Thyroid stimulating hormone (TSH) hormone levels are normally tightly regulated within an individual; relatively small individual variations may indicate thyroid disease. Genome-wide studies (GWAS), primarily in European descent populations, have suggested that variants in *PDE8B* and *FOXE1* are associated with TSH levels. Variants in *FOXE1* have been previously associated with increased thyroid cancer risk. *PDE8B* may influence TSH levels through regulation of cAMP signaling. The Electronic Medical Records and Genomics (eMERGE) Network is a collaboration across institutions with biobanks linked to electronic medical records (EMRs); eMERGE members are Group Health Cooperative/University of Washington, Marshfield Clinic, Mayo Clinic, Northwestern University, Vanderbilt University, and the eMERGE Administrative Coordinating Center. The eMERGE Network uses EMR-derived phenotypes to perform genomic association studies in diverse populations. At each site, GWAS was conducted for complex diseases (e.g. dementia, cataracts, peripheral arterial disease (PAD), type 2 diabetes) and medically relevant quantitative traits (e.g. cardiac conduction); overall, approximately 17,000 subjects were genotyped. Because eMERGE DNA samples are linked to EMRs, the network can “reuse” the genotype data to conduct network-wide GWAS for additional diseases and traits. In this report, we performed a “no additional genotyping” GWAS for a quantitative trait—serum TSH level—in ~5000 European Americans (EAs) and ~500 African Americans (AAs). Tests of association were performed using linear regression and adjusted for age, sex, and principal components, assuming an additive genetic model. Our results replicate the known association of *PDE8B* in EAs (rs1382879 $p=1.52\times10^{-16}$,) =0.07823) and *PDE8B* SNPs were the only SNPs to reach genome-wide significance in EAs. *FOXE1* variants failed to reach genome-wide significance in the EAs (rs1443434: $p=2.04\times10^{-5}$,) =-0.0404). No SNPs in *PDE8B* or *FOXE1* were significant in AAs including rs1382879 (p=0.398,) = -0.03151). No SNPs reached genome-wide significance in AAs, with the most significant being *MX2* rs886451 ($p=2.61\times10^{-6}$,) =-0.3637). These results support the previously reported association of *PDE8B* with serum TSH levels in EAs while highlighting the variability of association study results in diverse populations with differing allelic spectrums and linkage disequilibrium patterns.

718T

Genome-wide Analysis Uncovers Putative Associations for Diabetic Retinopathy in Individuals Identified from Biobanks Linked to Electronic Medical Records. *C.A. McCarty[1], R. Goodloe[2], G. Pesicka[3], L. Rasmussen[4], J.C. Denny[5, 6], C. Blanquicett[6], C. Waudby[1], M.A. Brantley[7], M.D. Ritchie[2, 6, 8].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 2) Center for Human Genetics Research, Vanderbilt Univ, Nashville, TN; 3) Department of Opthamology, Marshfield Clinic Research Foundation, Marshfield, WI; 4) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 5) Department of Medicine, Vanderbilt Univ, Nashville, TN; 6) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN; 7) Ophthalmology and Visual Sciences, Vanderbilt Univ, Nashville, TN; 8) Department of Molecular Physiology & Biophysics, Vanderbilt Univ, Nashville TN.

Diabetic retinopathy (DR) is the most common ocular complication of diabetes and is estimated to cause 5% of blindness and low vision in White adults in the US and up to 14.5% in African Americans. Methods for the prevention and treatment of diabetic retinopathy include control of blood glucose and retinal laser photocoagulation for proliferative retinopathy and macular edema. The prevalence rates for people with diabetes have been estimated to 40.3% for retinopathy and 8.2% for vision-threatening retinopathy and are expected to increase with the rising prevalence of diabetes. The eMERGE network, funded by the NHGRI, was established to support genomic research in the context of biobanks linked to electronic health records. Individuals were initially selected for one of five genome-wide association studies (GWAS); then secondary phenotypes were selected that reuse the existing genotyped samples. DR was one of the secondary phenotypes selected for GWAS. DR cases were defined by ICD-9 and procedure codes related to DR. Controls were individuals previously diagnosed with diabetes who had an eye exam in the previous two years and no diagnosis of diabetic retinopathy. DNA samples were genotyped at the Broad Institute and at the Center for Inherited Diseases Research at Johns Hopkins University using the Illumina 660w-quad and merged for QC following the eMERGE Genomics workgroup QC pipeline. A total of 701 cases (50.4% male; 19.7% African American) and 2373 controls (49.8% male; 16.1% African American) passed phenotype and genotype QC for analysis. In the GWAS analysis adjusted for smoking, sex, decade of birth, three principal components for ancestry, and site our top hits include 2 SNPs on chromosome 20 near GHRH (rs6018428 p<4.95x10-10 and rs6018432 p<2.00x10-7) and an additional hit on chromosome 20 near DTD1 (rs6081341 p<4.21x10-8). Antagonist analogs of growth hormone releasing hormone (GHRH) have been studied for treatment of DR. Thus, GHRH is an excellent candidate for association with DR. Isoform 1 of D-tyrosyl-tRNA(Tyr) deacylase 1 (DTD1) has been shown to exhibit proteomic differences in retina from diabetic mice and normal mice; thus it is another reasonable candidate. While these putative associations need to be replicated, we are encouraged by the biological plausibility of the results. Identification of genetic architecture of DR risk may lead to improved identification of patients at risk and better prevention and treatment strategies.

719T

Variants mapping to the *WNT16* locus are strongly associated with total body mineralization in children of different ethnic background and with total body BMD of elderly adults. *C. Medina- Gomez[1,3], J.P. Kemp[5,6], K. Estrada[1], D. Heppe[3], L. Herrera[1], L. Oei[1], A. Hofman[2], V.W. Jaddoe[3], P.H.C. Eilers[4], D.M. Evans[5,6], A.G. Uitterlinden[1,2], J.H. Tobias[7], F. Rivadeneira[1,2].* 1) Internal Medicine, Erasmus MC, Rotterdam, Netherlands; 2) Epidemiology, Erasmus MC, Rotterdam, The Netherlands; 3) The Generation R Study Group, Erasmus MC, Rotterdam, The Netherlands; 4) Biostatistics, Erasmus MC, Rotterdam, The Netherlands; 5) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, UK; 6) School of Social and Community Medicine, University of Bristol, Bristol, UK; 7) School of Clinical Science at North Bristol, University of Bristol, Bristol, UK.

Aim: Bone Mineral Density (BMD) is a highly heritable trait used to assess skeletal health showing strong ethnic variation. Multiple BMD loci have been identified in large studies of adult individuals from Northern European descent. We ran a genome-wide association study (GWAS) on total body (TB-)BMD to identify genetic determinants of bone accrual in a multiethnic children cohort; we replicated findings in British children of Northern-European origin and in 3 studies of mature and elderly Dutch individuals. **Methods**: The discovery set is part of the Generation R study, a birth cohort in Rotterdam, The Netherlands with >40% children of non-Northern European ancestry. We included 2,196 children (mean age=6.2,SD=0.28 yrs) with TB-DXA measurements and GWAS data (Illu660K). Replication was pursued in 5,434 children from the Avon Longitudinal Study of Parents and their Children (ALSPAC)(age=9.9,SD=0.32 yrs), and adults from the Rotterdam Study I (RS-I;n=2436), II (RS-II;n=749), and III (RS-III;n=668), age range 45-95. Replication cohorts were genotyped on Illu550K. Linear regression models were adjusted for age, sex, weight and population stratification. In the discovery cohort different numbers of genomic principal components (PC) were used (4-20) whereas for the North-European cohorts 4 PCs were incorporated. Inverse variance meta-analysis was performed. Genome-wide significance (GWS) was set at P<5x10-8. **Results**: In Generation R discovery set, genomic inflation factors were ~1 after PC correction regardless of the number of PCs used (λ=2.9 before correction). Two SNPs (MAF=0.27) in high LD mapping to 7q31 near the *WNT16* gene reached GWS after correction for 20 PCs, top-hit explaining 1.7% of the variation in TB-BMD (B=0.22;P=3.8x10-10). The association was replicated in ALSPAC (B=0.13; P=1.1x10-9) and all adult studies RS-I (B=0.13;P=6.3x10-5), RS-II (B= 0.21;P=5.2x10-4) and RS-III (B=0.14;P=0.02). Meta-analysis of all four studies was highly significant (B=0.15;P=2.1x10-24). **Conclusion**: We robustly show that variants in *WNT16* exert an effect on bone mineralization in children of different ethnicities and influences total body BMD variation in adulthood. *WNT16* is highly expressed in periochondrium and periosteum of developing long bones, in line with our results suggesting a role of Wnt factors on bone formation throughout life. These early effects of *WNT16* are likely to affect attainment of peak bone mass and impact the risk of osteoporosis in later life.

720T

Novel FDR approach identifies genes predictive of breast cancer survival. *J. Millstein[1], D. Volfson[2], E.E. Schadt[3], J. Bergh[4].* 1) Division of Biostatistics, University of Southern California, Los Angeles, CA; 2) iPierian Inc., South San Francisco, CA; 3) Mt. Sinai School of Medicine, New York, NY; 4) Karolinska Institutet and University Hospital, Sweden.

Permutation-based testing strategies have become broadly accepted and extremely useful in the analysis of genomic data, where parametric assumptions are usually difficult, if not impossible to meet across an overwhelming number of variables. However, the difficulty is that permutation-based approaches are computationally intensive. Permutation-based False Discovery Rate (FDR) methods are especially common in genomic studies that often include tens of thousands of tests or more. With such an essential role played in the interpretation of results, it is of paramount importance to understand the uncertainty associated with the FDR estimate. It is also important to know the number of permutations required to provide a reliable estimate. We describe fully non-parametric FDR point and confidence intervals estimators that do not require additional replicate randomly permuted data sets and are therefore computationally highly efficient. In fact, reliable FDR estimates are demonstrated using as few as 5 permutations. We applied this approach to gene expression micro-array data from poor prognosis breast cancer patients to identify genes predictive of breast cancer survival. We identified a statistically significant set of 53 genes including Single Minded 2 (SIM2) as well as other genes that otherwise might have been overlooked in a more standard analysis.

721T

Searching for genetic interactions in a genome-wide association study of psoriasis: a comparison of methods. *J.E. Mollon[1,2], D. Speed[3], K.K. Nicodemus[4], M.E. Weale[1,2].* 1) Medical and Molecular Genetics, King's College London, London, United Kingdom; 2) MRC Centre for Transplantation, King's College London; 3) UCL Genetics Institute, University College London; 4) Wellcome Trust Centre for Human Genetics, University of Oxford.

There is much interest in methods for analysing data from genome-wide association studies which go beyond traditional single-SNP methods. In particular it would be useful to have reliable methods that can identify epistatic interactions (here defined as departure from linearity in the additive genetic model). Several methods have been proposed for finding epistasis. A restriction on many of these is that they cannot handle genome-wide data, so SNPs are generally filtered first, often using single-SNP association p-values. Interactions that involve SNPs which have no main single-SNP association could be missed. Recently several new methods or adaptations of existing methods have made it possible to search through genome-wide association study data for interactions. In this study we investigate three promising methods - SNPHarvester, Sparse Partitioning and Random Jungle - on data from the WTCCC2 psoriasis GWAS. Random Jungle and SNPHarvester were run on genome-wide data and followed by a post-processing modelling step. Sparse Partitioning was run on genome-wide data in a single-step process. Outcomes of interest included common results from the three methods, any novel results replicated in a second GWAS, and identification of an interaction that was discovered in the WTCCC2 study.

722T

ROSELLA: Region Oriented Stringent Elastic-net Logistic Likelihood Analysis. *K.I. Morley[1,2], L. Jostins[1], J.A. Morris[1], D.G. Clayton[3], J.C. Barrett[1], The UK Inflammatory Bowel Disease Genetics Consortium.* 1) Statistical Genetics, Wellcome Trust Sanger Inst, Cambridge, United Kingdom; 2) Centre for Molecular, Environmental, Genetic, and Analytic Epidemiology, School of Population Health, The University of Melbourne, Melbourne, VIC 3010; 3) Juvenile Diabetes Research Foundation/Wellcome Trust Diabetes and Inflammation Laboratory, Cambridge Institute for Medical Research, Wellcome Trust/MRC Building, Addenbrooke's Hospital, Cambridge, CB2 0XY.

Until recently, data from genome-wide association studies (GWAS) were principally analyzed in a SNP-wise fashion, with statistical tests and associated p-values generated for each individual SNP. This approach, although successful, does not explicitly account for the correlated nature of SNP data, nor permit simultaneous consideration of multiple independent signals within a region. Addressing both analytical issues may increase capacity to identify association signals from GWAS data sets. Penalized regression methods offer a potential solution as they are suitable for identifying a small subset of the most important predictors from a large number of correlated variables. Some, such as the lasso, have previously been applied to GWAS data at a chromosomal or genome-wide level. However, broad use of these models has been hampered by difficulties in selecting appropriate values for penalization parameters and determining statistical significance. We have developed a gene-region oriented test for association that uses another penalized regression model, the elastic-net. Our test incorporates novel methods for identifying appropriate values for alpha (the mixing parameter for the elastic-net penalty) and lambda (the penalization parameter), as well as a test statistic for assessing the statistical significance of a region, based upon a mixture of chi-square distributions. The method is implemented in a software package, ROSELLA, which provides a user-friendly interface to region-based analyses on a genome-wide level. It is written in C++ and builds upon the implementation of an elastic-net estimation algorithm recently developed by Friedman et al. (2010) for the R statistical programming environment. Using simulated data sets, we demonstrated that the test implemented in ROSELLA has acceptable type-I error across genomic regions of variable size and SNP coverage, and greater power to detect regions of allelic heterogeneity than most currently available alternatives. We used ROSELLA to re-analyze GWAS data sets for Crohn's disease (WTCCC1) and ulcerative colitis (WTCCC2), using the GENCODE gene list. For both data sets we identified all loci found in the original study, and some additional loci that were subsequently identified in larger meta-analyses. For regions of known allelic heterogeneity (e.g. *NOD2* and *IL23R* in Crohn's disease) the significance of the region-oriented test surpassed that of any single SNP in the region by several orders of magnitude.

723T

SNPs near CCNL1 associated with infant adiposity in multi-ethnic mega analysis with strongest effect observed in European ancestry newborns. *J. Morrison[1], D.A. Scheftner[2], A. Pluzhnikov[1], L.P. Lowe[2], C. Ackerman[2], L. Armstrong[2], A.R. Dyer[2], H. Lee[2], M. Urbanek[2], C. McHugh[3], D. Mirel[4], B.E. Metzger[2], M.G. Hayes[2], N.J. Cox[1], W.L. Lowe[2], The HAPO Study Cooperative Research Group.* 1) The University of Chicago, Chicago, IL; 2) Northwestern University, Chicago, IL; 3) University of Washington, Seattle, WA; 4) The Broad Institute, Cambridge, MA.

We investigated genetic factors contributing to variation in infant size and adiposity in infants enrolled in the Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) Study. To assess adiposity in newborns, caliper measurements of flank, tricep and sub-scapular skinfolds were taken in millimeters. We used the square-root of the sum of these three measurements [SQ_SSK] as our phenotype of interest. In analysis of 1303 infants of self-identified mothers of northern European ancestry from four study sites in Europe, North America and Australia, we found SNPs in a haplotype upstream of CCNL1 on chromosome 3 to be significantly associated with the SQ_SSK phenotype. The major T allele of rs17451107 was found to be associated with an increase in SQ_SSK of 0.074 per T-allele (se 0.013; p-value 1.71*10-8) which corresponds to an increase of 0.005 mm in summed skinfold measurements. When the Caucasian cohort was combined in mega-analysis with a data set of 874 Mexican-American infants and a set of 1284 Afro-Caribean infants, we estimated an effect size of 0.141 per T allele (se 0.023; p-value 8.97*10-10). SNPs in this haplotype have been previously found to be associated with infant birth weight and ponderal index, however, we did not find significant associations with any fetal phenotypes other than SQ_SSK. The SNPs in this haplotype did not reach genome-wide significance in either of the non-European ancestry data sets though we did observe moderately significant results with similar magnitude effect sizes in both cohorts. In Mexican-American infants we found an effect size of 0.192 per T allele (se 0.05; p-value 8.84*10-5) and in Afro-Carribean infants we found an effect size of 0.087 per T allele (se 0.04; p-value 0.042). The allele frequencies in the three cohorts are similar (0.35-0.42 minor allele frequency) and the distribution of the phenotype is also comparable between cohorts with the infants in the Mexican-American cohort having slightly higher SQ_SSK measures than the European ancestry infants and the Afro-Caribbean infants having slightly lower measures. This suggests that the different effects estimated in the three populations may result from an interaction with an undiscovered factor which differs between the groups.

724T

A genome wide association scan on the levels of inflammatory markers in Sardinia reveals associations with genes related with malaria resistance. *S. Naitza[1], E. Porcu[1], P. Scheet[2], J. Strait[3], X. Xiao[2], D.D. Taub[3], M. Dei[1], S. Lai[1], A. Mulas[1], F. Busonero[1], A. Maschio[1], G. Usala[1], M. Zoledziewska[4], C. Sidore[1,5], M.B. Whalen[6], D.L. Longo[3], E. Lakatta[3], A. Cao[1], G.R. Abecasis[5], D. Schlessinger[3], M. Uda[1], S. Sanna[1], F. Cucca[1,4].* 1) IRGB, CNR, Monserrato, Italy; 2) University of Texas, MD Anderson Cancer Center, Department of Epidemiology, Houston, Texas, USA; 3) Intramural Research Program, National Institute on Aging, 5600 Nathan Shock Drive, Baltimore, Maryland 21224, USA; 4) Dipartimento di Scienze Biomediche, Università di Sassari, Sassari, Italy; 5) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, Michigan, USA; 6) Center for Advanced Studies, Research and Development in Sardinia (CRS4), AGCT Program, Parco Scientifico e tecnologico della Sardegna, Pula, Italy.

Identifying the genes that influence levels of pro-inflammatory molecules can help to elucidate the mechanisms underlying inflammation, and has implications, both positive and negative, about the co-evolution of host and parasites and diseases. We thus conducted a genome-wide association scan (GWAS) in a cohort of 4,694 individuals from the founder Sardinian population for key inflammatory biomarkers Interleukin-6 (IL-6), the general measure of inflammation erythrocyte sedimentation rate (ESR), monocyte chemotactic protein-1 (MCP-1) and high-sensitivity C-reactive protein (hsCRP). Overall, we typed 731,213 autosomal or X chromosome SNPs and imputed an additional ~1.9 million variants in the cohort. For IL-6, the strongest association was in the ABO locus, with a tag of the O allele (p= 2.69x10-21), providing a mechanistic clue for previous associations with the O blood group. For ESR, genome-wide significance was found for SNPs in CR1 (p=9.31x10-11). For MCP-1, strong confirmatory evidence was found for association with the DARC gene (p=1.68x10-30) and near the CCR2 receptor (p=8.49x10-08). For hsCRP, the strongest association signal was in the CRP gene (p=2.82x10-16) with a novel independent signal near the DARC gene (p=4.75x10-07). All the top signals were replicated in 1,392 individuals from an independent sample of Sardinians. Strikingly, three of the observed loci, ABO, DARC and, CR1, are known to be involved in resistance to malaria, which was endemic in Sardinia until a few decades ago. Indeed, by Fst analysis we showed that the frequency of the CR1 and ABO variants associated with ESR and IL-6, respectively, differs significantly in Sardinians when compared to other populations where malaria was not endemic and are more similar to that detected in malaria endemic populations. These results suggest that the genetic selection imposed by malaria may have contributed to increased levels of inflammation in this population.

725T

Genome wide linkage and family-based association analysis in musical aptitude. *J. Oikkonen[1,2], L. Ukkola-Vuoti[1], P. Onkamo[2], P. Raijas[3], K. Karma[4], I. Järvelä[1,5].* 1) Department of medical genetics, University of Helsinki, Helsinki, Finland; 2) Department of Biosciences, University of Helsinki, Helsinki, Finland; 3) DocMus Department, Sibelius Academy, Helsinki, Finland; 4) Department of Music Education, Sibelius Academy, Helsinki, Finland; 5) Laboratory of Molecular Genetics, Helsinki University Central Hospital, Helsinki, Finland.

Musical aptitude is a complex cognitive function of the human brain. It provides an excellent system for studying human behavior and brain functioning. Family and twin studies, brain imaging studies and molecular genetic studies suggest biological background contributing to musical aptitude. However, mechanisms underlying musical aptitude are largely uncharacterized. Our previous linkage study showed evidence for linkage for several loci. In this study we try to verify the previous results with a high-density marker panel of single nucleotide polymorphisms on extended family material. 96 extended families (N=1011) were collected from Finnish population. Musical aptitude was tested using auditory structuring ability test (Karma music test), and Seashore pitch and time discrimination subtests. DNA from 688 individuals was analyzed on the Illumina HumanOmniExpress 12 1.0v SNP chip. Preliminary results from family-based association analysis show association in several loci. One of these loci is located near corticotropin releasing hormone receptor 2. Interestingly we also detected an association near the best scoring area of the previous linkage study at chromosome 4q. We also carry out linkage analyses, the results of which will be presented in the meeting.

