) and was overweight (>95p, BMI: 39 kg/m2). She had acanthosis nigricans on both the neck and axillary regions, previously not described before. Her fifth fingers were short, especially on the right hand. The fingernails and toenails were hypoplastic. X-ray of the right hand revealed a hypoplastic fifth metacarpal. Additionally, her bone age was advanced (14 years) which is unusual for this disorder. She also had high insulin level and impaired glucose tolerance. Cranial MRI and abdominal ultrasonography revealed no pathology. Her cardiological and opthalmological examinations were normal. Karyotype and FISH analysis for Prader-Willi Syndrome were normal. Metabolic diseases such as hypothyroidism, lysosomal storage disorders, biotinidase deficiency were excluded. In conclusion, all presented features apart from advanced bone age, acanthosis nigricans and obesity were typical of Coffin-Siris syndrome. Therefore, this patient's additional clinical features may represent a new variant of Coffin-Siris syndrome which may contribute to the understanding of this genetic disorder.

1016W

Richieri-Costa-Pereira syndrome. *T.M. Felix[1], I.G. Mazzucco[1], G. Carvalho[1], J.C.L. Leite[1], L.Z. Bonilha[2], M.V. Collares[2].* 1) Medical Genetics Service, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil; 2) Plastic Surgery Service, Hosp Clinicas Porto Alegre, Porto Alegre, RS, Brazil.

Richieri-Costa and Pereira described in 1992 an autosomal recessive acrofacial dysostosis syndrome. The clinical findings include short stature, Robin sequence, cleft mandible, pre and post axial limb anomalies and club foot. Thirty one cases had been described in the literature and all of them except one are from Brazil. The majority of the Brazilian cases are from a region in São Paulo called Ribeira Valley. This data suggest that this disorder is caused by an unknown rare mutation due to a founder effect. We report on a case of a female newborn, born in the Southern state of Brazil. She is the third child of a young and non-consanguineous couple. She was born by cesarean section due to breech presentation at 38 weeks of gestational age. Her birth weight was 2350g. At the physical examination we noticed micrognathia, cleft palate, hypoplasic of the fifth fingers and toes and calcaneus hyploplasia. She was submitted to the following exams: Karyotype (46,XX), limb x-rays showed hyploplastic fifth fingers, short fibulas and ulnas, hypoplastic calcaneus and club feet. A face bone CT scan showed agenesis of the mandible, micrognathia, zygomatic arch and paramentonian region hypoplasia. She evolved with respiratory distress and nasofibrobroncoscopy showed grade III glossoptosis leading to tracheostomy procedure. She was submitted to mandible osteoplasty with double layer parietal bone graft.

1017W

Clinical review of 21 patients with chromosome 22q11.2 deletion syndrome. *J. Garcia-Sagredo, J. Lopez-Ribera, P. Cabello, E. Garcia-Galloway, C. Villalon, J. Cabrejas, M. Talavera, M.T. Ferro.* Dept Med Gen, Univ Hosp Ramon y Cajal, Madrid, Spain.

22q11.2 deletion syndrome is the most frequent microdeletion disorder. This syndrome is associated to a wide variety of phenotypes including Di George syndrome (88%), velocardiofacial syndrome (75%), and conotruncal anomaly face syndrome (72%). We report a review of 75 patients with congenital heart diseases (CHD) referred from the Cardiology Department during the last 4 years to analyze the presence of 22q11.2 deletion using the Di George/VCFS probe (Vysis). Twenty one patients out 75 (28%) showed the 22q11.2 microdeletion. Among the 21 patients, no differences were found in sex ratio. All had CHD, mainly conotruncal malformations, 14 (66.6%) complex CHD, 11 (52.3%) Fallot tetralogy, 7 (33.3%) right aortic arch, 2 truncus arteriosus, 2 with pulmonary atresia and ventricular septal defect, and 2 with auricular septal defect associated to valvular disorders. The majority of the patients (95.2%) showed facial or skeletal malformations. By frequency, the most frequent dysmorphic findings were: (1) Oral malformations (66.6%) including lips malformations, bifid uvula, short and high arched palate, micrognathia, and prognathism. (2) Ear malformations (66.6%), including tags; no hearing loss was found. (3) Eye malformations (52.3%) including eyelids, epicanthic folds, strabismus and myopia. (4) Nose malformations (38.1%). Additionally there were 5 patients (23.8%) with skeletal malformations including polydactyly, clinodactyly, and scoliosis. Furthermore, 57.1% showed psychomotor retardation or cognitive defects ranging from mild to moderate. Two patients have behavioral disorders. For the contrary, more than 50% of the evaluated patients without 22q11.2 deletion had normal phenotype. Our results, similar to previous reports, showed that the most frequent CHD, Fallot tetralogy, are not the most predictive of 22q11.2 deletion syndrome. Fallot tetralogy is associated with this syndrome in one out 8 patients with CHD, while the right aortic arch is associated in 1 out 2 patients. On the contrary, the association of CHD with facio-skeletal malformations is the best predictor of this syndrome. In conclusion, the clinical heterogeneity of 22q11.2 deletion syndrome makes FISH analysis the choice test among the patients with CHD, but the efficiency of this test is low using only CHD as the only indication. Otherwise, association of facial malformations with CHD or neurocognitive disorders is a better indication of carrying out 22q11.2 FISH microdeletion test.

1018W

A seven years follow-up of a new case of Ehlers Danlos Syndrome type VIIB. Major problems are represented by bilateral, extremely severe, hip dislocation. *M. Giovannucci Uzielli[1, 5], C. Giunta[4], G. Scarselli[2], N. Dayan[5], E. Lapi[3], L. Di Medio[5].* 1) Dept Pediatrics, Univ Florence, Florence, Italy uzielli_ml@unifi.it; 2) Dept Pediatric Neurology, Univ Florence, Florence, Italy; 3) Azienda Ospedaliera Universitaria "A. Meyer", Florence, Italy; 4) Div. of Metabolism and Molecular Pediatrics, University Children Hospital, Zurich, Switzerland; 5) Genetica Science - Piazza Savonarola 11 - 50132 Florence, Italy.

The Ehlers-Danlos Syndrome (EDS) is a heterogeneous group of heritable connective tissue disorders whose primary clinical features include marked joint hypermobility, soft hyperextensible skin, dystrophing scarring, easy bruising. An initial classification defined 10 distinct types of EDS, but with recent advances in our understanding of the molecular pathology, a revised nosology has been proposed. In the original classification, EDS type VII, a subgroup characterised by extreme joint laxity, was divided into three subtypes, EDS VIIA, VIIB, and VIIC. In the revised nosology, EDS VIIA and B,(both AD disorders) are combined as the arthrochalasia type of EDS. EDS VIIB, (harbouring mutations in the COL1A2 gene) shows peculiar aspects of the collagen fibrils in skin, bone and fascia, that are near circular in cross - section. Congenital hip dislocation, often bilateral, is described in all patients with EDS VIIB. We report the clinical phenotype and the natural history of a girl, firstly evaluated at birth, because a generalised joint hypermobility, especially expressed at feet and hands level, with the so-called "swan neck deformities of the fingers". Soft skin, umbilical hernia, blue sclerae were also obvious. Direct sequencing of a 358 bp by PCR fragment encompassing intron 5 to 6 of the COL1A2 gene has shown, at the first position G+1 of the donor 5' splice site, a heterozygous G to A (IVS6+1G>A) substitution which alters the obligatory GT nucleotide to AT. The mutation is known to cause skipping of exon 6 in COL1A2 and to be responsible for EDS VIIB. From the periodical, follow-up controls, we especially underline that the bracing was unsuccessful in stabilizing the hips, but the patient is able to walk, jump, cycle, without any pain, or apparent limitation. The legs are now well developed with normal muscular component. The stature is a little below the 3rd centile. The X-rays revealed verticalized acetabulum, marked hip dislocation with valgism of femoral neck and "climbing up" of proximal femoral epiphyses with a "new-joint" with the iliac hip-bones. Surgical correction of the hip situation was considered but rejected by the orthopaedic specialists on the basis of the presently good quality of the patient's life, and due to the limits and risks of the currently offered techniques.

1019W

The Floating-Harbor syndrome: report of the first case series in South America. *I. Gomy, C.R.D.C. Quaio, D.R. Bertola, C.A. Kim.* Pediatrics, Genetics Unit, Instituto da Criança - Universidade de Sao Paulo, Sao Paulo, São Paulo, Brazil.

The Floating-Harbor syndrome (FHS) is characterized by facial gestalt, typical body habitus, short stature with delayed bone age and both speech and language disorders with a peculiar voice. To date, more than 40 FHS patients were reported worldwide and its etiology remains unknown, although either autosomal dominant inheritance or microdeletion have been suggested. Associated abnormalities include congenital heart defects, genitourinary anomalies, precocious puberty and celiac disease. Growth hormone therapy has been used with discrepant outcomes. We report a series of six unrelated patients aged from 12 to 28 years (mean of 18) with typical features of FHS and some individual peculiarities. Archetypal facial dysmorphisms, intellectual disability, short stature, language delay and normal motor development were universal findings. Their height varied from -2 to -4.3SD, with an average Z score of -3.1. Low birth weight (4/6), delayed bone age (3/6), microcephaly (3/6), hypothyroidism (2/6), trigeminal neuralgia (1/6), inguinal hernia (1/6), conductive hearing loss (1/6), posterior urethral valve (1/6) and strabismus (1/6), brachydactyly (3/6) clinodactyly(4/6) digital clubbing (2/6) were also remarkable findings. GH therapy was tried in two patients but only one responded. All patients presented normal karyotype, while three had normal studies for the 22q11 region and one normal CGH array. We described the first South American case series of FHS. The recognition of FHS remains a challenge mainly because it depends upon the recognition of the facial gestalt that changes over time. Furthermore, consensus diagnostic criteria have not been established yet. Whether the association of FHS, non-immune hypothyroidism and trigeminal neuralgia is a mere casualty or expands the phenotype remains uncertain. Therefore, we emphasize the need for prompt recognition and better delineation of this rather underdiagnosed syndrome.

1020W

Autosomal dominant natal teeth with selective tooth agenesis. *J. Graham[1], V. Funari[1], O. Klein[2], K. Seidel[2], P. Kantaputra[3], K. Taylor[1].* 1) Medical Genetics Institute, Cedars Sinai Medical Center, Los Angeles, CA; 2) Dept Orofacial Sciences, University of California, San Francisco, CA; 3) Faculty of Dentistry, Chiang Mai University, Chiang Mai, Thailand.

We report a 5-generation family with multiple natal teeth and selective tooth agenesis segregating in an autosomal dominant fashion. Natal teeth are usually a sporadic isolated finding in an otherwise normal infant, and familial occurrence is uncommon. Selective tooth agenesis is usually genetic and not associated with natal teeth. In affected persons in the family we report, at least 6-8 natal teeth are usually present at birth, and this is followed by selective tooth agenesis that results in absence of as many as 16 permanent teeth. Natal teeth with hypodontia occurs in some ectodermal dysplasia syndromes. In the family we report, natal teeth with selective tooth agenesis did not include ectodermal dysplasia or any other problem. DNA from 28 family members was analyzed on the Illumina OMNI-express chip using 733,120 SNPs and mapped to an approximately 2Mb segment on chromosome 1q36.11 with LOD score 2.97 at 23.8 Mb to 25.8 MB (GRCh37/hg19; MERLIN). By dividing the pedigree into three 3-generation families, a region of association was found located between LOC284632 and GRHL3 (parenTDT, p=0.005 for rs11249039, rs11249045, or rs7526505). GRHL3 is a gene expressed exclusively in surface ectoderm in drosophila, where it plays an essential role in cuticle formation. Expression of the murine Grhl3 gene is evident in ectodermally derived tissues, including the oral epithelium. We speculate that variation in the regulation of this gene may play a role in the phenotype we describe in this family.

1021W

Congenital neutropenia with retinopathy, a new phenotype without mental retardation caused by VPS13B mutations. *L. Gueneau[1], L. Jego[1], P. Sarda[2], C. Hamel[3,4], B. Aral[1,5], E. Lopez[1], N. Gigot[1,5], MC. Lavigne[5], A. Donzel[5], P. Callier[1,6], A. Masurel-Paulet[8], JR. Teyssier[5], N. Droin[7], S. El Chehadeh[1], L. Faivre[1,8], C. Thauvin[1,8].* 1) Equipe émergente GAD (Génétique et Anomalies du Développement), IFR 100 Santé STIC, Université de Bourgogne, Dijon, France; 2) Service de Génétique Médicale, Hôpital Arnaud de Villeneuve, CHU Montpellier, France; 3) Service d'ophtalmologie, Hôpital Gui de Chauliac, CHU Montpellier, France; 4) Département de génétique et thérapie des cécités rétiniennes, INSERM U583 - Institut des Neurosciences de Montpellier, France; 5) Laboratoire de Génétique Moléculaire, Plateau Technique de Biologie, CHU Dijon, France; 6) Laboratoire de Cytogénétique, Plateau Technique de Biologie, CHU Dijon, France; 7) Inserm UMR 1009, Integrated Research Cancer Institute Villejuif (IRCIV), Institut Gustave Roussy, Villejuif, France; 8) Centre de Génétique et Centre de Référence (Anomalies du Développement et Syndromes Malformatifs) du Grand Est, Hôpital d'Enfants, CHU Dijon, France.

Cohen syndrome, a rare autosomal recessive disease, presents with a highly homogeneous phenotype, including developmental delay, microcephaly, characteristic facial dysmorphism, pigmentary retinopathy, intermittent isolated neutropenia and cheerful disposition. Major clinical criteria with high sensibility have been published. This disorder is due to mutations in the VPS13B gene with over hundred different previously reported mutations including mostly frameshift, leading to truncated protein and predicting to non-functional allele. Here, we report on an adult patient carrying two VPS13B heterozygous splice mutations (IVS34+2T_+3AinsT and IVS57+2T>C) with an atypical phenotype including microcephaly, retinopathy diagnosed at age 22 years and congenital neutropenia diagnosed at age 2 years, but neither obesity nor mental retardation. Indeed, she weighted 43 kg for 153 cm, BMI 18.4 (normal 18.5-25), and her IQ was evaluated at 100. Each parent carried one mutation. In silico analyses predicted abnormal splicing. RNA RT-PCR sequencing analysis up- and downstream IVS57+2T>C mutation showed three abnormal splice isoforms plus the normally spliced one. RNA RT-PCR sequencing analysis around the IVS34+2T_+3AinsT mutation failed to reveal any abnormal spliced fragments. First results of the quantitative RT-PCR in patient's lymphoblastoid cell line showed decrease of the VPS13B mRNA expression on three different fragments, suggesting nonsense-mediated mRNA decay process. These results lead us to suspect the expression of residual normal VPS13B mRNA and normal protein activity, responsible for partial phenotype in this patient, in contrast to patients with Cohen syndrome who present only with expression of abnormal VPS13B mRNA and truncated protein.

1022W

Novel *GJA1* mutation in a patient with Oculo-Dento-Digital Dysplasia and evolving basal ganglia abnormalities. *E.M. Honey, E.J. van Rensburg.* Department Genetics, University of Pretoria, Pretoria, Gauteng, South Africa.

Oculo-dento-digital dysplasia [ODDD, OMIM 164200] is an autosomal dominant disorder characterized by facial dysmorphisms (thin nose with hypoplastic alae nasi) , ocular defects (microphthalmia, microcornea, cataract, glaucoma and optic atrophy), enamel hypoplasia, syndactily of fingers and toes and dry lusterless hair that fails to grow. Neurological abnormalities can also be present and mild mental retardation is commonly noted. Diffuse white matter abnormalities and calcifications of the basal ganglia have been described. Mutations in the human gap junction alpha 1 (*GJA1*) gene on chromosome 6q22-23 coding for Connexin 43 are associated with ODDD.

We report a 14 year old girl who presented with syndactily between the 4th and 5th fingers (surgically corrected) and facial features suggestive of ODDD. She had a thin tapered nose with hypoplasia of the alae nasi, a prominent nasal bridge, micro-opthalmia and abnormally shaped small teeth. Her psychomotor development was in the low normal range and she had to attend a special school. An MRI of her brain showed significant signal changes in the lentiform nucleus in the area of the globus pallidus on the T1 and T2 weighted images at the age of 8 years. The white matter showed a normal signal pattern. These signal changes was more limited on an MRI repeated at 11 years of age. Sequencing of the *GJA1* gene revealed a novel missense mutation, p.L228P (c.683T > C), located in the fourth transmembrane region (TM4) of Connexin 43. She is currently at the age of 21 years in a full-time occupation living with her parents.

The basal ganglia abnormalities in the absence of white matter changes have not been described before in association with ODDD. Could this be the preceding changes to the basal ganglia calcification seen in older patients with ODDD?

1023W

5q31.3 microdeletion syndrome is a clinically discernible new syndrome characterized by severe neonatal hypotonia, feeding difficulties, respiratory distress, and severe developmental delay. *K. Hosoki[1], T. Ohta[2], J. Natsume[3], S. Imai[4], A. Okumura[5], T. Matsui[6], N. Harada[6], F. Scaglia[7], C.A. Bacino[7], N. Niikawa[2], S. Saitoh[8].* 1) Department of Pediatrics, Hokkaido University Graduate School of Medicine; 2) The Research Institute of Personalized Health Science, Health Science University of Hokkaido; 3) Department of Pediatrics, Nagoya University Graduate School of Medicine; 4) Department of Pediatrics, Sagamino Social Insurance Hospital; 5) Department of Pediatrics, Juntendo University School of Medicine; 6) Nagasaki Laboratory, Cytogenetics, 2nd Group Molecular Genetics Testing Department, Clinical Laboratory Center Mitsubishi Chemical Medience Corporation; 7) Department of Molecular and Human Genetics, Baylor College of Medicine and Texas Children's Hospital, Clinical Care Center; 8) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences.

Chromosomal microarray technology has led to the identification of many novel microdeletion/microduplication syndromes demonstrating multiple congenital anomalies and intellectual disability (MCA/ID). We have applied microarray analysis to the patients with MCA/ID and/or neonatal hypotonia. Three overlapping *de novo* microdeletions at 5q31.3 with the shortest region of overlap (SRO) of 370kb were detected in unrelated patients. These patients showed similar clinical features including severe neonatal hypotonia, feeding difficulties and respiratory distress followed by severe developmental delay. They presented with facial dysmorphisms with narrow forehead with metopic prominence, lateral sparseness of the eyebrows, hypertelorism, depressed nasal bridge, open and tented mouth, marked philtrum and micrognathia. Recently, Shimojima et al. [2011] reported two patients with 5q31.3 microdeletions in which the 370kb SRO was completely included, and these patients demonstrated strikingly similar clinical features to our patients. The 370kb SRO encompasses only four RefSeq genes including *NRG2* and *PURA*. As *NRG2* is a member of the neuregulin family related to growth and differentiation of neurons and development of glial cells, *NRG2* may be a good candidate for this phenotype. *PURA* also remains as a good candidate because *Pura* deficient mice demonstrate postnatal neurological manifestations. We conclude that the 5q31.3 microdeletion syndrome is clinically discernible, and hypothesize that *NRG2* and *PURA* are good candidates to cause this clinical phenotype.

1024W

A novel autosomal dominant Pierre-Robin microtia type I syndrome. *A. Hunter[1], K. Boykott[1], N. Roy[2].* 1) Genetics, Ottawa, ON, Canada; 2) Genetics Service, Porcupine Health Unit, Timmins, Ontario.

In this paper we describe mother and son with an apparently new syndrome, whose predominant signs include type I microtia and Pierre-Robin syndrome. The patients shared normal size, length and OFC at birth but both demonstrated postnatal growth failure that included the OFC. By late childhood the mother showed remarkable catch-up with adult height at the 10th centile and OFC at the 5th. The microtia, hearing loss and middle ear changes were variable; scalp hair was sparse with a high anterior hairline. Childhood photographs of mother and child were remarkable similar; with time the mother's face has become very long and narrow with some asymmetry and a very deep lower jaw that remains retrognathic. Other shared characteristics include a prominent wide nasal bridge, bow-shaped upper lip with some asymmetry of movement, mild clinodactyly and smallish nails. The mother's developmental disabilities appear milder than those of her son who currently shows marked developmental delays. The mother's adult radiographs showed fusion of C4-C5 and an increased height to AP ratio of the lumbar vertebrae so that mild anomalies of the spine may also be part of this syndrome. Given that the mother's parents are normal, we hypothesize that this is an autosomal dominant syndrome which has arisen de novo in the mother and been passed on to her son. Chromosomal microarray analysis was normal suggesting that this syndrome is caused by a de novo change in a single gene. Although there are almost 30 syndromes that include Pierre Robin as a finding most can be distinguished easily on the basis of other associated findings and/or autosomal recessive inheritance. Those few that bare some resemblance will be discussed. The dorsal component of the first pharyngeal arch appears as the embryological site of the two most characteristic components, that is the Pierre-Robin anomaly and microtia. We will use comparative exome sequencing of the mother and her normal parents to attempt to reveal the genetic basis of this syndrome.

1025W

A *de novo* 10.6 Mb tandem duplication of 17q11.2-q12 in a 1 year old boy: Expanding the phenotype. *S. Jamal[1,2], R. Basran[1,2], T. Maher[1], Y. Zou[1,2], X. Huang[1], J. Milunsky[1,2,3].* 1) Ctr Human Genetics, Boston Univ Sch Medicine, Boston, MA; 2) Department of Pediatrics, Boston Univ Sch Medicine, Boston, MA; 3) Department of Genetics and Genomics, Boston Univ Sch Medicine, Boston, MA.

The use of whole genome microarray technologies has the ability to identify novel microdeletion and microduplication syndromes. We describe a 21 month old male with a history of delayed tooth eruption, bilateral hip dislocation, persistent generalized hypotonia, developmental delay, and dysmorphism. His dysmorphic features include a long midface, deep set eyes, thin eyebrows, tubular nose, anteverted nares, thin upper lip, unusual dentition, relative brachydactyly, tapered digits, and a shawl scrotum. In pursuing a syndromic work-up, a renal ultrasound at 22 months was normal; a transthoracic echocardiogram at 23 months revealed a possible anomalous accessory pulmonary vein; a head MRI at 27 months revealed possible mega cisterna magna and hypoplastic cerebellar vermis. Affymetrix 6.0 SNP array revealed a 10.6 Mb interstitial duplication of chromosome 17q11.2-q12. BAC FISH analysis determined the duplication to be in tandem. Subsequent BAC FISH testing of maternal and paternal blood samples were negative for this duplication (paternity confirmed), thus determining the *de novo* nature of this alteration. This duplication contains over 100 annotated genes, and includes 2 well known micro*deletion* syndromes: Neurofibromatosis type 1 contiguous gene syndrome (*NF1* gene [MIM 613113], [MIM 613675]) and Renal Cysts And Diabetes syndrome (*HNF1B/TCF2* gene [MIM 189907], [MIM 137920]). Both recurrent genomic disorders are thought to arise from NAHR due to the presence of flanking segmental duplications, resulting in either duplication or deletion of the intervening segment. In 2008, *NF1* micro*duplications* were observed in patients with intellectual disability, early baldness, and dental enamel hypoplasia (Grisart et al, 2008). Similarly, *HNF1B/TCF2* micro*duplications* were reported in patients with renal disease, diabetes, epilepsy and/or intellectual disability (Mefford et al, 2007; Nagamani et al, 2009; Morena-De-Luca et al, 2010; Faguer et al, 2011). Caselli *et al* (2010) was the first to describe a 12.6 Mb *de novo* duplication of 17q11.2-q12 in a 6 year old boy with developmental delay and minor anomalies. To our knowledge, our patient is the second report of a large sized duplication involving 17q11.2-q12 that encompasses two recently elucidated genomic disorders. As our patient is quite young and the phenotype corresponding to this large duplication continues to be delineated, providing anticipatory guidance remains challenging.

1026W

Phenotypic features of the 14q deletion syndrome in balanced translocation carrier family members. *N.J.B. Kapalanga[1, 2, 3], D. Wong[2,3], A.C. Gandy[2,3].* 1) Pediatrics/Genetics, GBHS, Owen Sound, Ontario, Canada; 2) Pediatrics Dept, Dalhousie University, Halifax, NS, Canada; 3) Summerside Medical Center, Summerside, PEI, Canada.