726T

Largest UK rheumatoid arthritis genome wide association study to date of 8,300 samples strengthens confirmed loci and highlights more potential RA genetic risk factors. *G. Orozco, S. Eyre, J. Bowes, E. Flynn, A. Barton, J. Worthington.* Arthritis Research UK Epidemiology Unit, University of Manchester, Manchester, United Kingdom.

The number of confirmed rheumatoid arthritis (RA) loci currently stands at 31 but many lines of evidence indicate this is unlikely to be the final number, and that additional, well powered genome wide association studies (GWAS) will still be required to develop a full picture of the genes involved in RA. The objective of this study was to extend our previous Wellcome Trust Case Consortium RA GWAS adding more independent cases and control samples, with the aim to increase power to confirm previously identify loci and to detect novel association signals for the susceptibility to RA. We had available 3223 UK RA cases and 5272 UK controls, which adds 1361 cases and 2334 controls to the original GWAS. All samples were genotyped using Affymetrix or Illumina arrays. The genotype data for all samples was imputed using IMPUTE2, with the 1000 Genomes Project and HapMap3 data as reference panels, to increase and unify the genomic coverage between samples. After a stringent QC was applied, we had 3034 cases and 5271 controls and 1831729 SNPs. Association analysis was performed using PLINK. We confirmed association to 22 of the 31 previously known RA susceptibility loci. For 15 of them, increased evidence of association was found when compared to the WTCCC GWAS. We also found association evidence for 2 loci that were at a suggestive significance level from the latest meta-analysis, *CD247* and *UBE2L3*. We did not find association with 5 of the known RA loci. However, these were not associated with RA in the original WTCCC GWAS either, so it is possible that they have a modest effect in RA predisposition in UK population. We could not find proxies for 4 of the known RA loci. 12 novel loci were associated with disease at genome-wide significance level. In addition, we found 10 novel RA loci in the next tier of significance ($P<10^{-5}$) that have been associated with other autoimmune diseases or have shown suggestive evidence of association with RA in previous meta-analysis of GWAS data. These 22 novel loci were selected for follow up. Preliminary validation data for 9 of these novel RA loci has confirmed association to 22q12, a region that has been associated with Crohn's disease and type 1 diabetes. In conclusion, we present preliminary results on the largest UK RA GWAS performed to date. Our initial findings suggest that there will be novel loci discovered in this study, but validation in a larger, independent UK cohort is required and is currently ongoing.

727T

Extremely low-coverage sequencing enables cost effective GWAS. *B. Pasaniuc[1,2,3], N. Rohland[3,4], H. Li[3], N. Zaitlen[1,2,3], P. McLaren[3,5], K. Garimella[3], L. Liang[1,2,3], P. deBakker[3,5], S. Sunyaev[3,5], N. Patterson[3], D. Reich[3,4], A.L. Price[1,2,3].* 1) Epidemiology Dept, Harvard School of Public Health, Boston, MA; 2) Biostatistics Dept, Harvard School of Public Health, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Genetics Dept, Harvard Medical School, Boston, MA; 5) Division of Genetics, Brigham and Women's Hospital, Boston, MA.

Genome wide association studies (GWAS) have proven to be a powerful method for scanning the genome for common genetic variants contributing risk for disease. To date GWAS have been carried out using single nucleotide polymorphism (SNP) arrays. Here we show that extremely low-coverage sequencing (0.1-0.5x) is able to capture almost as much of the common (>5%) and low-frequency (1-5%) variation across the genome as SNP arrays. As an empirical demonstration of the power of this approach, we show that genome-wide SNP genotypes can be inferred at an r2 of 0.73 with genotyping arrays using off-target data (at an average of 0.5x) in an exome sequencing study of 127 samples of European ancestry from the International HIV Controllers Study, AIDS clinical trials group and the Swiss HIV Cohort Study. At known associated variants, imputation-aware association statistics are of similar magnitude as statistics computed using typed genotypes while properly controlling the false positive rate (genomic control (GC) of 1.03 for imputed as compared to 1.04 for typed genotypes). In light of recent reductions in sample preparation and sequencing costs, funds invested in ultra low-coverage sequencing are expected to yield several times the effective sample size of SNP-array GWAS for appropriately designed studies. Thus, for projects that wish to maximize statistical power as a function of cost, ultra-low coverage sequencing may be an attractive option.

A Bayesian Association Testing Approach that Accounts for Epigenetic Characteristics as well as Prior Molecular and Pathway Information. *C. Rakovski.* Mathematics, Chapman University, Orange, CA.

We propose a novel strategy applicable to association studies of all scales that advantageously addresses two important issues, accounting for epigenetic characteristics of the subjects and incorporation of important prior information regarding molecular characteristics of the proteins and putative pathway structure. We conduct a large scale simulation study to assess both the type I error rate behaviors of the new method as well as the power gains in comparison to classical association strategies under various scenarios that include genomewide/candidate gene data, complete/incomplete knowledge of the prior and the epigenetic variables as well as prior misspecification. Our results provide important details in understanding the benefits and risks of incorporating complex additional information to current genetic association studies.

730T

Genome-wide meta analyses of human anthropometric traits across 270,722 individuals reveal 6 new genetic associations with evidence for sexual dimorphism as well as evidence for sexual dimorphism at 8 previously reported overall genetic associations. *J.C. Randall[1,2], Z. Kutalik[3,4], T.W. Winkler[5], S.I. Berndt[6], A.U. Jackson[7], T.O. Kilpeläinen[8], K.L. Monda[9], L. Qi[10,11], T. Workalemahu[10], J. Czajkowski[12], F. Day[8], T. Esko[13], M.F. Genome-wide association studies (GWAS) of complex traits have previously reported sexually dimorphic associations, but were limited to variants found in overall analyses, performing sex-specific analyses only in follow-up. To increase power to detect sexually dimorphic genetic variants with an effect on human anthropometric traits, we conducted sex-specific meta-analyses of 9 phenotypes: height (HT), weight (WT), body mass index (BMI), waist circumference (WC), hip circumference (HC), WC/HC ratio (WHR), WC adjusted for BMI (WCadjBMI), HC adjusted for BMI (HCadjBMI), and WHR adjusted for BMI (WHRadjBMI).

In the discovery stage, we performed sex-specific meta-analyses of 58 GWAS, comprising 60,586 men and 73,137 women. Each study used an additive model to test up to ~2.8M imputed SNPs for association with inverse-normal transformed phenotypes. We controlled for false discovery rate at 5% across all analyses, yielding a set of 619 independent loci taken forward into follow-up, which included 63 additional studies comprising 62,399 men and 74,660 women, many of which were genotyped on Metabochip, a custom Illumina iSelect array to which we submitted sex-specific SNPs.

We replicated sex-specific associations at 205 independent loci (combined $P<5x10^{-8}$ with consistent effect direction), and tested the difference in effect estimate between men and women, yielding 4 loci with significant ($P<0.05/205$), 14 loci with suggestive ($P\leq0.05$), and 186 loci with no ($P>0.05$) evidence for sexual dimorphism. Among the 18 loci showing evidence for sexual dimorphism, we discover new sex-specific associations with evidence of sexual dimorphism at 6 loci (1 WCadjBMI, 3 WHRadjBMI, 2 HT), confirm previously reported sexual dimorphism of WHRadjBMI at 4 loci (*GRB14*, *LYPLAL1*, *VEGFA*, and *ADAMTS9*), and find suggestive evidence for sexual dimorphism at 8 loci previously reported as overall associations (2 WT, 6 HT).

Novel associated loci include those implicated in breast cancer and testis development (*MAP3K1*, WCadjBMI sex-diff. $P=1.1x10^{-4}$), in peroxisomal fatty acid oxidation (*HSD17B4*, WHRadjBMI sex-diff. $P=3.3x10^{-3}$), and in the regulation of adipocyte differentiation (*PPARG*, WHRadjBMI sex-diff. $P=8.4x10^{-3}$). We conclude that sexually dimorphic genetic variants do exist for some anthropometric traits, while for other traits we may have been underpowered to detect them.

An evaluation of several statistical approaches to detect rare variants in Genome Wide Association data of Parkinson's disease. *M. Saad[1,2], S. Lesage[3], A. Brice[4], M. Martinez[1,2].* 1) Inserm, UMR 1043, Toulouse, France; 2) Paul Sabatier University, Toulouse, France; 3) Inserm UMR_S975, Paris, France; 4) UMR_S975, AP-HP, Pitié-Salpêtrière Hospital, Paris, France.

The common disease-multiple rare variant hypothesis has recently received much attention. Different statistical methods have been developed for testing the hypothesis that collections of rare variants are associated with a disease in a case-control sampling design [Am J Hum Genet 2008, 311-21; PLoS Genet 2009, e1000384; Genet Epidemiol 2010,188-93; Am J Hum Genet 2010, 832-8]. The detection of rare polymorphisms requires high-quality whole-genome sequence data of a large number of cases and controls and remains expensive. Alternatively, recent studies showed that rare variants can be imputed into existing GWAS datasets from publicly available sequenced data, as the 1000 Genomes Project (i.e., pseudo-sequencing data). In addition, it has been reported that collapsing-based test of single-marker dosages in pseudo-sequencing data may have greater power than haplotype-based methods in genotyped data [Am J Hum Genet 2010,718-35]. Here, we evaluate such approaches in the genome-wide association data of Parkinson's disease [Hum Mol Genet 2011, 615-27]. Imputations were conducted with IMPUTE. We tested association at the gene level. The lowest rates of positive signals (exceeding a given significance threshold) are observed when the cumulative sum test is limited to the uncommon variants. We also show that depending on the approach, different sets of genes may be identified as being associated to the disease. Thereby, drastically different conclusions might be reached.

Genome-wide association and interaction studies identify risk alleles for Congenital Heart Defects in Down syndrome. *M.R. Sailani[1,2], P. Makrythanasis[2], S. Deutsch[2], E. Migliavacca[2], A.J. Sharp[2], J.M. Delabar[3], L. Perez-Jurado[4], C. Serra-Juhe[4], G. Merla[5], S. Vicari[6], E. Kanavakis[7], R. Rabionet[8], X. Estivill[8], Y. Grattau[9], G. Dembour[10], A. Megarbane[9,11], R. Touraine[12].* 1) NCCR Frontiers in Genetics, University of Geneva; 2) University of Geneva, Geneva, Switzerland; 3) Université Paris Diderot, Paris, France; 4) Universitat Pompeu Fabra, Barcelona, Spain; 5) IRCCS, San Giovanni Rotondo, Italy; 6) Children's Hospital Bambino Gesù, Rome, Italy; 7) Laboratory of Medical Genetics, University of Athens Medical School, Athens, Greece; 8) Centre for Genomic Regulation, Barcelona, Spain; 9) Institut Jerome Lejeune, Paris, France; 10) Cliniques universitaires Saint-Luc, Bruxelles, Belgium; 11) Université Saint-Joseph, Beirut, Lebanon; 12) CHU de Saint-Etienne, hôpital Nord, Saint-Etienne Cedex 2, France.

Congenital heart defect (CHD) in Down syndrome (DS) is a common developmental defect occurring in 40% of these cases. Here, we show that genomic variation in concert with the trisomy 21 contributes to the risk for CHD in DS. We performed GWAS and Genome Wide Interaction Study (GWIS) in 192 DS with CHD (AVSD=72, ASD=53, VSD=67) as cases and 156 DS and 215 healthy individuals without CHD as controls. Single-locus association reveals rs2832616, rs1943950, rs2822392, and rs1785683 on chr21 as CHD risk alleles (Bonferroni P-values < 0.05). The first 2 of these SNPs are also cis-eQTLs for KRTAP7-1 gene. Also rs2822392 was identified as a risk factor for AVSD+VSD combined, while rs2183593 (cis-eQTL for the KRATP10-9, C21orf57, and C21orf123 genes) was identified as risk factor for ASD and AVSD+ASD combined. Non-chr21 GWAS reveals rs2066843 and rs2076756 ($P < 5 \times 10E-8$) both located in NOD2 gene as risk factors for CHD and VSD+ASD combined, both showing cis-eQTL effects for the HEATR3 gene. Furthermore, a 2-locus genomewide analysis shows significant interaction signals between loci on chr5 and chr6 ($P < 5 \times 10E-11$). Since DS is likely to be a disorder of gene expression, 2-locus interaction was applied for whole genome eQTLs as a subset of the SNPs space. Interestingly, eQTLs analyses reveal an interaction between eQTLs for CLCNKA on chr1 and USMG5 on chr10 ($P < 5 \times 10E-11$). We propose that the CHD risk of DS is determined by variations on chr21, variations on other chromosomes, and genome-wide interaction of specific alleles.

Adjusting Rare Variant Association Tests for Population Stratification Using the Stratification Score. *G.A. Satten[1], Q. Ling[2], M.P. Epstein[3], A.S. Allen[4,5].* 1) Div Reprod Hlth, CDC, Atlanta, GA; 2) Dept of Biostats and Bioinf, Emory Univ, Atlanta GA; 3) Dept of Human Genet, Emory Univ, Atlanta GA; 4) Dept of Biostats and Bioinf, Duke Univ, Durham NC; 5) Duke Clinical Research Inst, Duke Univ, Durham NC.

Background: Association studies that collect sequence-level data can be used to compare the proportion of case and control participants that have rare variants in a region of the genome (or exome). As with SNP association studies, it is important that test findings reflect true association, not confounding due to population stratification. However, many such tests like the C(( ) test [Neale et al. PLoS Genet e1001322] are not regression-based, so principal-components-based adjustment for population stratification is problematic.

Methods: We show how the stratification score (Epstein, Allen & Satten ASHG 2007 80: 921-930) can be used to form strata such that stratified versions of any test statistic account for confounding. Alternatively, we reformulate tests like the C(( ) test as a comparison between the proportion of case and control participants having a rare variant at each locus, then standardize these proportions the over strata after Allen and Satten (Amer J Epid 2011 173:752-760). This gives the test statistic that we would have obtained if cases and controls each had the same population substructure. Significance can be assessed either asymptotically or by within-stratum permutation, which preserves population substructure but removes disease-variant associations.

Results: We study the size and power of the stratification-score-based C(( ) test using coalescent-based simulated data that mimics the African-American population. We also consider the effect of choice of standardizing distribution on the power of the test.

Statistics for Global Scanning of Gene Sets using Genome Wide Association Studies. *D.J. Schaid, J.P. Sinnwell, S.K. McDonnell, G.D. Jenkins.* Dept Hlth Sci Res, Mayo Clinic Col Med, Rochester, MN.

Gene-set analyses have been widely used in gene expression studies, and some of the developed methods have been extended to genome wide association studies (GWAS). Yet, complications due to linkage disequilibrium (LD) among single nucleotide polymorphisms (SNPs), and variable numbers of SNPs per gene and genes per gene-set, have plagued current approaches, often leading to ad hoc "fixes". To overcome some of the current limitations, we developed a general approach to scan GWAS SNP data for both gene-level and gene-set analyses, building on score statistics for generalized linear models, and taking advantage of the directed acyclic graph structure of the gene ontology (GO) when creating gene-sets. However, other types of gene-set structures can be used, such as the popular Kyoto Encyclopedia of Genes and Genomes (KEGG). Our approach combines SNPs into genes, and genes into gene-sets, but assures that positive and negative effects of genes on a trait do not cancel. To control for multiple testing of many gene-sets, we use an efficient computational strategy that accounts for LD and provides accurate step-down adjusted p-values for each gene-set. Application of our methods to two different GWAS provide guidance on the potential strengths and weaknesses of our proposed gene-set analyses.

Genome Wide Association Study Reveals Genetically Distinct Phenotypic Subtypes of Age-Related Macular Degeneration Distinct. *M. Schu[1], G. Jun[1,2,3], M.A. Morrison[6,7], J. Farrell[1], I.K. Kim[6], D.J. Morgan[7], G.S. Hageman[7], L.A. Farrer[1,2,3,4,5], M.M. DeAngelis[6,7].* 1) Dept Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA; 2) Dept Ophthalmology, Boston University School of Medicine, Boston, MA; 3) Dept Biostatistics, Boston University School of Medicine, Boston, MA; 4) Dept Neurology, Boston University School of Medicine, Boston, MA; 5) Dept Epidemiology, Boston University School of Medicine, Boston, MA; 6) Dept Ophthalmology, Massachusetts Eye & Ear Infirmary, Boston, MA; 7) Ophthalmology & Visual Sciences, John A. Moran Eye Center, Center for Translational Medicine, University of Utah, Salt Lake City, UT.

Age related macular degeneration (AMD) affects over 10% of individuals older than age 40. The late stage of the disease has two main forms, geographic atrophy (GA) and neovascular "wet" AMD. GA is characterized by degradation of retinal pigment epithelial cells, whereas wet AMD is associated with growth of abnormal blood vessels which results in blood and fluid leakage into the macula. Both forms of the disease cause severe debilitating vision loss. Genome wide association studies (GWAS) have identified loci in two gene regions associated with increased risk for AMD, CFH and a haplotype spanning the HTRA1/ARMS2 region of chromosome 10. Previous studies have looked for associations with the collective late forms of AMD, however, in this study we performed genome-wide association tests using HapMap2 imputed SNPs for wet AMD and GA as distinct outcomes while accounting for two known genetic risk factors as well as age at exam and sex. The discovery sample comprised three Caucasian datasets including the Age Related Eye Disease Study (AREDS), the Michigan, Mayo, and Pennsylvania (MMAP) dataset, and the New England Sibling Cohort, yielding a total of 761 wet AMD cases, 394 GA cases, and 1369 controls. Each dataset was analyzed separately and then meta-analyzed using the inverse variance method implemented in METAL. The top-ranked result for both outcomes was obtained with CFH intronic SNP rs10737680 (Wet: $p=1.7x10^{-10}$, GA: $p=1.4x10^{-13}$) which is 20kb distal from the Y402H polymorphism (rs1061170). Because these two SNPs are modestly correlated ($R^2=0.28$) and the rs10737680 was significant after adjusting for rs1061170, this finding suggests there may be distinct multiple functional variants within the CFH region. Both end-stage forms of AMD were also associated with SKIV2L (Wet: $p=1.9 x10^{-10}$, GA: $p=1.7x10^{-7}$) and C3 (Wet: $p=1.1x10^{-7}$, GA: $p=3.4x10^{-9}$). Novel associations were observed for wet AMD with PRKD1 ($p=4.4x10^{-7}$), TCL1A ($p=6.5x10^{-7}$), and ADAM19 ($p=9.9 x10^{-7}$). Two loci were found to be associated primarily with GA, the ITGB8/ABCB5 region (Wet: p=0.02, GA: $p=2.1x10^{-7}$) and MIR2053 (Wet: p=0.0017, GA: $p=3.6x10^{-7}$). These results support the hypothesis that GA and wet AMD are likely distinct diseases that have both common and unique genetic risk factors. Replication of these results in independent cohorts is currently underway.

Quality assessment of parallelization strategy for genome-wide imputation using beagle. *H. Sicotte, M. de Andrade, M.E. Matsumoto, N. Prodduturi, J.P. Kocher.* Health Sciences Research, Mayo Clinic, rochester, MN.

Genome wide imputation methods are rapidly becoming standard practice in genome wide association studies (GWAS) to enable merging of multiple datasets, to enable cross-platform comparison of results, and to find candidate functional variants in linkage disequilibrium (LD) with SNPs with significant GWAS association. Performing imputation on thousands of samples for millions of SNPs can take months of computer time with little parallelization possible using current software. Segmenting the genome in non-overlapping segments could lead to shorted run time on a computer cluster, but this naïve strategy might lead to lower quality imputation near segment edges since these edges would not benefit from the information provided by markers in LD with the imputed region. We have parallelized the BEAGLE imputation software by segmenting chromosomes in overlapping segments. To ensure that this strategy gave results as accurate as the whole chromosome imputation, each imputed segment was run using an extra buffer region. Each buffer regions contributed to the imputation of the segment region, but the imputed values in the buffer region were discarded. We studied the difference between the whole chromosome imputation and the buffered segment approach as a function of buffer size. To control for run to run variation, we also compared whole chromosome imputation run with different random seeds. There were no significant differences between whole chromosome imputation and the overlapping segmentation strategy for buffer sizes from 4MB down to 125kB. Differences between the two strategies were located in reproducible spots whose location was not related to the distance from the edges of segments. Some of those hotspots correlated with peaks of low estimated r^2 (the correlation between the true genotype and the imputed genotypes) while some hotspots were variable when running the whole chromosome algorithms with different random seeds, even though the estimated r^2 was excellent. Our results indicate that parallelizing by segmenting with a small buffer region (125Kb) provides as good imputation as imputating for an entire chromosome at a time. Our results also indicate that some SNPs have variable imputation that is not captured by the r^2 statistic. These variable SNPs can be detected by performing multiple runs of imputation. Although our results were derived using BEAGLE, they should apply to other imputation methods as well.

Free Controls and Two-stage Designs: An opportunity to reduce cost and increase power. *A.D. Skol[1], S.A. Stanhope[2].* 1) Dept of Medicine, Sec of Genetic Medicine, Univ Chicago, Chicago, IL; 2) Dept of Human Genetics, Univ Chicago, Chicago, IL.

The two-stage genome-wide association study (2S-GWAS) was conceived as a way to maintain the power of a single stage GWAS while reducing its cost. In a 2S-GWAS, a proportion of the cases and controls are genotyped in stage 1 using a whole genome genotyping platform, and markers that demonstrate sufficient evidence of disease association are genotyped in stage 2 on the remaining cases and controls. Information from stages 1 and 2 are then combined and association between these markers and disease is evaluated. We have extend the 2S-GWAS to allow different proportions of cases and controls to be assigned to stage 1. Such flexibility is especially necessary when incorporating genome-wide genotype information from free controls (FCs). We demonstrate that allowing different proportions of cases and controls to be assigned to stage 1 can substantially improve the cost advantage of the standard 2S-GWAS. Further, we show that FCs can be used to either increase the power of a two-stage design while holding study costs constant or decrease the cost while maintaining the same power. Finally, we illustrate how 2S-GWAS designs that incorporate FCs can simultaneously yield both increased power and lower cost relative to those that do not use FCs. In summary, the use of more flexible 2S-GWAS that properly use FCs can further aid the GWAS community to identify disease predisposing variation. We have developed software, FreeConCaTS, that can be used to either calculate power for or determine the optimal design of a 2S-GWAS.

Incorporating Genetic Ancestry into Risk Prediction Models. *N. Solovieff[1], C. Baldwin[2], M. Steinberg[3], T. Perls[3], P. Sebastiani[1].* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Center for Human Genetics, Boston University School of Medicine, Boston, MA; 3) Department of Medicine, Boston University School of Medicine, Boston, MA.

Genome-wide association studies have identified many disease associated variants for complex traits and have brought much attention to constructing genetic risk prediction models. Typically, investigators use a small number of genome-wide significant SNPs to construct a genetic risk model, either by including the individual SNPs as covariates in a regression model or by summarizing the risk alleles into a genetic risk score (GRS). However, these models do not account for varying SNP effects in subgroups of subjects, for example different ethnic groups, which may improve the discriminatory accuracy. For example, in a study of exceptional longevity the SNP rs405509 in APOE, a gene known to be associated with aging and dementia, has varying allele frequencies and odds ratios across Europe. Models that leverage this type of ancestral information may improve genetic risk prediction models. We present extensions to a Bayesian naïve classifier and to the traditional GRS that incorporate information about genetic ancestry. In practice, we often build a model using a training dataset and then want to use the model to make a prediction in a new individual or new set of data. However, if the ancestry of the new individual is unknown the typical prediction models cannot be used. We describe an extension to the Bayesian classifier that allows one to predict the phenotype in a new individual when ancestry information is not available. We compare these methods and show that incorporating genetic ancestry improves the accuracy of the prediction when SNPs with varying effects across ancestry are included. An improvement in accuracy is observed both in the Bayesian framework and in the GRS model; however, the accuracy is higher in the Bayesian framework. Finally, these models are not specific to ancestry and can incorporate any environmental factor that modifies the association between the SNP and the phenotype.

739T

Increasing Power of Groupwise Association Test with Likelihood Ratio Test. *J. Sul[1], B. Han[1], E. Eskin[1,2].* 1) Computer Sci, Univ California, Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, Univ California, Los Angeles, Los Angeles, CA.

Sequencing studies have been discovering a numerous number of rare variants, allowing the identification of the effects of rare variants on disease susceptibility. As a method to increase the statistical power of studies on rare variants, several groupwise association tests that group rare variants in genes and detect associations between groups and diseases have been proposed. One major challenge in these methods is to determine which variants are causal in a group, and to overcome this challenge, previous methods used prior information that specifies how likely each variant is functional. Another source of information that can be used to determine causal variants is observation data because case individuals are likely to have more causal variants than control individuals. In this paper, we introduce a likelihood ratio test (LRT) that uses both data and prior information to infer which variants are causal and uses this finding to determine whether a group of variants is involved in a disease. We demonstrate through simulations that LRT achieves higher power than previous methods such as a variable-threshold approach by Price et al., a weighted sum statistic by Madsen and Browning, and an optimal weighted aggregate statistic by Sul et al. Unlike previous methods that use a sum or a linear combination of mutation counts as their statistics, LRT uses a nonlinear combination of mutation counts. We discuss how this difference influences the statistical power of groupwise methods by showing their decision boundaries. We show that the nonlinear combination of mutation counts yields a nonlinear decision boundary that allows LRT to achieve higher power than previous methods. In addition, we evaluate our method on mutation screening data of the susceptibility gene for ataxia telangiectasia, and show that LRT can detect an association in real data. To increase the computational speed of our method, we show how we can decompose the computation of LRT, and propose an efficient permutation test. With this optimization, we can efficiently compute an LRT statistic and its significance at a genome-wide level. The software for our method is publicly available at http://genetics.cs.ucla.edu/rarevariants.

Association Testing on the X-Chromosome in Case-Control Samples with Related Individuals. *T. Thornton[1], M.S. McPeek[2,3].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Statistics, University of Chicago, Chicago, Il; 3) Human Genetics, University of Chicago, Chicago, IL.

It is now common for association studies to have data for hundreds of thousands of markers across the entire genome. Despite the potential for complex traits to have X-linked causal genes, association methods have primarily been developed for the analysis of markers on the autosomal chromosomes, and significantly less attention has been given to analyzing X-linked markers. We consider the problem of case-control association testing with markers on the X-chromosome when some sampled individuals are related, with known relationships. We propose a method that appropriately adjusts for correlated alleles and genotypes among same and different gender relatives and also accounts for allele copy number differences in females and males. Some of the features of the method include: (1) it is applicable to completely general combinations of family and case-control designs, (2) it allows for both unaffected controls and controls of unknown phenotype to be included in the same analysis, (3) it can incorporate phenotype information on relatives with missing genotype data, and (4) it adjusts for sex-specific trait prevalence values. In simulation studies with related individuals, we demonstrate that the method has the correct type 1 error. We apply the method to X-chromosome data from the Collaborative Study of the Genetics of Alcoholism in a sample of moderate-size pedigrees of European descent, from Genetic Analysis Workshop 14. We detect a significant association, after Bonferroni correction, with alcohol dependence and a SNP located within the MAOA gene. The MAOA gene has previously been found to be associated with substance abuse and antisocial behavior. We also demonstrate the potential improvement of the test statistic when using a robust variance estimator over a variance estimator that assumes HWE at the marker.

741T

How much information is disclosed from the margins of high dimensional data? *A.L. Voorman[1], K.M. Rice[1], T. Lumley[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Biostatistics, University of Auckland, New Zealand.

In recent years concern has arisen over the ability to identify confidential subject-specific trait information from publicly available GWAS results. However, the amount of information that `leaks' in this way has not been assessed, for realistic situations. Existing measures of leakage require and complete genetic data from the study subject, and genetic variants in linkage equilibrium. In truth, an attacker may have incomplete or noisy measurements of a subject's genotype, and information is still present from SNPs in LD.

In a novel approach, we formulate the leakage problem as one of regression and over-fitting, and present a closed form expression for the extent of information leakage in terms of the sample correlation between pairs of SNPs. In it, we see precisely how the R-squared for prediction of subjects' trait values depends on the number of SNPs measured, the sample size, and the extent of pairwise correlation between SNPs.

Using data from the Cardiovascular Health Study, we demonstrate the accuracy of our approach, when different amounts of SNP information are available, and for different sample sizes. While the presence of LD makes trait prediction substantially less accurate than would be expected if variants were assumed uncorrelated, we still achieve more leakage of information than the upper bounds based on using only independent SNPs. We also show that the amount of correlation between distant SNPs (i.e. the extent of population structure) is an important determinant of the amount of trait leakage.

742T

Selection of top SNPs for genome-wide association study using p values and magnitude of odds ratios. *J. Wang, S. Shete.* Dept Epidemiology, UT MD Anderson Cancer Ctr, Houston, TX.

Genome-wide association (GWA) study is a powerful approach for detecting genetic variants for common diseases. Generally, in GWA studies, the most significant SNPs associated with top-ranked p values are selected in stage one, with follow-up in stage two. However, when minor allele frequencies are relatively low, less-significant p values can still correspond to higher odds ratios (ORs), which might be more useful for prediction of disease status. Therefore, if SNPs are selected using an approach based only on significant p values, some important genetic variants might be missed. We proposed an approach for selecting SNPs from stage one of GWA study, based on both p values and ORs, and conducted a simulation study to demonstrate the performance of our approach. The simulation results showed that our selecting approach was more powerful than the existing ranked p value approach for identifying relatively less-common SNPs. Therefore, in GWA studies, SNPs should be considered for inclusion based not only on ranked p values but also on ranked ORs.

Follow-up GWAS analysis and in silico candidate gene study for dental caries in permanent teeth. *X. Wang[1], A.R. Vieira[1], J.R. Shaffer[2], F. Begum[2], M. Lee[1], K.T. Cuenco[1], Z. Zheng[2], D.E. Polk[3], M.M. Barmada[2], J. Noel[1], I. Anjomshoaa[1], D.E. Weeks[2], E. Feingold[2], M.L. Marazita[1].* 1) Dept of Oral Biology, Univ Pittsburgh, Pittsburgh, PA; 2) Dept of Human Genetics, Univ Pittsburgh, Pittsburgh, PA; 3) Dept of Dental Public Health, Univ Pittsburgh, Pittsburgh, PA.

Dental caries is a common chronic disease that causes pain and disability across all age groups. Untreated dental caries can lead to pain and infection, tooth loss, and edentulism (total tooth loss). Approximately 91% of dentate adults aged ⁄ 20 years have had caries (NHANES surveillance summaries on oral health, 2005). Genetic components make substantial contributions to caries susceptibility (heritability of up to 55% for permanent teeth in adults). Our previous GWAS analysis (based on over 2000 non-Hispanic whites aged ⁄ 17 from the GENEVA dental caries project) nominated 4 genomic regions that demonstrated suggestive significance (i.e. P<1.0*E-05) and harbored plausible biological candidate genes. Recently, we genotyped an additional 291 individuals with similar genetic backgrounds from the Univ. Pittsburgh Dental Registry and DNA Repository using the same Illumina Human610-Quad Beadchip. We repeated the GWAS analysis on the expanded cohort. Signals from two of the above four genomic regions (genes) were replicated in both the new cohort alone as well as in the combined cohort. In particular, p values from GWAS analysis became smaller in the combined cohort for the CNIH and ZNF98 genes on chromosomes 14 and 19 respectively, both of which are involved in tooth agenesis. In a separate analysis, we independently created a list of 98 caries candidate genes: genes involved in enamel and dentin formation, salivary composition and flow, tooth morphology and dietary and taste preference. We then used our GWAS data to perform an in silico candidate gene study by testing association between caries status in permanent teeth and the SNPs within and near the candidate genes. Our results showed several candidate genes (such as vitamin D receptor and taste receptor genes) and gene families (Matrix MetalloProteinase and calcium channel families) in which multiple SNPs from the same gene were observed to have P values of 0.001 or less. Of note, two SNPs (rs6445703 and rs3935714) from the CACNA2D3 and NFATC2IP genes respectively had P values less than 0.0005, significant under Bonferroni correction for multiple testing (i.e., 98 genes, (= 0.00051). Support: NIH U01DE018903, R01DE014899, R03DE021425, UL1RR024153.

744T

Genome-wide characterization of methyl-CpG-binding protein 2 (MECP2) recruitment in primary human CD4+ T cells. *M. Dozmorov[1], T. Hughes[1], R. Webb[2], J.D. Wren[1], A.H. Sawalha[1,3,4].* 1) Arthritis and Clinical Immunology Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) College of Pharmacy, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Department of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 4) US Department of Veterans Affairs Medical Center, Oklahoma City, OK.

MECP2 is a dual transcriptional regulator that either activates or represses transcription. Here, we used chromatin immunoprecipitation followed by microarray hybridization to characterize genome-wide MECP2 binding sites in human primary CD4+ T cells. RNA polymerase II (Pol II) binding, an indication of active transcription, was similarly localized in the same sample. We identified 3,813 MECP2 binding sites (FRD<0.1) located within -5kb to +1kb from the transcription start site of 5,767 transcripts of known genes. Out of the genes that recruited MECP2 within their promoter region, 44% also recruited Pol II indicating active transcription. When MECP2 and Pol II are found at the same promoter region, they tend to co-localize. In these promoter regions, MECP2 is recruited closer to transcription start sites as compared with promoter regions that recruited MECP2 but not Pol II (P= 3.18X10-8). Within promoter sequences, only 13% of MECP2 binding sites occurred in methylated genomic regions. C+G nucleotide content in MECP2 binding sites were significantly lower when Pol II was co-recruited within the same promoter sequence compared to promoters with only MECP2 (P= 1.0X10-63). Together, our findings suggest that MECP2 preferentially binds unmethylated DNA and that the distance between MECP2 and the transcription start site and the DNA sequence directly recruiting MECP2 might play a role in dictating whether MECP2 will behave as a transcriptional activator or repressor.

745T

Genome-wide identification of new differentially methylated regions associated with imprinted genes. *C. Borel[1], F. Cheung[1], A. Guilmatre[1], B. Steiner[2], H. Brunner[3], D. Mackay[4], G. Perez de Nanclares[5], T. Eggermann[6], G. Gimelli[7], C. Schwartz[8], J. Vermeesch[9], P. Papenhausen[10], C. Ruivenkamp[11], A.J. Sharp[1].* 1) Department of Genetics and Genomic Sciences, Mount Sinai School of Medicine, New-York; 2) Kinderspital Luzern, Switzerland; 3) University Medical Center Nijmegen, Netherlands; 4) Southampton University School of Medicine, UK; 5) Hospital de Cruces, Barakaldo, Spain; 6) Institut für Humangenetik, Aachen, Germany; 7) Istituto G. Gaslini, Genova, Italy; 8) Greenwood Genetic Center, SC; 9) Center for Human Genetics, Leuven, Belgium; 10) Laboratory Corporation of America, Research Triangle Park, NC; 11) Leiden University Medical Center, Netherlands.

Genomic imprinting is a mechanism in which alters the expression of genes depending on whether they are maternally or paternally inherited. Imprinting occurs through an epigenetic mechanism involving differential DNA methylation and histone modifications on the two parental alleles, with most imprinted genes marked by CpG-rich differentially methylated regions (DMRs). Approximately 60 human imprinted genes have been identified to date, and imprinted loci have been associated both with rare syndromes, and with common diseases including diabetes and cancer. Previously we showed that DNA methylation profiling in cases of uniparental disomy (UPD) provides a unique system that allows the isolated study of DNA derived from a single parent. We have now assembled an unprecedented collection of DNA from 113 patients with uniparental disomy for 18 different chromosomes, allowing the efficient detection of DMRs associated with imprinted genes for 84% of the human genome. We also included in our study samples obtained from androgenetic Complete Hydatidiform Moles and gynogenetic Ovarian Teratomas, allowing uniparental studies of the entire genome. We performed genome-wide DNA methylation profiling in this UPD cohort using Illumina Infinium Methylation BeadArrays that yield quantitative data on ~480,000 CpGs at single-nucleotide resolution. Imprinted DMRs were defined by sites at which the maternal and paternal methylation levels for multiple probes diverged significantly from the biparental average. Using stringent thresholds, we were able to detect 19 out of 20 (95%) previously described DMRs, validating our methodology for the detection of imprinted loci. Using these same criteria we identified a total of 93 DMRs genome wide. This included novel DMRs associated with known imprinted loci, and novel DMRs in regions not previously thought to be imprinted. Taking advantage of the highly quantitative nature of our data, we also observed much more subtle reciprocal methylation differences between the two parental alleles that extended across large chromosomal domains at known imprinted loci. We confirmed DMRs by bisulfite sequencing in UPD patients and biparental controls. These data provide a genome-wide map of imprinted sites in the human genome.

Detection of epigenetic defects in Korean patients with Beckwith Wiedemann syndrome and Silver-Russell syndrome. *G.H. Kim[1], B.H. Lee[1,2], J.J. Lee[1], S.H. Choi[1], J.Y. Lee[1], H.W. Yoo[1,2].* 1) Medical Genetics Center, Asan Medical Center, Seoul, Korea; 2) Department of Pediatrics, Asan Medical Center children's Hospital, Seoul, Korea.

Beckwith-Wiedemann Syndrome (BWS) is overgrowth malformation syndrome, whereas Silver-Russell syndrome (SRS) is characterized by pre- or postnatal growth retardation. BWS and SRS share molecular genetic pathology of epigenic defects in chromosome 11p15. A small number of patients with SRS harbor maternal uniparental disomy of chromosome 7 as well. The aim of our study is to identify the epigenic detects in Korean patients with BWS and SRS. Fifteen BWS patients and 15 SRS patients were enrolled. Extensive genetic analyses comprising methylation specific (MS) PCR-RFLP, MS-MLPA, or MS-pyrosequencing analysis were performed. Ten out of 15 BWS patients (66.7%) showed imprinting detect as hypomethylation in imprinting center 2 (IC2). One BWS patient harbored hypermethylation in IC1 (6.7%). Two BWS patients had both IC and IC2 methylation defects, indicating paternal UPD (13.3%). Nine out of 15 SRS patients (60.0%) showed hypomethylation in IC1. One SRS patient (6.7%) had hypomethylation in GRB10 at 7p12. MS-pyrosequencing analysis revealed that methylation status was decreased at 9.5 ± 6.6 % (2.0 - 20.5 %) in 10 BWS with IC2 defects (normal range, 48.4 ± 8.7 %), whereas it was decreased at 21.6 ± 6.2 % (13.7% - 29.8%) in 9 SRS patients with IC1 defects (normal range, 56.4 ± 6.7 %). With extensive genetic analyses, we could identify genetic defects in 13 out of 15 BWS patients (86.7%) and 10 of 15 SRS patients (66.7%). These positive rates are higher than previously reported as 80% in BWS and 50% in SRS. In addition, with MS-pyrosequencing analyses, quantification of methylation defects was available, which could identify partial methylation defects that might not be revealed by MS-PCR-RFLP or MS-MLPA. The validity of MS-pyrosequencing method for the genetic diagnosis of BWS or SRS is needed to be investigated in a large patient cohort.

The role of Ube3a-ATS in Ube3a imprinting and Angelman syndrome. *L. Meng, R. Person, A. Beaudet.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Angelman syndrome is a neurodevelopmental disorder mostly attributed to deficiency of *UBE3A* located at 15q11. Unlike ordinary autosomal genes, *UBE3A* is subject to genomic imprinting with expression only from maternal chromosome in neurons. It is unknown how the imprinting status of *UBE3A* is established, since no differential DNA methylation was found to be associated with its promoter. However, an imprinted antisense non-coding RNA named *UBE3A-ATS* overlapping *UBE3A* locus was identified and hypothesized to suppress *UBE3A in cis*. By studying a mouse model carrying 0.9kb genomic deletion of the paternal *Snrpn* major promoter, we found reduction of *Ube3a-ATS* associated with partial reactivation of paternal *Ube3a*. Such reactivation is not a result of imprinting defects because DNA methylation and expression of other imprinted genes remain normal, suggesting a direct role of *Ube3a-ATS* in mediating paternal *Ube3a* silencing. To better define the function of *Ube3a-ATS* in *Ube3a* imprinting and Angelman syndrome, knock-in mice expressing a truncated form of *Ube3a-ATS* were generated. Preliminary data show elevated *Ube3a* expression in this mouse model. In order to further understand the mechanism of *Ube3a* sense-antisense interaction, we performed strand-specific microarray analysis and found *Ube3a-ATS* RNA covers the entire locus of *Ube3a*, with its termination upstream of the *Ube3a* transcriptional start site. In addition, we found equal binding of transcription initiation complex at paternal and maternal *Ube3a* promoters by ChIP analysis, indicating silencing of paternal *Ube3a* might arise from defects of transcription elongation. Overall, our studies revealed a direct role of *Ube3a-ATS* in paternal *Ube3a* silencing. Further studies on the interaction between the sense and antisense transcripts may help us understand more about *Ube3a* imprinting and provide unique insights into therapeutic development for Angelman syndrome.