The clinical phenotype of the majority of cases with terminal 14q deletion syndrome is characterized by distinctive craniofacial features, feeding difficulties, hypotonia, developmental delay in motor skills and speech, communication and mental function difficulties. The clinical phenotype of terminal 14q deletion syndrome has been described in about 22 reports in the literature. About 13 of these cases are pure terminal deletions and only 4 cases involved autosomal translocations and only one of these 4 cases involved a deleted derivative 14 chromosome from a 14;17 balanced paternal cryptic translocation; t(14;17)(q32.32;qter). None of the published reports describe phenotypic features of the terminal 14q deletion syndrome in balanced translocation carriers with a chromosome 14q32.3 breakpoint. We report on a family with a child with 14q32.3 terminal deletion syndrome and balanced translocation carrier family members who share certain phenotypic features with the proband. The shared phenotypic features include telecanthus, epicanthic folds, prominent nose, broad philtrum and mild speech difficulties. The distinctive facies were observed in all family members who are balanced translocation carriers and in none of the family members with normal karyotypes. All these phenotypic features have previously been reported in other cases with the terminal 14q deletion syndrome. As these features are present only in family members with a 14q32.3 breakpoint it is tempting to speculate that these facies have some association with the chromosome 14 breakpoint involved in the translocation in this family. It was also observed that all offsprings of the father carrying the t(14:17) translocation have a 14q32.3 breakpoint. We hypothesize that the 14q32.3 breakpoint results in haploinsufficiency of a gene(s) involved in facial morphogenesis. Further several imprinted genes have been reported in this region and it has been suggested in a previous report that imprinted genes could be involved in the terminal 14q deletion phenotype. Thus, the combination of maternally imprinted genes on 14q and inactivation of functionally active, paternally derived alleles at the 14q32.3 breakpoint could explain the 14q terminal deletion features also observed in translocation carriers.

1027W

Aicardi Goutiere Syndrome- first molecularly confirmed case in Malaysia. *W.T Keng[1], G.I Rice[2], H. Gornall[2], Y.J Crow[2], V. Ganesan[3], R. Ariffin[1].* 1) Deparment of Genetic, Hospital Kuala Lumpur, Kuala Lumpur, Wilayah Persekutuan, Malaysia; 2) Academic Unit of Medical Genetics, School of Medicine, The University of Manchester; 3) Paediatric Dept, Hospital Pulau Pinang.

Aicardi Goutiere syndrome is a rare, early but typically subacute onset encephalopathy characterized by severe learning difficulties, irritability, intermittent fever, developmental regression, seizures, chilblain skin lesions and microcephaly. Mutations in 5 genes [TREX1, RNASEH2B, RNASEH2C, RNASEH2A and SAMHD1] are associated with AGS. Our patient who has Indian parentage, presented with severe learning difficulties and epilepsy in association with profound microcephaly. She cried a lot and fed poorly since birth but there was no documentation of microcephaly at birth, abnormal liver function or abnormal blood count. She did not have scoliosis, cardiomegaly or hypothyroidism. Lumbar puncture showed leucocytosis while the brain CT scan showed basal ganglia, dentate nuclei and periventricular white matter calcifications. CSF interferon and neurotransmitter were not assayed. Sequence analysis showed homozygous R69W mutation in RNASEH2C gene, which interestingly is a recurrent mutation found in many Pakistani families due to founder effect.

1028W

A clinical description of an adult patient with Wolf-Hirschhorn syndrome caused by the unbalanced translocation t(4;8)(p16.1;p23.1). *J. Liu, M. Thomas.* Dept of Medical Genetics, University of Calgary, Calgary, Alberta, Canada.

We describe a 36-year-old woman with Wolf-Hirschhorn syndrome (WHS) associated with the relatively common translocation t(4;8)(p16.1;p23.1). The monosomy 4p in the patient is due to the unbalanced de novo translocation between 4p and 8p. This translocation is likely the second most common recurring translocation and mediated by olfactory receptor gene clusters. Therefore, this particular imbalance is a recurring abnormality in WHS patients, warranting further clinical description. This need in the literature has previously been raised from the 2008 workshop “WHS and Related 4p- Conditions: Defining a Research Agenda”. Conventional cytogenetic analysis identified an abnormal chromosome 4 with additional material on the distal short arm - add(4)(p16.1), with an otherwise normal female karyotype. Metaphase subtelomere FISH studies demonstrated that the additional chromosome segment is derived from chromosome 8p and the distal 4p is deleted, including the WHS critical region (D4S96-). Therefore, this is a derivative chromosome 4 from a translocation between 4p and 8p. By G-banding, the breakpoints correspond to t(4;8)(p16.1;p23.1). As both parental karyotypes were normal, the chromosome rearrangement is presumed to be de novo in this patient. Our patient has been in relatively good health but has significant intellectual disability and lives in a group home. She is able to walk, participate in physical activities, and can feed herself. Although she does not use words, she manages to communicate with those who know her with specific sounds and basic sign language. She is social and interactive and enjoys many activities, including shopping and office work. She had seizures as a child and has not had one in years, although recently had a probable recurrence. She is otherwise in good healthy. Her growth parameters are well below the 3rd percentile. She has distinct facial features, as will be shown with pictures, some in keeping with WHS. Overall, she is not on the severe end of the spectrum of WHS patients. This derivative 4 from a de novo translocation between 4p and 8p has been reported in several large scale WHS studies. There are two different breakpoints which are recurrent on 4p: the common one located at about 9 Mb, and the less common one located at about 4.5 Mb from the telomere. Array comparative genomic hybridization will be performed to determine the precise breakpoints and to further delineate the genotype-phenotype correlation.

1029W

Delineation of the interstitial 6q25 Microdeletion Syndrome: refinement of the critical causative region. *M. Michelson-Kerman[1,2], C. Vinkler[1,2], I. Nezer[1,2], M. Yanoov-Sharav[1,2], T. Lerman-Sagie[2,3], D. Lev[1,2].* 1) Inst Med Genetics, Wolfson Medical Ctr, Holon, Israel; 2) Metabolic Neurogenetic Clinic, Holon, Israel; 3) Pediatric Neurology Unit, Holon, Israel.

Cryptic chromosomal aberrations are associated with various syndromes. Microdeletion of the long arm of chromosome 6q is rare but specific clinical entity. Phenotypic presentation includes mental retardation, acquired microcephaly, dysmorphic features, structural brain malformations and other features. The smallest reported region of microdeletion responsible for the phenotype was mapped between 6q24 and 6q27 and spans >3MB with more than 12 coding genes. A 2 years old boy presented with mental retardation, acquired microcephaly, dysmorphic features and dysgenesis of corpus callosum. He has deep set eyes, prominent forehead, posteriorly rotated ears, short neck, short proximal phalanges, transverse creases, fetal pads and hypoplastic scrotum. Neurological examination revealed mixed axial hypotonia with limbs hypertonia. He is the fourth child of an unrelated generally healthy couple. The mother is carrier of a Robertsonian translocation (14;15). Our patient was found to be a carrier of the same translocation and his karyotype is 45 XY,der(14;15)(q10;q10) Affymetrix Wnole-Genome 2.7M Array Chip revealed deletion of 1191 kbp at 6q25.3. The deleted region contains 2 coding genes: ARID1B and ZDHHC14. These genes are highly expressed and evolutionarily conserved. ARID1B encodes a subunit of chromatin-remodeling complex. The encoded protein is expressed in different brain regions during fetal development suggesting its important role in CNS development. ZDHHC14 belongs to a palmitoylating enzyme family proteins. Protein palmitoylation is crucial in CNS development and plays an important role in neurite outgrowth and synaptogenesis. We found two attractive genes, ARID1B and ZDHHC14 whose haploinsufficiency caused the distinct phenotype of 6q deletion syndrome with dysgenesis of corpus callosum.

1030W

Toriello-Carey Syndrome: First brazilian case with unusual manifestation phenotype. *M.P. Migliavacca[1], T.A. Zanolla[1], N.L.M. Sobreira[2], A.B.A Perez[1].* 1) Medical Genetics Center (Federal University of São Paulo Brazil); 2) Mckusick-Nathans Institute of Genetic Medicine (Johns Hopkins University).

BACKGROUND: Toriello and Carey first described in 1988 four patients comprising with agenesis of corpus callosum, unusual facial appearance, Pierre Robin sequence, and others anomalies. Since then, 16 patients were described with a similar phenotype. PURPOSE: Describe a patient with an addition finding in order to try to further delineate the syndrome. PATIENT AND METHODS: TMS, 7 years age, first child of unrelated parents. No family history, uneventful pregnancy, born by cesarean section at term. Presented at birth congenital skin atrophy, poor sucking reflex, club foot and cardiac anomaly (atrioventricular septal defect), cryptorchidism and pyloric stenosis. Progressed with physchomotor development delay. Physical examination: weight, stature and head circumference at mean percentile ; autistic behaviour; arching of eyebrows, ocular hypertelorism, ptosis of eyelid, downslanted palpebral fissures, short columella, upturned nares, long and smooth philtrum, micrognathia, short neck, clinodactyly of fifth fingers in both hands, camptodactyly of left fifth finger, partial cutaneous syndactyly, small penis, limited atrophic scar area in limbs. Complementary evaluation: Karyotype 46, XY; normal T4/TSH testing; normal transfontanel and abdominal Ultrasound; Brain Magnetic Resonance Imaging: delayed myelinization; Audiometry: bilateral hearing loss; BERA: conductive hearing loss. CONCLUSION: Autosomal recessive inheritance has been hypothesized and chromosome abnormalities have been reported but the etiopathogenesis remains unknown. The phenotype is not completely delineated yet. Our patient presents with a similar phenotype of those already described and in addition with a rare skin anomaly: congenital skin atrophy localized in the limbs, that we believe it is part of the syndrome. We describe findings in a patient, presumed to be another case of the Toriello-Carey syndrome, which extend the phenotype of the syndrome.

1031W

Polymorphism of MTHFR A1298C, a marker in northern Indian mothers with DS babies and its association with biochemical risk factors and CHD. *P.K. Mohanty, S. Kapoor, A.P Dubey, R. Saha, S.K Pandey, S.K Pollipali.* Department of Pediatrics, Maulana Azad Medical College, New delhi, India.

Background:-Down syndrome is a chromosomal disorder due to trisomy 21which is the most common aneuploidy at birth and occurs as a result of nondisjunction in maternal meiosis. Maternal genetic polymorphism of methylene tetrahydrofolate reductase due to low folate, high homocysteine metabolism has been implicated a risk factor.Objective: To evaluate A1298C polymorphism as a risk factor in DS babies and its association with biochemical parameters and congenital heart disease. Methods: Eighty one mothers (mean age 24.9±3.2yrs) with babies having free trisomy 21 of north Indian ethnicity and 99 mothers (mean age 26.9±4.6yrs) who had no children with Down syndrome were evaluated after an informed consent. Fasting blood was collected to determine plasma homocysteine, folate (serum and RBC) and for PCR amplification for MTHFR gene. The MTHFR A1298C polymorphisms were done by allele specific polymerase reaction and enzyme digestion. Homocysteine quantification was done by liquid chromatography-tandem mass spectrometry.Cardiovascular system examination and Echocardiography was done to delineate CHD.Results:The prevalence of A1298C polymorphism with trisomy 21 DS in cases and controls were 66.7% vs. 39.4% respectively. The heterozygous and homozygous genotype frequencies at 1298 (AC and CC) among case and control were (38.3% vs. 22.2% and 28.4% vs. 17.25% respectively, OR= 3.10, 95% CI 1.6-5.79, P= 0.002)Low serum folate in 33.3% % of cases vs.8.0%% in controls (OR= 5.68, CI 95% 2.41-13.4, P= 0.0001).Low RBC folate was found in 28.3% of cases vs. 11.1% in controls,(OR= 3.172, CI 95% 1.43-6.99 P= 0.005).High serum homocysteine was found in 9.8% of cases vs. 2.0% in controls. The median intraquartile range serum homocysteine in cases was 10.2(Q1-Q3, 8.2-12.0) vs. 7.6(Q1-Q3, 5.7-10.1) in controls. No relationship was observed among A1298C polymorphism and CHD(Pvalue=0.601).Conclusion:MTHFR A1298C polymorphism associated with 3 times more risk of developing DS. Low serum, RBC folate and high serum homocysteine are significantly associated with MTHFR polymorphism and therefore the risk of occurrence of DS. Homocysteine levels were higher in DS mothers as compared to controls. Maternal A1298C is associated with an increased incidence of CHD in absolute number. Peri or preconceptional folate supplementation may therefore lead to a decline in DS births and CHD. Key words: Down syndrome, serum and RBC folate, serum homocysteine, MTHFR gene,CHD.

1032W

New mutations in Brazilian patients with overgrowth syndromes. *D. Moretti-Ferreira[1], G.H. Vieira[1], C.E.F. Domingues[1], R.L.L.F. Lima[2].* 1) Genetics, São Paulo State University - UNESP, Botucatu, São Paulo, Brazil; 2) General Biology - Federal University of Bahia - Salvador - Bahia- BRAZIL.

Overgrowth syndromes are a heterogeneous group of disorders resulting from the dysfunction of various processes involving cell proliferation, cell growth or apoptosis. The NSD1 gene (nuclear receptor-SET-domain-containing protein) was isolated by Kurotaki et al. in 2002. Its function are associate with enhances androgen receptor (AR) transactivation. Haplosufficiency of the NSD1 gene has been described as the major cause of both Sotos Syndrome and Weaver Syndrome. NSD1 microdeletions at the 5q35 region have been detected in 10% of the patients with Sotos Syndrome from the United Kingdom, France, Germany and Italy and about 90% of the patients of those countries showed NSD1 gene point mutations while in the japonese population these frequencies are in opposition. In Brazil, Fagali et al in 2009 screened 30 Brazilian patients with a clinical diagnosis of Sotos syndrome using Multiplex ligation-dependent probe amplification (MLPA) and they had been described a total NSD1 deletions and two new partial deletions in three individuals. In this study we screened a cohort of 49 patients with a suggestive diagnosis of overgrowth syndromes and included patients of Sotos Syndrome (21), Weaver Syndrome (6), Bannayan-Zonnana Syndrome (3), Beckwith-Wiedemman Syndrome (3), MOMO syndrome (3) and cases with mental retardation + overgrowth (13). These cases were analyzed using MLPA for the 5q35 region and sequencing of NSD1 gene. We didn't detect deletions in 5q35 region in this cohort. Four different mutations were found (c.1414C>T; c.4779C>T; c.5279delTCTG; c.5950C>T). The mutation c.5950C>T are described previous by Cecconi et al. in 2005, the others mutations are no described. Since NSD1 alterations were not seen in all patients, our study shows that, in addition to the genetic heterogeneity observed in the etiology of SS and SW, ethno-geographical differences in NSD1 alterations are evidenced when patients with SS or SW from Asia, Europe, and North America are compared to South American patients.Finacial support by FAPESP#2005/01880-8.

Clinical and molecular study of a cohort of 28 patients with suspicion of Rothmund-Thomson, Baller-Gerold and RAPADILINO syndrome referred for RECQL4 analysis. *J. Piard[1, 2], M. Holder[3], C. Baumann[4], G. Baujat[5], L. Martorell[6], F. Boralevi[7], N. Philip[8], B. Aral[9, 2], N. Gigot[9, 2], P. Callier[2, 10], M. Payet[10], C. Ragon[10], L. Van Maldergem[1], P. Vabres[2, 11], L. Faivre[2, 12], C. Thauvin-Robinet[2, 7].* 1) Centre de Génétique Humaine, CHU Besançon, France; 2) Equipe émergente GAD (Génétique des Anomalies du Développement), IFR Santé - STIC, Université de Bourgogne, Dijon, France; 3) Service de Génétique, CHU Lille, France; 4) Service de Génétique, Hôpital Robert-Debré, APHP Paris, France; 5) Service de Génétique, Hôpital Necker, APHP Paris, France; 6) Service de Génétique, CHU Sant Joan de Déu, Espagne; 7) Service de Dermatologie, CHU Bordeaux, France; 8) Service de Génétique, CHU Marseille, France; 9) Service de Génétique Moléculaire, Plateau technique de Biologie, CHU Dijon, France; 10) Service de Cytogénétique, Plateau technique de Biologie, CHU Dijon, France; 11) Service de Dermatologie, CHU Dijon, France; 12) Centre de Référence Maladies Rares (Anomalies du Développement et Syndromes Malformatifs) de la région Grand Est, Centre de Génétique, Hôpital d'Enfants, CHU Dijon, France.

Three autosomal recessive overlapping conditions have been attributed to RECQL4 mutations: Rothmund-Thomson syndrome (RTS), Baller-Gerold syndrome (BGS) and RAPADILINO syndrome. RTS is characterized by congenital poikiloderma associated with extracutaneous symptoms such as juvenile cataract, short stature, dysplastic hair and nails, skeletal anomalies, radial ray defects, gastrointestinal problems, premature aging and an increased risk for osteosarcoma. The association of craniosynostosis and radial ray hypoplasia characterizes BGS and the acronym RAPADILINO refers to the association of radial ray defect, patella hypoplasia and cleft or arched palate, diarrhea and dislocated joints, little size and limb malformation, nose slender and normal intelligence. Differential diagnoses of RTS include Clericuzio-type Poikiloderma with Neutropenia (CPN) due to mutations in the C16orf57 gene. We report here on the clinical and molecular data in a series of 28 patients referred to the laboratory for ReCQL4 analysis with a clinical suspicion of RTS (17 patients), BGS (10 patients) or RAPADILINO syndrome (1 patient). One or two deleterious ReCQL4 mutations were found in 7 patients with RTS and 1 patient with BGS. Clinical features between positive and negative ReCQL4 patients are discussed. Sequencing of the C16orf57 gene was performed in 10 patients with poikilodermia. Two C16orf57 heterozygous nonsense mutations (p.W81X/p.Y89X) were identified in a 5-year-old female child presenting with generalized poikiloderma, dental dysplasia, gingivitis, nail dystrophy, palmoplantar keratoderma and pachyonychia of the first toenails. Previously undetected and silent neutropenia was evidenced after the molecular analysis. This result allows us to confirm that neutrophil count should be performed in all patients with poikiloderma to target the C16orf57 gene sequencing analysis, prior to RECQL4 analysis. Array-CGH did not identity any genomic rearrangements in 8 patients with poikiloderma, and is currently in progress in the rest of the series.

1034W

Variable features of dominantly inherited Cornelia deLange syndrome (CdLS). *M.E. Pierpont[1,2], B. Hall[1,3], R. Temme[1].* 1) Dept Gen, Children's Hospital of Minnesota, St Paul, MN; 2) Dept Pediatrics, University of Minnesota, Minneapolis MN; 3) Minnesota Perinatal, United Hospital, St Paul, MN.

CdLS is characterized by typical facial features, hirsutism, small hands/feet, limb reduction anomalies, cardiac defects and growth/cognitive delays. CdLS is genetically heterogenous, caused by mutations in the NIPBL gene on chromosome 5p13 or by mutations of SMC1A on the X chromosome. We report here a family with CdLS caused by an NIPBL mutation in a father and his 5 offspring. The first child, a female has IUGR, feeding difficulties and clinical findings of CdLS. Physical exam reveals microcephaly, synophrys, arched eyebrows, long flat philtrum, downturned mouth with thin lips, high palate, micrognathia, upturned nose, thick lowset ears, bilateral clinodactyly/ syndactyly with small hands/feet. This child also had severe reflux requiring a gastrostomy tube. The father has microcephaly, synophrys, arched eyebrows, short stature, hirsutism, small hands/feet and moderate learning disability. The next child, a male full sibling, has similar facial/physical features, but also had a VSD and severe myopia. The third child, a female paternal half sibling, has similar facial features, growth retardation, bilateral peripheral pulmonary artery stenosis and persistent 5th aortic arch. She also has bilateral hearing loss requiring aids. The fourth child of this father, a female half sib, has IUGR, characteristic facial/physical findings, mild peripheral pulmonary artery narrowing and small kidneys with pelviectasis. The next half sibling, a female, has facial features of CdLS, IUGR, and unilateral oligodactyly of the right hand with single digit and short forearm. The remaining extremities are small with syndactyly of 2nd- 3rd toes on right foot. All 5 offspring have varying degrees of developmental delay. Other familial cases of CdLS with dominant inheritance have been described in the literature. This is the first known family of 5 children with CdLS from the same affected father, and significant intrafamilial variability in CdLS is demonstrated.

1035W

LEOPARD syndrome in Finland. *M. Poyhonen[1,2], K. Avela[3], J.S. Moilanen[4], O. Saksela[5], S-L. Sallinen[6], M-L. Vaisanen[7], S. Kivirikko[2].* 1) Dept Med Gen, Univ Helsinki, Helsinki, Finland; 2) Dept Clin Gen, HUSLAB, Helsinki Univ Hospital, Helsinki, Finland; 3) Vaestoliitto, The Family Federation of Finland, Dept of Med Gen, Helsinki, Finland; 4) Dept of Clin Gen, Oulu Univ Hospital and Univ of Oulu, Oulu, Finland; 5) Dept of Dermatology, Helsinki Univ Central Hospital (HUCH), Helsinki, Finland; 6) Dept of Dermatology Tampere Univ Hospital, Tampere, Finland; 7) Dept of Clinical Chemistry, Oulu Univ Hospital and Univ of Oulu, Oulu, Finland.

LEOPARD syndrome (multiple **L**entigines, **E**lectrocardiographic conduction abnormalities, **O**cular hypertelorism, **P**ulmonary stenosis, **A**bnormal genitalia, **R**etardation of growth, and sensorineural **D**eafness) [MIM 151100] is a Noonan-like syndrome caused by mutations in *PTPN11*, *RAF1*, and *BRAF* genes. Mutations in exons 7, 12, and 13 of *PTPN11* gene account for 90% of LEOPARD syndrome. We describe two sporadic patients and one two-generation family with LEOPARD syndrome. The first patient was the second child of healthy, non-consanguineous Caucasian parents. He was born at full term and his birth measurements were 3640 g/ 50 cm/ 34,5 cm. A VSD and hypertrophic cardiomyopathy were diagnosed after birth. The patient had hypotonia and a delay in psychomotoral development. He was initially referred to a clinical geneticist at the age of 11 years for evaluation of suspected neurofibromatosis type 1 (NF1). On examination he had Noonan-like facial features, 5 CALM over 1 cm in diameter and freckling in axillary and inguinal area, no neurofibromas, and no iris Lisch nodules. His length was -1.4 SD, BMI 18.9, and OFC -1.9 SD. *PTPN11* gene mutation analysis revealed c.1528C>G (p.Gln510Glu) mutation in exon 13. The second patient was referred to a clinical geneticist at the age of 8 years for evaluation because of several CALM and lentigines. *PTPN11* gene mutation analysis revealed c.1403C>T (p.Thr468Met) mutation in exon 12. In the two-generation family both mother and daughter had hypertrophic cardiomyopathy, prominent lentigines, short stature (-3SD in the mother) and hypertelorism. *PTPN11* gene mutation analysis re-vealed the same p.Gln510Glu mutation in exon 13 as in patient one. The families are not related to each other. According to our knowledge these are the first Finnish patients with LEOPARD syndrome.

1036W

Orofacial phenotype of van der Woude and Poplyteal Pterygium Syndrome patients with IRF6 mutations. *M. Quentric[1,2], A. Petraud[3], M. Legendre[4], M. Ghassibé[1], L. Desmyter[1], I. Jéru[4], S. Marlain[4], M. Gonzales[5], S. Amselem[4], M.P. Vazquez[2,3], A. Berdal[2], M. Vikkula[1], A. Picard[2,3].* 1) Laboratory of Human Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Laboratoire de Physiopathologie Orale Moleculaire, Centre de Recherche des Cordeliers, Université Pierre et Marie Curie-Paris 6, INSERM, UMRS 872, Paris Cedex06, France; 3) AP-HP, Hôpital d'enfants Armand-Trousseau, Service de Chirurgie Maxillo-Faciale et Chirurgie Plastique, Paris, F-75012, France; Université Pierre et Marie Curie-Paris 6, UFR de Médecine Pierre et Marie Curie, Paris, F-75005, France; 4) Institut National de Santé et de Recherche Médicale (INSERM) U.933, Université Pierre et Marie Curie-Paris 6 and Assistance Publique-Hôpitaux de Paris, Hôpital Armand-Trousseau, 75571 Paris cedex 12, France; 5) AP-HP, Hôpital d'enfants Armand-Trousseau, Unité de Génétique du Développement Embryo-Foetal, Paris, F-75012, France.

Van der Woude syndrome (VWS, OMIM #119300) is a dominantly inherited developmental disorder characterized by pits and/or conical elevations of the lower lip, cleft lip and/or palate, and hypodontia. Popliteal pterygium syndrome (PPS, OMIM #119500) shares the clinical features of VWS, with the addition of other signs such as popliteal webs (pterygia), synechiae connecting the upper and lower jaws, ankyloblepharon, syndactyly and genital anomalies. Since many signs occur in the orofacial region and the penetrance is incomplete, it is of great interest to better characterize VWS/ PPS patients to see if an oral phenotype-genotype correlation exists. For this, nineteen families (17 VWS + 2 PPS) from Trousseau hospital (Paris) were seen by a multidisciplinary staff, focusing on the orofacial phenotype. Panoramic imaging were used to check for dental agenesis. The coding exons of the IRF6 gene, including intron-exon boundaries, were sequenced, and Multiplex Ligation-dependent Probe Amplification was performed to test for intragenic deletions or amplifications. We identified a mutation in IRF6 in 82% (14/17) of VWS and 100% (2/2) of PPS families. Affected individuals had clefts (79%), lower lip pits (78%), dental agenesis (72%), and abnormal dental morphology (60%). The upper lateral incisors and the second upper premolars were the most affected. This prospective study demonstrates the high frequency of dental anomalies in VWS/PPS patients, affecting mostly the upper lateral incisors and the second upper permanent premolars. This may be a useful clinical clue for correct diagnosis, as lips pits are not always present.