High Resolution Methylation Map in Suicide Completers. *C. Nagy[1,6], M. Suderman[2,3,4], C. Ernst[1], M. Szyf[2,3], N. Mechawar[1,6], G. Turecki[1,5,6].* 1) McGill Group for Suicide Studies, Douglas Mental Health University Institute, McGill University, Verdun, Quebec, Canada; 2) Sackler Program for Epigenetics & Developmental Psychobiology, McGill University, Montreal, Quebec, Canada; 3) Department of Pharmacology and Therapeutics, McGill University , Montreal, Quebec, Canada; 4) McGill Centre for Bioinformatics, McGill University, Montreal, Quebec, Canada; 5) Department of Human Genetics, McGill University, Montreal,Quebec, Canada; 6) Department of Neurology and Neurosurgery, IPN, McGill University, Montreal,Quebec, Canada.

Background: There is mounting evidence to suggest that epigenetic modifications are the environment's means of regulating gene expression. Epigenetic mechanisms have been shown to be mediated by environment and are in turn, capable of mediating gene expression and potentially behaviour. This provides a compelling avenue for investigation of the altered gene expression described in the brains suicide completers Methods: A homogeneous subgroup of suicide completers (n=21) were selected based on a common genetic phenotype of low expression in astrocytic genes. These samples were matched to non-suicide, psychiatrically unaffected control samples, with no difference in age, PMI or pH (n=21). Each sample was enriched using MBD for methylated DNA isolating and sequenced on the Illumina GAII. For analysis the sequencing data was combined resulting ~250 million sequencing reads per group. Analysis: Sequencing was completed for all 42 samples but due to concerns of sequencing quality, the sequencing data from 17 suicide completers and 16 controls samples, were used to assess differentially methylated regions (DMRs). Reads were trimmed, duplicates removed and the resulting data was mapped to the human genome (hg19) using BWA. The genome was tiled using overlapping 500 bp windows at every 250 bp and reads were counted for each 500 bp interval. Using the DESeq software, a negative binomial test was implemented to obtain DMRs between suicides and controls. Read counts were used to estimate methylation levels. Results: We have identified 211 DMRs (FDR< 0.2) in the brains of a subgroup of suicide completers and controls. Chromosomes 1, 4, and 16 have the most regions of differential methylation. While of the some DMRs are in traditional gene regulatory regions, the use of next generation sequencing allowed us to identify DMRs in distal regions. Antibody/protein enrichment techniques are expected to pull down a large fraction of the genome reducing the power to identify methylation differences between samples, however our pooling by group technique allowed us to identify these differences. This method gives us a high resolution map of methylation differences, keeping the cost similar to microarray projects.

Large Scale Genome-Wide Methylation Analysis of Schizophrenia. *K. Aberg[1], J. McClay[1], G. Rudolf[1], S. Nerrella[1], J. Bukszar[1], L. Xie[1], A. Hudson[1], A. Khachane[1], S. Vunck[1,2], S. Snider[2], P. Beardsley[1,2], C. Hultman[3], PKE. Magnusson[3], P. Sullivan[3,4], E. van den Oord[1].* 1) Center of Biomarker Research and Personalized Medicine, School of Pharmacy, Virginia Commonwealth University, Richmond, VA, USA; 2) Department of Pharmacology and Toxicology, School of Medicine, Virginia Commonwealth University, Richmond ,VA, USA; 3) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 4) Department of Genetics, University of North Carolina at Chapel Hill, NC, USA.

DNA methylation studies represent a promising complement to traditional genetic studies. We performed a whole methylome association study in 1,575 schizophrenia (SCZ) case-control samples and then followed up the top findings in 1,600 independent case-control samples. The assays involved the use of MethylMiner to pull down the methylated part of the genome followed by next generation sequencing (NGS) of these enriched samples on SOLiD 4. Because procurement of human brain tissue is not feasible on a large scale and in living patients, the assays were performed with DNA from whole blood. To analyze this massive dataset we developed a pipeline that included alignment, quality control, novel estimators for calculating CpG coverage, association testing, and bioinformatics annotation. We obtained an average of 67 million reads per sample. Based on analysis of 75 duplicates we selected about 30% of the 30 million CpG sites for the association analyses as the methylation status of these sites varied across subjects making them potential disease biomarkers. To further prioritize marker selection for follow-up, we integrated our results with external data (e.g. a large scale replication study of 18 SCZ GWAS studies) using the MIND software. The most promising results are currently followed-up using a customized VeraCode GoldenGate assay and targeted PyroMark pyrosequencing. Using the same NGS approach as above, we also compared the methylation pattern in DNA from cortex, hippocampus and whole blood in mice. This investigation showed concordance rates between blood and brain of 0.3-0.5, suggesting that in addition to acting as biomarkers, methylation sites found in whole blood may point to relevant brain processes. The top findings from our studies represent one of the first sets of CpG sites identified through a large scale methylome wide approach that potentially can be used to improve treatment, diagnosis and disease etiology.

Friedreich ataxia demonstrates increased levels of 5-hydroxymethylcytosine within the FXN gene. *S. Al-Mahdawi, C. Sandi, M. Pook.* Biosciences, Brunel University, Uxbridge, United Kingdom.

Friedreich ataxia (FRDA) is caused by a homozygous GAA repeat expansion mutation within intron 1 of the FXN gene, leading to reduced expression of frataxin protein. Evidence suggests that the mutation induces epigenetic changes and heterochromatin formation, thereby impeding gene transcription. Thus, studies using FRDA blood and lymphoblastoid cell lines have detected increased DNA methylation of specific CpG sites upstream of the GAA repeat, together with histone acetylation and methylation changes in regions flanking the GAA repeat. Our lab has previously reported that such epigenetic changes are also present in FRDA brain, cerebellum and heart tissues, which are the primary affected systems of the disorder. Bisulfite sequence analysis of the FXN flanking GAA regions revealed a shift in the FRDA DNA methylation profile, with upstream CpG sites becoming consistently hypermethylated and downstream CpG sites becoming consistently hypomethylated. We also identified differential DNA methylation at three specific CpG sites within the FXN promoter and one CpG site within exon 1. It has recently been shown that the modified base, 5-hydroxymethylcytosine (5-hmC), is present in mammalian DNA, and in approximately 20% of all CpGs in cerebellar Purkinje cell DNA. However, classical bisulfite sequence analysis cannot distinguish between 5-hmC and 5-mC residues. Therefore, we have now analysed the DNA methylation status at one of the upstream GAA CpG sites in 3 FRDA cerebellar DNA samples and 3 unaffected control samples using an approach that does allow distinction between 5-hmC and 5-mC. Our analysis has confirmed the previously identified increases in DNA methylation in FRDA samples, but now reveals that all of the modified CpG in both FRDA and unaffected DNA samples comprises 5-hmC. The potential role of such 5-hmC-modified CpG residues in normal functioning and in FRDA pathogenesis is yet to be determined.

Genomic and Epigenomic Analysis of Primate Species-Specific DNA methylation Variation. *C.G. Bell, G.A. Wilson, L.M. Butcher, S. Beck.* Medical Genomics, UCL Cancer Institute, London, United Kingdom.

The assimilation of genomic, epigenomic and transcriptomic data will aid in the understanding of the effects of genetic variation, environmental perturbation and consequence outcomes on cell and tissue function. This integration will help unravel abnormal physiology in disease pathways. However, a detailed comprehension of each of these levels and particularly how they interface will be required to mesh these cogs of data together. In order to explore mutational mechanisms, time-invariant principles have been proposed to highlight potential commonality in somatic-, population- and species-specific change. Applying this concept with respect to the epigenetic mark of DNA methylation, significant somatic aberration in the cancer methylome is acknowledged, but only recently high resolution data has enabled the identification of dynamic tissue-dependent methylation changes in intermediate CpG density regions. Genomic CpG dinucleotides (CpGs) are distinct from other dinucleotides in that they have the ability to transmit both genetic and epigenetic information and this CpG methylation is vital in mammalian genomes in order to regulate transcription levels, isoform ratios and chromatin structure. Also compared to other dinucleotides, CpGs are substantially depleted (only ~25% of expected) due to >10-fold hypermutability in the germ-line caused by spontaneous deamination of methylated cytosines. Utilising comparative primate genomics focusing on the alignable Human, Chimpanzee, Gorilla, Orang-utan, Macaque and Marmoset genomes and subsequent epigenomic evaluation of DNA methylation variability with MeDIP-sequencing of Human, Chimpanzee and Macaque revealed unique sets of species-specific CpG clusters (Human genomic empirical $p = < 10^{-3}$). The creation of these clusters can be driven by neutral forces such as biased gene conversion, but were predominately not constitutively hypermethylated (Human 76.2%). This detailing of species-specific variation may in turn enable elucidation of intra-specific population epigenomic variation, with potential influence on disease susceptibility.

Genome-wide MeDIP-sequencing profiles identify differentially methylated regions in monozygotic twins discordant for pain sensitivity. *J.T. Bell[1,2], A.K. Loomis[3], B. Zhang[3], C.L. Hyde[3], G.J. Brock[4], I.D. Harrow[5], L.M. Butcher[6], R. McEwen[5], J.M. Harris[1], F.M.K. Williams[1], S. Beck[6], S. Phillips[5], W. Jun[7], G. Burgess[5], S. John[3], T.D. Spector[1].* 1) Department of Twin Research, Kings College London, London, UK; 2) Wellcome Trust Centre for Human Genetics, Univ Oxford, Oxford, UK; 3) Pfizer Global Research & Development, Groton, CT, USA; 4) Biogen Idec, Cambridge, MA, USA; 5) Pfizer Global Research & Development, Sandwich, UK; 6) UCL Cancer Institute, UCL, London UK; 7) BGI-Shenzhen, Shenzhen, China.

Recent studies of DNA methylation differences in disease-discordant monozygotic (MZ) twins show that epigenetic regulation of gene expression can play a pivotal role in complex traits. We obtained DNA methylation sequencing profiles in 25 MZ twin-pairs discordant for objective pain-sensitivity determined experimentally via heat-induced pain, of at least 2°C twin-pair discordance. Whole blood DNA methylation was assayed using methylation capture followed by immuno-precipitation and sequencing (MeDIP-sequencing), resulting in 50 million paired-end reads per sample. We developed a computational and statistical pipeline to quantify MeDIP-seq reads into relative methylation levels across the genome in bins of size 1kb, and validated the resulting methylation levels using bisulfite sequencing in 8 selected genomic regions. To identify differentially methylated regions related to pain-sensitivity (pain-DMRs), we compared methylation to pain using a linear mixed effects model and non-parametric correlation. We obtained evidence for two pain-DMRs at a Bonferroni-adjusted genome-wide significance threshold of $P = 0.05$ (nominal $P = 2.9\times10^{-8}$), which are currently being validated using bisulfite sequencing. The pain-DMRs showed modest but consistent methylation changes across all twins. Annotation of the top 100 pain-DMRs demonstrated the following genomic distribution: intergenic (54%), intronic (32%), and exonic (10%), suggesting an enrichment of exonic regions. GO and Reactome analyses also highlighted genes involved in Rho GTPase signaling, components of which have been linked previously to nociceptive sensitization. Our results suggest that epigenetic studies of disease-discordant MZ twins are a potentially powerful tool for identifying functional genomic changes that may contribute to complex traits.

DNA Methylation Alterations in CHARGE Patients with Heterozygous CHD7 Mutations. *D.T. Butcher[1], D. Grafodatskaya[1], T. Guha[1], W. Reardon[2], B. Gilbert-Dussardier[3], A. Verloes[4], F. Bilan[5], S. Bowdin[6,7], R. Mendoza-Londono[6], R. Weksberg[1,6,7].* 1) Genetics and Genome Biology, Sickkids Research Institute, Toronto, Ontario, Canada; 2) National Centre for Medical Genetics, Our Lady's Children's Hospital, Dublin, Ireland; 3) Service de Génétique, Centre de Référence Anomalies du Développement de l'Ouest, CHU Poitiers, France; 4) AP-HP, Groupe Hospitalier Pitié-Salpêtrière, UF de Génétique Clinique, Paris, France; 5) Institut de Physiologie et Biologie Cellulaires, Centre National de la Recherche Scientifique Unité Mixte de Recherche, Université de Poitiers, CHU Poitiers, France; 6) Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 7) Department of Paediatrics, The University of Toronto, Toronto, Canada.

CHARGE association is a rare autosomal dominant genetic disorder, with an incidence of 1 in 8500-10000 births. Clinical diagnosis for CHARGE is based on non-random associations of the following congenital abnormalities: Coloboma of the eye, Heart defects, Atresia of the choanae, Retarded growth and development, Genital abnormalities, Ear abnormalities/deafness/ vestibular disorder. In the majority of cases, CHARGE association is the result of haploinsufficiency due to a nonsense, missense, or deletion in the gene encoding Chromodomain Helicase DNA-binding protein (CHD7). Mutational studies in Drosophila and mouse have found phenotypes similar to those found in human. In Drosophila reduced expression of kismet/CHD7 results in deficits in axonal pruning, guidance and extension as well as defects in memory and motor function. Normal mammalian growth and development depend on the correct epigenetic programming of the genome. Epigenetic patterns are established by mechanisms including DNA methylation and covalent modifications of histone proteins. In Drosophila, kismet the ortholog of human CHD7 has been demonstrated to regulate the repressive histone H3 methylation mark of lysine 27. In human cell lines, CHD7 has been shown to bind to chromatin regions that are active as demonstrated by histone H3 lysine 4 methylation and DNAse1 hypersensitivity of these binding sites. These epigenetic modifications of histone H3 are tightly linked to DNA methylation patterns. We hypothesized that specific DNA methylation alterations occur as a result of the heterozygous CDH7 mutations and could reveal critical downstream targets associated with CHARGE phenotypes. We have found both hyper and hypomethylation changes using the Illumina Human Methylation27 microarray and have validated them using pyrosequencing. We will look for correlations between phenotype variability in individuals with CHARGE association which could be explained by variable epigenetic alterations in patients with different CHD7 mutations.

Methylation Profiling of Testicular Embryonal Carcinomas. *W.Y. Chan[1], O.M. Rennert[2], H.H. Cheung[2].* 1) School of Biomedical Sciences, Faculty of Medicine, the Chinese University of Hong Kong, Shatin, Hong Kong SAR, China; 2) Section on Clinical and Developmental Genomics, The Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland, USA.

Testicular embryonic carcinoma (EC) is a major subtype of non-seminomatous germ cell tumors in males. ECs are pluripotent, undifferentiated germ cell tumors believed to be originated from primordial germ cell. Molecular event during testicular EC tumorigenesis resembles that of embryogenesis in many ways, including DNA methylation. To identify epigenetic alterations during testicular tumorigenesis, we profiled the DNA methylome of 6 ECs. These samples represent different stages (stage I and stage III) and different extent of invasiveness. Two normal testicular tissues were also included as normal control. Genome-wide methylation analysis by MeDIP-chip revealed a distinct methylation signature between normal and tumors. Differential methylated regions (DMRs) were identified in metastatic ECs. The majority of these DMRs are hypermethylation. A total of 1167 hypermethylated DMRs were found in the metastatic ECs. Mapping of hypermethylated DMRs to Refseq identified only 39 DMRs located in gene promoters. The majority of DMRs (~97%) were located in gene bodies or non-genic regions, consistent to our previous finding in testicular cancer cell lines. Interestingly, we found several sex-linked genes that were hypermethylated, including X-linked genes STAG2, SPANXD/SPANXE, MIR1184, Y-linked genes RBMY1A1/RBMY1B/RBMY1D, BTBD2, ZNF699 and FAM197Y2P. We selected 9 genes for qPCR analysis on the expression changes. Among the genes analyzed, expression of AGPAT3, SUCLG2, RBMY1A, SPANXD, RNF168, USP13, FAM197Y2P were significantly decreased in ECs. One of the Y-linked genes, RBMY1A, has been reported to be regulated by DNA methylation in another urological prostate cancer. The role of RBMY1A in male germ cell tumor is not well understood. Immunohistochemistry analysis on normal testis, EC and seminoma tissues indicate down-regulation of this protein in testicular tumor. Expression of RBMY1A is restricted to male germ cells, and disappeared in ECs and seminomas. Our genome-wide analysis identified methylation changes in several previously unknown genes for testicular ECs, which might provide insight into the crosstalk between normal germ cell development and carcinogenesis.

DNA Methylation in Cerebellum of Bipolar Disorder, Schizophrenia and Depression Patients. *L. Cheng[1], C. Zhang[1], J. Badner[2], C. Chen[1], E. Gershon[2], C. Liu[1].* 1) Department of Psychiatry, University of Illinois at Chicago; 2) Department of Psychiatry and Behavioral Neuroscience, The University of Chicago.

DNA methylation of CpG dinucleotides is an epigenetic modification that plays an important role in regulating gene expression, X-chromosome inactivation, parental imprinting, development and complex diseases. Several studies have documented DNA methylation changes in the brains of patients with psychiatric diseases, as well as such changes induced by drug administration. However, genome-wide DNA methylation profile in brains of psychiatric patients remains poorly understood. Using the Illumina Infinium HumanMethylation27 BeadChip, we assayed 27,578 highly informative CpG sites spanning 14,495 genes on 153 human cerebellum samples from the Stanley Medical Research Institute. These samples included 45 schizophrenia (SZ), 46 bipolar disorder (BD) and15 depression (Dep) patients, and 47 unaffected controls. After ANCOVA analysis, using variables of age, gender, affection status, brain pH, PMI, smoking and use of antipsychotics, only age, gender and depression were associated with significant differential methylation (FDR $q < 0.05$). Of 83 genes showing depression-related differential methylation, 82 genes showed lower methylation in depression relative to controls, and only six of those genes showed differential expression, indicated that dominant down regulation of DNA methylation. Age-related differential methylation was observed in 355 genes, which included ten CpG sites which have been reported significantly changed with age in a previous study. Of 1448 genes showing gender-related differential methylation, 68% were on the X chromosome, while the remaining 465 genes were on autosomes. Methylation of CpG sites in 15 genes showed significant age-depression interactions. Methylation of two genes, OTUD5 and CETN2, were associated with gender-effects and depression. Validation of DNA methylation in depression is ongoing.

756T

Differential DNA methylation associated with anti-dsDNA autoantibody production in systemic lupus erythematosus. *S.A. Chung[1], K.E. Taylor[1], H.L. Quach[2], L.F. Barcellos[2], L.A. Criswell[1].* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) School of Public Health, University of California, Berkeley, Berkeley, CA.

Purpose: Aberrant DNA methylation has been implicated in the pathogenesis of systemic lupus erythematosus (SLE), with less DNA methylation observed in SLE patients compared to healthy controls. We conducted this study to identify differences in DNA methylation across the genome associated with anti-dsDNA autoantibody production, a clinically relevant autoantibody associated with kidney damage and more severe disease in SLE. **Methods**: Genomic DNA from peripheral blood leukocytes was isolated from 104 pairs of SLE cases (n=208 cases total). All SLE cases were female, of European descent, and had never smoked. Case pairs were discordant for anti-dsDNA autoantibody production status (positive vs. negative), and were matched (within 5 years) on age at DNA sample collection and SLE disease duration. Using the Illumina HumanMethylation27 Beadchip, the methylation status of 27,568 CpG sites across the genome were interrogated in all SLE cases. Paired t-tests were used to identify site-specific methylation differences associated with anti-dsDNA autoantibody production. P-values less than 1.8×10^{-6} (Bonferroni corrected) were considered statistically significant. **Results**: Overall, less methylation was observed in the anti-dsDNA positive group. Mean methylation levels were decreased in the anti-dsDNA positive cases when compared to anti-dsDNA negative cases for 63% of the CpG sites investigated (n=17,286). Increased methylation of 2 CpG sites in *PRIC285*, a transcriptional co-activator for nuclear receptors, was significantly associated with anti-dsDNA autoantibody production ($p= 1.9 \times 10^{-7}$ and 3.4×10^{-7}). Decreased methylation of a CpG site near *SOCS2* ($p=3.5 \times 10^{-7}$), an inhibitor of the STAT family of transcription factors, was also associated with anti-dsDNA autoantibody production. No evidence of interaction ($p>0.05$) was found between methylation of the associated *SOCS2* CpG site and rs7574865 of *STAT4*, a known SLE susceptibility and anti-dsDNA propensity locus. **Conclusions**: Similar to comparisons between SLE cases and controls, DNA from autoantibody positive SLE cases appears to be less methylated than autoantibody negative SLE cases. Abnormal methylation of specific genes such as *PRIC285* and *SOCS2* may contribute to autoantibody production in SLE. Lastly, studies of DNA methylation and other epigenetic modifications may identify additional biologic mechanisms involved in the pathogenesis of SLE.

757T

Effect of folic acid supplementation on DNA methylation among reproductive age women in Honduras. *K.S. Crider[1], J. Rosenthal[1], D.R. Maneval[2], G.P.A. Kauwell[2], L.B. Bailey[2].* 1) CDC, National Center on Birth Defects and Developmental Disabilities, Division of Birth Defects and Developmental Disabilities, Pediatric Genetics Team; 2) Food Science and Human Nutrition Department, University of Florida Gainesville, FL.