1037W

Chromosome 19p13.3 Deletion in a Child with Peutz-Jeghers Syndrome, Congenital Heart Defect, High Myopia, Learning Difficulties and Dysmorphic Features: Clinical and Molecular Characterization of a New Contiguous Gene Syndrome. *S. RASKIN[1], F. Faucz[1], V. Sotomaior[1], AF. Bonalumi[1], J. Rosenfeld[2], J. Souza[1].* 1) Group for Advanced Molecular Investigation (NIMA), Graduate Program in Health Sciences (PPGCS), Center for Biological and Health Sciences (CCBS), Pontificia Universidade Catolica do Parana, Parana, Brazil; 2) Signature Genomics, Spokane, Washington, USA.

Peutz-Jeghers syndrome (PJS) is an autosomal-dominant hamartomatous polyposis syndrome characterized by mucocutaneous pigmentation, gastrointestinal polyps and increased risk of multiple cancers. The majority of patients have a causative mutation in the STK11 gene, whereas partial and complete gene deletions account for about 30% of the cases. We report a girl with features of PJS, learning difficulties, dysmorphic features and cardiac malformation, with a 19p13.3 deletion. The deletion size and location was defined using an oligonucleotide-based whole-genome microarray. The patient has a novel, apparently de novo, 1.1 Mb deletion at 19p13.3. The deleted area encompasses at least 47 genes, including the STK11 gene responsible for PJS. This patient is the first report of a 19p13.3 deletion detected by array CGH who exhibits features of PJS and other minor and major malformations, suggesting a new contiguous gene syndrome.

The importance of genetic and congenital factors which causes many diseases and disabilities is obvious over the world. In Iran prevention of genetic disabilities program has been planned with the aim of implementation of a genetic counseling network. For implementing this program The network has gradually expanded since the year 1997. Now we have 169 genetic counseling centers throughout the country. One of the chief complaints of clients of these centers has been the history of Hearing Impairment. In this study we have gathered the data from 1999 until 2009 about Hearing Impairment in our provincial referral centers in the genetic counseling network. The total number of files having deafness history in pedigrees among 118786 files are 6521(5.5%).The total number of files having deafness history in each of spouses is 960(14.7%), in both spouses is 625(9.6%), in the offsprings is 1460(22.4%), in one offspring is 957(14.7%)& in two or more offsprings is 503(7.7%). The total number of files which are positive for Connexin 26 is 168(2.58%), Connexin 26 & 30 is 8(0.12%), other nonsyndromic AR genes is 7(0.11%), other syndromic AR genes is 26(0.4%), nonsyndromic AD genes is 1(0.015%) and syndromic AD genes is 5(0.08). The total number of Deaf people is 9825 : 5313(54%) males and 4512(46%) females. The number of different types of consanguinity between Deaf people's parents are: double cousins: 87(1.33%), first cousins: 2803(42.98%), first cousins once removed: 310(4.75%), second cousins:720(11.04)& nonconsanguineous: 2839(43.54%). The total number of different modes of inheritance in the pedigrees of clients with Hearing Impairment chief complaint are: environmental factors: 87(1.33%), nonsyndromic AR: 2961(45.41%), syndromic AR: 269(4.13%), nonsyndromic AD:400(6.13%), syndromic AD: 70(1.07%), nonsyndromic X-linked: 32(0.49%), syndromic X-linked: 9(0.14%), mitochondrial: 3(0.05%) & unknown causes: 1171 (17.96%).

1039W

DFNB49 is an important cause of non-syndromic deafness in Czech Gypsy patients but not in the general Czech population. *D. Brožková[1], J. Laštůvková[2], H. Štěpánková[3], M. Krůtová[1], M. Trková[4], P. Seeman[1].* 1) DNA laboratory, Department of Child neurology, Charles University, Prague, Czech Republic; 2) Department of Medical Genetics, Masaryk Hospital, Regional Health Corporation, Ústí nad Labem, Czech Republic; 3) Department of Clinical Genetics, Hospital České Budějovice, České Budějovice, Czech Republic; 4) Centre for Medical Genetics and Reproductive Medicine GENNET, Prague, Czech Republic.

Non-syndromic hearing loss is genetically extremely heterogenous, but in vast majority of cases follows autosomal recessive (AR) inheritance. Mutations in the GJB2 gene are the most common cause of AR non-syndromic hearing loss named as DFNB. The Gypsies have due to their known endogamy a higher risk for autosomal recessive disorders. In most recessive disorders Gypsy patients are homozygous for causal mutations. We used homozygosity mapping in a Czech Gypsy family with a deaf child and a known consanquinity of parents where mutations in the GJB2 gene were previously excluded. The genomic DNA samples from the family were hybridized on the Affymetrix GeneChip Human Mapping 250K NspI arrays. Data were analysed in the Affymetrix software - Genotyping Console. We searched for homozygous segments in the affected patient which were heterozygous in the parents. The 20 homozygous regions of 2Mb size or larger were found in the patient and compared to known loci or genes connected with the non-syndomic hearing loss (DFNB loci). The second largest homozygous region mapped to previously reported DFNB49 region, with the Marveld2 gene. Sequencing of all 6 coding exons and flanking intron parts of Marveld2 gene revealed the splice site mutation c.1331+2 T>C (IVS 4+2 T>C). This mutation was found in the homozygous state only in the patient, the parents and patient's sister were heterozygous. Testing of further 19 Czech apparently unrelated Gypsy deaf patients without GJB2 mutations revealed the same mutation in further two Gypsy patients, showing that DFNB49, namely the IVS 4+2 T>C Marveld2 mutation is probably an important cause of deafness in gypsy population. The same mutation IVS 4+2 T>C in the Marveld2 gene was previously described in six Pakistani families with nonsyndromic hearing loss.Further testing of 40 deaf non-Gypsy patients without GJB2 mutation did not revealed any Marveld2 mutation, showing that DFNB49 is rare cause of deafness in general Czech -Slavic population. Homozygosity mapping using SNP chips followed by sequencing of candidate genes within the largest homozygous intervals proved to be a powerful tool for finding causal mutations in Gypsy families with autosomal recessive disorders. Our results show that the mutations in the Marveld2 gene are important cause of non-syndromic hearing loss in Czech Gypsies and similar may apply for Gypsies also in other countries. Supported by GAUK 309 and IGA MH CZ 10552-3.

Recurrent children with TRPS I due to germline or low grade somatic mosaicism in healthy mothers. *H.J. Luedecke[1], S. Gkalympoudis[1], M. Heitmann[1], M. Krajewska-Walasek[2].* 1) Human Genetics, University Clinic, Essen, Germany; 2) The Children's Memorial Health Institute, Warszawa, Poland.

The tricho-rhino-phalangeal syndrome type I (TRPS I) is a dominantly inherited syndrome with craniofacial and skeletal anomalies. It is caused by deletion or mutation of the *TRPS1* gene on 8q23.3. Here, we present the first two families with multiple children with TRPS I born to apparently healthy parents. Especially, the characteristic facial features and anomalies of the hand skeleton were absent in all four parents. Family 1 has three healthy children and three children affected with TRPS I. Family 2 has one healthy daughter and three affected children, two of which are identical twins. Initial mutation and deletion screening was done on DNA isolated from leukocytes. All affected members of family 1were found to have an intragenic deletion comprising exons 2-5 of the TRPS1 gene. This generates an abnormal transcript with exon 1 spliced to exon 6, coding for a supposedly non-functional protein because the 887 N-terminal aa are replaced by 22 novel aa. Interestingly, the dosage for the seven MLPA probes (Kit P228, MRC Holland) for exons 2-5 appeared slightly reduced in the mother's DNA from leukocytes. Segregation analyses with polymorphic markers from the *TRPS1* region revealed that all affected children inherited the same maternal haplotype whereas the healthy children inherited the other. This suggested that the deletion is of maternal origin, and that the mother is a somatic mosaic. Dosage analyses with markers from the deletion region confirmed presence of the deletion in approx. 30 % of leukocytes and 9 % of fibroblasts of the mother. All affected members of family 2 are heterozygous for a c.1831C>T substitution in exon 4 that generates a premature translation stop codon (p.Arg611X). Again, the segregation analysis suggested maternal origin of the familial mutation. However, the point mutation could not be detected in DNA from the mother's leukocytes and fibroblasts. This indicates that the mother either has a germline mosaicism for the mutation or that the fraction of cells carrying the mutation in the analyzed tissues is below the detection threshold of sequence analysis. Although the reports of patients with TRPS II and mosaic deletions suggested that the normal function of the TRPS1 protein is extremely dosage sensitive, our results show that a low grade of somatic mosaicism is compatible with a normal phenotype. This should be considered when counseling healthy parents of patients regarding the recurrence risk for TRPS I.

GENECA: a French regional network for multidisciplinary management of patients at risk of inherited cancers. *C.M. Maugard[1,2,3,4,5], D. Lejri[1,3,6], M. Voltzenlogel[1,3,6], A.-L. Wetzel[1,3], L. Gilleron[1,6], L. Haar[1,3,6], M. Langeois[1,6], H. Nehme-Schuster[6], J.M. Limacher[3], J.-P. Fricker[6], C. Cordier[1,3,6].* 1) Unité d'Oncogénétique, Service d'Hémato-oncologie, Hôpitaux Universitaires de Strasbourg, Strasbourg France; 2) Laboratoire de diagnostic génétique, Nouvel Hôpital Civil, Hôpitaux Universitaires de Strasbourg, Strasbourg, France; 3) Unité d'Oncogénétique, Service d' Hémato-oncologie, Hôpital Pasteur, Colmar, France; 4) Département de Médecine, Université de Montréal, Montréal (QC), Canada; 5) CR-CHUM, Montréal (QC), Canada; 6) Unité d'Oncogénétique, CRLCC Paul Strauss, Strasbourg, France.

Recently, the French national cancer institute (INCa) launched an extramural program, the main goal of which was to integrate, facilitate and improve global risk management for patients at very high risk of cancers, based on their family history and/or genetic testing result. Seven pilot experiments were supported in five different geographic areas of France and received the following mandates: (1) to offer an individualized cancer screening and preventive recommendations program to patients at high risk of cancer, based on their familial and individual medical history using the latest knowledge in the field, (2) to coordinate the introduction of the new screening and preventive option procedures in the province, (3) to insure access to multidisciplinary services, since patients should be offered adequate screening strategies, and all necessary information and psychological support for prophylactic surgery when indicated, (4) to offer specialized expertise when difficult cases have to be discussed. Our pilot experiment takes place in Alsace province (Eastern part of France). First of all, with the support of the INCa grant, we created a regional network, which was named GENECA for «Genetic of Cancer in Alsace». Our network links three familial cancer clinics located in different hospitals with a total annual turnover of around 1100 consultations per year. Between June 2010 and January 2011, we recruited a core team dedicated to these new missions consisting of a genetic counsellor, an assistant-coordinator, two research assistants, and two psychologists coordinated by a medical geneticist. Since October 2010, individuals at high risk of cancer are invited to participate prospectively in the program. Our efforts are currently directed towards carriers of a *BRCA1* or *BRCA2* or a *MMR* (mismatch repair) gene mutation, as well as members of familial cancer aggregation at high risk of breast, ovarian, colonic or endometrial cancers as computed with Boadicea, BRCAPro and/or PREMM models of genetic susceptibility. We will show the information and tracing notebook and the personalized follow-up agenda we have developed to inform patients of the more recent national recommendations to be applied for follow-up of at risk patients. Finally, we will present new tools under development to coordinate the management of this program and assess the compliance of each participant as well as medical community's one to the national recommendations.

***BRCA1/2* testing, genetic counseling referral, risk knowledge, and use of guidelines among US primary care clinicians, 2010.** *C. Bellcross[1], K. Kolor[2], M.J. Khoury[2].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA.

Purpose: *BRCA1* and *BRCA2* (BRCA) testing for hereditary breast/ovarian cancer susceptibility has been available since 1996, though few recent studies have evaluated applications in primary care. The purpose of this study was to examine BRCA ordering and genetic counseling referral patterns, use of referral/testing guidelines and ability to identify high/low risk patients among primary care clinicians in the United States. **Methods:** Data from the 2010 DocStyles national survey (1504 respondents, 49% response rate) were used to assess parameters related to BRCA testing among 539 family practitioners (FP), 461 internists, 250 obstetricians/gynecologists (Ob-Gyn) and 254 nurse practitioners (NP). **Results:** Almost all clinicians (1484) were aware of BRCA testing. Many (64%) had referred a patient for BRCA genetic counseling in the last year, and 19% had referred 5 or more. Almost half (45%) had ordered a BRCA test in the last year, and 73% indicated they referred these patients for genetic counseling all or most of the time. When asked which of four clinical scenarios implied the highest likelihood for a healthy 30-year-old woman to carry a BRCA mutation, 59% correctly chose “a first-degree relative with a known *BRCA1/2* mutation”, with age less than 41 ($p=0.001$) the only predictor of a correct response in multiple logistic regression analysis. Predictors of correctly identifying the lowest risk scenario (88%) included practice specialty of Ob-Gyn or NP and female gender ($p\leq0.001$). Practice specialty and gender were similarly predictive of having referred 5 or more patients for genetic counseling in the last year, as was patient SES in the mid-upper range ($p\leq0.02$). The same practice specialties and high patient SES were also associated ($p<0.001$) with having ordered BRCA testing for 5 or more patients in the last year. Among clinicians (1202) who either referred or ordered testing, 80% used one or more guidelines, most commonly ACOG (39%), USPSTF (30%) and NCCN (20%). **Conclusions:** Compared to a related DocStyles survey we conducted in 2007, there was a significant increase in ordering BRCA testing among primary care clinicians (45% vs. 30%, $\chi2$ $p<0.0001$). In addition, it appears that clinicians are utilizing available guidelines and frequently referring patients for genetic counseling. Further study of clinician knowledge regarding patient risk status may be warranted along with efforts to increase access to services for low SES patients.

1043W

Germline *PTEN* and *SDHx* mutations and *KLLN* epimutation and thyroid cancer incidence and phenotypic characteristics in prospective series of individuals with Cowden and Cowden-like syndromes. *J. NGEOW[1,2], J. Mester[1,2,5], L. Rybicki[2,3,4], Y. Ni[1,2], K. Milas[5], C. Eng[1,2,3,5].* 1) Genomic Medicine Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 2) Lerner Research Institute, Cleveland Clinic, Cleveland, Ohio 44195,USA; 3) Taussig Cancer Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA; 4) Department of Quantitative Health Sciences, Cleveland Clinic, Cleveland, Ohio 44195, USA; 5) Thyroid Cancer Center, Endocrinology and Metabolism Institute, Cleveland Clinic, Cleveland, Ohio 44195, USA.

Thyroid cancer is an important component of Cowden Syndrome (CS) and is the fastest rising incident cancer in women in the US. The only population-based clinical epidemiologic study suggested that 2/3 of CS patients have benign thyroid disease and 10% malignant thyroid neoplasias. However, systematic study of thyroid neoplasms from a prospectively accrued series of individuals with CS and CS-like features has never been performed. Germline *PTEN* and *SDHx* mutations, and *KLLN* epimutation cause CS and CS-like phenotypes. Thus, we sought to compare the incidence of and clinical characteristics of epithelial thyroid cancers in a large prospectively accrued series of CS/CS-like individuals, in the context of PTEN, SDHx and KLLN status. All probands had comprehensive *PTEN* analysis; *SDHx* mutation analysis occurred in those without *PTEN* mutations/variations and elevated MnSOD; *KLLN* epimutation analysis was performed in the subset without any *PTEN* or *SDHx* mutation/deletion/variant/polymorphism. Gene-specific thyroid cancer histologies, demographic and clinical information and adjusted standardized incidence ratios (SIR) were analyzed. Of 2723 CS/CS-like patients, 664 had thyroid cancer. *PTEN* pathogenic mutations were seen in 36 (5.4%) patients. SIRs for thyroid cancer were 72 (95%CI51-99, $p<0.001$) for pathogenic *PTEN* mutations, 63 (42-92, $p<0.001$) for *SDHx* variants and 45 (26-73, $p<0.001$) for *KLLN* epimutations. Men with *PTEN* pathogenic mutations had a higher risk for thyroid cancers (SIR183) as compared to women (SIR57). Interestingly, all 6 (16.7%) cases diagnosed under aged 18yr carried pathogenic *PTEN* mutations. Follicular thyroid cancer (FTC) was over-represented in *PTEN* mutation positive cases compared to those with *SDHx* and *KLLN* alterations. *PTEN* frameshift mutations were more common in individuals with thyroid cancer (31%) than those without thyroid cancer (17%). We saw an over-representation of *PTEN* mutations in exon 4 ($p=0.05$) and in the promoter ($p=0.03$) in individuals with thyroid cancer compared to those with thyroid cancer but without mutations. Our data show that CS/CS-like patients have elevated sex-specific risks of FTC with earlier onset (median 37yr) due to *PTEN* pathogenic mutations and of PTC with later onset (median 52yr) from *SDHx* and *KLLN* alterations. Clinicians should consider evaluating all children presenting with thyroid cancer for *PTEN* mutation. Current surveillance guidelines for thyroid cancer in CS patients may miss pediatric cases.

1044W

MTHFR gene polymorphisms and their association with isolated cleft lip palate in Mexican children. *A. Gonzalez-del Angel[1], B. Estandía Ortega[1], J. Velázquez Aragón[1], MA. Alcántara Ortigoza[1], M. Reyna Fabian[1], C. Sabas Cruz Fuentes[3], M. Diaz Morales[1], S. Villagómez Martínez[2].* 1) Laboratorio Biología Molecular, Instituto Nacional de Pediatría, Mexico City DF, Mexico; 2) Unidad de Apoyo a la Investigación Clínica,Instituto Nacional de Pediatría; 3) Departamento de Genética, Instituto Nacional de Psiquiatría.

In Mexico, the incidence of CLP is 1.1 per 1000 live births. Many reports support a protective effect of folic acid (FA) intake during pregnancy on the risk for CLP. Also several studies have analyzed the association of MTHFR polymorphisms and CLP; in most of them, c.677C>T and c.1298A>C in both mothers and children were not associated with CLP. However, few studies support the association between the presence of the MTHFR polymorphisms and CLP. The aim of our work was to identify if there is an association between the presence of MTHFR c.677C>T and c.1298A>C with CLP and if FA supplement intake has a protective effect on the risk of CLP. A case-control study was carried out with 132 patients with CLP and 269 controls, all were from Mexico City between 0-18 years old. Mothers answered a questionnaire about FA supplement consumption before and during pregnancy. PCR-RFLP assay was used to detect polymorphisms c.677C>T and c.1298A>C in MTHFR gene. Results: The average age was 5.7 years in the children with CLP and 1.27 years in the healthy group. 46.5% mothers of the CLP group used a FA supplement compared with mothers of the control group (74.5%). Mothers who consumed a FA supplement had a lower risk of delivering a CLP child compared with mothers who did not use FA (OR 0.29, 0.19-0.44 p< 0.0001). Frequency of the 677T allele was higher in control infants (0.62) than in CLP cases (0.51), the frequency of the 1298C allele was similar among both groups (0.17 vs. 0.14). Subjects who carried the MTHFR 677TT genotype showed a lower risk for CLP (OR 0.39, CI 95%: 0.23-0.68, p: 0.00076) compared with those who carried the genotype 677CT OR 0.46, CI 95%: 0.27-0.77, p: 0.00293). When mothers consume FA supplement in combination with the presence of 677CT or 677TT genotypes in the children the OR observed was 0.32 (0.19-0.51, p <0.0001). We did not see an association of CLP with c.1298A>C polymorphism. Analysis of 10 ancestry informative markers did not reveal population stratification in case and control groups. In our study, although a small number of mothers consumed a FA supplement, we observed as described before, a lower risk for CLP with folic acid supplement intake during pregnancy. The only report performed in Mexican subjects did not demonstrated an association between MTHFR polymorphisms and CLP, however our results suggest that MTHFR 677TT genotype conditioned a lower risk for CLP, as mentioned before in few studies in the literature.

1045W

Homozygosity Mapping to Guide Clinical Molecular Testing in Consanguineous Families: A Pilot Study. *R.E. Lamont, I. Gjata, C. Beaulieu, R. Casey, R. Ferrier, R.B. Lowry, D.R. McLeod, A.M. Innes, F. Bernier, J. Parboosingh.* Alberta Children's Hospital, Calgary, AB, Canada.

Within the diagnostic setting, genetically heterogeneous disorders pose a distinct challenge requiring prioritization of multiple candidate genes for mutational analysis. If these disorders are identified in consanguineous families the likelihood of an autosomal recessive condition due to homozygosity for a causative mutation inherited from a common ancestor increases significantly. An approach that identifies regions of genomic material that are identical by descent in affected individuals can be used to narrow the number of candidate genes requiring sequencing. Thus, we sought to determine the clinical utility of using identity by descent mapping by SNP microarray to direct mutation screening in consanguineous families with heterogeneous presumably autosomal recessive disorders. To date, we have identified a probable pathogenic mutation in a family with a single affected individual with congenital muscular dystrophy, where commercial sequencing identified a P303L variant in POMGNT1, a known congenital muscular dystrophy gene. We have also identified a causative mutation in a family with mitochondrial complex I deficiency, where a homozygous frameshift mutation in NDUFS4 was identified in three affected individuals. Lastly, we have identified a likely mutation responsible for non-syndromic hearing loss in an extended pedigree where the entire first coding exon of TMC1, a previously identified non-syndromic hearing loss gene, has undergone a complex rearrangement. Here we present the approach to screening used in these families, additional disorders currently being investigated using this technique and a cost-benefit analysis of utilizing this method were it to be taken up in routine clinical testing.

Australian relatives' experiences of communicating genetic information following the unexpected death of a family member due to an inherited cardiac condition. *J. Hodgson[1, 2], L. Gallacher[1,2], N. Morgan[3], I. Macciocca[4], S. Metcalfe[1,2].* 1) Genetics Education and Health Research, MCRI, Royal Children's Hospital, Melbourne, Victoria, Australia; 2) Department of Paediatrics University of Melbourne, Victoria, Australia; 3) Genetic Health Services Victoria, Royal Children's Hospital, Melbourne, Victoria, Australia; 4) Victorian Institute of Forensic Medicine, Kavanagh St, Southbank, Victoria, Australia.

The sudden death of a relative is a traumatic event that is likely to disrupt the equilibrium in a family. The genetic implications of sudden death, particularly when it raises the possibility of a cardiac genetic condition in the family, are increasingly being recognised and clinical screening of relatives is being recommended with the autopsy findings. In Victoria, Australia the senior next of kin of the deceased is usually contacted and informed of these familial implications. However the communication of genetic information in families can often be a difficult process, even when a death has not occurred. This research aimed to explore the experiences of family members, where the death of a relative raised the possibility of a genetic condition within the family. Participants discussed the processes of hearing about the death, the legal and medical findings, how familial health implications are shared with surviving relatives, and available supports. Seventeen relatives of individuals who died suddenly between the years 2004-2009 were interviewed in-depth. Interviews were audio-recorded and qualitative thematic analysis was conducted on transcripts. A number of important themes emerged. Participants described in detail how the shock and grief associated with the loss impacted on their ability to process complex information at the time. They expressed frustration with the lengthy forensic and genetic investigations, and explained the struggle to make meaning of their loss when a cause of death or specific diagnosis could not be made. While there was confusion surrounding the multiple processes and roles of different health professionals following the death, individuals were highly appreciative when appropriate care was provided. Participants lamented that the opportunity to be forewarned had not been available for the deceased, and this subsequently provided strong motivation for individuals to disseminate relevant health information within the family. These findings highlight the importance of collaboration between forensic and genetic services to provide streamlined care and facilitate communication among at-risk relatives.

HAPLOTYPE FREQUENCIES LINKED TO S HEMOGLOBIN IN PATIENTS WITH SICKLE CELL ANEMIA AND SICKLE TRAIT IN THE ATLANTIC AND THE PACIFIC COLOMBIAN COAST. *G. Barreto Rodriguez, M. Lizarralde Iragorri, C. Fong Reales.* Universidad del valle, Cali-Colombia, Colombia.