Folic acid supplementation has been shown to reduce the risk of birth defects. As a result of the role of folic acid in one-carbon metabolism, it has been hypothesized that there may be additional positive and potentially negative unintended consequences. In order to determine if supplementation with folic acid changes global DNA methylation, we utilized samples collected as part of a 12 week double-blind randomized trial of two doses of folic acid, 5 mg once per week, and 1 mg once per day. Participants were reproductive age women (mean age 28 SD+/- 5.5 years; range 20-47 years). Global DNA methylation level was determined by liquid chromatography tandem mass spectrometry (% methylation= the ratio of methylated cytosine to total cytosine). The study included 108 subjects (n= 50 1mg/day and n = 58 5mg/week) and % DNA methylation was assessed at baseline, 6, and 12 weeks of folic acid supplementation. At baseline, DNA methylation level was 3.9% +/- 0.19 (min. 3.5% max. 4.3%) and there was no association of global DNA methylation level with age, BMI, or treatment group. Subjects were genotyped for the *methylenetetrahydrofolate reductase (MTHFR)* 677 C to T transition (23% CC, 49%CT, 28% TT). At baseline *MTHFR* genotype was not associated with DNA methylation level. No significant changes in global DNA methylation after six or 12 weeks of folic acid supplementation in either folic acid dosage group were detected using a general linear model for repeated measures including age, BMI, and *MTHFR* genotype. At completion of the 12 week trial, DNA methylation level was 3.9 95% Confidence Interval (CI) 3.89-4.00 in the 1 mg/day dose group and 3.86 95%CI 3.80-3.93 in the 5 mg/week dose group). In conclusion, we found no association of folic acid supplementation with changes in DNA methylation level in this double-blind randomized trial of folic acid supplementation in women of reproductive age.

758T

Genomic Analysis of Site-specific DNA Methylation Patterns in Primary Epithelial Ovarian Cancers and Endometrial Metastases to the Ovary. *L. Elnitski[1], D.L. Kolbe[1], T.C. Krivak[2], J.A. DeLoia[3], L.C. Brody[1].* 1) National Human Genome Research Institute, Rockville, MD; 2) University of Pittsburgh Medical School, Pittsburgh PA; 3) Georgetown University, Washington DC.

More than 20,000 new cases of epithelial ovarian cancer are diagnosed in the U.S. each year. Despite improved outcomes in the past 30 years, less than half of all women diagnosed with ovarian cancer remain alive 5 years after their diagnosis. Although typically classified as a single disease, EOC includes several distinct histological subtypes grouped by their resemblance to different gynecological tissues (such as fallopian tube, endometrium, and others). However, clinical treatment is not tailored to each subtype, even though these distinct pathophenotypes are likely to result from different genetic and epigenetic changes. In this study, we addressed questions regarding the site of origin and the pathways involved in ovarian tumorigenesis by comparing normal fallopian tube against papillary serous and endometrioid ovarian tumor subtypes. We profiled the methylation status of 27,578 CpG dinucleotides occurring in or near promoter regions of 14,495 genes. We used these molecular data, in a blinded fashion, to classify tumors based on methylation patterns alone. Our data show that classification of tumors via methylation patterns strongly recapitulates the histopathologic classifications and identifies outlier tumors with discordant methylation patterns. As potential biomarkers for serous tumors, thirty-six sites showed significant and consistent increases or decreases in methylation. The data are considered in pathway analyses that correspond to known mechanisms of disease in ovarian epithelial cancer. Comparisons among primary endometrioid tumors of the ovary and uterus with metastatic endometrioid tumors (from uterus to ovary) confirm that methylation profiles correlate strongly with histopathology regardless of tissue location and provide a quantitative molecular approach to discriminating conventional and atypical tumors that cannot be distinguished by a pathologist. We identify known and novel ovarian cancer genes that can be targeted by approved therapeutic compounds, suggesting alternative intervention strategies for specific subtypes of ovarian cancer.

Silver-Russell Syndrome : Phenotypic comparison between patients with *H19*-DMR epimutations and those with upd(7)mat, and 3 unique cases of SRS. *T. FUKE-SATO[1,2], K. YAMAZAWA[3], K. MATSUBARA[1], M. KAGAMI[1], K. NAKABAYASHI[4], K. HATA[4], T. OGATA[5].* 1) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan; 2) Department of Pediatrics, Keio University School of Medicine, Tokyo, Japan; 3) Department of Physiology, Development and Neuroscience, University of Cambridge, UK; 4) Department of Maternal-Fetal Biology, National Research Institute for Child Health and Development, Tokyo, Japan; 5) Department of Pediatrics, Hamamatsu University School of Medicine, Hamamatsu, Japan.

BACKGROUND : Silver-Russell syndrome (SRS) is a congenital developmental disorder characterized by intrauterine and/or postnatal growth retardation as well as associated somatic features, especially relative macrocephaly. To date, two major epigenetic and genetic abnormalities have been identified for SRS, i.e., maternal uniparental disomy for chromosome 7 (upd(7)mat) that accounts for 5-10% of SRS patients and epimutations of the *H19*-DMR on 11p15 that accounts for 30-60% of them. Here, we report on the phenotypic comparison between two groups and 3 unique cases of SRS that were identified through our analyses. EPIMUTATIONS OF THE *H19*-DMR AND UPD(7)MAT : We studied 38 patients with epimutations of the *H19*-DMR and 8 patients with upd(7)mat. These patients were identified through methylation analyses of the *H19*-DMR on 11p15 and the *MEST*-DMR on 7q32.2 and microsatellite marker analyses in 118 SRS patients. Some somatic features were significantly more frequent in patients with *H19*-DMR epimutations than in those with upd(7)mat, whereas speech delay were significantly more frequent in patients with upd(7)mat than in those with *H19*-DMR epimutations. CASE 1 : Parthenogenetic chimaerism/mosaicism with SRS-like phenotype. CASE 2 : Monozygotic female twins discordant for the SRS and hypomethylation of the *H19*-DMR. CASE 3 : A mosaic upd(7)mat case of SRS. CONCLUSION : The results imply that clinical phenotypes are somewhat different between patients with upd(7)mat and those with the *H19*-DMR epimutations. And 3 unique cases of SRS indicates the variety of pathogenic mechanism of SRS.

Identification of candidate epimutations in schizophrenia and autism brain samples. *J. Ge, K. Mohan, J. Wiszniewska, A. Beaudet.* Molecular and Human Genetics, Baylor College of Medicine, BCM MS:225, 1 Baylor Plaza, Houston, TX.

Epigenetic changes in DNA cytosine methylation could be associated with alternations in RNA expression, and may play a role in the etiology of psychological diseases. Specifically, monoallelic DNA methylation changes could result in functional haploinsufficiency equivalent to loss-of-function mutations that are known associated with schizophrenia and autism. The authors hypothesized that epimutaions may contibute to the pathogeny of some fraction of schizophrenia and autism. The Aim of this study is to discover candidate epimutations associated with schizophrenia and autism. A Genome-wide analysis of DNA cytosine methylation was performed in the Illumina Infinium human 27 methylation bead chip platform. For schizophrenia, frontal cortex samples (Broadmann Area 8, or BA8) of 22 patients and 30 controls were examined; and for autism, cerebellum samples of 13 patients and 23 controls were examined. The CpG island at the promoter region of LOC652276, a non-coding RNA gene, was found hypermethylated in one schizophrenia patient but not in any control; similarly, the CpG island at the promoter region of SERHL was found hypermethylated in one autism patient but not in controls. Bisulfite treatment of DNA followed by PCR and sequencing demonstrated the heterozygous methylation of both cases, and dramatic decreasing in RNA expression for both cases were observed in the real time RT-PCR assay. We also identified other hyper- and hypomethylation loci for both schizophrenia and autism cases. This work is being extended using the Illumina Human Methylation 450 DNA Analysis BeadChip and additional patient samples. This work is supported by the Simons Foundation Autism Research Initiative (SFARI).

DNA methylation and gene expression changes in monozygotic twins discordant for psoriasis: identification of functionally important genes involved in immune response. *K. Gervin[1], G. Gilfillan[1], M.D. Vigeland[1], M. Mattingsdal[2,3], M. Hammerø[1], H. Nygård[1], A.O. Olsen[4], I. Brandt[5], J.R. Harris[5], D.E. Undlien[1], R. Lyle[1].* 1) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Research Unit, Sørlandet Hospital, Kristiansand, Norway; 3) Institute of Psychiatry, University of Oslo, Oslo, Norway; 4) Department of Dermatology, Oslo University Hospital, Oslo, Norway; 5) Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway.

Psoriasis is a common chronic inflammatory disease affecting the skin, scalp, nails and joints. Psoriasis has a strong genetic component with ~20 susceptibility loci, but epigenetic changes are involved since concordance rates among monozygotic (MZ) twins are 35-70%. Here we used MZ twins (n=20 pairs) discordant for psoriasis to explore genome-wide differences in DNA methylation and gene expression. The study of discordant MZ twins is an attractive model to investigate epigenetic mechanisms in disease. Discordance in this context can be interpreted as a result of external factors that shape the epigenetic profile and thereby the susceptibility for disease through altered gene expression. We isolated different lymphocyte subpopulations and studied single-cell types (CD4+ and CD8+) to overcome the issue of epigenetic heterogeneity in whole blood. In order to detect gene specific DNA methylation differences, we used the 27K Infinium methylation assay (Illumina). To integrate the analysis of global methylation status and gene expression of approximately all associated genes we used HumanHT gene expression assays (Illumina). Analysis of these data identified genes where differences in DNA methylation between twins were correlated with gene expression in CD4+ cells, thus identification of genes where DNA methylation has a functional role in development of psoriasis. We also present preliminary data on genome-wide DNA methylation (RRBS) and ChIP. To our knowledge this is the first study using MZ twins discordant for psoriasis in order to reveal epigenetic alterations which potentially contributes to the development of disease.

Role of epigenetic dysregulation in neurodevelopmental syndromes: lessons from *KDM5C* mutations. *D. Grafodatskaya[1], B.H.Y. Chung[1,2], D.T. Butcher[1], S. Goodman[1], S. Choufani[1], Y. Lou[1], C. Zhao[1], R. Rajendram[1], F.E. Abidi[3], C. Skinner[3], J. Hamilton[4], S.W. Scherer[1,5], C.E. Schwartz[3], R. Weksberg[1,2].* 1) Gen & Genome Biol, Hosp Sick Children, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, Hosp Sick Children, Toronto, ON, Canada; 3) J.C. Self Research Institute, Greenwood Genetic Center,Greenwood, South Carolina, USA; 4) Division of Endocrinology, Hosp Sick Children, Toronto, ON, Canada; 5) The Centre for Applied Genomics, Hosp Sick Children, Toronto, ON, Canada.

Genes encoding proteins that function in epigenetic modification play an important role in normal neurodevelopment. However, the molecular mechanisms that underpin hierarchical epigenetic marks and drive normal development are not well understood. Human diseases caused by mutations in genes that modify epigenetic marks provide a unique opportunity to study the pathophysiology of epigenetic dysregulation. Mutations in the X-linked gene, *KDM5C*, encoding an lysine (K) specific demethylase 5C are implicated in intellectual disability and autism. Experiments in model organisms show that, in early embryonic development, Histone H3 lysine 4 methylation protects DNA from de novo methylation. Therefore, we hypothesized that the loss of function mutations in *KDM5C* result in loss of DNA methylation at specific genomic targets. To identify critical downstream DNA methylation targets, a genome-wide approach was used. DNA methylation profiles from white blood cells of 13 male patients with known *KDM5C* mutations were compared to 13 male controls using the Illumina Human Methylation27 microarray covering 27,578 CpG sites. Differential methylation analysis identified 13 genes with loss of DNA methylation in patients with *KDM5C* mutations. Three genes, *FBXL5*, *SCMH1*, and *CACYBP* with the most significant loss of DNA methylation are implicated in ubiquitin-mediated protein degradation. Loss of DNA methylation at these three genes was validated by bisulfite pyrosequencing. Since *KDM5C* escapes X-inactivation and has the Y-linked homologue *KDM5D*, we have evaluated the DNA methylation status of *FBXL5* in the context of various sex chromosome constitutions. We found significant differences in DNA methylation dependent on *KDM5C* and *KDM5D* dosage in XX females, XY males and X0 females, suggesting that gene targets regulated by KDM5C could be involved in neurophenotypes of females with Turner syndrome, as well as normal sex differences in brain function. Overall, these data suggest that DNA methylation alterations identified in blood could serve as a biomarker for epigenetic alterations occurring early in embryonic development. Further, the dysregulated epigenetic targets identified in this study could be relevant to the molecular pathophysiology of idiopathic forms of intellectual disability and autism.

Autism comprises a spectrum of behavioral and cognitive disturbances of childhood development that includes deficits in social interaction, language development and patterns of repetitive behaviors and/or restricted interests. Autism spectrum disorders (ASDs) have been shown to be highly heritable but are exceedingly heterogeneous at clinical presentation. Although the identification of ASD associated genetic variants and genomic rearrangements have contributed significantly to our understanding of the genetic architecture of ASDs, it is apparent they alone do not explain the developmental complexity of the disorder. Recent evidence supports a role for epigenetic regulatory mechanisms in the pathogenesis of ASDs. Suggestive links arise from duplications of an imprinted region of 15q11-13 where DNA methylation has been linked to Prader-Willi syndrome and Angelman syndrome; mutation within methyl-DNA-binding protein (MECP2) that causes Rett syndrome and is associated with ASDs; and our own data identifying differential methylation of the oxytocin receptor (OXTR) in peripheral blood and the temporal cortex of individuals with autism. In this study we report whole DNA methylome profiling of temporal cortex tissue from 28 individuals (15 autism cases and 13 controls from the Autism Tissue Program) using MethylMiner enrichment prior to next generation sequencing using Life Technologies SOLiD sequencing platform (MBD-Seq). Whole methylome profiles were correlated with expression data from 6 cases and 6 controls from the same dataset, as well transcriptome data of temporal cortex tissue of individuals with autism from recent literature. Initial analysis of the aggregate autism cases and controls identified an expected global hypomethylation in autism cases. MBD-Seq peaks (> 10 reads) that were enriched either within cases or controls were correlated with 353 known autism candidate genes and predicted CpG islands (CGI) in the UCSC genome browser. Forty three of the 353 genes that showed MBD-Seq/CGI correlation were processed in DAVID and showed post correction enrichment for postsynaptic membrane (p=0.00013) and synapse (p=0.0011) GO terms. These data provide further support for epigenetic mechanisms underlying the development of autism in an etiologically relevant tissue; identifies possibly epigenetically labile pathways of autism development; and pinpoints putatively important gene regions necessary for the regulation of autism candidate genes.

Genome-wide and Allele-Specific Differences in DNA Methylation in Mexican-American Children. *N. Holland, P. Yousefi, K. Harley, R. Aguilar, K. Huen, S. Venkat, L. Barcellos, B. Eskenazi.* School of Public Health, CERCH, University of California, Berkeley, CA, 94720.

Children's susceptibility to environmental toxicants may depend on their genotype, levels of exposure and their interactions. In the longitudinal birth cohort study of low-income Latino farmworker families in California (CHAMACOS) we found that trans-placental exposures to several pollutants were associated with birth outcomes and neurodevelopment at different ages (*Eskenazi et al, 2004, 2007, 2010; Young et al, 2005; Bouchard et al, 2011*). We also demonstrated that these health effects depend on phenotype and genotype of paraoxonase (PON1), a multifunctional enzyme involved in detoxification of pesticides and oxidative stress (*Holland et al, 2006; Huen et al, 2009*). Further, we observed a modification of effects of exposure on these health outcomes by PON1 (*Eskenazi et al, 2010; Harley et al, 2011*). Epigenetic mechanisms may explain how early life exposures may lead to diseases during childhood, adolescence and effects may be trans-generational, as postulated by the hypothesis of "fetal origin of human diseases". DNA methylation is one of the main types of epigenetic markers. Little is known about ontogenetic changes of DNA methylation and other epigenetic markers in children, and whether they mediate health effects remains largely unknown.

Genome-wide and site-specific DNA methylation was analyzed in samples of the same CHAMACOS children at birth and age 9 using Infinium Illumina 450K BeadChips to interrogate 485,577 CpG sites. After adjusting for multiple testing by controlling for the False Discovery Rate (FDR), we identified over 2,500 CpG sites that were differentially methylated by age and >70 CpG sites displaying sex-specific differences. Pathway analysis identified CpG sites associated with obesity that were significantly enriched with clusters of genes related to adipogenesis, insulin sensitivity, and Type II Diabetes. Furthermore, DNA methylation appeared to be allele-specific in some genes, including PON1, which has previously been associated with susceptibility to pesticides and health outcomes (*Huen et al, 2009; Eskenazi et al, 2010*). These data suggest that changes in site-specific DNA methylation, which can be age, sex, and allele-specific, may be associated with children's health and development.

Genome-wide hypermethylation and hypomethylation in renal cell carcinoma. *C.L. Hsiao[1], C.S.J. Fann[1], W.H. Weng[2], C.K. Chuang[3], B.T. Teh[4,5], S.T. Pang[3,*].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Department of Chemical Engineering and Biotechnology, Graduate Institute of Biotechnology, National Taipei University of Technology, Taipei, Taiwan; 3) Department of Urology, Chang Gung University College of Medicine and Memorial Hospital, Tao-Yuan, Taiwan; 4) NCS-VARI Translational Cancer Research Laboratory, National Cancer Centre, Singapore; 5) Laboratory of Cancer Genetics, Van Andel Research Institute, Grand Rapids, MI, USA.

In the past decade, DNA methylation is under intense investigation in a variety of tumors. Such epigenetic alterations in DNA methylation has been proved to play an important role in regulating gene expression and in development of cancer, either by hypermethylation of the promoter regions on tumor suppressor genes or hypomethylation on highly repetitive sequences. We have conducted a genome-wide methylation analysis on 32 renal cell carcinoma (RCC) patients by using methylated CpG island recovery assay (MIRA) method. To discover methylation markers of carcinoma, the MIRA-enriched tumor sample and its matching normal sample (normal-tumor paired design) were co-hybridized to a NimbleGen 385K RefSeq promoter array. Our results showed that 35 and 70 CpG islands were identified as recurrent hyper- and hypomethylation in 35 RCCs, respectively. The methylation and demethylation frequencies of those CpG islands in 35 RCCs were in a rage from 0.4 to 0.7 with median 0.45 and from 0.15 to 0.4 with median 0.25, respectively. The functional and validation analyses confirmed the results by using gene-expression microarray and qPCR. A better understanding of the mechanisms of methylation in oncogenesis can help with the early diagnosis and revolution for treating RCC.

Allele-specific Methylation - Epigenetics, GWAS and Autoimmune Disease. *J.N. Hutchinson[1], J. Fagerness[2], A. Gimelbrant[3], A. Zak[3], M.J. Daly[2], J.M. Seddon[4], A. Chess[5], R.M. Plenge[1].* 1) Division of Rheumatology, Immunology & Allergy, Brigham and Women's Hospital, Boston, MA, USA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA; 3) Department of Pathology, Harvard Medical School, Boston, MA, USA; 4) Ophthalmic Epidemiology and Genetics Service, New England Eye Center, Tufts Medical Center, Boston, MA, USA; 5) Department of Developmental and Regenerative Biology and Fishberg Department of Neuroscience, Mount Sinai School of Medicine, New York, NY , USA.

DNA methylation can control gene expression and is implicated in the pathogenesis of multiple diseases. Aside from the differentially methylated regions associated with imprinted genes and found on the X-chromosome, maternal and paternal DNA methylation patterns have often been assumed to be identical. However, recent studies have described the widespread occurrence of non-imprinted autosomal allele specific methylation (ASM). ASM is an example of the complex interaction of genetics and epigenetics, as many of these ostensibly epigenetic events are under at least partial genetic control. The strength of this genetic control falls on a continuum, with some ASM being neither purely sequence influenced (i.e. methylation is linked to a particular allele) or stochastic (i.e. either allele can be associated with methylation) but instead showing an intermediate, or skewed association of allele with methylation.

The examination of this process has great potential to maximize and extend genome wide association studies. ASM may explain the relationship between noncoding SNPs and disease in certain GWAS results; stochastic ASM, where putative disease-causing ASM is not be linked to particular allele, would not be well detected by traditional GWAS approaches.

Using Affymetrix 6.0 SNP arrays and methyl-sensitive restriction enzyme digests we have uncovered extensive amounts of ASM encompassing tens of thousands of autosomal regions. Our results indicate ASM to also have some classically epigenetic properties, as it varies in its penetrance between genetically identical monozygotic twins, providing a potential basis for any observed phenotypic discordances between twins. Further examination of these ASM regions reveals that some are associated with eQTLs in peripheral blood monocytes and have been implicated by GWAS in autoimmune diseases such as Crohn's disease and rheumatoid arthritis. Our results may indicate the biological mechanism underlying association of these GWAS derived SNPs with disease.