Sickle cell anemia, a monogenic disorder caused by homozygosity for a single) -globin gene (HBB) mutation (HbS;) 6 GAG→GTG; Glu→Val; glu6-val), has a high incidence in afro-descendant people. It's characterized by a deformation in the red blood cells, generating vaso-occlusions that may result from very mild to very severe symptoms. This condition has being associated with five haplotypes (Bantu, Benin, Senegal, and Cameroon Arab-Indian) which have been linked with the severity of sickle cell anemia , also, these haplotypes linked to the HbS can establish the origin of an individual depending of the haplotype, because they are specific to certain areas of Africa. With the objective to establish and compare the frequencies of the haplotypes linked to the HbS in patients with sickle cell anemia and sickle trait between the Colombian population of the Pacific Coast and the Atlantic Coast we studied 60 individuals from the Atlantic Coast (15 from Monteria, Córdoba, and 45 from Cartagena, Bolivar), and 26 from the Pacific Coast (15 from Buenaventura, 11 from Cali; Valle del Cauca). With relation to Atlantic Coast 53.3% from the studied individuals were homozygous and 46.7% heterozygous for the mutation that causes HbS while for Pacific Coast these values were 38.5% and 61.5% respectively. The observed frequencies of haplotypes associated with HbS for Atlantic Coast (N=92 chromosomes) were: 31.5% Benin, 30.6% Atypical (-++- 16.3% and -+--14.3%), 13.0% Bantu, 9.8% Senegal, 2.1% Arab-Indian and 1.1% Cameroon. In the Pacific Coast (N= 36 chromosomes) the Benin haplotype was the most frequent with 75%, then was the Bantu 14%, Senegal 3%, and in low raises the atypical ones (9%). These results show the Benin haplotype has the high frequency in the patients studied from both coasts (although more frequent in the Atlantic Coast by a 2.3 factor) and permit to infer that the slaves brought to each of the coasts, came from the same locations, the Gulf of Guinea. Atypical haplotypes present on the Atlantic Coast can be explained by recombinations between chromosome) S, either with a common haplotype) S or a less common haplotype associated with a) A chromosome, or mutations in the) -globin gene cluster. The high frequency of the atypical haplotypes may be caused by high levels of inbreeding.

Kulkarni[17].* 1) Centers for Disease Control and Prevention, Atlanta, GA; 2) Fullerton Genetics, Asheville NC; 3) Coriell Institute for Medical Research, Camden NJ; 4) Baylor College of Medicine, Houston TX; 5) Children's Hospital of Philadelphia, Philadelphia PA; 6) Nationwide Children's Hospital, Columbus OH; 7) Children's Memorial Hospital, Chicago IL; 8) Columbia University, New York NY; 9) Brigham and Women's Hospital and Harvard Medical School, Boston MA; 10) Roche Nimblegen, Madison WI; 11) Affymetrix, Santa Clara CA; 12) Agilent, Santa Clara CA; 13) ARUP Laboratories, Salt Lake City UT; 14) Hospital for Sick Kids, Toronto Canada; 15) Illumina, San Diego CA; 16) Medical University of South Carolina, Charleston, SC; 17) Washington University, St. Louis MO.

Chromosomal microarray analysis (CMA) is used to detect chromosomal variations throughout the human genome. Although this technology has become the standard of care, there are no commercially available, well-characterized genomic DNA reference materials (RM) for this technology. RMs are required for assay development and validation, quality control, and proficiency testing. To address this need, the CDC's Genetic Testing Reference Materials Coordination Program (GeT-RM), is collaborating with clinical cytogenetics experts, microarray manufacturers, and the National Institute of General Medical Sciences (NIGMS) Human Genetic Cell Repository (HGCR) at the Coriell Institute for Medical Research to develop genomic DNA RMs for CMA. The NIGHS HGCR includes hundreds of cell lines with chromosomal abnormalities. Many of these samples have been karyotyped or analyzed by fluorescence in situ hybridization (FISH). Additionally, more than 700 cell lines have been genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0. Using these Coriell cell lines, we have created a genomic DNA RM panel consisting of 96 characterized genomic DNA samples with specific chromosomal abnormalities typically detected in clinical cytogenetics laboratories. These include microdeletion and microduplications, subtelomeric abnormalities, uniparental disomy and other genetic variations. Each DNA sample was characterized using four separate CMA platforms to determine consensus genomic coordinates of the copy number alterations. The raw data was analyzed by 10 clinical cytogeneticists to establish the consensus breakpoints, the copy number status of each genomic imbalance and to assess each sample's suitability as a RM. New cell lines derived from patients with recently described novel microdeletion/ duplication syndromes will also be established and DNA from those samples will be used to develop RMs to supply additional chromosome variants absent from the panel of 96 Coriell cell lines. We are also developing a probe evaluation panel to characterize the performance of CMA oligonucleotide probes utilized in any CMA. This tool will include approximately 200 genomic DNA samples which contain large del/dups that collectively encompass most of the genome. We will present a summary of cell line selections showing the coverage of the genome, characterization of chromosomal abnormalities, and describe our progress to date. These characterized genomic DNA RMs are available from the NIGMS HGCR.

1049W

The 22q11.2 Duplication Syndrome - A Genetic Counseling Conundrum! *D.M. McDonald-McGinn, S. Saitta, A. Kohut, A. Bailey, M.D. Ha, B. Emanuel, E.H. Zackai.* Div Human Gen, Children's Hosp Philadelphia, Philadelphia, PA. and The Univeristy of Pennsylvania School of Medicine.

Background: 22q11.2 CNV's are well described entities involving deletions and duplications. Both are the result of unequal meiotic crossovers & thus aberrant interchromosomal exchanges (non-allelic homologous recombination) due to the presence of low copy repeats which flank the deletion/ duplication and define the breakpoints. Although expected to occur with equal frequency based on this common mechanism, we have previously found the deletion to occur approximately twice as often as the duplication. Moreover, in several instances we have identified the duplication in seemingly unaffected adults, raising important questions regarding: management; recurrence risk counseling; and prenatal diagnostic options. Methods: In an attempt to provide such anticipatory counseling, we reviewed our own database of 31 individuals with a 22q11.2 duplication specifically evaluating the size of the duplication; clinical findings; and familial variability. Results: 73% of patients had a standard A-D duplication. Clinical findings included: CNS abnormalities (8); GERD (7); congenital heart disease (4); craniofacial anomalies (4); ENT abnormalities (3); endocrine issues (3); FTT (3); hypospadias; development delay (12) & autism (5). Several patients were thought to have mild dysmorphic features but there was no consistent gestalt. 71% of families where both parents were available for testing were found to be familial. Features in affected relatives varied from developmental disabilities to completely normal intelligence including two unrelated parents with doctoral degrees. Conclusions: In summary, the 22q11.2 duplication is similar to the 22q11.2 deletion in many ways: the mechanism for the occurrence is the same; the majority of individuals have a standard A-D CNV (83% dup v. 85% del); and the clinical features are relatively similar when examining probands. However, the difference in familial cases is notable (71% dup v. 7% del); and despite the common mechanism, the prevalence for the 22q11.2 duplication syndrome is half as common as its counterpart. We believe this may well be explained by under ascertainment due to extreme variable expressivity as evidenced by our two parents with postgraduate degrees. Nonetheless, we caution that this data most definitely supports testing all parents of affected children in order to provide appropriate recurrence risk counseling as well as prenatal diagnostics options despite the perplexing and unpredictable associated phenotype.

1050W

If it's free, do people necessarily agree? Uptake of parental testing after abnormal array comparative genomic hybridization in our clinical genetics experience. *N. Shur[1, 2], J. Bernabe[2], J.T. Machan[1,2,4], K. Hovanes[3], E. Morrow[1,2], D. Abuelo[1,2].* 1) Rhode Island Hospital, Providence, RI; 2) Brown University, Providence, RI; 3) CombiMatrix Diagnostics, Irvine California; 4) University of Rhode Island, Kingston RI.

Array comparative genomic hybridization testing (aCGH) is now considered the gold standard for genetic evaluation of patients with developmental delay, intellectual disability, and/ or multiple congenital anomalies. In our patients whose aCGH testing shows abnormal results or variants of unknown significance (VUS), we routinely offer parental testing. Our purpose is to determine if a parent is likewise affected before providing prenatal counseling. The answer is not always obvious, given variable expression of most microdeletion/ duplication syndromes. It is also important to exclude the possibility of a balanced translocation carrier in one of the parents. In cases when aCGH reveals a VUS, the presence of the same result in an unaffected parent renders the VUS less likely to be diagnostic. Insurance approval for parental testing is not routine, and for most parents, the testing is prohibitively expensive. Therefore, we send aCGH testing to a laboratory that offers free parental testing when indicated. To determine what proportion of parents chose free parental testing, we received institutional review board approval for a retrospective chart review, and a research assistant randomly reviewed 51 charts from 10/27/2010 to 12/22/2010 with the only inclusion criterion that aCGH testing was done. The patients were evaluated as outpatients in Genetics Clinic or as inpatient consults. They ranged in age from 1 day - 10 years, and were evenly split in terms of gender (25 males, 26 females). Out of all patients, 14 patients had abnormal results (27%), 2 patients had VUS (4%), and the remainder were normal (69%). All parents of the 16 patients with abnormal results or a VUS were provided with genetic counseling and offered testing at no cost. Only 3/ 16 (19%) of the parents offered testing chose to complete it. Some laboratories claim that the high cost of parental testing makes it impossible to offer it for all abnormal cases or those with VUS, but in our experience, parental testing is indicated in the minority (31%), and a smaller group of all parents actually completes it (6%). Barriers to completion may include fear of an abnormal result, dislike of blood draws (saliva kits may offer a good alternative for aCGH cases), and lack of understanding regarding future relevance. Alternatively, some parents may not desire future prenatal counseling. Further research should include surveying parents regarding their decisions to accept or decline testing.

Resolving the genetics of a disease phenocopy by linkage mapping and high-throughput-sequencing. *J.L. Blouin[1], M. Failly[2], A. Letourneau[2], A. Munoz[2], C. Iseli[3,4], D. Robyr[2], C.D. Delozier[1], S.E. Antonarakis[1,2], S. Ala-Mello[5,6], L. Bartoloni[2].* 1) Genetic Medicine, University Hospitals of Geneva, Geneva, Switzerland; 2) Genetic Medicine and Development, University of Geneva School of Medicine; Switzerland; 3) Ludwig Institute for Cancer Research, Lausanne, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 5) Department of Clinical Genetics, Helsinki University Central Hospital, Helsinki, Finland; 6) Rinnekoti Foundation, Espoo, Finland.

In order to identify the genetic etiology of presumed Primary Ciliary Dyskinesia (PCD) in 5 out of 11 children from a consanguineous family, we performed High-Throughput-Sequencing (HTS) targeted to genes located within linkage interval. PCD was strongly suspected because of recurrent respiratory symptoms combined with immotility of nasal cilia and retinal degeneration. Lobectomies of the left lung were performed in 3 brothers due to bronchiectasis. DNA genotypes of 250K SNPs in 8 members of the family were analyzed for linkage, homozygous regions, and CNVs. No novel CNV could be identified. A 14 Mbp region of homozygosity and a highly suggestive linkage, which includes the MHC locus, was identified on chromosome 6p21-p22. Successive mutation searches were then performed on DNA from the index case by sequencing exons and splice sites within the linkage interval: i- in the 4 strong candidate genes; ii- in 24 genes coding for ciliary proteins (www.ciliaproteome.org); iii- in all refseq genes. HTS on microarray-selected DNA for all refseq genes (n= 5570 exons) within the larger linkage interval (Chr6:4'000'000-42'000'000) provided 3 strong homozygous mutation candidates. These 3 missense variants, with potential functional deleterious effects in genes ETV7, UHRF1BP1 and TAP2, segregate perfectly with the phenotype in this family. Mutations in TAP2 have been reported in Bare Lymphocyte syndrome type I (BLSI), an immunodeficient condition characterized by chronic bacterial infections of the respiratory tract. Bronchiectasis, bronchial obstruction and nasal polyps in BLSI are associated with lack of the HLA class I cell surface antigen. In this family, missense variant p.Leu516Arg in TAP2 occurs in a highly conserved 24-residue region and likely affects the conformation of a helix loop of the protein. Clinical presentation of the family is compatible with BLSI since: i- none of the affected individuals has situs inversus, which is expected to occur in about half of patients with PCD; ii- no fertility problems were reported, 3 of the affected men have 1-5 children each; iii- diagnoses of bronchial and lung infections and chronic sinusitis are compatible with diffuse panbronchiolitis. This study demonstrates that massive sequencing approach may help in the resolution of medically-uncertain diagnoses.

1052W

"Not knowing the odds is terrible": Patient and provider experiences with the uncertainties of prenatal microarray testing. *D. Soucier, B. Bernhardt for the NICHD Prenatal Microarray Study Group.* Medical Genetics - Penn CIGHT, University of Pennsylvania, Philadelphia, PA.

Background: Because of incremental yield of important genomic information, prenatal microarray (MA) testing for copy number variants (CNVs) is frequently offered in pregnancies with unexplained fetal anatomic anomalies and increasingly for routine indications. CNVs have variable expressivity and penetrance, complicating prenatal counseling and decision-making. An on-going NICHD-funded multicenter study is comparing the accuracy, efficacy and clinical advantages of prenatal diagnosis using MA analysis with conventional cytogenetic analysis, and has enrolled over 4,000 women having routine amniocentesis or CVS. Results, including potentially important variants of uncertain significance (VUS), are explained to the women by a genetic counselor and/or a clinical geneticist. Methods: We are conducting a qualitative study of the experiences of women in this study who received positive or VUS results, and their providers. To date, we have analyzed interviews with 15 women receiving abnormal results, 10 genetic counselors and 7 physicians. Results: Despite having participated in an informed consent session, few women recalled being told that results could be uncertain. Women reported being blindsided by an abnormal MA result after receiving normal chromosome results. Most women continuing pregnancies remained worried after delivery despite normal follow-up scans and delivering a healthy child. When asked what would have made the experience easier, most women mentioned a need for ongoing support from a knowledgeable and compassionate professional, and some needed more assistance arranging for a pregnancy termination. Several women regretted undergoing MA testing, and suggested that the potential uncertainty of results be highlighted during pre-test counseling. When asked about challenges of prenatal MA testing, nearly all providers first mentioned dealing with uncertain results. Providers expressed frustration with the lack of concrete information about expected fetal outcomes and were often unsure how to assist women making decisions in the face of uncertainty. Conclusions: As MA technology transitions into clinical care, pregnant women and their providers will need tools and support to help cope with uncertain results. Women considering prenatal MA testing need to clearly understand the implications of uncertain findings before being tested. Our results raise important ethical issues relating to reporting uninterpretable prenatal testing results.

Web-based expert review system of clinical genetics web site. *H. Numabe[1,2], S. Muzuno[2,3], N. Sakai[2,4], N. Okamoto[2,5], T. Ikeda[2,6], Y. Fukushima[2,7].* 1) Dept Med Ethics & Med Genetics, Kyoto Univ Graduate Sch Med, Kyoto, Kyoyo, Japan; 2) The Information and Communication Committee of Jap Soc for Genetic Counseling, Tokyo, Japan; 3) Dept of Pediatrics, Central Hosp, Aichi Human Service Center, Kasugai, Aichi, Japan; 4) Dept of Pediatrics, Osaka Univ Graduate Sch of Med, Suita, Osaka, Japan; 5) Dept of Med Genetics, Osaka Med Center & Res Institute for Maternal & Child Health, Izumi, Osaka, Japan; 6) Dept of Obst & Gyn, Kagoshima Univ, Kagoshima, Kagoshima, Japan; 7) Dept of Med Genetics, Shinshu Univ Sch of Med, Matsumoto, Nagano, Japan.

There are a large number of websites providing information relating to medical genetics or heredity, and more than a few of them are routinely used as reference. In addition, because most of the websites are open to non-healthcare professionals, people with genetic disorders and their families can also refer to them. However, when search engines are used to look for information on medical genetics or heredity, websites found are not always those with information based on evidence-based medicine, EBM, and patients or their families may obtain wrong information. This could, in quite a few cases, bring them a sense of distrust for healthcare professionals or hurt them emotionally. To deal with this issue, we selected some websites providing information relating to medical genetics or heredity and established an online system where several professionals can check some items to evaluate the contents of the websites. What makes this system different from ordinary evaluation systems is that the professionals can give not only a positive rating of 1 to 5 but also a negative rating of -5 to -1 to the websites. Therefore, if a website provides inappropriate information, it will receive negative feedback. We here present some examples of the website evaluation in our pilot system and talk about the challenges of the system we need to deal with.

1054W

Frequency estimation of low-level somatic mosaicism for pathogenic CNVs. *I.M. Campbell[1], S.C.S. Nagamani[1], A. Erez[1], C. Robberecht[2], A. Ester[1], M. Bartnik[3], B. Wisniowiecka-Kowalnik[3], K. Derwinska[3], E. Bocian[3], K.S. Plunkett[1], A.N. Pursley[1], C.A. Shaw[1], S-H.L. Kang[1], W. Bi[1], S.R. Lalani[1,4], C.A. Bacino[1], A. Patel[1], J.A. Veltman[5], L.E. Vissers[5], J.R. Vermeesch[2], S.W. Cheung[1], L.R. Lupski[1,4,6], P. Stankiewicz[1,3].* 1) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Centre for Human Genetics, University Hospital, Catholic University of Leuven, Leuven, Belgium; 3) Dept of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 4) Texas Children's Hospital, Houston, TX, USA; 5) Dept of Human Genetics, Nijmegen Centre for Molecular Life Sciences and Institute for Genetic and Metabolic Disorders, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 6) Dept of Pediatrics, Baylor College of Medicine, Houston, TX.

Only incidental observations of somatic mosaicism for copy-number variations (CNVs) have been reported in the literature, wherein patients or their healthy parents are mosaic for pathogenic genomic deletions or duplications. Recently, we reported a deletion of TGFBR2, in a female with microcephaly and global developmental delay. FISH analysis showed no evidence of this deletion in the parental peripheral blood; however, low-level somatic mosaicism was detected using PCR of the paternal peripheral lymphocyte DNA. We also previously reported low-level somatic mosaicism for a complex PMP22 exon 4 deletion in the mother of two sisters with Charcot-Marie-Tooth disease detected by PCR but not by aCGH; germ line mosaicism could be inferred by recurrence of the CMT causing complex rearrangement. Given the 5-30% sensitivity of diagnostic FISH, aCGH and SNP arrays, and that a significant number of CNVs arise due to microhomolgy-mediated DNA replication errors during mitotic cell divisions, we hypothesized that somatic mosaicism below the detection threshold of FISH and microarray methods in asymptomatic parents of children with genomic disorders may be more common than previously recognized. In support of this contention, we identified a family with two brothers with severe intellectual disability and microcephaly, who both had the same 2 Mb deletion involving AKT3. FISH analysis did not detect this change in either healthy parent. Using multiplex long-range PCR we obtained a patient-specific junction fragment that was subsequently found in the father, albeit with reduced band intensity. To estimate the frequency of this phenomenon, we retrospectively queried our aCGH databases for patients with nonrecurrent interstitial genomic deletions determined to be de novo by FISH or aCGH analyses of the parental DNA samples. We selected over 150 families, narrowed their deletion breakpoints by custom-designed high-resolution oligo aCGH or multiplex PCR, and obtain patient-specific junction fragments. PCR analysis was then performed on parental peripheral lymphocyte DNA with primers specific for their child's deletion. We will present the results of screening over 100 families. Our findings suggest low-level somatic mosaicism can lead to a clinically relevant number of potentially heritable CNV in humans. Moreover, we propose that new methodologies for detecting these low-level changes are needed for appropriate diagnosis, recurrence risk estimation and genetic counseling.

Trends in genetic counseling in India - experience from one Genetic Center. *S. Bijarnia, R.D. Puri, U. Kotecha, S. Kohli, M. Jain, J. Verma, R. Saxena, M. Lall, I.C. Verma.* Center of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, New Delhi, India.

With the advent of the human genome project, the practice of clinical genetics and prenatal diagnosis in India has changed for the better. A major contribution to the change has also been brought about by advancement in technologies for genetic testing and prenatal screening. The awareness among medical profession is also gradually improving. We analyzed the trends in genetic counseling at Sir Ganga Ram Hospital over the past 13 years. The categories of genetic disorders and reasons for referrals in 3850 patients in whom genetic counseling was provided in 2010 were compared to the initial 1370 patients seen in 1997-98. Majority (n=2234/3850, 58%) of the patients sought advice during pregnancy (or pre-pregnancy stage) for prenatal diagnosis. This is in contrast to 38.4 % patients seeking prenatal diagnosis in the nineties. The screening for chromosomal disorders (first trimester biochemical screen, triple test, ultrasonography) and amniocentesis for advanced maternal age and previous Down syndrome accounted for 1494 (38.8%) cases, compared to 21% in year 2000. Prenatal diagnoses for 329 (8.5%) single gene disorders were also carried out. Other causes for a genetic referral and counseling (with some overlap with prenatal diagnosis) included mental retardation, multiple malformations in child (339, 8.8%), Down syndrome and other chromosomal disorders (319, 8.28%) Thalassemia/hemophilia and other hemoglobinopathies (83, 2.15%), Muscular dystrophies & SMA (194, 5%), Neural tube defects and other birth defects (45, 1.16%), Metabolic disorders (223, 5.79%), Skeletal dysplasias and other endocrine disorders (114, 2.96%), and others. A significant number of previously unrecognized single gene disorders (263, 6.8%) including neurological, hepatic, renal, ear, eye and skin diseases etc were seen in 2010. Conclusion: The awareness of biochemical and ultrasound screening tests during pregnancy and its incorporation into obstetric practice has resulted in significant increase in prenatal diagnosis of chromosomal disorders. The advancement in molecular technology and knowledge of new genes has also increased the diagnosis of single gene disorders helping in accurate prenatal diagnosis and reduction in burden of genetic disorder in the families.

1056W

Characteristics of healthy participants in a whole genome sequencing study. *M.K. Cho, C. Caleshu, L. Hudgins, H. Greely, S.J. Lee, K.E. Ormond.* Stanford University, Stanford, CA.

In 2011, Stanford University began enrollment of up to 40 individuals in a whole genome sequencing (WGS) study that offered clinical interpretation to `genetically educated individuals,' primarily faculty in genetics and genomics. We designed behavioral surveys to assess the participants' characteristics and attitudes at various points in the process; this paper will present the initial enrollment data before and after the provision of pre-sequencing genetic counseling (GC). As of late-May 2011, the participants (N=12) are primarily scientists who self-report that they are non-smokers, moderate exercisers and low alcohol users. 70% have previously undergone genotyping through a DTC company, and most felt they would pay $500-1000 out of pocket for WGS results. Primary reasons for participating in the WGS study were curiosity, that `it is exciting', to improve teaching of genomics, cost (free), to contribute to research, for future clinical use, the potential to make health behavior changes in the future, and the right to know one's genetic data. Participants felt there was currently low clinical validity and utility, and that scientists, doctors and themselves currently have a limited ability to interpret WGS results. Nonetheless, most felt that WGS should be available to the general public. When asked about specific types of conditions they do not want to know about from their genome, participants indicated interest interested in all health information available, and prioritized obtaining ancestry and pharmacogenomic variant information. After GC (N=4), participants reported that the opportunity to receive GC services was an important, and they would pay up to $100. All would recommend GC for individuals with less genomics knowledge, and one participant reported that prior to GC (s)he had not considered the issues related to identifying late-onset and low penetrance alleles. While a biased population, most participants did not report anxiety about the potential information available or the decision to participate, and only one expressed moderate concerns re: confidentiality.

1057W

Evaluation of a molecular genetic testing strategy for autosomal dominant retinitis pigmentosa and its translation into the genetic counselling process. *M.A. Day[1], J.E. Sutherland[1], E. Heon[1,2,3].* 1) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetics and Genome Biology Program, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Department of Ophthalmology and Vision Sciences, University of Toronto, Toronto, Ontario, Canada.

Retinitis pigmentosa (RP), a genetically heterogeneous retinal condition, affects an estimated 1 in 3500 individuals of which 30-40% are thought to be autosomal dominant (AD). Twenty-one ADRP genes are now clinically available for testing. Rhodopsin is the most commonly involved (up to 30% of ADRP). Purpose: To effectively integrate advances in molecular knowledge into clinical care, we underwent a systematic review of our molecular genetic testing strategy for ADRP at the Hospital for Sick Children (Toronto). Implications for genetic counselling will be discussed using specific cases. Methods: A retrospective review of our ocular genetics database identified probands with a clinical diagnosis of RP and a clear or suspicious AD pedigree, who underwent molecular genetic testing. The family history was classified as “suspicious” when the questionably affected relatives lived geographically far from our proband and were not available. Results: Of the 115 probands identified, close to 70% have undergone some genetic testing. Mutations in the rhodopsin gene were the most common but responsible for only 15% of ADRP. This may reflect Toronto's ethnically diverse population, with 47% of individuals belonging to a visible minority. The *RDS* gene accounted for 5% and another 18 ADRP genes were involved. For probands for whom variants of unknown significance are identified, validating the results requires further testing and examining family members which increases counseling/clinic time and the time to deliver results. Those with a suspicious family history are invariably difficult to interpret. The number of patients with polygenic variants has increased as testing panels include multiple ADRP genes. The causative mutation is important for management, lifestyle choices and eligibility for human clinical trials. Probands who know their causative mutation are faced with the decision of presymptomatic diagnosis for their children. Conclusion: Mutation detection rates for ADRP improved. Periodic review of our testing yield and validation strategies will help us and others to improve upon them and may help guide lab clinicians in the improvement of their services. Our experience also highlights the need for a concerted effort to develop an international web-based mutation database that could be easily accessed and up-dated. Furthermore, the important post-testing genetic counselling issues of patients with ADRP must be highlighted.

1058W

A primary care model for assessing patient disease risk based on family health history: Description and preliminary analysis. *V.C. Henrich[1], E. Hauser[2], L. Orlando[3], C. Christianson[1], A. Buchanan[3], K.P. Powell[1], A. Agbaje[4], G. Ginsburg[5], Genomedical Connection.* 1) Ctr for Biotech, Genomics, and Health Research, Univ North Carolina,Greensboro, Greensboro, NC; 2) Center for Human Genetics, Duke University, Durham, NC; 3) Department of Medicine, Duke University, Durham, NC; 4) Cone Health System, Greensboro, NC; 5) Institute for Genome Sciences and Policy, Duke University, Durham, NC.

The positive impact of genomic medicine on human health will depend largely upon its successful practice in primary care. Yet, research shows several impediments to collecting family health history (FHH) - the most readily available and applicable piece of genomic information - and applying it to manage disease risk in primary care. The Genomedical Connection has developed a FHH-based decision support program to facilitate risk management for for three diseases: colorectal cancer, breast/ovarian cancer, and thrombophilia. An algorithmic computational tool (MeTree) assesses individual patient disease risk from the FHH provided by the patient, and offers risk management recommendations to the practitioner and patient. For this study, patients were recruited prior to a regularly scheduled wellness visit at two community-based primary care practices; the frequency of medical recommendations based on FHH assessments are noted here. Among 523 patients recruited so far, 59.1% were female, 83% were Caucasian; mean age was 58.3±12.3 years. Based on the MeTree analysis of FHH, 26.8% (N=140) of all patients received a recommendation to see a cancer genetic counselor. A larger percentage of females (32.4%, 100 of 309) were recommended to see a cancer counselor than males (18.7%, 40 of 214). Seven female patients (1.3% of all patients) received a recommendation to see a genetic counselor concerning their risk for thrombophilia. An elevated risk for breast/ovarian cancer led to recommendations for 43 female patients (13.9% of females), including chemoprevention (N=32, 10%), breast MRI exams (N=6, 1.9%), and gynecological surveillance (N=5, 1.6%). Early colorectal cancer screening was recommended for 54 patients (10%), with about equal frequency in both sexes. Primary care providers referred 46 patients for genetic counseling, and 20 of them received a counseling session. Whether the risk levels seen in this patient population reflect overall risk levels in the general population cannot be ascertained. However, the percentage of participants for whom some increased-risk management was recommended is similar to findings from earlier research. This supports a conclusion that the use of FHH can be a valuable component of a genomic medicine model in primary care.

A comparison study of the practices of genetic counsellors between France and Canada. *E. Le Boette[1,2], M. Edmont[2,3], M-A. Voelckel[2,4], J-L. Mandel[5], H. Sobol[6], C. Cordier[2,7].* 1) Dept of medical genetic, University Hospital, Strasbourg, France; 2) AFCG, French Association of Genetic counsellors, Marseille, France; 3) Dept of genetic, University Hospital, Montreal, Canada; 4) Dept of medical genetic, Timone's Hospital, Marseille, France; 5) Laboratory of medical genetic, University Hospital, Strasbourg, France; 6) Dept of oncology, Institut P.Calmettes, Marseille, France; 7) Dept of oncology and haematology, University Hospital, Strasbourg, France.

Genetic counsellors are Health Professionals with specialized training and experience in the areas of clinical genetics and counselling. They did work as members of a multi-disciplinary healthcare team that provides genetic services. In France, the profession of genetic counsellors is relatively recent (2005). This profession has been created due to the increasing number of genetic consultations but also face to the decrease of medical professional in this field. About Canada, the profession has been created, for the same reason, since 1985 by a genetic counsellor graduated in the United-states and by the auspices of geneticists who exercise their profession in Canada. Members of different groups (French and Canadian) have received an electronic survey based on their background,the role and the practice of the profession of genetic counsellors in their own country. The questionnaire was sent to the Association of Genetic Counsellors which transmitted it to all their members. Data were collected during the first quarter of 2011. We are looking to see if there are major differences in the practice of exercising the profession, but also in the education and in the collaboration established between genetic counsellors and medical geneticist.

Personal genotyping in genetics faculty members considering personal whole genome sequencing. *K.E. Ormond, L. Hudgins, C. Caleshu, H. Greely, S.J. Lee, M.K. Cho.* Stanford Univ, Stanford, CA.

Genetics faculty members who were participating in a whole genome sequencing research project (which plans to enroll up to 40 participants by summer 2011) completed an online behavioral survey that assessed, in part, their personal experiences with genotyping through a DTC company. As of late-May 2011, 8 of 11 (70%) participants reported undergoing genotyping. Of the 3 who had not had genotyping noted cost, lack of clinical utility, and `waiting for whole genome sequencing' as reasons. Of the 8 tested, 5 reported having paid between $100-300 out of pocket for the testing. None shared results with a health care provider, nor planned to. The most common reasons listed for undergoing the testing were: general curiosity, to obtain information that may be clinically useful in the future, because the data is “exciting,” may improve teaching of genetics/genomics, and to inform family members of risks. 5 of the 8 appear to be regularly engaging in research about the meaning of their genotype results, and 4 have shared information with family members. Seven participants felt they would recommend genotyping to others, although only 4 individuals reported that the experience improved their understanding of or teaching of genetics and genomics. Six participants report sharing with students that they have undergone genotyping (4 of whom share their results as part of a lecture), and they used this information primarily as a way to perform additional research for their lectures; 3 participants reported the experience made them consider the implications on individuals undergoing such testing. Views were mixed on whether personal genotyping should be offered to students, and if so whether it should be an optional exercise within a required or an elective course, although only those who had undergone genotyping were supportive of its inclusion in required courses. These experiences should be considered when offering faculty genotyping as an educational tool and when offering whole genome sequencing to `early adopters.'.

An integrated program for care of children with agenesis of the corpus callosum encompassing caregivers, clinical services and research. *K. Pope[1], M. Spencer-Smith[1], D. Amor[4, 1], M. Delatycki[3, 5], P. Lockhart[5], A. McIlroy[1], G. McGillivray[4], V. Anderson[1], R. Leventer[2].* 1) Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 2) Royal Childrens Hospital, Parkville, Victoria, Australia; 3) Clinical Genetics, Austin Health, Heidelberg West, Victoria, Australia; 4) Victorian Clinical Genetics Service, Parkville, Victoria, Australia; 5) Bruce Lefroy Centre for Genetic Health Research Murdoch Childrens Research Institute Parkville,Victoria Australia.

Purpose: Agenesis of the corpus callosum (ACC) is a common brain malformation diagnosed by neuroimaging. Children present with neurocognitive impairment ranging from severe developmental delay to mild to no learning or behavioural. Although there have been major advances in understanding the structural features and causes of ACC, for many families we are still unable to adequately explain why their child is not developing as expected. The ability to provide accurate prognostic and genetic counselling also remains deficient. We are attempting to address this through the Genetics of Brain Development (GBD) Program at the Murdoch Childrens Research Institute, which is contributing to greater understanding and support for families and children with a brain malformation. This project is multifaceted, with major strengths in 1. Understanding caregiver wellbeing, a crucial factor in ensuring quality of care for families, who provide the majority of care for these patients. 2. Provision of clinical care and genetic counselling 3. The application of new genomic technologies to understanding the underlying molecular basis of ACC. To the best of our knowledge, this approach is unique in its application to the wellbeing of caregivers and children with ACC. ACC Families were recruited through the GBD Clinic. Five families will be described. Caregivers completed: i) a structured interview to examine medical history, interventions, schooling and current concerns about their child; and ii) the Hospital Anxiety and Depression Scale to examine their own anxiety and depression symptoms. Some families were also enrolled in linkage and molecular genetic studies to identify the causative gene associated with ACC. High density SNP CHIP arrays provides data for copy number analysis and linkage analysis. Genes in candidate regions are then analysed by whole exome capture and massively parallel sequencing. Conclusions: There was a wide range in functioning and most children require intervention. Caregivers experienced considerable uncertainty about the health, academic abilities and future for their child; most demonstrated increased levels of anxiety. Uncertainty about possible causes and recurrence risks are also important issues and there was considerable enthusiasm for research aimed at identifying `their' gene. Caregivers reported feeling isolated, and we are planning a support group for families of children with ACC in Australia to address this.

1062W

Utility of Fetal Autopsy Evaluation on Genetic Counseling in Developing Countries. *R.D. Puri, U.K. Kotecha, S.B. Bijarnia, M.L Lall, P.S Savior, R.S Saxena, I.C.V. Verma.* Center of Medical Genetics, Sir Ganga Ram Hospital, New Delhi, INDIA, Delhi, India.

Antenatal ultrasound detection of fetal malformations is increasing with improving technology. The threshold of continuing a pregnancy in the presence of a fetal abnormality is low in India and most of such pregnancies are terminated. The fetal autopsy data was analyzed from April 2003 through May 2011 at a tertiary care genetic referral center. The aim was to evaluate the common indications for referral, autopsy diagnosis and its utility to counsel families. Of 733 fetal autopsies performed from 2003 to date, the indications were intrauterine death and spontaneous abortion, structural malformations, hydrops fetalis, growth retardation and chromosomal disorders. Of the 116 autopsies performed for intrauterine death / spontaneous abortion, a definitive etiology was identified in 47% cases. These were fetal malformations, infections, cord and placental abnormalities and chromosomal disorders. In 274 fetuses with antenatally detected structural malformations, diagnosis was established in 49.6 % cases. Chromosomal defects, rubella infection, isolated malformations / multiple malformation syndromes were seen. In hydrops fetalis, etiology was established in 50% cases, mainly multiple malformations and chromosomal syndromes. In the lethal skeletal dysplasias we demonstrated in 21 fetuses, that a detailed physical examination and radiographs were imperative for diagnosis of the type of dysplasia. Definitive diagnosis was established in 73.2 % of autopsies performed, of which in 43% the diagnosis was revised or further defined. In 26.8% cases no definitive diagnosis could be established after autopsy evaluation Minimum basic investigations essential to establish a definitive diagnosis and improve perinatal care was evaluated. For skeletal dysplasias, fetal photograph and radiographs with DNA storage are imperative. Fetal karyotype is essential for fetuses with multiple malformations. When fetal blood is unavailable or placental tissue culture unsuccessful, parental karyotype for a balanced translocation is done. In fetuses with non immune hydrops fetalis, we found antenatal karyotype, hematological and infection evaluation most rewarding. Placental histopathology is important in unexplained intrauterine death. In developing countries expertise of antenatal ultrasound diagnosis varies greatly and fetal autopsy remains the gold standard for evaluation and appropriate counseling to prevent recurrence.

UK Recognition of International Genetic Counsellor Training and Registration: A Continuing Dialogue. *B. Stayner[1,4], J. Walford-Moore[2,4], A. Middleton[3,4] on behalf of the Genetic Counsellor Registration Board.* 1) Clinical Genetics, Churchill Hospital , Oxford, Oxfordshire, United Kingdom; 2) West Midlands Regional Genetics Service, Birmingham Women's NHS Foundation Trust, Birmingham, United Kingdom; 3) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 4) Genetic Counsellor Registration Board (GCRB), Wessex Genetics Service, Princess Anne Hospital, Southampton, United Kingdom.

Internationally, the number of Masters programmes in Genetic Counselling has doubled over the past 10 years to over 60, creating challenges for regulating bodies who receive requests from overseas trained individuals seeking employment abroad. The Genetic Counsellor Registration Board (GCRB) is the independent, not for profit company who registers Genetic Counsellors (GCs) and accredits MSc Genetic Counselling Programmes in the United Kingdom (UK). Registration (certification) began as a voluntary process in the UK in 2002 and today approximately 50% (151/300) of members of the Association of Genetic Nurses and Counsellors (AGNC) are registered with the GCRB, a number of whom were trained overseas. It is generally accepted that most Genetic Counsellors (GCs) in the UK are working towards registration. Increasingly, National Health Service employers are hiring only those GCs eligible to register with the GCRB, as the GC profession draws closer to being formally adopted by the Health Professions Council (HPC), the British Parliamentary regulatory body. The GCRB assesses the registration of overseas trained GCs within the UK, using formalised pathways agreed by a GCRB Working Group in 2006. Recognition is afforded to GCs who have trained and certified in the USA/Canada and Australasia, thus GCs from these countries who have completed a recognised training and certification in their own country are able to complete a reduced UK registration portfolio that takes account of their experience. The GCRB completed a large mapping exercise, which evaluated each country's training, accreditation of training and professional regulation process. There is an increasing demand for registration in the UK by recognised and non recognised overseas trained GCs. In addition to this British registered GCs often wish to work outside of the UK and require that the GCRB act on their behalf to establish reciprocal registration agreements so that their British training and experience is recognised outside the UK. The GCRB present here current pathways for GCs trained outside of the UK to register professionally in the UK, and the evaluation model used for assessing overseas MSc Courses to facilitate this dialogue at the International Congress of Human Genetics.

Introducing "Lexigene": An Online French-English Lexicon of Terms Related to Genetic Counselling. *R. Vanneste[1], G. Sillon[1], J. Hathaway[2], M. Cloutier[3].* 1) McGill University Health Centre, Montreal, Quebec, Canada; 2) IWK Health Centre, Halifax, Nova Scotia, Canada; 3) Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

To facilitate the provision of genetic services in both of Canada's official languages and to contribute to the development of the genetic counselling profession, a French-English lexicon of terms was created by genetic counsellors for the specific use of genetic counselling. Trainees in bilingual genetic counselling training programs, as well as francophones who have access to the mainly anglophone scientific literature are in particular need of such a tool. While there exists a few French-English medical genetics glossaries, none were created specifically for the field of genetic counselling and therefore lack many of the terms relevant to this profession. Lexigene was funded through the Canadian Association of Genetic Counsellors (CAGC)'s Small Project Grant. This bilingual website, www.lexigene.com, allows an individual to search for genetics related terms in either French or English and find the equivalent term in the other language. Terms are also listed by specific category, which may be downloaded as PDF files for offline reference. The terms in the lexicon were gathered through 6 main resources where French-English translations currently exist. Seventy other documents were also used to populate the lexicon and/or confirm a word's translation; however, every translation was also verified for accuracy by the four authors. Following the website's creation, a pilot project was undertaken to ensure that the website was user friendly and contained words relevant for genetic counselling. Eighty percent of terms searched for by respondents were found using Lexigene. All respondents rated the website as "very easy to use" and indicated that they would use it in practice. This online tool boasts over 3500 translated terms, with more being added regularly. Lexigene will be used by genetic counsellors, geneticists, and others who work in the field of genetics in both English and French on an international scale.

The First Year: Impressions from Clinicians and Families Following Clinical Utilization of Whole Genome Sequencing. *R. Veith[1], S. Dugan[1], A. White[1], A. Laedtke[1], J. Kopesky[1], D. Bick[1,2], D. Dimmock[1,2].* 1) Genetics, Children's Hospital of Wisconsin, Milwaukee, WI; 2) Medical College of Wisconsin, Milwaukee, WI.

Clinical utilization of whole genome sequencing (WGS) faces many challenges from both clinician and patient/family perspectives. Our program utilizes a categorical model of choice related to result(s) disclosure and data analysis. The parents work with the genetics team to create a patient/family specific result(s) disclosure and follow-up plan. Over the past two years we have worked with several families to facilitate informed decision-making, discuss key parental concerns, and begin to explore the patient/family experience surrounding results disclosure and the consent process for whole genome sequencing. Informed by these experiences, our institution has established a clinical WGS program with structured protocols for patient selection, data evaluation, informed consent, results disclosure and follow-up. We have reached the 1 year follow-up for our initial patients. To date, 43 families have been reviewed by our clinical program; of the cases reviewed 13 have been approved for sequencing and are in various stages of consent, analysis, disclosure and follow-up. Of the 13 approved cases, eight have completed counseling/informed consent. After counseling, seven of these cases have elected to pursue WGS, one family remains undecided. Of the seven who have elected to proceed, all wanted additional information beyond the mandatory pathogenic result; seven have asked for non-actionable findings in childhood, seven have asked for actionable results in adulthood, and six have asked for non-actionable adulthood findings--with one not wanting this information. Ongoing discussion with parents suggests consistency over time with types of results they desire returned. Our experiences have provided unique insight into parental impressions and concerns regarding clinical whole genome sequencing. Information will be updated on the other cases at the time of presentation.

1066W

MutaDATABASE, a standardised, centralised, open access database of variants leading to human genetic disease. *P. Willems.* GENDIA-MutaBASE, Antwerp, Belgium.

A small fraction of the variants causing genetic disease have been published in the literature or listed in public DNA variant databases, as most novel disease variants identified over the last decade have been identified in clinical diagnostic laboratories. International journals have published individual or lists of variants without accompanying detailed clinical and/or functional data, which is generally not available to the diagnostic laboratory. Many variants are not introduced into mutation databases because at present there is no easy or efficient way for a busy diagnostic laboratory to submit novel variants into a standardized database platform. Furthermore, there is only limited exchange of information about variants between different diagnostic laboratories. Consequently, the clinical significance of many novel variants remains undetermined. Furthermore, no standardized, centralized, and open access database of variants exists that includes well-vetted information on the common disease genes and variants implicated in human genetic diseases. To address these problems we have developed MutaDATABASE, a standardized, centralized, and free open access database. Included for each disease gene is : i) general information on the disease gene, including genomic sequence, cDNA sequence, amino acid sequence, genomic structure, intron-exon boundaries, functional domains, and function, ii) general information on the diseases associated with variants in that gene, iii) tables of exon-intron sequences and disease-causing variants, and iv) figures of the cytogenetic position, genomic structure of the gene, and disease-causing variants, v) lists of MutaCIRCLES -- labs working on the same disease gene that are linked in community groups. MutaDATABASE currently is supported by hundreds of gene curators and genetic labs. MutaDATABASE has a real-time bidirectional communication with a new software interface, MutaREPORTER, which is designed to define, characterize and archive variants in human disease genes. MutaREPORTER currently provides: • A genome browser • A HGVS nomenclature checker • In silico prediction tools (Splice site prediction, SIFT, POLYPHEN) • Possibility to automatically import variants from in-house databases • Possibility to easily submit variants into MutaDATABASE • Possibility to communicate with other genetic (MutaCIRCLES).

1067W

Application of next-generation sequencing in molecular diagnosis of mitochondrial disorders. *R. Bai, M. saifi, S. Suchy, J. Higgs, M. Knight, S. Warren, J. Compton, F. Gibellini, S. Buchholz, S. Benhamed, B. Boggs, C. Chinault, Y. Shevchenko, G. Richard, S. Bale, J. Compton.* GeneDx Inc, Gaithersburg, MD.

Mitochondrial disorders (MtD) are genetically highly heterogeneous, similar clinical features can be caused by different mutations in the mitochondrial (Mt) genome, or mutations in many different nuclear genes. In the practice of molecular diagnosis of MtD, mutation-by-mutation or gene-by-gene testing has been time-consuming, laborious, costly and inefficient; whole genome or whole exome sequencing is still far from ready to be used for routine clinical molecular diagnosis; we have applied targeted next-generation sequencing technology to significantly increase the efficiency and cost-effectiveness of mutation detection in MtD: Deep-parallel sequencing is used to detect any mutations in the Mt genome (at low levels of heteroplasmy) and mutations in 24 nuclear genes important for normal Mt function (accounting for about 80% of known nuclear gene mutations associated with MtD). Samples of 162 patients suspected of MtD (22 definite, 41 probable, 49 possible, others with clinical information not provided) were sequenced at GeneDx, 73 for Mt genome and 108 for 24 nuclear genes (19 for both). All variants identified were compared with specific mutation databases (Mitomap for MtDNA variants, HGMD for nuclear gene variants), other online resources and GeneDx internal variant databases. All novel variants were thoroughly evaluated and classified as novel mutations (nMut), variants of unknown significance: likely mutation (VLM), undetermined (VOUS), or likely benign (VLB), or as a benign polymorphism (Poly). Some published pathogenic mutations without solid evidences were re-evaluated. Results: For the 73 samples tested for Mt genome sequencing, 11 (15.1%) were positive for a definite mutation (8 for a point mutation and 3 for a large deletion, 4.5kb, 5.0kb, and 5.2 kb each), 8 (11%) positive for a nMut/VLM, 6 (8.2%) for a VOUS, and 8 for a VLB; In the 108 samples tested for defects in 24 nuclear genes, homozygous/hemizygous, or compound heterozygous mutation(s) were identified in one gene and confirmed the diagnosis in 12 (11.1%) of the patients, 5 of them also harbor a heterozygous nMut/VLM/VOUS in 1-2 other genes in the panel; Heterozygous nMut/VLM/VOUS were identified in 1-3 genes in another 16 (15%) patients, subsequent aCGH array analysis identified a heterozygous exon deletion in two of them. Conclusion: Targeted next generation sequencing of the Mt genome and a panel of selected nuclear genes is an efficient way to perform molecular diagnosis of MtD.

1068W

Novel *MLL2* mutations identified in Kabuki Syndrome. *R.K. Basran[1, 2], A. Milunsky[1,2], T.A. Maher[1], J.M. Milunsky[1,2,3].* 1) Center for Human Genetics; 2) Department of Pediatrics; 3) Department of Genetics and Genomics, Boston University School of Medicine, Boston, MA.

Kabuki syndrome (KS, MIM147920) is a rare autosomal dominant genetic disorder characterized by intellectual disability and multiple congenital anomalies including distinctive craniofacial features. Other clinical features include postnatal growth restriction, clefting, hearing loss, skeletal, cardiac and renal anomalies, as well as ophthalmic and immune abnormalities. Recently the gene responsible for KS, myeloid/lymphoid or mixed-lineage leukemia 2, *MLL2*, was identified through exome sequencing. It has been reported that sequence analysis of all coding exons of the *MLL2* gene detects mutations in up to 76% of patients with a clinical diagnosis of KS; suggesting either the presence of other yet unknown loci within the genome or mutations occurring within regions of the *MLL2* gene not included in routine sequence analysis. Herein, we report our clinical experience of molecular testing of the *MLL2* gene. Our laboratory performs sequence analysis of the fifty-four coding exons and intron-exon boundaries of the *MLL2* gene. In addition, we are the only laboratory to offer dosage analysis using a custom design multiplex ligation dependent probe amplification (MLPA) strategy for 10 selected exons spanning the entire *MLL2* gene. Among the 76 individuals referred to our laboratory for clinical molecular testing, we identified 30 alterations including: frameshift (n=12), missense (n=11) termination (n=6) and splice site (n=1). Of the 30 alterations we identified in our laboratory, all were novel except for one mutation which has been previously reported. In addition, the clinical significance of one missense alteration identified in a proband and his mother is currently being investigated through molecular testing of other family members and therefore the pathogenicity of this alteration currently remains unknown. Four previously unreported missense alterations identified in our laboratory were designated polymorphisms/variants either because they were inherited from an asymptomatic parent or co-inherited with a pathogenic alteration. MLPA analysis was undertaken in 40 patients and to date no deletions/duplications have been identified in the selected exons tested for within the *MLL2* gene. Further analysis is currently underway to characterize the clinical phenotype of the patients' harboring a *MLL2* gene alteration. This report expands the spectrum of mutations associated with *MLL2* and reports an additional 24 mutations causing KS.

1069W

Autosomal dominant congenital nonprogressive spinocerebellar ataxia is associated with a missense mutation in the *ITPR1* gene. *L. Huang[1, 2], R. Zou[2, 3], M. Carter[4], D.E. Bulman[2, 3], K.M. Boycott[1, 2].* 1) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 2) University of Ottawa, Ottawa, Ontario, Canada; 3) Ottawa Hospital Research Institute, Ottawa, Ontario, Canada; 4) Hospital for Sick Children, Toronto, Ontario, Canada.

The spinocerebellar ataxias (SCA) are a group of genetically heterogeneous disorders characterized by slowly progressive incoordination of gait and often associated with poor coordination of hands, speech, and eye movements. In contrast to the common SCAs, congenital nonprogressive spinocerebellar ataxia (CNPCA) is characterized by early gross motor delay, hypotonia, gait ataxia, and mild dysarthria and dysmetria. The clinical presentation improves or remains stable throughout the patient's life. Families with autosomal dominant CNPCA have been reported approximately nine times since 1985. Linkage to 3pter has been demonstrated in an Australian family and the locus designated as SCA29.

We present a three-generation family with autosomal dominant CNPCA. The proband is a 3 year old girl with global developmental delay, hypotonia, truncal ataxia, and cerebellar vermis atrophy on MRI. Her father had early gross motor delays and did not walk until the age of 6. He has an ataxic gait, mild dysarthria, saccadic eye movements and poor balance. His sister and mother are less severely affected.