Neuronal methylome mapping in bipolar disorder and schizophrenia. *K. Iwamoto[1], M. Bundo[1], J. Ueda[2], T. Asai[1,3], T. Miyauchi[2], A. Komori-Kokubo[2], K. Kasai[3], T. Kato[2].* 1) Department of Molecular Psychiatry, Graduate School of Medicine, University of Tokyo, Bunkyo-ku, Japan; 2) Laboratory for Molecular Dynamics of Mental Disorders, RIKEN Brain Science Institute; 3) Department of Neuropsychiatry, Graduate School of Medicine, University of Tokyo.

Epigenetic factors such as DNA methylation and histone modification are believed to be important for the pathophysiology of major psychiatric diseases such as schizophrenia, and bipolar disorder. We have previously established the method for the separation of neuronal and non-neuronal nuclei from the fresh-frozen postmortem brain, and have successfully performed genome-wide DNA methylation analyses. Here we performed a large-scale neuronal and non-neuronal methylation analyses using brains of patients with schizophrenia (N = 35), bipolar disorder (N = 35) as well as controls (N = 35) with promoter tiling arrays. Postmortem prefrontal samples were obtained from the Stanley Medical Research Institute. In both psychiatric diseases, we identified several significant DNA methylation differences compared to control subjects. Interestingly, some differences were only found in neuronal nuclei or non-neuronal nuclei. In addition, to assess the effect of medication, we have profiled the DNA methylation pattern of the human neuroblastoma cell line that was cultured with various treatment drugs. Their DNA methylation profiles were used for identifying the possible treatment-dependent or -independent epigenetic changes. The treatment-independent epigenetic changes may have greater importance in the pathophysiology of schizophrenia or bipolar disorder.

768T

Genome-wide epigenetic regulation by early-life trauma. *B. Labonte[1,2], M. Suderman[3,5], G. Maussion[1], Y. Volodymyr[1], I. Mahar[1,2], A. Bureau[6], N. Mechawar[1,2,4], M. Szyf[5], M.J. Meaney[2,4,7], G. Turecki[1,2,4].* 1) McGill group for suicide studies, Douglas Mental Health University Institute, McGill University, Montreal, Quebec, Canada; 2) Department of Neurology and Neurosurgery, McGill University, Montreal, Quebec, Canada; 3) McGill Centre for Bioinformatics, McGill University, Montreal, Quebec, Canada; 4) Department of Psychiatry, McGill University, Montreal, Quebec, Canada; 5) Department of Pharmacology and Therapeutics, McGill University, Montreal, Quebec, Canada; 6) Centre de recherche Robert-Giffard, Université Laval, Quebec City, Quebec, Canada; 7) Singapore Institute for Clinical Sciences, Singapore.

Our genome adapts to environmental influences in part through epigenetic mechanisms, including DNA methylation. Variations in the quality of the early environment associates with alterations in DNA methylation in rodents and recent data suggest similar processes in humans in response to early life adversity. Here we report a genome-wide study of promoter methylation in individuals with severe abuse during childhood. Promoter DNA methylation levels were profiled using MeDIP followed by microarray hybridization in hippocampal tissue from 41 French-Canadian men (25 with a history of severe childhood abuse and 16 controls. Methylation profiles were compared to corresponding genome-wide gene expression profiles obtained by mRNA microarrays. Methylation differences between groups were validated on neuronal and non-neuronal DNA fractions isolated by fluorescence-assisted cell sorting (FACS). We identified 362 differentially methylated promoters in individuals with a history of abuse compared to controls. Among these promoters, 248 showed hypermethylation and 114 hypomethylation. Validation and site-specific quantification of DNA methylation in the most differentially methylated gene promoters indicated that methylation differences occurred mainly in the neuronal cellular fraction. Genes involved in cellular/neuronal plasticity were among the most significantly differentially methylated. Amyotrophic lateral sclerosis 2 (ALS2) was the most significant finding. Methylated ALS2 constructs mimicking the methylation state in samples from abused suicide completers showed decreased promoter transcriptional activity associated with decreased hippocampal expression of ALS2 variants. Our results suggest that childhood adversity associates with epigenetic alterations in the promoters of several genes in hippocampal neurons.

DNA methylation analysis of IPSCs(induced pluripotent stem cells) using methyl-CpG binding domain (MBD) protein captured sequencing. *D.S. Lee[1,2,5], J.Y. Shin[1,4], Y.S. Ju[1,2,3,5], J.I. Kim[1,2,4,5], A. Nagy[6,7], J.S. Seo[1,2,3,5].* 1) GMI, Seoul national university, Seoul, Seoul, Korea; 2) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul 110-799, Korea; 3) Macrogen Inc., Seoul 153-023, Korea; 4) Psoma Therapeutics Inc., Seoul 110-799, Korea; 5) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul 110-799, Korea; 6) Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Ontario M5G 1X5, Canada; 7) Department of Molecular Genetics, University of Toronto, Toronto M5S 1A8, Canada.

Induced pluripotent stem cells (iPSCs) offer immense potential for regenerative medicine and studies of disease and development. Somatic cell reprogramming involves epigenomic reconfiguration, conferring iPSCs with characteristics similar to embryonic stem (ES) cells. However, it remains unknown how complete the reestablishment of ES-cell-like DNA methylation patterns is throughout the genome, and how the methylation pattern changes throughout the reprogramming process. Here we report the profiles of DNA methylation in ES cell, primary iPSC reprogrammed from MEFs by piggybac transposition, MEF redifferentiated from primary iPSC, secondary iPSC induced from this MEFs, and 7 cells, under reprogroming process of day 2, 5, 8, 11, 16, and 18, using methyl-CpG binding domain (MBD) protein captured sequencing. iPSCs show significant reprogramming variability, including somatic memory and aberrant reprogramming of DNA methylation.

770T

The epigenetic modification of FLI1 in the colorectal cancer. *SK. Lee[1], JW. Moon[1], JO. Lee[1], JH. Kim[1], GY. You[1], J. Kim[2], HS. Kim[1], SH. Park[1].* 1) Dept Anatomy, Colledge of Medicine, KOREA University, Seoul, Korea; 2) Department of General Surgery, Korea University Medical Center, Seoul, Korea.

Epigenetic DNA methylation is an alternative mechanism to genetic events lead to the inactivation of gene expression. The promoter hypermethylation of gene has been frequently observed during the pathogenesis of colorectal cancer (CRC). However, the precise information regarding the colorectal cancer mechanism is still not sufficient even though a lot of ongoing research. We analyzed the methylation profile of 27,578 CpG sites spanning more than 14,000 genes in 20 CRC and 20 adjacent non-tumor containing tissues with methylation bead chip array technology. Four-hundreds genes were revealed significantly hypermethylated in CRC. Friend leukemia integration 1 transcription factor (FLI1) is one of the significantly hypermethylated genes at the promoter CpG island region in CRC tissues. FLI-1 has been described to be a useful marker for Ewing sarcoma as a fusion protein form with EWS to be an aberrant transcription factor. However, the mechanism for the cancer development is unclear. To prove the epigenetic mechanism of FLI1 in CRC, we investigated the expression levels both CRC tissues and cell lines using reverse transcription polymerase chain reaction (RT-PCR). The expression level of FLI1 was suppressed in CRC tissues compared with adjacent non-tumor containing tissues (8/10, 53.3%). The down-regulated expression level of FLI1 was also observed both mRNA and protein levels in CRC cell line, DLD-1. Moreover, the suppressed expression was recovered by treatment of 5-Aza-2'-deoxycytidine, a DNA methyl-transferase inhibitor. These results show that promoter methylation of FLI1 gene is frequently occurred and gene silencing may play an important role in colon carcinogenesis.

Differential DNA methylation in TrkB gene in frontal cortex of suicide completers. *G. Maussion, C. Ernst, J. Yang, N. Mechawar, G. Turecki.* Department of Psychiatry, Mental Health University Institute , Douglas Hospital, Montreal, QC, Canada.

TrkB gene codes for a receptor of BDNF.Previous studies by our group indicate that a subgroup of suicide completers have low expression levels of TrkB-T1, an isoform which has no tyrosine kinase domain and is highly expressed in astrocytes. In previous studies, we observed epigenetic modifications in the TrkB promoter, which partially explained TrkB-T1 low expression level in brain tissue from suicide completers. The general aim of this study was to investigate DNA methylation throughout the TrkB-T1 gene sequence and adjacent genomic regions which could be responsible for the significant deregulation in TrkB-T1. Twelve low TrkB-T1 expressor suicides and 12 normal TrkB-T1 expressor controls were investigated. DNA was extracted from BA8/9, treated with sodium bisulfite and submitted to whole genome amplification. Microarray studies were performed using custom-made Agilent arrays tiling the whole TrkB-T1 gene and adjacent genomic sequence. Statistical correction was applied for multiple testing. We used Sequenom's EpiTYPER method to validate sequences shown as differentially methylated according the microarray study. After statistical correction for multiple testing, 9 DNA sequences located in TrkB gene were identified hypermethylated in frontal cortex of suicide completers. Four out of nine probes matched with intronic regions of TrkB gene whereas the five remaining probes corresponded to TrkB-T1 3'UTR sequence. These data are in agreement with the hypothesis of a transcript-specific deregulation through DNA methylation. Intergenic and extragenic regions present differential methylation between groups. Additional studies need to assess the functional significance of these findings.

772T

The promoter hypermethylation of ADHFE1 gene in the colorectal cancer. *JW. MOON[1], SK. LEE[1], JH. KIM[1], GY. YOU[1], JO. LEE[1], J. KIM[2], HS. KIM[1], SH. PARK[1].* 1) Department of Anatomy, College of Medicine, Korea University, Seoul, Korea; 2) Department of General Surgery, Korea University Medical Center, Seoul, Korea.

The colorectal cancer (CRC) is one of the most common cancer in the Korea, and constantly being increased. Aberrant methylation of gene promoters and corresponding loss of gene expression has been frequently observed during initiation and progression of CRC. These aberrantly methylated genes are attractive predictive markers for molecular diagnostics, early detection, and targeted therapies. In this study, we analyzed the methylation profile of 27,578 CpG sites spanning more than 14,000 genes in 20 CRC tissues and in 20 adjacent non-tumor containing tissues with methylation bead chip array-based technology. We screened 739 CpG sites as aberrant methylation CpG sites ($p<0.005$), and identified 125 CpG sites located in promoter CpG islands that were strongly hypermethylated in CRC compared to adjacent normal tissue ($p<0.005$). Among these genes, alcohol dehydrogenase, iron containing, 1 (ADHFE1) was methylated highly in 20 CRC tissues compared with 20 adjacent non-tumor containing tissues ($p<0.005$). We identified that expression level of ADHFE1 was decreased in CRC tissues compared with in the adjacent non-tumor containing tissues (10/14, 72%) using a reverse transcription PCR (RT-PCR). In addition, we identified of the promoter methylation status of ADHFE1 gene in two normal colon cell lines and in two CRC cell lines using methylation-specific polymerase chain reaction (MSP). As a results, the methylation of ADHFE1 was detected in two CRC cell lines but not detected in two normal colon cell lines. The expression of ADHFE1 was confirmed using RT-PCR and immunoblot analysis in four cell lines. Gene expression was silenced or down-regulated in HT-29 cells with methylated-ADHFE1, but was restored by treatment with 5-aza-2'-deoxycytidine, a DNA methyl-transferase inhibitor. This study suggests that the promoter hypermethylation of ADHFE1 is frequently present in colon cancer and gene silencing may play an important role in colorectal carcinogenesis.

Phosphodiesterase 11A (Pde11a) expression in mouse tissues and characterization of a Pde11a mouse knock-out model. *I. LEVY[1], M. STAROST[2], E. BALL[1], F. FAUCZ[1], S. KOLIAVASILLIS[1], A. HORVATH[1], K. TSANG[1], K. NEDELLA[1], M. ALATSATIANOS[1], M. NESTEROVA[1], C. STRATAKIS[1].* 1) Program in Developmental Endocrinology and Genetics. NICHD / National Institutes of Health. Bethesda, Maryland, USA; 2) Division of Veterinary Resources. National Institutes of Health. Bethesda, Maryland, USA.

Phosphodiesterases catalyze the hydrolysis of cyclic nucleotides and maintain physiologic levels of intracellular concentrations of cAMP and cGMP. Increased cAMP signaling has been associated with genetics disorders that lead to adrenocortical tumors and Cushing syndrome. Genetics defects in the phosphodiesterase 11A are associated with increased levels of cAMP and bilateral adrenal hyperplasia; they also contribute to the development of adrenocortical, prostate, and testicular tumors in the general population. The aim of the present work is to study the expression of Pde11a in mouse tissues, as well as to understand better the Pde11a defect in a previously published Pde11a-/- knockout(KO) mouse model.A colony of Pde11a-/-(KO), Pde11a+/-(Het) and wild type(wt) mice was studied in a complete phenotypical gross and microscopy pathological study. Molecular, immunohistochemical and biochemical studies were done to determine the function and expression of Pde11a in the tissues of normal and mutant mice. In normal mice higher PDE11A immunoreactivity(PDE11A-IR) was found in small intestine villi, thyroid follicular cells, prostate and spermatocytes; moderate PDE11A-IR in brain, liver hepatocytes, and exocrine pancreas and little, if any, in the pituitary gland. In mutant mice RNA studies showed a reduced Pde11a expression in steroidogenic tissues (adrenals and testis), lung, brain, and liver while prostate and kidney presented comparable expression with normal mice. PDE11A protein expression and activity assays did not show differences among three groups. Pathological studies showed differences: Adrenal subcapsular hyperplasia and foamy cells were more frequent in Het(37.7% and 30.2% respectively, $p<0.05$) than in wt group (26.3% and 15.8% respectively); Spinal epidermoid cyst in Het (15%) and wt mice (10%); kidney-pelvis interstitial lymphocytes only in KO mice (10.7%, $P<0.05$). KO mice showed increased absolute and organ specific weight. This study show a clear profile of Pde11a protein expression in endocrine and other mouse tissues, as well as convincing evidence of only partial Pde11a suppression in the previously published KO mouse. These mice developed adrenal hyperplasia and other abnormalities like humans with heterozygote PDE11A defects and partial inactivation of the enzyme. These data support the involvement of PDE11A in the pathogenesis of adrenocortical hyperplasia, but also provide significant insight into a previously reported mouse model.

PHYLOGENOMICS STUDDIES AND STRUCTURALIST MODEL OF INFORMATION. *P. Grigoriu, Bogota.* Medical Departament, Kinio S.A., Bogota, Colombia.

My previous research focused on the interaction studies of different repair mechanisms in Drosophila melanogaster. It was found that pre-replication repair mechanisms, which are specific for each type of lesion and which faithfully reestablish the information present before DNA damage, interact additionally to maintain cellular viability. In contrast, post-replication repair mechanisms (non-homologous recombination and translesion synthesis), which do not always recover genetic information, interact synergistically to reestablish cellular viability. Consequently I proposed the following: (1) Post-replication repair mechanisms are archaic repair mechanisms which function principally to reestablish cell viability by adding repetitive sequences, which can result in loss of genetic information; (2) Pre-replication repair mechanisms, which have appeared more recently in evolution, have the function of correctly recovering genetic information; (3) A structuralist model of genetic information which identifies two principal elements of information systems: (1) a repetitive structure or carrier wave and (2) information as alterations of the repetitive structure. The human genetic project data allow for phylogenetic studies which can support the structuralist model of information and the DNA repair evolution model. Following these models: (1)ligase 4, which operates in non homologous recombination and considered as an archaic repair mechanism, is present in both prokaryotes and eukaryotes. The same occurs with the translesion synthesis enzymes, which also appear the two karyotes groups; (2)In contrast enzymes operating in nucleotide excision repair are different in the two karyotes groups. The same occurs with base excision repair mechanisms It is expected that additional phylogenetic studies will further support the information presented here.

Replacement of the myotonic dystrophy type 1 CTG repeat with `non-CTG repeat' insertions in specific tissues. *M.M. Axford[1,2], A. Lopez-Castel[1,3], M. Nakamori[4], C.A. Thornton[4], C.E. Pearson[1,2].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Valentia Biopharma, Parque Cienti fico de la Universidad de Valencia, Paterna, Spain; 4) Department of Neurology, University of Rochester School of Medicine and Dentistry, Rochester, New York, USA.

Recently, curious mutations have been reported to occur within the (CTG)n repeat tract of the myotonic dystrophy type 1 (DM1) locus. For example, the repeat, long presumed to be a pure repeat sequence, has now been revealed to often contain interruption motifs in a proportion of cases with expansions. Similarly, a few de novo somatic CTG expansions have been reported to arise from non-expanded DM1 alleles with 5-37 units, thought to be genetically stable. This study has characterised a novel mutation configuration at the DM1 CTG repeat that arose as somatic mosaicism in a juvenile onset DM1 patient with a non-expanded allele of (CTG)12 and tissue specific expansions ranging from (CTG)1100 to 6000. The mutation configuration replaced the CTG tract with a non-CTG repeat insertion of 43 or 60 nucleotides, precisely placed in the position of the CTG tract with proper flanking sequences. The inserts appeared to arise from a longer human sequence on chromosome 4q12, and may have arisen through DNA structure mediated somatic inter-gene recombination or replication fork template switching errors. De novo insertions were detected in cerebral cortex and skeletal muscle, but not in heart or liver. Repeat tracts with -1 or -2 CTG units were also detected in cerebellum, which may have arisen by contractions of the short (CTG)12 allele. This non-CTG configuration expands current understanding of the sequence variations that can arise at this hypermutable site.

Blood platelet as a new model to study the interactions of the fragile X mental retardation protein with the cytoskeleton. *A.J. Meunier, F. Corbin.* Département de biochimie, Université de Sherbrooke, Sherbrooke, Quebec, Canada.

Fragile X syndrome is the most common form of inherited intellectual disability. This disease results from the expansion of CGG repeats in the *FMR1* gene leading to its methylation and thus, its transcriptional silencing. The absence of the corresponding product, FMRP (Fragile X Mental Retardation Protein), is responsible for the clinical features. FMRP possesses RNA-binding motifs essential to its interaction with the mRNA of polyribosomes and would modulate protein synthesis. However, additional functions have also been demonstrated in other cellular models. Uncovering novel observations in a simpler human biological system, will allow us to better understand the real contribution of those suggested functions. In fact, we confirm in blood platelets, characterized by low rates of translation, the presence of FMRP in soluble form. In contrast, in most of the other cell types studied, including neurons, where this protein was rather found in the polyribosome's fraction. Since platelet activation triggers many intracellular processes including cytoskeleton's reorganisation and protein synthesis, we therefore investigated the behavior of FMRP upon platelet activation. Human platelets were activated by means of different agonists and subjected to cell fractionation protocols in order to determine the subcellular localization of FMRP. We observed a shift of FMRP from the soluble to the cytoskeletal fraction, supporting that platelet activation promotes the interaction of FMRP with certain components of this fraction. Moreover, this shift was proportional to the percentage of platelet aggregation and independent of the stimulation pathway employed. Interactions of FMRP during platelet activation were also assessed in the presence of various chemical agents that influence different cellular processes. Agents affecting actin network polymerization modified FMRP's behavior, suggesting that FMRP might interact with components of the microfilaments. The resultant redistribution of FMRP, although consistent with some models described by other groups, suggests a new function for this protein in connection with the platelet cytoskeletal reorganization upon activation. Since this process can easily be modulated in blood platelets, its has the potential to be a very promising model for studying FMRP. This new human cell model will not only allow us to deepen our knowledge of FMRP functions, but also to improve our understanding of the fragile X syndrome.

777T

The role of AGG interruptions in the *FMR1* CGG repeat during transmission in a clinical sample. *C.M. Yrigollen[1], B. Durbin-Johnson[2], R.J. Hagerman[3,4], F. Tassone[1,3].* 1) Biochemistry Molecular Medicine, University of California Davis, Sacramento, CA; 2) Department of Public Health Sciences University of California Davis, School of Medicine, Davis, California; 3) M.I.N.D. Institute, University of California Davis Medical Center, Davis, California; 4) Department of Pediatrics, University of California Davis Medical Center, Davis, California.