The SCA29 overlaps with the SCA15 locus at 3pter. SCA15 is a slowly progressive cerebellar ataxia with mid-life onset; heterozygous *ITPR1* deletions are disease-causing. Given the significant clinical overlap between the Austrian SCA29 family and our family, we genotyped all the family members with microsatellite makers from 3pter and found the region containing *ITPR1* cosegregated with the disease. Sequencing all of the exons and the exon/intron boundaries of *ITPR1* in one affected individual identified a missense change (c.1804A>G; p.N602D), which cosegregated with the disease phenotype. The change is located at a highly conserved amino acid position, is predicted to be pathogenic and was not found in over 100 normal Caucasian controls.

ITPR1 is an intracellular ligand-gated $Ca2^{+}$; release channel, playing a critical role in modulating intracellular $Ca2^{+}$; signaling. Mutations in *CA8*, encoding an inhibitor of ITPR1, causes a recessive form of CNPCA, supporting our finding that mutations in *ITPR1*, or genes in the *ITPR1*-related pathway, can give rise to CNPCA. Analysis of the original Australian SCA29 family is currently underway.

Discovery of a probable gene mutation causing mental retardation, microsomia, and signs of skeletal dysplasia in an Arab family with a previously undelineated autosomal recessive disorder. *M. Osman, Y. Al-Saraj, G. Billedo, S. Zaineddin, H. El-Shanti, J. Alami.* Shafallah Medical Genetics Center, Doha, Qatar.

Autosomal recessive diseases are the largest category of single-gene disorders among Arab population. Our goal is to identify the genetic causes of undelineated autosomal recessive disorders among Arab families. We have recruited a family with three siblings with a mental retardation (MR) syndrome who were born to consanguineous Qatari parents. The clinical problems comprised significant mental retardation, microsomia, signs of skeletal dysplasia, and thoracolumbar kyphosis. The oldest patient suffers also from epileptic seizures. The parents and the other three of their six children are healthy. The disease gene mapping strategy focused on large genomic regions demonstrating homozygosity in all of the affected individuals. Homozygosity mapping revealed a single large, shared region of homozygous SNPs on the long arm of chromosome 4 flanked by rs28419770 (4q13.1)and rs 4105671 (4q21.23). This block contains more than 120 genes, none of which has been implicated in MR or any of the above mentioned phenotype so far. Sequencing of candidate genes within the region revealed two novels missense variations in FRAS1 gene; an Arg3099Gln and Thr3149Met. Both variations were found in the three affected siblings in homozygous status, while the parents were heterozygous. Furthermore, these two variations have not been found in 140 individual controls in homozygous pattern, however, a heterozygous pattern of variations were found in three individuals.

1071W

Exome sequencing for noncoding regions : identification of the first branch point deletion in Aarskog-Scott syndrome. *M.H. Breuning[1], Y. Sun[1], E. Aten[1], R. al Momani[1], T. Messemaker[1], J.F.J. Laros[1], S.M. Maas[2], J.T. den Dunnen[1].* 1) Department of Human and Clinical Genetics, Leiden University Medical Center, Leiden, The Netherlands; 2) Department of Clinical Genetics, Academic Medical Centre, UVA, Amsterdam, the Netherlands.

Exome sequencing is an attractive method to identify causative mutations in coding regions responsible for Mendelian disorders. Aarskog-Scott syndrome (ASS) is clinically and genetically heterogeneous. It is characterized by short proportionate stature, broad hands and feet, genital hypoplasia (shawl scrotum) and facial dysmorphisms. Defects in FGD1 gene cause the ASS. However, only in ~ 20% of the patients mutations in FGD1 are identified by conventional sequencing methods. Here, we report a Dutch family with ASS with two affected boys where diagnostic Sanger sequencing failed to detect mutations in FGD1. The siblings were sequenced by whole exome sequencing (Sureselect and GAIIX) and a routine analysis for the exonic variants (nonsense, missense, splice site, frameshift) was performed. No obvious candidate was identified using the normal criteria and thresholds. An additional analysis was performed, extending the region to+/-50bp of exons. This revealed an intronic variant, 35 nucleotides upstream of an exon, which could affect splicing. The deletion is in the predicted branch point of an exon in FGD1, important in lariat formation. This variant was not reported in any disease or control database and cosegregated with the disease in this family. RNA isolated from peripheral blood showed a skip of the exon involved. The out of frame product generates a premature stop codon. To establish genotype-phenotype correlations, effects of NMD and X-inactivation were studied. The extended analysis, searching outside the exonic region up to 50bp, increased the number of detected variants by 55%. This may be caused by a high variant rate in introns and by lower coverage and strand bias towards the end of the exons. Minimal future changes in primer design for exome capture will ensure valuable extension of the current sequenced regions. The low mutation detection rates in ASS may be explained by branch point mutations currently missed by conventional diagnostic techniques. The location of the variant is within the region where standard DNA diagnostics protocols allow primer design. Splice site mutations affecting the branch-site might often go unrecognized due to allelic dropout in amplification and this might be the reason why they are rare in published literature. These data demonstrate that whole exome sequencing allows the recognition of mutations outside exonic regions and application in diagnostics might help to uncover more branch point mutations.

1072W

Regulation of *PLP1* alternative splicing by secondary structure. *G. Hobson[1], J. Taube[1], K. Sperle[1], B. Cavan[2], J. Garbern[3].* 1) Nemours Biomedical Res, A I duPont Hosp Children, Wilmington, DE; 2) Cebu Institute of Medicine, Cebu City, Philippines; 3) University of Rochester Medical Center, Rochester, NY.

Alternative splicing is an important mechanism to increase protein diversity. Much attention has been devoted to the role of exon and intron splicing elements (ESEs and ISEs) and their binding factors in regulation of alternative splicing, but several recent discoveries have highlighted the important role of secondary structure. The X-linked proteolipid protein 1 gene (*PLP1*) produces two alternatively spliced transcripts, *PLP1* and *DM20*, due to alternative splice donor sites in exon 3. The *PLP1* transcript is 105 bases longer than *DM20* and gives rise to a protein that is 35 amino acids larger. Mutations that affect the *PLP1/DM20* alternative splice ratio, even without any amino acid changes, result in the leukodystrophy called Pelizaeus-Merzbacher disease (PMD). We reported that an ISE at bases c.453+28_+46 in intron 3 regulates alternative splice site selection. To localize other sequences that regulate alternative splice site selection, we performed deletion scanning of intron 3 using a splicing mini-gene construct of the *PLP1/DM20* alternative splice and transfection into the Oli-neu cell line. Results of these studies demonstrated regulatory sequences throughout the intron, but a particularly strong regulatory sequence that is highly conserved from mouse to man resides between bases c.454 -346 and -307 in intron 3. Two families with PMD and strong X-linked inheritance pattern, but without mutations in the *PLP1* coding region, had mutations within this region, c.454-322G>A and c.454-314T>A. Both of these mutations decreased the *PLP1/DM20* ratio from the mini-gene construct in transfections, providing further evidence of a regulatory sequence in this region. Prediction of secondary structure using mfold revealed that intron 3 bases c.454-323 to -308 can form a secondary structure stem with bases c.454+151 to +166. Both patient mutations are predicted to destabilize the secondary structure. We demonstrated that mutations in each arm of the stem that disrupt the secondary structure also decrease the *PLP1/DM20* ratio, while swap mutations that restore the secondary structure bring the *PLP1/DM20* ratio to near normal levels. Taken together, our data strongly suggest that secondary structure within intron 3 is important in regulating the *PLP1* alternative splice.

1073W

Splice site variants in the Wilson disease gene, *ATP7B*, that affect splicing of an exon 18 minigene. *G. Macintyre[1], A.M.E. Wilson[2], D.W. Cox[2].* 1) Department of Medical Genetics, University of Alberta, Faculty of Medicine & Dentistry, Edmonton, AB, Canada; 2) Department of Medicine, Faculty of Medicine & Dentistry, University of Alberta, Edmonton, AB, Canada.

Wilson disease (WND; OMIM 27790) is an autosomal recessive disorder of copper transport affecting approximately 1 in 30,000 people worldwide. When ATP7B, the protein encoded by the WND gene, is defective, copper overload in the liver, brain and kidney can result. This leads to tissue damage and in some cases organ failure. At present, there are greater than 600 *ATP7B* variants listed in the Wilson Disease Mutation Database (http://www.wilsondisease.med.ualberta.ca/), and 54 are splice site variants. Splicing disruptions can lead to exon skipping, generating aberrant mRNAs and/or proteins that are defective. To functionally characterize these splice site variants, we have developed a minigene approach. A portion of the *ATP7B* gene, exons and introns included, is inserted into a mammalian expression vector. This allows expression in Chinese hamster ovary (CHO) cells, which do not express endogenous *ATP7B*, allowing specific detection and analysis of the splicing products. We have successfully used this approach to identify splice site and exonic variants of *ATP7B* that result in skipping of exon 8. Here, we present a minigene that starts in intron 16 and continues to intron 19, with all introns and exons in between. This was used to characterize five splice site variants adjacent to exon 18. c.3700-2A>T, c.3700-1G>A, c.3700-1delG, c.3903+1delG, and c.3903+6C>T were introduced into a wild-type minigene by site-directed mutagenesis, then transfected into CHO cells. RNA was extracted and exon 18 splicing was analysed by reverse transcriptase PCR. Altered splicing patterns were observed for four of the five *ATP7B* variants. We have categorized these as probable disease-causing variants that are likely to affect the production of normal levels of wild-type ATP7B protein, and/or generate defective truncated proteins. It is important to consider intronic splice-site variants of *ATP7B* as probable disease-causing. We previously identified *ATP7B* exon 8 variants, both synonymous and non-synonymous, that result in altered transcript processing. The construction of the exon 18 minigene will allow similar analysis of exon 18 variants. These studies are essential to the correct interpretation of the contribution of each variant to WND. Functional testing of missense variant proteins may be misleading, as splicing defects may have a significant impact upon the type and stability of ATP7B proteins produced and influence the severity of the WND phenotype.

Discovery of mRNA Splicing Mutations in the Human Gene Mutation Database by SNP-based Information Theory Prediction Confirmed by Expression Microarray Analysis. *E.J. Mucaki[1], X. Sun[1], P.K. Rogan[1,2].* 1) Department of Biochemistry, University of Western Ontario, London, Ontario, Canada; 2) Department of Computer Science, University of Western Ontario, London, Ontario, Canada.

Mutations affecting mRNA splicing have been associated with more than 15% of all inherited single gene disorders. Potential effects on mRNA splicing may not be recognized because mutation screening is based predominantly on genomic sequence analysis. We predict point mutations which may affect splicing in genetic databases such as the Human Gene Mutation Database (HGMD) using information theory-based methods. We then exploit expression microarray results from published variants at other expressed genomic loci which carry the same sequence to support or refute these predictions. New software was developed for batch analysis of changes in information content at mRNA splice sites that result from any point mutations recorded in HGMD. We previously reported a MySQL database with Affymetrix exon1.0 ST microarray expression data of HapMap individuals which correlated information analysis of splicing changes for all Phase II HapMap SNPs. This database was updated to add the sequences surrounding each SNP. SQL queries identified SNPs and adjacent sequences identical to the predicted splicing mutations in HGMD. Whisker plots and statistical analysis of multiple individuals with the same genotypes revealed differences in expression of HapMap SNP alleles which were concordant with the information theory-based predictions of altered splicing for a number of HGMD variants. We find 2520 (of 51245) point mutations were predicted to affect splicing, of which 1049 occurred at natural splice sites, and 1471 affect the strengths of cryptic splice sites. Exon expression data for sequences circumscribing HapMap SNPs identical in sequence to two natural and 14 cryptic splicing mutations in HGMD were concordant with predictions. The mutations affecting natural sites are F8: c.787G>A and PROS1: c.727G>A. The 14 mutations altering exonic cryptic splice sites include: MATN3: c.361C>T, PHGDH: c.1468G>A, NSD1: c.1357G>T, HADHA: c.1234G>T, BRCA1: c.1141A>T, F8: c.5665C>T, NPHS1: c.1250G>T, TG: c.6461G>A, AVPR2: c.673C>T, PRF1: c.757G>A, SLC45A2: c.298G>A, DSG1: c.430A>T, TLR4: c.2081A>G and SLC4A11: c.478G>A. Many of these HGMD mutations induce aberrant mRNA splicing either alone or in combination with protein coding changes. Information analysis of suspected eSNPs, concordant with allele-specific changes in expression, can provide insight into the pathogenic mechanisms of splicing mutations in unrelated genes with identical splice site sequences and variants.

1075W

Novel MFN2 mutations in two familial cases with Charcot-Marie-Tooth type 2A. *M. Muglia[1], A. Patitucci[1], D. Messina[1], A. Magariello[1], G. Nicoletti[1], R. Mazzei[1], FL. Conforti[1], C. Ungaro[1], L. Citrigno[1], I. Mikerezi[2], W. Sproviero[1,3], A. Gambardella[1].* 1) Institute of Neurological Sciences, Mangone, Italy; 2) Department of Biology, Faculty of Natural Sciences, University of Tirana, Albania; 3) Institute of Neurology, University `Magna Graecia', Catanzaro, Italy.

Charcot-Marie-Tooth type 2A is a dominantly inherited neuropathy characterized by axonal degeneration of sensory and motor nerves. The disease is caused by mutations in the mitochondrial fusion gene (MFN2). Mfn2 is an integral outer mitochondrial membrane protein composed of a large GTPase domain and two heptad repeat domains that face on cytoplasm. The aim of this study was to identify the causative mutation in a cohort of CMT2 patients. We identified two novel variations in two patients originated from Southern Italy and Albania, respectively. The Italian patient is a twenty-four year old man, who, by the age of 18 years, complains muscles weakness in the distal legs, and more recently burning feet. The mother and one brother are also affected, but with a milder phenotype. The second patient is a 64 years old man affected by an axonal neuropathy associated with deafness. His sister reportedly has similar symptoms, but denied neurophysiological testing or genetic analysis. The entire coding region were analyzed by DHPLC and fragments showing altered profiles were directly sequenced. In the Italian patient we identified the variation c.775C>T leading to the p.Arg259Ser amino acid substitution. The analysis of the other family members confirmed the co-segregation of the mutation with the CMT2 phenotype in the affected subjects. In the PolyPhen program, the PSIC (Position-Specific Independent Counts) score difference for the two amino acids R and S was 2.61 (>2.0). The variant is predicted to be probably damaging. The mutation p.Arg259Ser is located in the GTPase domain of the protein, the region of the MFN2 molecule necessary to induce fusion to other mitochondria. Disruption of functional domain of the protein is particularly likely to cause neuropathy. In the Albanian patient, a variation in c.1287+325C->T has been detected. The Splice Site Prediction program predicts that the variation could create a novel accept splice site in the c.1287+277_278AG of MFN2. Based on the results from similar studies, in which mutations occurring in intronic regions have been found to cause various levels of normal and aberrant transcripts, we presume that the c.1287+325C->T mutation affects the splicing of MFN2, and leads to a dysfunctional protein. Further investigation on mRNA will be needed in order to verify the real functional effect of the variation.

1076W

Deep intronic mutations flanking the alternatively spliced *NF1* exon 31/23a cause missplicing preferentially including exon 31/23a in the transcript. *J. Xie, T. Callens, J. Williams, L. Messiaen.* Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, Birmingham, AL.

Neurofibromatosis type 1 (NF1), a common autosomal dominant disorder affecting 1 in 3000 individuals worldwide, is caused by mutations in the *NF1* gene, which encodes neurofibromin, a negative regulator of the Ras signaling pathway. The *NF1* gene harbours at least 3 alternatively spliced tissue-specific exons (9br, 23a and 48a) and these isoforms have been detected at the protein level. The two major *NF1* isoforms are distinguished by the absence (type I) or presence (type II) of an alternatively spliced cassette exon 23a, located in the GTPase activating protein- (GAP-) related domain (GRD). Type II neurofibromin has higher affinity for Ras-GTP but lower GAP activity compared with the type I isoform. Using comprehensive *NF1* mutation analysis including direct cDNA sequencing of the entire coding region we identified 9 different splice defects in 11 individuals, leading to exonisation of different parts of intron 30 (23.2) or 31 (23a). Analysis of the flanking gDNA sequences allowed identification of the underlying mutations causing the splice defects. Alternative splicing of the in-frame exon 31 (23a) is highly regulated with multiple evolutionary highly conserved intronic sequence blocks flanking this exon. In blood, both isoforms are equally expressed in NF1 patients and controls alike. We investigated if the deep intronic mutations equally affected missplicing of the 2 major isoforms, including and excluding exon 31 (23a). Interestingly, the deep intronic mutations residing either 5' or 3' of exon 31 (23a) were shown, by fragment and cloning analysis, to predominantly affect the isoform 2. Among *NF1* mutations about 27% are splicing mutations. So far only 9 deep intronic *NF1* mutations have been reported in literature. We report a hotspot region for *NF1* deep intronic mutations: 12% of all deep intronic splice mutations detected by comprehensive RNA-based mutation analysis reside in introns 30 (23.2)-31 (23a) comprising only 2% of the total *NF1* intronic sequence. Our results may shed light on the intronic sequences functionally contributing to alternative splicing of the cassette exon 31 (23a).

1077W

The genetic etiology of otosclerosis in the genetic isolate of Newfoundland, Canada. *N. Abdelfatah[1], A. Griffin[2], K. Hodgkinson[1], T. Batten[4], S. Moore[3], J. Houston[1], C. Negrijn[1], T. Young[1].* 1) Discipline of Genetics, Faculty of Medicine, Memorial University, St. John's, NL A1B 3V6; 2) Central Regional Integrated Health Authority, Grand Falls-Windsor, NL A2A 2E1; 3) Department of Pediatrics, Memorial University of Newfoundland, St. John's, NL, Canada; 4) ENT Consultants, 1Paton St, St John'S, NL A1B 4S8.

Introduction: Otosclerosis (OTSC)is the most common cause of hearing loss among adult Caucasians, with an estimated prevalence of 0.3-0.4 worldwide.It is characterized by conductive hearing loss due to fixation of the stapes bone to the oval window. Sensorineural hearing loss may develop later in the disease or rarely presents as first symptoms. To date, 8 OTSC loci have been mapped OTSC1-OTSC10 (OTSC6,9 recalled), however, no genetic cause has been discovered for this disease. Purpose of the study: To identify the disease-causing gene(s) for otosclerosis in NL families Methods: Two large multiplex NL families (2114, 2081) and seven other probands, total of forty eight members; 23 members with otosclerosis were recruited. DNA samples from families 2081 and 2114 were genotyped for microsatellite markers spanning the intervals of all previously mapped OTSC loci, and three associated genes (COL1A1, COL1A2 and NOG). Disease-associated haplotypes were compared within and between pedigrees. DNA samples from family2114 were sent to genome wide scan for SNP genotyping and analysis, and positional candidate genes were sequenced using Sanger sequencing Results: Our previous results suggest that family 2081 is linked to the whole length of OTSC4 (10Mb). Comparing OTSC4 haplotype of family 2081 with haplotypes of four proband that belong to other NL otosclerosis families minimize the linked region from 10Mb into 4Mb. To determine the boundaries of the OTSC4 linked locus in family 2081, haplotypes were extended using microsatellite markers that flank OTSC4. As a result, family 2081 and family 2114 show a suggestive linkage to a region of 7 Mb that located downstream of OTSC4. We are using a combination of next-generation and Sanger sequencing to sequence the otosclerosis exome in order to discover the first-ever causative mutation for this disease. Summary: Families 2114 and 2081 are linked to an expanded region that overlaps with the OTSC4 critical region at chromosome 16q with different haplotype. Furthermore, family 2081 is also linked to the whole length of OTSC4. We hypothesize the gene to be located in the extended locus, and the patients of two families likely harbour a different mutation in the sa gene. To confirm our result, we will use the Illumina 610-quad microarrays to genotype the family members of 2114. We are also currently engaged in sequencing entire exomes from affected and unaffected members of family 2081 and 2114.

1078W

Homozygous chromosomal microdeletion of *NEUROG1* in a consanguineous family: A new human gene for the development of cranial sensory ganglia and inner ear neurons causing syndromic hearing loss, Mondini malformation, and gulp and mouth motor disorder. *O. Bartsch[1], J. Schröder[1], A.K. Lä) ig[2], A. Keilmann[2], W. Müller-Forell[3], D. Galetzka[1].* 1) Institute of Human Genetics, Johannes Gutenberg-University Mainz, Mainz, Germany; 2) Department for Communication Disorders, Johannes Gutenberg-University Mainz, Mainz, Germany; 3) Institute for Neuroradiology, Johannes Gutenberg-University Mainz, Mainz, Germany.

A homozygous chromosomal microdeletion sized > 111 kb, 46,XY.arr 5q31.1(134,764,990-134,875,801)x0 (GRCh37/hg19 assembly), was identified in a boy with profound congenital sensorineural hearing loss, bilateral cochlear hypoplasia with single widened cochlear turn (Mondini malformation), and severe gulp and mouth motor disorder. He also had low-set posteriorly rotated ears, plagio- and scaphocephaly, wide/long palpebral fissures, high and very narrow palate, sacral dimple, and developmental retardation. The parents were first cousins, they were unaffected and heterozygous for the chromosome 5q31.1 deletion. The deletion interval harbored 3 genes, all in full length; *DCNP1* (*C5orf20*), *TIFAB*, and *NEUROG1*. None of these genes was previously associated with deafness or disorders of brain development in humans, but in Xenopus neurogenin-1 (ngn1) was reported to convert ectodermal cells into neurons (Ma et al. Cell 87:43-52, 1996). In mice, *Ngn1* null mutant embryos failed to generate neuronal precursor cells for the proximal cranial sensory ganglia, leading to a loss of the vestibulo-cochlear, trigeminal and other ganglia, and to neonatal lethality by interfering with suckling (Ma et al. Neuron 20:469-82, 1998). *Ngn1* -/- mice showed complete absence of the inner-ear sensory neurons; neither afferent, efferent, nor autonomic nerve fibers were detectable (Ma et al. J Assoc Res Otolaryngol 1:129-43, 2000). In contrast, *DCNP1* and *TIFAB* are not likely candidate genes for deafness. DCNP1 is thought to function in the pathogenesis of depressive disorders and in the hypothalamic stress response, and TIFAB is highly expressed in spleen and inhibits TRAF6-induced cellular functions such as B-cell maturation and maturation of macrophages and dendritic cells. The human *NEUROG1* gene maps within a yet unresolved locus for autosomal recessive non-syndromic hearing loss, DFNB60 on chromosome 5q22-q31, but recent linkage data have excluded *NEUROG1* from being causative in the DFNB60 patients (R. Smith and M. Hildebrand, personal communication). The 5q22-q31 area is large, spanning 35 Mb and > 100 genes, and may well contain more than one deafness gene. Collectively, our results identify a new gene, *NEUROG1*, for autosomal recessive syndromic hearing loss. This is the first report on the human phenotype associated with *NEUROG1* null mutations and there is excellent concordance with experimental findings in *Ngn1* null mutant mice.

1079W

***AQP4* and Syndromic Menière's disease.** *C.A. Campbell[1,3], N.C. Meyer[1,3], L.T. TeGrootenhuis[1], C.C. Della Santina[2], J.P. Carey[2], L.B. Minor[2], M.R. Hansen[3], B.J. Gantz[3], R.J.H. Smith[1,3].* 1) Molecular Otolaryngology Research Laboratories, Department of Otolaryngology - Head and Neck Surgery, University of Iowa, Iowa City, IA; 2) Department of Otolaryngology-Head & Neck Surgery, The Johns Hopkins University, Baltimore, MD; 3) Department of Otolaryngology - Head and Neck Surgery, University of Iowa, Iowa City, IA, 52242, USA.

Menière's disease (MD) is a complex idiopathic disorder of the inner ear characterized by hearing loss, tinnitus, and vertigo (1995). Its histopathologic feature is endolymphatic hydrops or swelling of one of the inner ear compartments. In this study we completed a candidate-gene association study by screening Aquaporin 4 (*AQP4*) for rare and common variants as a test of the Common Disease Rare Variant (CDRV) and Common Disease Common Variant (CDCV) hypotheses. We selected *AQP4* because: 1) this member of the aquaporin family is expressed in multiple cell types in the cochlea and vestibule; 2) its targeted deletion in the mouse is associated with hearing loss; and 3) its function as a water channel suggests a possible role in maintaining endolymph and perilymph homeostasis in the inner ear.

Mutation screening of the coding region of *AQP4* in 124 sporadic MD patients and matched controls identified two cases carrying the same rare variant: M224T. This variant was not identified in an expanded screen of 848 control chromosomes and functional studies have shown that it decreases water permeability. Genetic counseling, pedigree analysis, detailed medical histories and screening of additional family members revealed additional phenotypes in both families, with the *AQP4* M224T variant segregating with a partial MD phenotype and with MD associated with migraine. Haplotype reconstruction surrounding M224T also indicates that the two families may share a small region of autozygosity by descent.