Background: The most common cause of Fragile X syndrome is the expansion of a trinucleotide repeat (>200 CGG) in the *FMR1* promoter. This expansion occurs during transmission in cases where a mother is a premutation carrier. Many *FMR1* CGG repeat alleles contain AGG sequences interspersed among the CGG repeats. These AGG "interruptions" are thought to confer DNA stability and reduce the risk of expansion. It has been theorized that pure CGG repeat length is the underlying factor. The smallest premutation alleles documented to expand to full mutations have lacked AGG interruptions. **Methods:** We used a novel CGG Repeat Primed PCR-based approach to identify AGG interruptions in 275 mothers of children with an expanded allele (>44 CGG). Twelve mothers had an intermediate range allele and 263 had a premutation range allele that was transmitted to the child. Additionally, we looked for an association between the presence of AGG interruptions and *FMR1* transcription levels, measured by qRT-PCR, within the mothers. **Results:** Modeling the probability of transmission, we found the optimal cutoff for total CGG length as a predictor of transmission status to be 75 while the pure stretch was determined to be 65. The risk for expansion increased as a function of 3'-continuous CGG repeat length. No association between presence of AGG interruptions and transcriptional levels was observed. **Conclusion:** We have used a novel approach to assess the AGG structure in 275 premutation women, representing 381 transmissions. Our findings point to a relevant role of AGG interruptions in the stability of the CGG repeats in mothers. The risk of expansion in equally sized alleles is determined by pure CGG stretch. Knowledge of the AGG structure in intermediate and premutation alleles is of great importance in determining risk stratification for women and improving genetic counseling.

778T

Differential functional analyses of (-actinin isoforms. *C.P. Hsu, B. Moghadaszadeh, B.E. Rider, A.H. Beggs.* Division of Genetics and Program in Genomics, The Manton Center for Orphan Disease Research, Children's Hospital Boston, Harvard Medical School, Boston, MA.

The (-actinin proteins are a highly conserved family of actin crosslinkers that mediate interactions between a host of cytoskeletal and sarcomeric proteins: (-Actn1 and (-Actn4 crosslink actin filaments in the cytoskeleton, while (-Actn2 and (-Actn3 serve a crucial role in anchoring actin filaments to the sarcomeric Z-line. In an effort to better understand the protein-protein interactions of each (-actinin isoform, as well as perform further structure/function analysis of the (-actinin family, we are utilizing Fluorescence Recovery After Photobleaching (FRAP) to investigate their association dynamics at the Z-line. These FRAP studies are performed using primary mouse *flexor digitorum brevis* cultures, which we have determined to all express (-Actn2, with a subset (66%) co-expressing (-Actn3. Using an adenoviral transduction system, we are expressing GFP-tagged (-Actn1, (-Actn2, (-Actn3, and (-Actn4 in these cultures and quantitating their fluorescence recoveries after photobleaching. We have found that the recovery kinetics of these proteins follow one of three distinct patterns, with (-Actn2/(-Actn3 recovering the least, (-Actn1 recovering to an intermediate degree, and (-Actn4 recovering most fully. This suggests that different (-actinin isoforms have unique association kinetics at the Z-line. Currently, we are creating chimeric constructs to map the interactive domains, and we plan to use this methodology to further investigate the specific sequences and binding partners of each isoform responsible for these functional differences. Although we have not detected any significant difference in protein dynamics between (-Actn2 and (-Actn3, there nevertheless remains the question of whether they are fully compensatory for one another in skeletal muscle (as they share 90% identity and 80% similarity). Previously, we have found that a lack of (-Actn2 causes embryonic lethality. Since it has been shown that (-Actn2 can compensate for (-Actn3, we investigated whether the converse would be true, using a murine knock-in approach to replace the endogenous *Actn2* gene with *Actn3* (Actn3-KI). Remarkably, we find that Actn3-KI homozygotes die during late embryogenesis. Thus, although expression of (-Actn2 clearly compensates for absence of (-Actn3, the converse does not appear to be true, suggesting that (-Actn2 serves unique physiological functions.

Genome-wide Expression Profiling Implicates a *MAST3* Controlled Gene Set in Colonic Mucosal Inflammation of Ulcerative Colitis Patients. *C. Labbé[1, 2], G. Boucher[1], S. Foisy[1], A. Alikashani[1], H. Nkwimi[1], G. David[1], M. Beaudoin[1], P. Goyette[1], G. Charron[1], J.D. Rioux[1, 2].* 1) Montreal Heart Institute, Montréal, Qc, Canada; 2) Département de médecine, Université de Montréal, Montréal, Qc, Canada.

Inflammatory bowel diseases (IBD) refer to Crohn's disease and ulcerative colitis (UC), two common autoimmune diseases of the gastrointestinal tract, most prevalent in urban areas of North America and Europe. Genome-wide association studies have already identified about 100 loci responsible for the susceptibility to IBD. Estimates of heritability suggest that many more are still to be discovered. The next challenge is to explain the individual role of each of these modest effect loci in the disease state. We have previously identified *MAST3* as an IBD gene through association mapping of the 19p linkage region and shown that MAST3 modulates the activity of inflammation master switch NF-2B. In this follow-up study, we wish to further characterize the role of MAST3 in the cell using an unbiased genome-wide survey of MAST3 controlled gene expression. More specifically, we looked at differential gene expression resulting from overexpression and knockdown of the *MAST3* gene in HEK293 and THP1 cells, respectively. The overexpression model resulted in 28 genes being significantly overexpressed by 2-fold or greater. Expression from genome-wide microarrays was validated by qPCR in the overexpression model and further confirmed in the knockdown model. The activity of NF-2B was found to correlate to differential gene expression. Additionally, expression of the MAST3 controlled gene set was measured in biopsies of control and UC patient's inflamed and non-inflamed regions of the colon. Expression was found to be enriched in patients inflamed regions compared to non-inflamed regions. The MAST3 controlled genes are heavily involved in the immune response. Among them are pro-inflammatory cytokines (*CCL20*, *IL8*, etc), regulators of NF-2B (*TNFAIP*3, *LY96*, *NFKBIA*, etc), genes involved in interferon induced defence against pathogen invasion (*IFIT1*, *ISG15*, etc), and genes involved in cell adhesion/or migration (*CD44*, *TMOD1*, etc). Taken together these results confirm MAST3 as a modulator of the NF-2B pathway and suggest its control over the expression of a set of immune genes directly involved in the onset of inflammation typical of IBD.

BAC-Based Small-Molecule Screen to Investigate Regulation of the Macular Degeneration Candidate Gene HTRA1. *J.D. Hoffman, P.C. Mayo, N.C Schnetz-Boutaud, D.P. Mortlock, J.L. Haines.* Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

Age-Related Macular Degeneration (AMD) is one of the most common causes of visual impairment among the aging Caucasian population in the United States. Recent genome-wide association studies have implicated HtrA serine peptidase 1 (HTRA1) and age-related maculopathy susceptibility 2 (ARMS2) as being associated with AMD. Although these genes are located in close proximity to one another on chromosome 10, their individual roles in the pathogenesis of AMD are the subject of debate. We present a high-throughput small-molecule screen to characterize expression at the HTRA1 locus. Screening was carried out using a bacterial artificial chromosome (BAC) due to the ability of BACs to capture the local and distant cis-regulatory elements that are necessary to recapitulate the endogenous cis-regulatory architecture. To measure expression from the HTRA1 locus in response to small molecules, a luciferase reporter cassette was inserted at the HTRA1 translational start site within the RP11-72B24 BAC clone. The BAC was transfected into HeLA cells and these were screened against a small molecule library of 2,000 compounds that have a mixture of known and unknown pharmacological effects. 167 compounds gave a significant response as measured by greater than 3 standard deviations from the luciferase expression measured in a vehicle-only control, and were followed up with 4-point dose-response curve tests for further validation. At present, 7 of 16 compounds have been validated for repression of endogenous HTRA1 expression in wild-type HeLa cells using quantitative-PCR. Three compounds that repress HTRA1 mRNA include podophyllotoxin acetate, an antimitotic agent that inhibits tubulin polymerization; propargite, a pesticide with ATP-synthase inhibitory activity; and monensin sodium, a monovalent cation inhibitor. Menadione was also marginally able to repress HTRA1 transcripts. Menadione has vitamin-K-like properties, stimulates the ERK/MAPK pathway and can regulate connexins via interaction with EGFR signaling. We also confirmed previous reports that the proteasome inhibitor MG132 represses HTRA1 mRNA. Analysis of the preliminary results is promising but requires further investigation and optimization.

Determination of SNPs in miR-9 genes related regions in alcoholism using COGA samples. *Y. Wang, O. Anees, N. Kinstlinger, A. Pietrzykowski.* Rutgers University, Department of Animal Sciences, 67 Poultry Farm Lane, New Brunswick, NJ 08901.

Alcoholism has a strong genetic component, however the exact genetic and molecular underpinnings of this debilitating disease are yet to be determined. Work of others and us have recently indicated that expression of miR-9, a member of non-coding gene expression regulators (microRNA) is modulated by alcohol. We observed that exposure of rodent neurons to alcohol leads to the development of tolerance to this drug via upregulation of the mature form of miR-9 in these cells. Typically, one microRNA can regulate expression of hundreds of targets, therefore microRNAs are very important master regulators of gene expression. Mature form of miR-9 is a product of three different miR-9 genes located on three different chromosomes. We observed that, in humans, each miR-9 gene has a different architecture, particularly differing in the promoter region. Interestingly, two out of three miR-9 genes are located within loci of high susceptibility to alcoholism. We focused on one of these genes, miR-9-3, located on chromosome 15 to search for single nucleotide polymorphisms (SNPs) associated with alcoholism. We used COGA samples and performed a bidirectional direct sequencing using high fidelity Taq polymerase of nested PCR products covering miR-9-3. We discovered several new SNPs in the stem, loop and mature miR-9 regions, including the seed region. These SNPs can change the secondary structure of miR-9, its biogenesis and affinity to targets.

Deciphering of the molecular events governing hMSH4 protein homeostasis in human cells. *Y. Xu, C. Her.* School of Molecular Biosciences, College of Veterinary Medicine, Washington State University, Pullman, WA 99164.

The ability to maintain proper levels of protein factors involved in DNA repair and damage response is critical for sustaining genomic stability. Recent evidence suggests that deviations from homeostatic levels of many proteins can be as detrimental as mutations to cells. The levels of the human MutS family protein hMSH4 are strictly regulated in such a way that its presence in mitotic cells is near detection limits, whereas its expression rises during the onset of meiotic recombination and coincides with the generation of DNA double-strand breaks. To this end, we are intrigued by the physical interaction between hMSH4 and the von Hippel-Lindau binding protein 1 (VBP1), of which the latter is a binding partner of the VHL ubiquitin E3 ligase as well as a subunit of the prefoldin complex. Here, we demonstrate that VBP1 promotes hMSH4 polyubiquitination and therefore proteasome-mediated degradation. Knockdown of VBP1 significantly increases the hMSH4 protein levels by flow cytometry analysis, while overexpression of VBP1 decreases hMSH4 protein levels. In addition to proteasome inhibitor MG-132, hMSH4 degradation could also be slightly inhibited by leupeptin or 3-MA, suggesting the potential involvement of other pathways. Furthermore, RNAi-mediated silencing of VBP1 or VHL leads to a decrease in polyubuiquitination of hMSH4 by an in vivo ubiquitination assay, suggesting that VBP1-mediated degradation of hMSH4 is accomplished through the CUL2/VHL E3 ligase pathway. Together, our studies provide an insight into the regulation of hMSH4 by VBP1 and imply that this mechanism might be important in maintaining the low levels of hMSH4 protein in mitotic cells. It is known that ectopic recombination between repetitive sequences is a major source for genomic instability in cancer cells, thus this study will also provide a foundation for a better understanding of the molecular mechanisms controlling recombination and genomic stability in human cells.

Clinical and genetic characteristics of patients with X-linked deafness. *R. Birkenhager, E. Prera, N. Lueblinghoff, S. Arndt, A. Aschendorff, R. Laszig.* Otorhinolaryngology H&N Surg, Univ Freiburg, Freiburg, Germany.

Hearing impairment is the most common sensory disorder in humans, affecting approximately one to three in 1000 newborns, with 50 % due to genetic causes. The majority of these cases (70 %) are non-syndromic, about 2 % of these are X-linked. So far five different X-linked loci have been mapped, but the causative gene POU3F4 (MIM 300039) has been identified only for the Locus DFNX2. Clinical characteristics of DFNX2 include, in most cases, a mixed type of hearing loss. This hearing loss is often progressive, with temporal bone abnormalities and stapes fixation. Temporal bone anomalies include dilation of the fundus of the internal acoustic canal (IAC) (3), that can increase the risk of CSF gusher during stapes or cochlear implant surgery. During inner ear development, the homologous mouse Pou3f4 gene is exclusively detected in the mesenchymal tissue adjacent to the otic epithelium. Knockout Pou3f4 mice have abnormalities in mesenchyme derived structures including the scala tympani, spiral limbus and spiral ligament fibrocytes of the cochlea as well as variances in the temporal bone. POU3F4 belongs to a sub-family of transcription factors, which are characterized by two conserved DNA binding domains, a POU and a HOX domain, both helix-turn-helix (HTH) structural DNA binding motifs. Several molecular genetic studies of gusher patients have identified mutations in the POU3F4 gene, including partial or complete deletions of the gene, as well as deletions, inversions, and duplications of the DFNX2 genomic region not encompassing the POU3F4 coding sequence. Little is known about how such mutations affect the normal function of the POU3F4 protein, which leads to characteristic inner ear malformations and hearing impairment. Here we present the clinical characteristics of patients of four independent German families. Additional analyses were performed in the POU3F4 gene. Mutations analysis in the POU3F4 gene was brought by direct sequencing of the coding exons including the intron transitions. Due to the radiological findings, mutation analyses of the POU3F4 gene were performed. Sequence analyses in one family revealed a novel missense mutation at nucleotide position 973, thymine to adenine (c.973 T>A, p.W325R) and in the second patient a missense mutation at nucleotide position (c.902C>T, p.P301L). Until now two novel strongly conserved mutations in the HOX-domain of the POU3F4 transcription factor were identified leading to an effect in the protein function.

Identification of protein sub-networks implicated in Autism Spectrum Disorders. *C. Correia[1,2], Y. Diekmann[1], J.B. Pereira-Leal[1], A.M. Vicente[1,2], Autism Genome Project Consortium.* 1) Instituto Gulbenkian de Ciência, Oeiras, Portugal; 2) Instituto Nacional de Saúde Dr.Ricardo Jorge, Lisboa, Portugal.

Autism Spectrum Disorders (ASDs) represent a group of childhood neurodevelopmental disorders characterized by three primary areas of impairment: social interaction, communication, and restricted and repetitive patterns of interest or behavior. Although autism is one of the most heritable neuropsychiatric disorders, most of the known genetic risk has been traced to rare variants. Genome-wide association studies (GWAS) have thus far met limited success in the identification of common risk variants, suggesting that ASD may result from the interaction of many variants with low or moderate individual risk, which cannot be detected in current GWAS in a single SNP analysis framework. Recently, molecular interaction networks have been integrated with high-throughput expression data, and the success of this application has been demonstrated through the identification of biologically meaningful subnetwork markers that are more reproducible and with a higher prediction performance. To identify subnetworks implicated in autism and with predictive value for autism diagnosis we have applied a network-based approach to the Autism Genome project consortium GWAS. We have integrated family- based association data from 2588 ASD families genotyped for 1 million single-nucleotide polymorphisms (SNPs) with a Human Protein-Protein interaction (PPI) network. We show, in line with observations in other complex diseases, that the proteins encoded by top genes (genes including one or more SNPs with a Transmission Disequilibrium Test $P<0.01$ or 0.005) are significantly closer to each other in a PPI network, suggesting that they are functionally related. Furthermore, these proteins were found to preferentially directly interact with each other, and were connected in a significantly larger component than random expectation, indicating that they are involved in a small number of interconnected biological processes. Having validated our initial assumption that autism-associated genes are confined to a limited number of biological processes, we searched for subnetworks that locally maximize the proportion of genes with low *P*-values in the GWAS dataset. Validation of the results in an independent GWAS and determination of prediction value of these subnetworks are underway. With this approach, we expect to identify biological processes associated with increased susceptibility to ASD, and eventually to derive clinically useful predictive markers.

TAS2R38 variation and its impact on bitter and thermal tasting in humans. *A.B. Bering[1], G. Pickering[1,2,3], P. Liang[1].* 1) Biological Sciences, Brock University, St. Catharines, Ontario, Canada; 2) Cool Climate Oenology and Viticulture Institute, Brock University, St. Catharines, Ontario, Canada; 3) Department of Psychology, Brock University, St. Catharines, Ontario, Canada.

TAS2R38 is a bitter taste receptor known to be associated with PROP (6-n-propylthiouracil) taster status. PROP tasting is a proxy for general taste responsiveness, and has been linked with diet-related behavior and health outcomes, including alcohol consumption, alcoholism, body mass index and cardiovascular disease risk. Ability to taste PROP allows classification of individuals into 3 phenotypes: super-tasters (pST), medium-tasters (pMT) or non-tasters (pNT). Recently, another form of taste phenotype, also serving as a proxy for general taste responsiveness, was discovered and known as thermal taster status, in which the heating and cooling of a region of one's tongue evokes a phantom taste response in approximately 20-50% of individuals. The mechanism behind thermal taste is not yet known. In this study, we sought to investigate the relationship between the TAS2R38 sequence variation with both PROP and thermal taster status. DNA extractions from buccal cells obtained from 56 individuals via mouthwashes were performed, and analysis of TAS2R38 variation was conducted through PCR amplification and sequence analysis. Among a total of 15 SNPs identified, a statistically significant correlation between PROP taster status and three TAS2R38 SNPs was evident as previously reported, with SNP site 1 having the strongest correlation compared to the other 2 known SNPs. However, not all PROP phenotype differences can be explained by variation at these 3 SNP sites, suggesting the involvement of additional sites either in TAS2R38 or other TAS2R genes. There was no association between thermal taster status and the TAS2R38 genotype suggesting the involvement of different genes in this phenotype. Our research provides the first genetic evidence to support previous phenotype-based observation that there is no association between PROP and thermal taster status by excluding the involvement of TAS2R38 in thermal tasting.

Genetic Regulation of ABC Transporter Expression in Human Liver and Kidney. *A. Chhibber, SW. Yee, C. Wen, RJ. Eclov, H. Fukushima, KM. Giacomini, DL. Kroetz.* Dept of Bioengineering & Therapeutic Sciences, Univ of California, San Francisco.

ATP -Binding Cassette (ABC) transporters are responsible for the transport of endogenous compounds, xenobiotics, and pharmaceutical agents across cell membranes. Inter-individual variation in expression of these transporters can explain differences in drug efficacy and toxicity, or susceptibility to a variety of conditions caused by a disruption in homeostasis of endogenous compounds. While several large studies have been conducted linking genetic variation to changes in gene expression (eQTLs) in lymphoblastoid cell lines, variation in expression caused by genetic differences is often highly tissue specific. For many ABC transporters, the liver and kidney are key sites of function. In this study we identify both tissue specific and cis and trans eQTLs that regulate ABC transporter expression in healthy human liver and kidney tissue. Gene expression for 48 ABC transporters was evaluated in 58 kidney and 60 liver samples from surgical resection or postmortem collections in Caucasian males and females using the Biotrove Open Array™ qPCR platform. Of these samples, 58 kidney samples and 34 liver samples were successfully genotyped on the Affymetrix Axiom genotyping platform using the Axiom Genome-Wide EUR Array Plate. After initial QC, 52 kidney samples and 34 liver samples were included in subsequent analyses. We identify associations between variants and expression levels by linear regression, and use the co-expression patterns between genes to propose possible regulatory pathways for ABC Transporters. Cis-eQTLs within 50 kb of transcription start and stop sites were identified for nine ABC transporters, each with one to three independent eQTLs; additional eQTLs were identified for 35 transporters within 500 kb of each gene. Trans-eQTLs were identified for 31 transporters, including several putative “hotspots” that may regulate expression of multiple genes. Both tissue-specific and cross-tissue QTLs were identified. This study includes the first genotype-expression study in healthy human kidney tissue, and the results may elucidate new clinically relevant sources of inter-individual variation. Further, this data will provide insights on the pathways regulating expression of ABC transporters. Functional validation of selected hits is ongoing. (This work was funded by NIH grant GM61390.).

Identification of putative causal genes for IBD in the 1q32 region: from genetics to biological mechanism. *G. David[1,2], M. Budarf[2], G. Charron[2], S. Foisy[2], A. Gardet[3], R.J.W. Heath[3], R.J. Xavier[3], J.D. Rioux[1,2].* 1) Medicine, Universite de Montreal, Montreal Heart Institute, Montreal, Quebec, Canada; 2) Montreal Heart Institute, Montreal, Quebec, Canada; 3) Center for computational and integrative biology, Massachusetts General Hospital, Harvard University.