Our data show that rare variants in *AQP4* are causally related to MD and an MD-like phenotype that includes migraine. This finding is significant because it is the first to implicate aquaporins in human hearing loss and identifies for the first time a gene - *AQP4* - that is associated with syndromic MD. (This research was supported in part by a grant from the American Otological Society (RJHS).).

1080W

Rationalization of molecular diagnosis of Usher syndrome in the Spanish population. *T. Jaijo[1,2], E. Aller[1,2], G. Garcia-Garcia[1], MJ. Aparisi[1], JM. Millan[1,2,3].* 1) Grupo de Enfermedades Neurosensoriales, IIS-La Fe, Valencia, Spain; 2) CIBER de Enfermedades Raras (CIBERER), Valencia, Spain; 3) Unidad de Genetica y Diagnostico Prenatal, Hospital Universitario La Fe, Valencia, Spain.

Usher syndrome (USH) is an autosomal recessive inherited disease that associates sensorineural hearing loss with a progressive loss of vision due to retinitis pigmentosa (RP). To date, nine causative genes have been identified for the three clinical subtypes distinguished: USH1 (*MYO7A*, *USH1C*, *CDH23, PCDH15* and *USH1G*) USH2 (*USH2A, GPR98* and *DFNB31*) and USH3 (*USH3A*). Early diagnosis is critical for adapted educational and patient management choices, and for genetic counseling. PURPOSE: The purpose of this study is to determine the genetic epidemiology of USH in Spain and establish an accurate molecular diagnosis algorithm for our population. PATIENTS and METHODS: Currently, our series has 247 USH families collected from several Spanish Hospitals. From these, 70 are classified as USH1, 116 as USH2 and 16 as USH3. 15 families present with atypical Usher features (USHA) and detailed clinical data could not be obtained from 30 patients remaining as non-classified (USHNC). These patients have been screened for mutations in Usher genes using different methods: direct sequencing, the genotyping microarray for Usher syndrome, MLPA and array-CGH. RESULTS: In this study a total of 155 different mutations have been identified. Interestingly, 85 out of these (54.8%) have been detected only in the Spanish population. We could determine the genetic cause of the disease in 193 out of the 247 families studied. Pathologic mutations have been found in 95.7% of USH1 families: 52.9% have mutations in *MYO7A*, 21.4% in *CDH23*, 14.3% in *PCDH15*, 2.9% in *USH1C* and 4.3% in *USH3A*. Regarding USH2 families, mutations have been found in 85.3% of them: 81% have mutations in *USH2A*, 4.3% in *GPR98* and 1.7% in *CDH23*. For USH3 families, mutations have been detected only in 31.25%: 12.5% have mutations in *USH3A*, another 12.5% in *USH2A* and 6.25% in *PCDH15*. Heterogeneous results have been obtained for USHA and USHNC families, pointing out the importance of an accurate clinical diagnosis. No mutations have been identified in *USH1G* and *DFNB31*. CONCLUSION: Our study has allowed us to determine the genetic cause of the disease in 78.1% of USH Spanish families. However, it has been a long and hard task. Currently, there is no satisfactory solution for rapid in-depth and simultaneous mutation screening of the known USH genes. However, next generation sequencing technologies promise to be able to fulfil this task within the next few years.

1081W

Assessment of GJB6, GJB4, and GJC3 genes for double heterozygosity with GJB2 heterozygots in autosomal recessive non-syndromic hearing impairment patients. *D. Kooshavar[1,2], M.R. Noori Daloii[1], M. Hashemzadeh Chaleshtori[2].* 1) Department of Medical Genetics, Tehran University of Medical Science, Tehran, Iran; 2) Cellular and Molecular Research Center, Shahrekord University of Medical Science, Shahrekord, Iran.

Hereditary non-syndromic hearing loss is inherited in autosomal recessive pattern in about 80% of cases. Up to 50 percent of all autosomal recessive nonsyndromic hearing impairment (ARNSHI) cases in different populations are caused by mutations in the GJB2 gene which encodes the gap-junction (GJ) protein connexin (Cx) 26. However 10 to 50 percent of patients with recessive GJB2 mutations carry only one mutant allele. GJB6, GJC3, and GJB4 encoding Cx30, Cx30.2, and Cx30.3 respectively, are expressed in cochlea and the same inner-ear structures as GJB2. GJB6 is shown to be normally co-assemble with GJB2 into GJs in the cochlea. Besides, mixing of different connexins in heteromeric and heterotypic GJ assemblies is also possible. This study aims to determine whether variations in any of the genes GJB6, GJC3 or GJB4 can be the second mutant allele causing the disease in the GJB2 heterozygous cases studied. We examined 44 unrelated GJB2 heterozygous ARNSHI subjects from different geographic and ethnic areas in Iran, for any sequence variations in three genes, using polymerase chain reaction followed by direct sequencing. Sequence analysis of GJB4 showed 3 heterozygous substitutions (c.451C>A, c.507C>G, c.542C>T) also one frameshift caused by 4bp deletion (c.155_158delTCTG) causing the changes (p.Arg151Ser, p.Cys169Trp, p.Thr181Met, p.Ala52ValfsX55) in amino acid sequence. There was one heterozygous substitution (c.173C>T) in GJB6 in one case which leads to the change of (p.Pro58Leu) in amino acid sequence. We found no variations in GJC3 gene sequence. So our detected GJB4 and GJB6 allelic variations can be considered as second allelic variation in patients with only one GJB2 mutant allele but variations of GJC3 was not the second allele in studied samples. Further examinations on control samples and co-segregational family studies are in progress to confirm the pathogenicity of the detected allelic variations as the second complementary mutation responsible for the disease in double heterozygote pattern.

1082W

Examination of Gene Expression Patterns Associated with PMP22-Related Auditory Dysfunction. *M.J. Kovach, T.A. Carver, W.R. Bolus.* Biological & Environmental Sci, Univ Tennessee, Chattanooga, TN.

Characterization of expression patterns of genes responsible for deafness, can help dissect the molecular events underlying both deafness and normal hearing. A variant of Charcot-Marie-Tooth (CMT1E) disease associated with deafness, has been linked to point mutations in the *PMP22* gene. *PMP22* is largely expressed in Schwann cells responsible for nerve myelination, but is also detected in a variety of non-neural tissues, including the cochlea and lungs, at critical times of tissue development. The mouse homolog of *PMP22*, *Gas3*, was first isolated as a Growth Arrest Specific gene. In non-neural tissues, Gas genes are induced during growth arrest and repressed at terminal differentiation. Thus, PMP22 appears to play a role in nerve myelination and cell growth regulation of non-neural tissues. This dual expression is consistent with both neural and cochlear hearing loss in CMT1E patients. We hypothesize that PMP22 expressed in non-neural tissues serves to regulate expression of genes important in normal tissue development. More specifically, PMP22 is regulating genes involved in development of the inner ear, which may explain the deafness phenotype of CMT1E. The Trembler-J mouse was chosen as a model for PMP22-associated auditory dysfunction to study gene expression patterns throughout development. Lung tissue was used as a non-neural surrogate for the cochlear membranous labyrinth. Tissues were collected from WT and TrJ mice throughout development and gene expression profiles were characterized by differential display and qRT-PCR. Thus far, 85 differentially expressed transcripts have been identified, verified and classified according to cellular function, 55% of which are homologs or family members of genes in the human cochlear library. In an effort to understand the molecular pathology of the disease state, these genes have been categorized into groups by cellular function. Major groups include: cell communication and signal transduction (25%), nucleic acid metabolism (22%), and cell growth/maintenance (15%). Ten genes differentially expressed in the TrJ mouse model were identified as candidates for the deafness phenotype. Differential expression patterns of candidate genes were characterized by qRT-PCR throughout embryonic and adult development. Two developmental time points, E11.5 and P14, consistently exhibited divergent expression patterns between WT and TrJ samples, and may indicate critical junctures in non-neural tissue development.

Pitfalls in the etiological diagnosis of sensorineural hearing loss in Brazil. *P.Z. Ramos[1], A.M. Castilho[2], V.C.S. de Moraes[1], E.L. Sartorato[1].* 1) Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade Estadual de Campinas (UNICAMP), Campinas, São Paulo, Brasil; 2) Departamento de Otorrinolaringologia, Hospital de Clínicas, UNICAMP, Campinas, SP, Brasil.

Deafness is considered the most prevalent sensory disorder in humans, caused by a variety of environmental and genetics factors. The environmental factors include frequent exposure to high intensity sound, acoustic trauma, infections, and ototoxic drugs, whereas the genetics factors are caused by mutations in different genes or regulatory elements that are involved in proper development, structure, and function of the ear. In developed countries, most of hearing loss cases are due to genetic factors, however, in Brazil, environmental factors are among the major causes. Although a simultaneous testing approach, including clinical exams, audiological, laboratorial, imaging and genetic expands the etiological diagnosis, overloads the healthcare system due to high costs. The goal of the present study was to evaluate the effectiveness of imaging and genetics tests and their impact on public health, aiming to increase efficiency and reduce costs. It was conducted an analysis of 50 patients submitted to cochlear implantation between 2005 and 2010 at our tertiary referral university hospital. Clinical and audiological data were retrieved from patient's charts. Results of computed tomography and magnetic resonance scans were reviewed. In addition, a molecular analysis was conducted, including *GJB2*, *GJB6*, *SLC26A4* genes and A1555G mitochondrial mutation in 12S ribosomal RNA gene. Radiologic abnormalities were identified in 13 patients, while molecular alterations were found in 18 individuals, including 35delG, V27I, M34T, V37I, E47X, L90P, V95M, K168R, W172X in *GJB2* gene and V609G in *SLC26A4* gene. Imaging and genetic findings were important to establish the diagnostic of hearing loss in 22 and 20% of the patients, respectively. After specific tests, the number of individuals with unknown cause was thus reduced from 36 to 22 (39% of reduction). The etiology was environmental in 22% of the cases, genetics in 20% and inner ear malformations in 14%. Data obtained in the present work confirmed the high prevalence of mutations in *GJB2* gene, especially 35delG mutation, in cases of severe to profound bilateral sensorineural hearing loss. This study also demonstrated that both imaging and genetic analysis are important in the identification of the etiology of hearing loss. Moreover, we observed that the unknown etiology prevailed, which points to the need of carrying out detailed genetic studies in order to elucidate the etiological diagnosis.

Forward genetics to identify novel neuromuscular genes in zebrafish. *V. Gupta[1], S.R. Gundry[1,2], M. Discenza[1], A.T. Chen[3], Y. Zhou[3], L.I. Zon[3,4], A.H. Beggs[1].* 1) Genomics Program and Division of Genetics, The Manton Center for Orphan Disease Research, Children's Hospital Boston, Harvard Medical School, Boston, MA-02115, USA; 2) Behavioral Neurosciences, School of Arts and Sciences, Northeastern University, Boston, MA-02115, USA; 3) Stem Cell Program and Hematology/Oncology, Children's Hospital Boston, Harvard Stem Cell Institute, Harvard Medical School, Boston, MA-02115, USA; 4) Howard Hughes Medical Institute.

Primary inherited disorders of muscle include both muscular dystrophies and non-dystrophic myopathies. These disorders, characterized by muscle weakness and impaired locomotion, form a heterogeneous group of heredity diseases affecting both children and adults. Owing to genetic and clinical heterogeneity, variable penetrance and mortality, genetic studies of some of the more rare myopathies in humans are difficult and studying the pathophysiology can be problematic in the absence of suitable animal models. The zebrafish, Danio rerio, is a powerful developmental and genetic system for dissection of skeletal muscle disorders and diseases. Several features of zebrafish, such as a well-characterized genome with high degree of synteny and sequence homology (50-90% of amino acids) to humans, conserved structure of vertebrate skeletal muscles, transparency at embryonic stages and rapid and ex vivo development, make it ideal for skeletal muscle biology research. We have employed a forward genetics approach in zebrafish as a tool to identify novel genes causing muscular disorders, and have recently identified 12 unique mutants with defective skeletal muscle. One of the mutants identified in this screen, Osoi, displays impaired motility behavior and exhibits skeletal muscle hypotrophy with extensive central nucleation. Ultrastructural studies identified sarcomeric disorganization and prominent chromatin changes in the nuclei of the mutant fish. Genetic mapping of the mutant locus in Osoi has identified a loss of function mutation in a novel RNA binding protein. Preliminary studies suggest a role for this gene in ribosomal biogenesis in skeletal muscles. The central nucleation is reminiscent of centronuclear myopathy, a human congenital myopathy. Through an understanding of the molecular pathways controlling skeletal muscle hypotrophy using this mutant, we hope to gain insights into this and related conditions, and can begin to develop corrective therapies for such muscle defects.

1085W

A multiplex kindred with severe Buruli Ulcer displaying Mendelian inheritance. *Q.B. Vincent[1], A. Chauty[2], M.F. Ardant[2], H. Dokponou[2], J. Gnossike[2], H. Koussemou[2], L. Marsollier[3], J.L. Casanova[1,4], L. Abel[1,4], A. Alcais[1,4].* 1) Laboratory of Human Genetics of Infectious Diseases, Necker Branch, Institut National de la Recherche Medicale U980 (INSERM), Université Paris-Descartes, 156 rue de Vaugirard, 75015 Paris, France; 2) Centre de Détection et de Traitement de l'Ulcere de Buruli (CDTUB), BP 191, Pobe, Benin; 3) Groupe d'Etude des Interactions Hote-Pathogene, Universite d'Angers, Angers, France; 4) Saint-Giles Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, The Rockefeller University, 1230 York Avenue, Box 163, New York, NY 10065, USA.

Buruli Ulcer (BU), caused by Mycobacterium Ulcerans, is the third most common mycobacteriosis worldwide after tuberculosis and leprosy, and has been flagged in 1998 by the World Health Organization as an emerging neglected infectious disease. The physiopathology of Mycobacterium ulcerans infection primarily involves the lipidic toxin mycolactone, a unique feature among mycobacteria. The resulting extensive skin ulcers and osteomyelitis cause pathologic scarring responsible for severe life-lasting functional disabilities in the affected population, mainly composed of children of less than 15 year of age. Buruli ulcer mainly strikes in Western Sub-Saharan Africa but cases have been reported in more than 30 countries worldwide. A common characteristic of the endemic countries consists in the extreme clustering of BU cases in families living in the vicinity of slow-flowing or stagnant waters in rural areas. However, only a fraction of these heavily exposed individuals develop Buruli ulcer, which leads us to hypothesize a genetic etiology accounting for this variability. To tackle this issue, we adopted an extreme-phenotype strategy, which consisted in recruiting the most severe of the >1,500 BU cases diagnosed and treated during the last 7 years at the Centre de Détection et de Traitement de l'Ulcère de Buruli in Pobè, Benin. We report here the analysis of a single highly-informative consanguineous family in which two siblings were affected with exceptionally severe PCR-confirmed BU. The index case suffered from a multifocal edematous form of BU, which disseminated under treatment and involved the four limbs, eventually requiring amputation to heal. Blood was obtained from the 2 parents, 2 affected and 3 unaffected children. DNA was processed for the genotyping of >900,000 Single Nucleotide Polymorphisms by the Affymetrix Genome-Wide 6.0 array. After quality control procedures, 120,156 independent SNPs were used for linkage analysis by homozygosity mapping. Three regions, on chromosome 5 and 8, cosegregated with the affected status following a Mendelian recessive inheritance mode, i.e. were shared homozygous by descent by the 2 affected individuals but not the 3 unaffected siblings, yielding the maximum possible LOD score given the pedigree. Sequencing of genes in these regions is currently ongoing and show promising results. This first description of a genetic etiology for extremely severe BU will have far reaching biological and medical implications.

1086W

Target gene selection and dual genome analysis by Next Generation Sequencing for mitochondrial disorders. *W. Zhang, H. Cui, F. li, l. Wong.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Background: Mitochondrial disorders are a group of complex diseases that can be caused by mutations in nuclear or mitochondrial genomes. More than 90% of the proteins involved in mitochondrial biogenesis and function are encoded by the nuclear genome. To capture the full spectrum of genetic defects, multiple different and complementary methods are required. For example, current molecular analytical methods include Sanger sequencing for the detection of point mutations, and qPCR/Southern blot/MLPA/array CGH for large insertion/deletion. These procedures are labor intensive, time consuming, and costly. Methods: A target gene enrichment using RNA probes to capture 360 nuclear genes targeted to mitochondria followed by a high throughput “deep” coverage next generation sequencing (NGS) approach was developed for the application in clinical settings. In addition to the targeted nuclear genes, the capture library also contains probes for the entire mitochondrial genome. Results: With the gene enrichment, about 40% of the sequence reads are mapped to target genes. An average coverage of >500X for targeted nuclear genes and >5000X for each of the 16,569 bases of the mitochondrial genome was achieved. The high coverage allows not only the highly accurate detection of nucleotide changes in both nuclear and mitochondrial genomes, but also the degree of heteroplasmy at every single base of the mitochondrial genome. This method accurately detected a heterozygous c.761T > A (p.I254N) mutation and a heterozygous deletion of exons 1 and 2 of the TK2 gene in a sample with known diagnosis. An average of 20 nonsense and/or novel mutations were identified in each of the 7 samples analyzed. However, all of these mutations occurred as a single heterozygous allele, not consistent with autosomal recessive inheritance. Conclusion: Our results demonstrated the superior sensitivity and specificity of base calls compared to the gold standard Sanger sequencing. With deep coverage, measurement of mitochondrial nucleotide heteroplasmy is easily achieved. This approach can be used for simultaneous sequence analyses of a group of selected genes related to mitochondrial disorders for molecular diagnosis.

***FKBP10*-null mutation in recessive type XI OI leads to abnormal collagen trafficking to Golgi.** *A.M. Barnes[1], W.A. Cabral[1], E. Makareeva[2], M. Weis[3], W. Chang[1], L. Felley[1], D. Eyre[3], S. Leikin[2], C. Trujillo[4], J.C. Marini[1].* 1) Bone and Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD, United States; 2) Section on Physical Biochemistry, NICHD/NIH, Bethesda, MD, United States; 3) Orthopaedic Research Laboratories, University of Washington, Seattle, United States; 4) Genetics Unit, Dr. Erfan & Bagedo General Hospital, Jeddah, Saudi Arabia.

Osteogenesis imperfecta (OI), or "brittle bone disease", is a genetic disorder characterized by bone fragility and deformity and short stature. Dominant OI (85-90% of cases) is caused by mutations in either of the genes for type I collagen, *COL1A1* or *COL1A2*. Recessive OI is caused by defects in genes whose products interact with type I collagen for modification and/or folding. We identified a 5-generation Palestinian pedigree with both moderate and lethal forms of recessive OI caused by homozygous mutations in *FKBP10* or *PPIB*, which encode the ER-resident peptidyl-prolyl cis-trans isomerases FK506-binding protein 65 (FKPB65) and cyclophilin B (CyPB), respectively. For each mutation, we compared transcripts and protein levels of collagen chaperones, steady state collagen, chain incorporation, differential scanning calorimetry, amino acid analysis, and immunofluorescence (IF) staining in proband and control fibroblasts. One pedigree branch includes a child with moderate type XI OI and a homozygous *FKBP10* mutation (c.1271_1272delCCinsA); both parents and one sibling are carriers. *FKBP10* transcripts in proband fibroblasts are 6% of control; the mutation leads to intronic retention in ¼ of transcripts, but both forms have premature stops. FKBP65 protein is absent in proband cells analyzed by Western blot and IF microscopy. Transcripts for other proteins that interact with collagen are normal for CRTAP and P3H1, while HSP47 is increased approximately 2.5 fold in proband cells. CRTAP, P3H1 and HSP47 protein levels are near normal. Proband collagen gel electrophoresis reveals moderate band broadening, with a 13% increase in hydroxylysine and a 7% increase in hydroxyproline as compared to control, with normal chain incorporation. Proband collagen (1(I)Pro986 3-hydroxylation is normal, as is collagen T_m. Collagen in proband cells is not aggregated on IF and appears to remain in the ER. A second pedigree branch includes two children with lethal OI. Both parents carry a 4 nt deletion in exon 5 of *PPIB* (c.563_566delACAG), predicting type IX OI in offspring. Mutant transcripts would likely escape NMD. Truncated CyPB would be predicted to cause severe dysfunction of the collagen 3-hydroxylation complex, compatible with the lethal outcome. In conclusion, *FKBP10*-null cells have a slight folding delay, with a ~10% increase in hydroxylation. This delay is associated with abnormal collagen trafficking to the Golgi and may lead to a delay in secretion.

1088W

Leri Weill Syndrome caused by a duplication of cis-regulatory DNA elements downstream of SHOX gene. *D. Coviello[1], L. Capone[2], M. Baffico[1], R. Bertorelli[2], L. Iughetti[3], B. Predieri[3], S. Vanelli[4], B. Stasiowska[4], M. Baldi[1], A. Forabosco[2].* 1) Laboratory of Human Genetics, E.O. Ospedali Galliera, Genova, GE, Italy; 2) Laboratory of Molecular Biology and Medical Genetics, Cante di Montevecchio Institute, Fano, Italy; 3) Pediatric Department, University of Modena and Reggio Emilia, Modena, Italy; 4) Auxology Unit, University of Tourin, Tourin Italy.

Leri-Weill syndrome (LWS)(MIM127300) is a dominantly inherited skeletal dysplasia characterized by mesomelic disproportionate short stature and Madelung deformity of the wrist. Heterozygous deletions or mutations of the short-stature homeobox-containing gene (SHOX) (MIM 312865) have been identified as the molecular basis of LWD. Homozygous or compound heterozigous SHOX mutation have been demonstrated to be responsible for the most severe dwarfism known as Langer mesomelic dysplasia (LMD) (MIM 249700). The disturbance of the long range regulation of gene expression, essential for producing the gene product in the proper time and place and in the correct quantity, has been proposed as the cause of a number of diseases in which the suspected target genes appeared to be completely normal. The discovery in the last few years that heterozigous and homozogous DNA deletions downstream the intact SHOX gene cause the LWS and LMD syndrome respectively, led to hypothesize the presence of DNA elements acting as enhancers in the 3' region downstream of SHOX. It has been shown that this enhancer action is due to conserved non coding DNA elements (CNEs). Many authors have identified a number of CNEs, showing enhancer activity both in vitro and in vivo. Recently, LWD has been reported also in subjects with cis-interstitial duplications of the PAR1/SHOX region encompassing entirely or partially the SHOX gene. The precise mechanisms of the pathogenic effect caused by the microduplication of the CNEs-containing region are unclear. It is possible that duplication exerts a negative effect on SHOX transcription. Recently, it has been demonstrated that the proper gene regulation depends not only on the required transcription factors and associated complexes being present but also on the integrity, chromatin conformation and nuclear positioning of the gene chromosomal segments. On the basis of the above considerations it is not unlikely that the duplication alters the three dimensional chromatin spatial organization impeding in some way the enhancer to contact the promoter, resulting in a lack of gene activation resulting in a condition of haploinsufficiency. We report the first cases of "pure" duplications of the region downstream the SHOX gene containing CNEs regulatory elements in two LWS families, suggesting that duplications may represent an additional class of mutations implicated in the molecular etiology of the Leri Weill syndrome.

1089W

Musculo-contractural Ehlers-Danlos syndrome (EDS type VIB): a new EDS-subtype caused by a defect in proteoglycan biosynthesis. *A. De Paepe[1], P. Vlummens[1], D. Syx[1], S. Nampoothiri[2], S. Symoens[1], F. Malfait[1].* 1) Center for Medical Genetics, Ghent University Hospital, Belgium; 2) Amrita Institute of Medical Sciences and Research Center, Cochin, Kerala, India.

Musculo-contractural Ehlers-Danlos syndrome (MC-EDS) is a recently described autosomal recessive form of EDS characterized by craniofacial abnormalities, congenital joint contractures, especially of fingers and toes, talipes equinovarus, tapering fingers and excessive palmar wrinkling, severe progressive muscle hypotonia and multi-systemic tissue fragility with ophtalmological, gastro-intestinal and genito-urinary manifestations, in addition to skin fragility, wound healing problems, bleeding diathesis and joint hyperlaxity. The condition is caused by homozygous mutations in *CHST14*, encoding dermatan-4-sulfotransferase 1 (D4ST-1). The clinical phenotype of MC-EDS strongly overlaps with that of adducted thumb-clubfoot syndrome (ATCS), and with "EDS Kosho type", a Japanese EDS-variant, two conditions that were independently shown to be caused by *CHST14* mutations. Detailed phenotypic analysis of the 20 patients reported with *CHST14* mutations strongly suggests that these conditions form a single entity with multi-systemic, but age-dependent and variable phenotypic features, of which joint contractures and generalized muscle weakness are distinguishing features, hence the name "musculo-contractural EDS". Hitherto reported *CHST14* mutations comprise six missense, two nonsense and one frameshift mutation, some of which were shown to result in loss of function of D4ST-1. This is a key enzyme in the biosynthesis of dermatan sulfate (DS), catalyzing 4-O-sulfation of N-acetyl-galactosamine. Loss of D4ST-1 activity results in the replacement of DS by chondroitin sulfate. The broad array of physiological events in which DS plays a role, including the correct assembly of collagen fibrils mediated by decorin, a DS proteoglycan, explains the multisystemic manifestations of this condition.

Novel canine chondrodysplasia mutation. *K. Kyöstilä[1,2,3], H. Lohi[1,2,3].* 1) Department of Veterinary Biosciences, University of Helsinki, Finland; 2) Research Programs Unit, Molecular Medicine, University of Helsinki, Finland; 3) Department of Molecular Genetics, Folkhälsan Institute of Genetics, Finland.

Skeletal dysplasias are heterogeneous disorders of bone and cartilage. Chondrodysplasias affect cartilage tissue and often result in disproportionate short stature or dwarfism. We report here the identification of a recessive canine chondrodysplasia mutation in a gene that represents a new candidate for human chondrodysplasias. The novel mutation was identified in Norwegian Elkhounds, a Nordic hunting breed that suffers from hereditary chondrodysplasia. The condition results from generalized disturbance in the endochondral ossification process. Abnormalities are seen in both the arrangement and structure of growth plate chondrocytes. At a histopathological level, the disorder is reported to bear resemblance to human spondylometaphyseal dysplasias. Our pedigree analysis suggested a recessive mode of inheritance for the condition. We applied the genome-wide association method to map the causative mutation to a novel canine chondrodysplasia gene on CFA17. Nine affected dogs and nine control dogs were genotyped using Illumina's canine SNP chip of 22K SNPs. Association analysis revealed a 2 Mb disease associated locus on CFA17 (Praw=6.46E-06, Pgenome= 0.012). Mutation screening of a plausible candidate gene on the locus revealed a homozygous nonsense mutation in all affected dogs, predicted to result in a premature stop-codon in the encoded protein. Segregation of the mutation was studied further in 157 unrelated population controls none of which were homozygous for the mutant allele. To the best of our knowledge, this is the first report of a spontaneous disease causing mutation for this gene which now serves as a plausible candidate gene in human chondrodysplasias as well. We have initiated screens in human patients with related phenotypes. We hope our findings will improve the understanding of the endochondral ossification processes and related molecular pathways in health and disease.

Identification by exome sequencing of truncating mutations in the last exon of NOTCH2 as a cause of Hajdu-Cheney syndrome, a rare disorder with osteoporosis. *C. Le Caignec[1,2,3,4], B. Isidor[1], P. Lindenbaum[1,2,3], O. Pichon[1], S. Bezieau[1], C. Dina[2,3,4], S. Jacquemont[5], D. Martin-Coignard[6], C. Thauvin-Robinet[7], M. Le Merrer[8], J.L. Mandel[9], A. David[1], L. Faivre[7], V. Cormier-Daire[8], R. Redon[1,2,3].* 1) Service de Genetique Medicale, Institut de biologie - CHU, Nantes, France; 2) INSERM, UMR915, l'institut du thorax, Nantes, France; 3) Université de Nantes, Nantes, France; 4) CNRS, ERL3147, Nantes, France; 5) CHUV, Service de Génétique Médicale, Lausanne, Switzerland; 6) Unité de Génétique Clinique, Centre Hospitalier du Mans, Le Mans, France; 7) Centre de Génétique, Centre de Référence Maladies Rares “Anomalies du développement et syndromes malformatifs de l'interrégion Est” Hôpital d'Enfants, CHU, Université de Bourgogne, Dijon, France; 8) INSERM U781 and Département de Génétique, Université Paris Descartes, Hôpital Necker-Enfants Malades, Paris, France; 9) Translational Medicine and Neurogenetics Program, Institut de Génétique et de Biologie, Moléculaire et Cellulaire (IGBMC), INSERM U964, CNRS UMR 7104, Université de Strasbourg, CHU de Strasbourg, Collège de France, Illkirch, France.

Hajdu-Cheney syndrome is a rare skeletal disorder characterized by the association of facial anomalies, radiological findings (acro-osteolysis, general osteoporosis, insufficient ossification of the skull) and periodontal disease (premature loss of permanent teeth). Although most cases are sporadic, transmission in a few families suggests autosomal dominant inheritance. We sequenced the exomes of six unrelated patients and identified nonsense and frameshift heterozygous mutations in NOTCH2 for five of them. The five mutations are invariably located within the last 3' coding exon of NOTCH2, distal to the ankyrin repeats and NLS necessary for the transcriptional activity of Notch2 intracellular domain, while deleting the PEST domain. These results suggest that mutant mRNA products escape nonsense-mediated decay and that truncated NOTCH2 proteins act in a gain-of-function or dominant-negative manner. This mutational mechanism also suggests that modulating Notch2 signaling using selective gamma-secretase modulators may have therapeutic interest in this severe and progressive disease. Finally, our findings establish an important role for Notch2 signaling in bone homeostasis that may notably be relevant to better understanding of mechanisms leading to osteoporosis.

1092W

Mutations in the TGFβ binding protein-like domain 5 of FBN1 are responsible for acromicric and geleophysic dysplasias. *C. Le Goff[1], C. Mahaut[1], L.W. Wang[2], S. Allali[1], A. Abhyankar[3], S. Jensen[4], L. Zylberberg[5], G. Collod-Beroud[6], C. Bole-Feysot[7], P. Nischtke[8], P. Handford[4], J.L. Casanova[9], C. Boileau[10], S.S. Apte[2], A. Munnich[1], V. Cormier-Daire[1], clinical consortium of gelophysic and acromicric dysplasias.* 1) Dept Gen, INSERM U781, university Paris Descartes Hopital Necker, Paris, France; 2) Department of Biomedical Engineering, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, Ohio, USA; 3) St. Giles Lab of Human Genetics of Infectious Diseases, Rockefeller Branch, The Rockefeller University, New York, NY, USA; 4) Department of Biochemistry University of Oxford, South Parks Rd Oxford UK; 5) ISTEP, CNRS UMR71 93, Université Pierre et Marie Curie, Paris, France; 6) INSERM, U827, F-34000 France and Université Montpellier1, UFR Médecine, Montpellier France; 7) Plateforme Génomique, Fondation Imagine Université Paris Descartes, Paris, France; 8) Plateforme de Bioinformatique, Université Paris Descartes, Paris, France; 9) Lab of Human Genetics of Infectious Diseases, University Paris Descartes and INSERM U980, Necker Medical School, Paris, France, and St. Giles Lab of Human Genetics of Infectious Diseases, , The Rockefeller University, New York, NY, U; 10) INSERM U698, Bichat Claude Bernard and Laboratoire de Biochimie et de Génétique Moléculaire, hôpital Ambroise Paré, Boulogne, France.

Geleophysic (GD) and acromicric dysplasia (AD) belong to the acromelic dysplasia group and are both characterized by severe short stature (<-3SD), short hands and feet, joint limitations and skin thickening. GD is distinct from AD by an autosomal recessive mode of inheritance and a progressive cardiac valvular thickening often leading to an early death. AD is transmitted with an autosomal dominant mode of inheritance and is characterized by distinct dysmorphic features, a hoarse voice and an internal notch of the femoral head. We recently identified mutations in A Disintegrin And Metalloproteinase with Thrombospondin repeats-like 2 gene (ADAMTSL2) in GD. We demonstrated an involvement of ADAMTSL2 in TGFβ bioavailability. However, absence of ADAMTSL2 mutations in 19/33 GD patients suggested genetic heterogeneity. AD has unknown molecular basis. We performed exome sequencing in 2 GD cases with no ADAMTSL2 mutations and in 3 AD patients. Based on the phenotypic overlap between AD and GD, we searched for a shared mutated gene among the 5 exomes. We identified changes in three genes: MUC17, HYDIN and FBN1. The presence of tall stature in Marfan syndrome caused by FBN1 mutations prompted us to consider FBN1 as the best candidate gene. We identified 16 heterozygous FBN1 mutations (15 missense and one insertion) all located in exon 41-42, encoding TGFβ binding protein-like domain 5 (TB5) of FBN1 in 19 GD and 10 AD cases. While GD has been described as an autosomal recessive disorder, the identification of heterozygous FBN1 mutations demonstrates a dominant form of GD, strictly fulfilling the diagnostic criteria for GD (including progressive cardiac valvular thickening, and early death in 3/19). Similarly, all AD cases fulfilled the diagnostic criteria of AD and had no cardiac involvement or early death. These data demonstrate that GD and AD are distinct but allelic conditions. Microfibrillar network disorganization and enhanced TGFβ signaling were consistenty observed in GD/AD fibroblasts. Importantly, a direct interaction between ADAMTSL2 and FBN1 was demonstrated suggesting a dysregulation of FBN1/ADAMTSL2/ TGFβ interrelationship as the underlying mechanism of the short stature phenotypes. Our findings support that TB5 mutations in FBN1 are responsible for short stature phenotypes. Ongoing studies will hopefully help to further understand how enhanced TGFβ signaling caused by FBN1 mutations can trigger either Marfan syndrome or GD/AD.

1093W

Sc65 is a novel regulator of bone homeostasis. *R. Morello[1,4], B. Hendrix[1], K. Gruenwald[1], P. Castagnola[2], D. Gaddy[1], L.J. Suva[3].* 1) Dept Physiology & Biophysics, Univ Arkansas, Little Rock, AR; 2) National Institute for Cancer Research, Genoa, ITALY; 3) Dept of Orthopaedic Research and Physiology & Biophysics, Univ Arkansas, Little Rock, AR; 4) Division of Genetics, Univ Arkansas, Little Rock, AR.

Leprecan-like 4 (*Leprel4*, aka Sc65) is a member of the Leprecan family of genes which include *Crtap* (encoding cartilage associated protein), *Lepre1* (*Leprecan* encoding prolyl 3-hydroxylase 1 or P3h1), *Leprel1* (*Leprecan-like 1* encoding prolyl 3-hydroxylase 2 or P3h2) and *Leprel2* (*Leprecan-like 2* encoding prolyl 3-hydroxylase 3 or P3h3). We and others showed that mutations in two Leprecan genes, *CRTAP* and *LEPRE1* cause recessive forms of osteogenesis imperfecta (OI). Such findings shifted much of the current OI interest from matrix components (i.e. type I collagens) to endoplasmic reticulum resident proteins, led to the identification of additional genes (*PPIB*, *FKBP10*, and *SERPINH1*) linked to recessive OI and greatly increased the molecular understanding of this disease. Having previously characterized the collagen prolyl 3-hydroxylation complex, containing Crtap, P3h1 and Cyclophilin B (CypB), we now extended our studies to determine the function of *Sc65*, a poorly described gene encoding the most closely related protein to Crtap. The hypothesis being that Sc65 could also be involved in collagen prolyl 3-hydroxylation and perhaps interacting with the other members of the Leprecan family. Sc65 was originally described as a nuclear epitope and more recently as a cytoplasmic `adaptor protein'. In human fibroblasts we showed that Sc65 localizes to the rER similarly to the other Leprecan proteins. In addition, Sc65 is highly expressed during skeletal formation. Using a gene-trap ES cell clone containing a proviral insertion in exon 5 of the *Sc65* gene we generated homozygous mice. Western blot analyses using osteoblasts from Sc65 mutant and WT mice revealed the absence or markedly reduced Sc65 protein in the mutants. Micro-CT analysis of the appendicular skeleton at 10 weeks of age showed a statistically significant reduction in BV/TV and other static parameters in both the tibia and femur. Scans of the femoral midshaft also demonstrated a significantly reduced cortical cross sectional area (CSA) and thickness, with increased total CSA and endosteal perimeter. Histomorphometric analysis showed no difference in dynamic indices of bone formation or in osteoclast parameters in the tibias of *Sc65* mutant mice compared to controls. Current efforts are aimed at elucidating the cellular and molecular mechanisms responsible for the low bone mass. Our data suggest that impaired *Sc65* function has an impact on bone homeostasis and may be linked to human osteoporosis.

1094W

Whole-exome sequencing in Fine-Lubinsky syndrome reveals a promising candidate gene. *D.R. Murdock[1], P. Campeau[2], J. Lu[1], M-C. Gingras[1], D. Scott[2], R. Gibbs[1], B. Lee[2,3].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Howard Hughes Medical Institute, Houston, TX.

Fine-Lubinsky syndrome is an autosomal recessive condition characterized by craniosynostosis/abnormal calvaria, prominent frontal bones, a flat facial profile, a small nose, microstomia, hearing loss, developmental delay/mental retardation, and abnormal digits. We investigated by whole-exome sequencing two siblings previously described (Holder AM et al. AJMG 2007). A homozygous missense mutation was identified in *RPA1*, and compound heterozygous missense variants were identified in *ASPM* , *FMN1*, *CAST*, and *DOCK2* in both sibs. In humans, *ASPM* mutations are known to cause non-syndromic microcephaly and CNS malformations, while *FMN1* homozygous deletions are associated with oligosyndactyly and radioulnar synostosis in both humans and mice. The protein encoded by *FMN1*, formin1, inhibits BMP signaling and the mutations identified (p.T42M and p.A440S in isoforms 3 and 5) affect highly conserved amino acids. *Cast* knockout mice do not have an obvious phenotype, *Dock2* knockout mice have an impaired lymphocyte migration and *Rpa1* heterozygous mutations in mice cause a susceptibility to lymphoid tumors. *FMN1* is thus the most likely candidate gene based on its function and deletion effect in mice and humans. We are currently sequencing these genes in other individuals with Fine-Lubinsky syndrome and confirming the effect of the *FMN1* mutations on BMP signaling.

1095W

The ratio of urinary pyridinoline to deoxypyridinoline crosslinks — a promising diagnostic tool in Osteogenesis imperfecta. *M. Rohrbach[1], M. Kraenzlin[2], D. Eyre[3], I. Kennerknecht[4], Ch. Netzer[5], O. Semler[5], F. Rutsch[6], B. Steinmann[1], MR. Baumgartner[1], C. Giunta[1].* 1) Division of Metabolism, University Children`s Hospital and Children's Research Centre, Zurich, Switzerland; 2) Division of Endocrinology, Diabetes, and Clinical Nutrition, University Hospital, Basel, Switzerland; 3) Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, Washington, USA; 4) Institute of Human Genetics, Münster University, Germany; 5) Institute of Human Genetics, University of Cologne, Cologne, Germany; 6) Department of General Pediatrics, Munster University Children's Hospital, Münster, Germany.

Urinary pyridinoline crosslinks, hydroxylysyl-pyridinoline (HP, or pyridinoline PYD) and lysyl-pyridinoline (LP, or deoxypyridinoline DPD) are well characterized markers for bone resorption and collagen degradation, and proven diagnostic tools for genetic disorders of collagen metabolism such as EDS VIA, SCD-EDS and Bruck syndrome. Osteogenesis imperfecta (OI) is a heterogeneous genetic disorder characterized by increased susceptibility to fractures. The majority of OI is inherited as an autosomal dominant trait caused by mutations in *COL1A1* and *COL1A2* resulting in quantitative and/or qualitative alterations of type 1 collagen. A small proportion of OI is inherited in an autosomal-recessive manner due to mutations in seven different genes encoding for proteins of the prolyl 3-hydroxylation complex (*CRTAP, LEPRE1, PPIB*); for collagen chaperones (*SERPINH1, FKBP10*); for a transcription factor (*SP7/OSX*) assumed to regulate the differentiation of preosteoblasts to osteoblasts; and for *SERPINF1*, a secreted glycoprotein of the serpin superfamily, probably involved in bone homeostasis. The aim of this study was to evaluate the ratio of total urinary pyridinolines LP/HP (or DPD/PYD) as a non-invasive, reliable and cost effective screening tool in individual OI patients, prior to collagen biochemical and/or molecular genetic analyses. We analyzed spot urines of OI patients of known genetic background, including three with defects in *LEPRE1*, two with mutations in *CRTAP*, and two with defects in *SERPINF1*, as well as two heterozygous carriers for a *CRTAP* mutation. Compared to control LP/HP ratios (0.20 ± 0.03, n=325), we found markedly decreased LP/HP ratios in OI caused by mutations in *LEPRE1* (mean: 0.078) and in *CRTAP* (mean: 0.117), but normal LP/HP ratios in OI caused by mutations in *COL1A1/COL1A2* (mean: 0.21± 0.028; n=4), in *SERPINF1* (mean: 0.195), and in the two heterozygous carriers for a *CRTAP* mutation (mean: 0.172). Bisphosphonate treatment did not influence the ratio of total urinary pyridinoline crosslinks. Thus, LP/HP ratios have the potential to detect recessive forms of OI caused by mutations in the genes *LEPRE1* and *CRTAP*, and therefore to improve the efficacy of the final diagnosis and reducing the costs of molecular genetic investigations. We expect a similar result in OI cases caused by some mutations in *PPIB*. With this report, we hope to attract more cases of OI with a known genetic defect in order to statistically validate this preliminary study.

Mutations in NOTCH2 in families with Hajdu-Cheney Syndrome. *M. Samuels[1], J. Majewski[2], J. Schwartzentruber[2], A. Caqueret[1], L. Patry[1], J.P. Fryns[3], K. Boycott[4], L.-G. Ste-Marie[5], F. McKiernan[6], I. Marik[7], H. Van Esch[3], J. Michaud[1].* 1) Centre de Recherche du CHU Ste-Justine, University of Montreal, Montreal, PQ, Canada; 2) McGill University, Montreal, PQ, Canada; 3) Center for Human Genetics, University Hospitals Leuven, Leuven, Belgium; 4) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Centre de Recherche du CHUM, University of Montreal, Montreal, PQ, Canada; 6) Center for Bone Disease, Marshfield Clinic, Marshfield, WI; 7) Ambulatory Centre for Defects of Locomotor Apparatus, Praha, Czech Republic.

Hajdu-Cheney syndrome is a rare genetic disorder whose hallmark is acro-osteolysis, shortening of terminal phalanges and generalized osteoporosis. We assembled a cohort of 7 families with the condition and performed whole exome resequencing on a selected set of affected patients. One protein-coding gene, NOTCH2, carried heterozygous truncating variants in all patients and their affected family members, consistent with being the likely causal gene for the disorder. In total we identified five novel and one previously reported mutation, all clustered near the carboxyl terminus of the gene, suggesting an allele specific genotype-phenotype effect since other mutations in NOTCH2 have been reported to cause a form of Alagille syndrome. Notch mediated signaling is known to play a role in bone metabolism. Our results support a potential therapeutic role for the notch pathway in treatment of osteoporosis.

We used a next-generation sequencing approach to determine the underlying cause of the unusual combination of spondyloepiphyseal dysplasia (SED) and adult-onset retinitis pigmentosa, co-segregating in members of a large family in Newfoundland. Based on the rare presentation and autosomal recessive inheritance pattern with known consanguinity, we predicted the underlying genetic cause would be novel and homozygous in affected individuals and heterozygous in the obligate carriers. To rapidly select candidate variants fulfilling this inheritance pattern and to eliminate potential false positives, we sequenced the exomes of 3 affected individuals and one carrier. This revealed, on average, 412 novel non-synonymous variants, 242 novel indels and 60 splice site variants per case. Of these, only 2 novel variants fulfilled our criteria. Both were validated, and shown to segregate with disease, by Sanger sequencing on 14 further family members. The more promising candidate variant was an in-frame 6bp deletion (p.80K_81Ydel) in GNPTG, which encodes the . -subunit of GlcNAc-1-phosphotransferase. The deletion was predicted to be probably damaging by Polyphen and was absent from 368 ethnically-matched control chromosomes. Loss-of-function mutations in GNPTG are known to cause mucolipidosis III. , a disorder of lysosomal enzyme targeting. Biochemical analysis of serum from 4 affected and 3 unaffected-carrier family members, run in parallel with 4 healthy controls from the same population, showed greater than 10-fold elevations of four lysosomal enzymes in affected individuals compared with controls. These findings confirmed the diagnosis of mucolipidosis III. (MLIII.). The phenotypic spectrum of MLIII is notoriously broad and the clinical presentation in this family was atypical. Rod-cone dystrophy has not previously been reported in MLIII patients, although evidence from null mice models does imply a causal link between loss of phosphotransferase function and retinal degeneration. Variable presentations of MLIII now need to be considered as a possible etiology for other reported syndromes of SED or related skeletal disorders seen together with retinal manifestations. The approach taken has allowed for rapid diagnosis of this family's complex phenotype and further broadening of the phenotypic spectrum of MLIII. . Our study provides support for the utility of next-generation sequencing in diagnosing phenotypically and genetically heterogeneous Mendelian disorders.

Dominant and recessive forms of fibrochondrogenesis resulting from mutations at a second locus, *COL11A2*. *S.W. Tompson[1,2,3], E. Ali Faqeih[4], L. Ala-Kokko[5], J.T. Hecht[6], R. Miki[1,2,3], T. Funari[3], V.A. Funari[3,7], L. Nevarez[1,2,3], D. Krakow[2,8,9], D.H. Cohn[1,2,8].* 1) Dept of Molecular, Cell and Developmental Biology, University of California, Los Angeles, CA; 2) Dept of Orthopaedic Surgery, University of California, Los Angeles, CA; 3) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 4) Dept of Pediatric Medicine, Children's Hospital, King Fahad Medical Center, Riyadh, Saudi Arabia; 5) Connective Tissue Gene Tests, Allentown, PA; 6) Dept of Pediatrics, University of Texas Medical School, Houston, TX; 7) Dept of Pediatrics, University of California, Los Angeles, CA; 8) International Skeletal Dysplasia Registry, Cedars-Sinai Medical Center, Los Angeles, CA; 9) Dept of Human Genetics, University of California, Los Angeles, CA.

Fibrochondrogenesis is a severe, recessively inherited skeletal dysplasia that can result from mutations in the gene encoding the pro(1(XI) chain of type XI procollagen, *COL11A1*. We studied a case in which sequence analysis of *COL11A1* failed to identify mutations. As the parents were known to be consanguineous, consistent with autosomal recessive inheritance, whole-genome SNP genotyping was performed to identify blocks of homozygosity, identical-by-descent, wherein the disease locus would reside. *COL11A1* was not within a region of homozygosity, excluding it as the disease locus. However, the gene encoding the pro(2(XI) chain of type XI procollagen, *COL11A2*, was located within a large block of homozygosity. Sequence analysis identified homozygosity for a splice donor mutation that was confirmed, by exon trapping, to result in exon 18 skipping and deletion of 54bp of coding sequence. Since homozygosity for null mutations in *COL11A2* is associated with the milder otospondylomegaepiphyseal dysplasia (OSMED) phenotype, we infer that the mutation was not a null allele and that the presence of abnormal chains has a detrimental effect on type XI collagen function. Mutant transcripts are predicted to encode a protein with an 18 amino acid deletion at position 556-573, toward the amino-terminal end of the triple helical domain, disrupting the structure of all type XI procollagen molecules.

In a second case, sequence analysis of *COL11A1* and *COL11A2* revealed heterozygosity for a single mutation, a 9bp deletion in exon 40 (c.2899_2907del9) of *COL11A2*. Analysis of parental DNA showed that neither carried the sequence change, and genotypes at 12 informative pan-genomic microsatellite markers were consistent with parentage. We conclude that the disease was caused by a *de novo* dominant mutation in *COL11A2*, resulting from incorporation of pro(2(XI) chains harboring a 3 amino acid deletion (p.967_969del3) within the triple helical domain. These results demonstrate that *COL11A2* is a second locus for fibrochondrogenesis and that mutations in the gene can result in either dominant or recessive forms of the disorder. Perinatal lethal fibrochondrogenesis can now be recognized as the most severe disease phenotype associated with mutations in *COL11A2*.

Fibroblast growth factors (FGFs) play diverse roles in several developmental processes. Mutations leading to deregulated FGF signaling can cause human skeletal dysplasias and cancer. Here we report a missense mutation Ser99Asp in exon 2 of FGF9 in 12 patients with multiple synostoses syndrome (SYNS) in a large Chinese family. In vitro studies demonstrate that FGF9S99N is expressed and secreted as efficiently as wild-type FGF9 in transfected cells. However, FGF9S99N induces compromised chondrocyte proliferation and differentiation, which is accompanied by enhanced osteogenic differentiation and matrix mineralization of bone marrow-derived mesenchymal stem cells (BMSCs). Biochemical analysis reveals that S99N mutation in FGF9 leads to significantly impaired FGF signaling, as evidenced by diminished activity of Erk1/2 pathway and decreased b-catenin and c-Myc expression when compared with wild-type FGF9. Importantly, the binding of FGF9S99N to its receptor is severely impaired although the dimerization ability of mutant FGF9 itself or with wildtype. FGF9 is not detectably affected, providing a basis for the defective FGFR signaling. Collectively, our data demonstrate a previously uncharacterized mutation in FGF9 as one of the causes of SYNS, implicating an important role of FGF9 in normal joint development.