Crohn's disease (CD) is an inflammatory bowel disease (IBD) characterized by chronic inflammation. This complex disease appears to be the result of an immune system dysregulation. Genome-wide association studies have identified 99 loci that contribute to IBD susceptibility. Chromosome 1q32 has been identified as a CD (rs 11584383, p=1,43x10e-11) and UC locus (p= 5,71x10e-7). This region contains four genes: Chromosome 1 open reading frame 106 (*C1orf106*), Kinesin family member 21B (*KIF21B*), Calcium channel, voltage-dependant, L type, alpha 1S subunit (*CACNA1S*) and Chromosome 1 open reading frame 81 (*C1orf81*). The goal of the present study is to place these genes in a biological context and to determine their possible involvement in IBD. First, using quantitative PCR, we established expression profile of the 1q32 genes in murine tissues and human cell lines. We determined that only *KIF21B* and *C1orf106* were expressed in immune and gastrointestinal tissues. Next, we tested the involvement of KIF21B and C1orf106 in biological pathways, more specifically NF-2B activation and ER stress that are both involved in pro-inflammatory processes. We found that an overexpression of KIF21B, in HEK293T cells, decreased ER stress response as well as the activation of NF-2B pathway, whereas C1orf106 increased ER stress response and slightly upregulated the NF-2B activation. Taken together our results suggest that KIF21B and C1orf106 are good candidate causal genes for IBD based on functional studies of the 1q32 region. Additional investigations are needed to fully explain the mechanism of KIF21 and C1orf106 activity in IBD pathogenesis.

Immunodeficiency, centromeric instability and facial anomalies syndrome (ICF; MIM 242860) is a rare autosomal recessive primary immune deficiency. It is mainly characterized by recurrent, often fatal, respiratory and gastrointestinal infections due to greatly reduced serum immunoglobulin levels. About half of ICF patients (ICF1) have mutations in the DNA methyltransferase 3B (*DNMT3B*) gene, resulting in reduced enzymatic activity and hypomethylation of specific repetitive DNA sequences in their genome. The remaining ICF patients carry unknown genetic defects (ICF2) but share with the ICF1 patients largely identical immunological and epigenetic features, including hypogammaglobulinemia and hypomethylation of juxtacentromeric heterochromatic DNA. By a combination of homozygosity mapping, whole exome sequencing and Sanger sequencing we identified loss-of-function mutations in the zinc-finger- and BTB (bric-a-bric, tramtrack, broad complex)-domain-containing 24 (*ZBTB24*) gene in the majority of ICF2 cases.

ZBTB24 is a member of a family of transcriptional repressors, such as BCL-6 (also known as ZBTB27) and PATZ1 (ZBTB19), with prominent regulatory roles in hematopoietic development and malignancy. Fluorescence activated cell sorting (FACS) followed by quantitative RT-PCR analysis showed that ZBTB24 is ubiquitously expressed with highest mRNA levels in human peripheral blood B lymphocytes, especially in naive B cell-subpopulation. Moreover, expression of ZBTB24 seemed to be co-regulated with DNMT3B during B cell development. Together, these data suggest that ZBTB24 is involved in the methylation of juxtacentromeric heterochromatic DNA and in the regulation of B-cell development and/or function. Current efforts focus on the elucidation of the molecular function of ZBTB24 in B-cell development and on the identification of the gene defect in the remaining ICF cases.

The Asthma Susceptibility Gene, *DENND1B* Regulates TNF(Signaling. *M.E. March, P.M.A. Sleiman, C. Hou, J. Bradfield, C.E. Kim, E.C. Frackleton, J.T. Glessner, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Asthma is a chronic inflammatory condition of the lungs, characterized by excessive responsiveness of the lungs to stimuli, in the forms of infections, allergens, and environmental irritants. Currently, 22.9 million Americans suffer from asthma, and the prevalence has increased dramatically since 1980. Asthma is the leading chronic illness in U.S. children, with 6.8 million affected in 2006. Twin studies have shown that there is a genetic element to asthma susceptibility (with heritability of the condition estimated at between 0.36 and 0.77), but only a fraction of the heritability is explained with previously identified loci. In a genome wide association screen (GWAS), we identified *DENND1B* as a novel asthma susceptibility locus in populations of both European and African descent. The single nucleotide polymorphisms (SNPs) that marked DENND1B were all noncoding (either intergenic or intronic), suggesting that factors such as mRNA stability, alternative splicing, and expression level may be involved. Expression of DENND1B was determined in EBV transformed B cells from patients using Affymetrix arrays, and the expression was analyzed based on the individuals' genotypes at the most statistically significant SNP (rs2786098) identified in the GWAS. The minor allele at this SNP, which was more prevalent in non-asthmatic individuals of European descent, correlated with lower expression of DENND1B. DENND1B is a guanine nucleotide exchange factor for Rab35, and associates with the clathrin-mediated endocytosis machinery. It is therefore possible that it influences the surface expression, endocytosis, or turnover of cell-surface receptors, thereby altering signaling. Through overexpression of various splice isoforms of DENND1B, we show that the molecule has the potential to regulate signaling through the TNF(receptor, a pathway important in asthma pathogenesis. The longer isoform enhances the TNF(response, while the shorter isoform reduces it. We are currently determining which of the multiple splice isoforms are expressed in different cell types, and if splicing is altered in individuals with either asthma-susceptible or -resistant genotypes. Additionally, studies on intracellular localization and the effect of DENND1B on receptor expression and intracellular trafficking are currently underway.

Functional characterization of the role that components of the retrograde transport machinery play in early HIV events. *S. Liu[1], M. Dominska[1], D. Dykxhoorn[1,2].* 1) John P. Hussman Institute for Human Genomics, Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Microbiology and Immunology University of Miami Miller School of Medicine, Miami, FL.

Human Immunodeficiency Virus (HIV) is a highly lethal lentivirus which is responsible for a tremendous amount of suffering and death in the United States and throughout the world. By attacking the host's immune system, HIV leaves the infected individual susceptible to a wide variety of opportunistic infections. HIV, like all viruses, relies on host cell factors for successful infection, replication and release of progeny virus. Previously, a large-scale functional genomic screen identified over 230 novel factors whose silencing inhibited viral replication in cultured cells. A more detailed examination of these HIV-dependency factors (HDFs) showed a significant enrichment for factors involved in the trans-Golgi network (TGN), a pathway which had not been previously implicated in HIV replication. Initial characterization of several of these factors suggested that their silencing resulted in an early defect in HIV replication prior to integration of the viral genetic material into the host genome. Once integrated, the viral DNA is maintained and replicated with the host genome. Anti-retroviral drugs can be used to suppress new viral production but they can't eliminate the integrated virus. Therefore, the identification of HDFs that inhibit viral integration could have tremendous therapeutic potential. To examine the role that the TGN-HDFs play in the HIV-1 life cycle, a series of cell lines were developed which are silenced for the various factors and submitted to biochemical and cell biological analysis. Our results indicate that many TGN genes (Rab5, Rab6, SNX1, SNX2, VPS26, VPS53) play important roles in early HIV events that precede gag translation, either viral fusion with the host cell, reverse transcription, intracellular trafficking, or preintegration, and silencing of them can effectively inhibit viral transmission.

791T

***Mycobacterium leprae*-dependent antigen presentation in primary human macrophages with *PARK2* gene mutations.** *R.H.M. Sindeaux[1], V.S. Sotomaior[1], D.E. Costa[1], A.C Senegaglia[2], M.T. Mira[1].* 1) Advantage Core of Molecular Investigation, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil; 2) Laboratory of Experimental Cell Culture, Pontifical Catholic University of Paraná, Curitiba, Paraná, Brazil.

Genetic control of human susceptibility to leprosy is widely accepted; however, the biological basis of this genetic effect is far from understood. A series of previous studies resulted in the identification of genetic variants shared by two genes, *PARK2* and *PACRG*, as major risk factors for susceptibility to leprosy “per se” in three distinct ethnic populations. Interestingly, severe mutations of the *PARK2* gene, that encodes Parkin, an E3 ubiquitin-protein ligase, have been implicated as causative of an autosomal recessive early-onset form of Parkinson's disease (AR-EOPD). The aim of this initiative was to use monocyte-derived macrophages (MDM) from AR-EOPD patients with *PARK2* spontaneous mutations as a model to investigate several aspects of host cellular response against *M. leprae*. Here, we applied the model to investigate antigen-presentation capability. Primary peripheral blood mononuclear cells isolated from three AR-EOPD patients with *PARK2* mutations and three healthy controls matched by age were cultured *in vitro* in 24-well culture plates for 5 days to obtain MDM (approximately 1.5-2.0x10^5 cells/ well). The cells were treated with irradiated *M. leprae* (multiplicity of infection bacilli to monocyte of 50:1) for 24 hours; MDM were incubated with anti-HLA-ABC, HLA-DR, CD80, CD86 and ICAM-I and the percentage of positive cells before and after challenge with *M. leprae* was scored by flow cytometry - FACScan. Basal and post-challenge *in vitro* expression of HLA-ABC, HLA-DR, CD80 and ICAM-I did not differ between AR-EOPD and control cells. However, *PARK2* mutant macrophages expressed higher levels of co-estimulatory molecule CD86 as compared to control cells, independently on *M. leprae* challenge. This result indicates promising directions for further experiments, as well as validates our model as suitable for investigation of the molecular basis of leprosy pathogenesis.

Delineating causal variation and the regulatory landscape at *TNFSF4* in systemic autoimmunity. *H. Manku[1], R. Torres[2], C. Langefeld[3], S. Guerra[1], T. Malik[4], G. Gilkeson[5], J. Edberg[6], R. Kimberley[6], S. Nath[7], B. Tsao[8], R. Festenstein[2], T. Vyse[1], LLAS2, SLEGEN.* 1) Division of Genetics and Molecular Medicine, Kings College London, London, United Kingdom; 2) Division of Medicine, Imperial College London, London, United Kingdom; 3) Wake Forest School of Medicine, Winston-Salem, NC, USA; 4) Division of Immunology and Inflammation, Imperial College, London, United Kingdom; 5) Division of Rheumatology and Immunology, Medical University of South Carolina, Charleston, SC, USA; 6) Division of Clinical Immunology and Rheumatology, Department of Medicine, University of Alabama at Birmingham, Alabama, USA; 7) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 8) Division of Rheumatology, Department of Medicine, David Geffen School of Medicine at UCLA, LA, USA.

Introduction: The TNF superfamily member *TNFSF4* operates at the T-cell-APC interface as a late-stage lymphocyte costimulator. This gene is an established SLE risk locus in European and Asian populations. Genetic polymorphisms in the 5' region of *TNFSF4* predispose to SLE and form an overtransmitted 100Kb haplotype (P_p<10^{-12}, *OR=1.6 [CI=1.27-1.89]*) associated with disease risk. However, causal variants have remained elusive due to strong linkage disequilibrium exhibited by alleles at *TNFSF4* in these populations. *Objectives:* Delineation of causal variation and the regulatory landscape at *TNFSF4*. *Methods*: We used massively parallel 454 sequencing to define causal variation at the 200Kb *TNFSF4* locus (n=100) and inferred fine-scale recombination maps in 2 ancestral and 2 admixed populations (n=6000). We fine-mapped the locus in a multi-ethnic SLE-control cohort of 17,900 individuals by Illumina Beadexpress. Putative causal variants were then profiled by ChiP (n=30) against H3K27me1, H3K27me3 and transcription factors identified by our bioinformatic scan. Chromosome conformation capture (3C) was used to characterise long range cis-interaction between risk variants and a novel upstream SLE susceptibility locus (n=20). *Results:* We find strong association of *TNFSF4* risk alleles in all groups tested; the novel African-American (AA) association replicates in AA Gullah and increased recombination in AAs refines the associated haplotype to 10Kb. *rs2205960-T* ($_UP_{META}$=7.1x10^{-32}, *OR=1.41[1.25-1.59]*) explains the risk in all four cohorts and our ChIP data suggest risk variant individuals have altered chromatin patterns at this location. Specifically, *rs2205960-T* alters a PU1 transcription factor binding site in LCLs and we have suggestive replication in B lymphocytes from *rs2205960-T* homozygotes. Overall results of our ChIP and 3C experiments are in analysis. Our phenotypic data demonstrate strong association of *rs2205960-T* with autoantibody production in AAs, Europeans and Hispanics ($_UP_{META}$=6.8x10^{-35}, *OR=2.2[1.78-2.5]*). *Conclusion:* In this study, increased haplotypic diversity in AAs reveals the association of *rs2205960-T* with SLE. Presence of this marker alters transcription factor binding. Our phenotype scan in multiple groups specifically associates *rs2205960-T* with autoantibody production to suggest a role for *TNFSF4* in lymphocyte dysregulation during SLE pathogenesis. These data confirm the validity of transancestral mapping in complex traits.

The protection roles of phosphorylated Heat Shock Protein 27 in human cells harboring MERRF A8344G DNA Mutation. *M. Hsieh[1], H.F. Chen[1], C.Y. Chen[1], Y.S. Ma[2], Y.H. Wei[2].* 1) Deptartment of Life Science, Tunghai Univ, Taichung, Taiwan; 2) Department of Biochemistry and Molecular Biology, School of Life Sciences, National Yang-Ming Univ, Taipei, Taiwan.

Mitochondria play an important role in the life and death of cells. They have their own DNAs which encode subunits of mitochondrial electron transport chain complexes. Mitochondrial DNA (mtDNA) mutations are associated with a large number of neurological and muscular diseases. Myoclonus Epilepsy with Ragged Red Fibers (MERRF) is a maternal inheritance mitochondrial disease. The most common mutation in MERRF disease, A8344G, is associated with severe defects in mitochondrial protein synthesis, which impaires electron transport chain assembly and respiratory chain activity. Our previous findings showed a decreased level of heat shock protein 27 (HSP27) and phosphorylated HSP27 (p-HSP27) in MERRF cybrids, compared with the control cybrids. Over-expressed wild type HSP27 in mutated cybrids resulted in a significant decrease of activated caspase 3 under staurosporine (STS) treatment, suggesting a protective function of HSP27 in cells harboring MERRF mutation. In the present study, we further examined the protective function of p-HSP27 in the disease cellular model. Even though the steady-state level of p-HSP27 was reduced in mutant cybrids, normal phosphorylation and dephosphorylation responses were observed upon stresses, indicating normal kinase and phosphatase activities. To explore the roles that p-HSP27 may play, transfection experiments with HSP27 mutants, in which three specific serine residues were substituted with alanines or aspartic acids, showed that the phosphomimicking-HSP27 desensitized mutant cybrids to apoptotic stress induced by STS. After heat shock stress, p-HSP27 entered the nucleus immediately after heat shock. With prolonged recovery intervals after heat shock, p-HSP27 returned to the cytoplasm in normal cybrids but not in mutant cybrids and this translocation is correlated to cell viability, as evidenced by the increased apoptotic cells after p-HSP27 returning to the cytoplasm. In summary, our results demonstrate that p-HSP27 provides significant protective functions when cells are under different stresses in the MERRF disease cellular model. Therapeutic strategies against anomalous HSP27 phosphorylation might be a potential treatment for the disease.

Advances in understanding the molecular mechanism of Goldberg-Shprintzen syndrome. *L. Drévillon[1,2], A. Megarbane[3], D. Gaillard[4], P. Benit[5], C. Matar[1,6], A. Briand-Suleau[1,2], J. Ghoumid[1,2], M. Nasser[1,2], V. Bodereau[1], M. Conti[1,6], M. Doco-Fenzy[4], P. Rustin[5], M. Goossens[1,2], I. Giurgea[1,2].* 1) Service de Génétique, Hopital Henri Mondor, CRETEIL, France; 2) INSERM, Unité U955, Equipe 11, and Université Paris-Est, Créteil, France; 3) Laboratory of Molecular Biology and Cytogenetics, Faculty of Medicine, University Saint-Joseph, Lebanon; 4) Service de Génétique, CHU, UFR de médecine, IFR53, Reims, France; 5) INSERM U676, Hôpital Robert Debré, Paris, France; 6) INSERM, Unité U955, Equipe 07, and Université Paris-Est, Créteil, France.

Goldberg-Shprintzen syndrome (GOSHS, MIM #609460) is an autosomal recessive disorder associating severe intellectual disability, typical facial gestalt and Hirschsprung disease. *KIAA1279* was identified as the disease causing gene with homozygous nonsense mutations. The encoded protein, named KBP (KIF-binding protein) due to its related interaction with kinesin-like protein, was initially claimed to be located at the mitochondria, a subcellular localization not confirmed by a recent study. KBP was implicated in axonal in structure, outgrowth and maintenance in zebrafish, however its underling mechanism remains unknown.

The aim of this study was to assess the functional consequences of two novel *KIAA1279* mutations (c.599C>A, p.Ser200X and c.604-605delAG, p.Arg202IlefsX2) on the mitochondrial function and to advance in the understanding of the molecular mechanism of Goldberg-Shprintzen Syndrome. In parallel, we detailed the phenotype of four patients from two different families carrying theses mutations. In fibroblasts of patients with truncating homozygous mutation, *KIAA1279* mRNA was barely detectable and in heterozygous carriers it was two-fold decreased, suggesting a NMD (nonsense mediated decay) mechanism. The subcellular localization of KBP by immunocytochemistry did not show mitochondrial localization in human fibroblasts. The activities of respiratory chain complexes by spectrophotometry were normal in fibroblasts of patients with *KIAA1279* homozygous nonsense mutations.

In conclusion, we report for the first time a *KIAA1279* NMD as the molecular mechanism of GOSHS. The absence of normal KBP protein did not influence mitochondrial respiratory chain complex activity in human fibroblasts.

795T

Genetic and functional characterization of the RNF114 psoriasis susceptibility gene implicates dysregulation of innate antiviral responses in disease pathogenesis. *F. Capon[1], A. Onoufriadis[1], S. Kanneganti[1], A.D. Burden[2], J.N. Barker[1], M.J. Bijlmakers[3], R.C. Trembath[1].* 1) Division of Genetics and Molecular Medicine, King's College London, London, United Kingdom; 2) Glasgow Western Infirmary, Glasgow, United Kingdom; 3) Division of Immunology, Infection and Inflammatory Disease, King's College London, London, United Kingdom.

Psoriasis is a chronic inflammatory skin disorder that is inherited as a complex genetic trait. Genome-wide association scans (GWASs) have successfully identified more than 20 disease susceptibility genes, highlighting the pathogenic role of pathways related to antigen presentation, IL-23 and NF-2B signalling. GWASs have also uncovered a number of genes of unknown function, which could provide novel insights into disease processes. Here we have investigated the role of RNF114, which was first identified as a psoriasis susceptibility gene in a GWAS carried out by our group (Capon et al., Hum Mol Genet 2008 17:1938-45). Homology searches indicate that RNF114 is a paralogue of RNF125, an E3 ubiquitin ligase which regulates the innate antiviral response (i.e. the production of IFN(/)) driven by the RIG-I and MDA5 receptors. To investigate the possibility that RNF114 may have a similar function, we carried out a range of biochemical assays, which indicated that RNF114 has ubiquitin ligase activity in-vitro. We next showed that RNF114 is up-regulated by IFN(and poly (I:C), a synthetic RIG-I/MDA5 ligand. Finally, we demonstrated that RNF114 overexpression results in increased IFN) reporter activity in response to poly (I:C) stimulation. These data suggest the existence of a positive feedback loop, whereby the IFN(/) produced upon viral infection up-regulates RNF114 expression, which in turn drives the release of more IFN(/) . To investigate the mechanisms whereby disruption of this pathway may contribute to disease pathogenesis, we re-sequenced RNF114 in 171 psoriatic patients, looking for rare functional variants. We did not detect any changes in the gene coding sequence, but identified two novel promoter substitutions, which were not found in 842 controls analysed in house or in the 1,094 individuals sequenced by the 1,000 genome project. Functional assays demonstrated that both variants affect Sp1 binding and result in reduced promoter activity. Taken together, these data point to dysregulation of gene expression as the mechanism underlying association signals at the RNF114 locus and pave the way for further studies into the alteration of innate immune responses in psoriasis.

Secretion-defective genetic variants of Decoy Receptor 3 in pediatric-onset Crohn's disease. *C.J. Cardinale[1], S. Panossian[1], F. Wang[1], E.C. Frackelton[1], C.E. Kim[1], F.D. Mentch[1], R.M. Chiavacci[1], K. Kachelries[2], R. Pandey[1], S.F.A. Grant[1], R.N. Baldassano[2], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA., USA; 2) Division of Gastroenterology, Children's Hospital of Philadelphia, Philadelphia, PA., USA.

Decoy Receptor 3 (TNF Receptor Superfamily 6B) is a secreted protein which binds to and neutralizes tumor necrosis factor superfamily ligands TL1A, Fas ligand, and LIGHT. Based on the results of genome-wide association studies, we expect DcR3/TNFRSF6B to play a role in early-onset Crohn's disease and ulcerative colitis (Kugathasan et al., 2009). We have sought to identify nonsynonymous amino acid variants of DcR3/TNFRSF6B that may underlie the GWAS signal by Sanger sequencing of the three exons comprising the gene in 532 pediatric Crohn's disease cases and 169 pediatric ulcerative colitis cases. We identified 12 novel nonsynonymous variants of which 11 are unique to cases and absent from public databases or 1100 genotyped controls. Six of these variants are defective in secretion from HEK 293T cells when expressed from plasmids. Investigation of the pedigrees of mutation carriers showed that the rare secretion-defective variants are present in parents with and without a phenotype. Further investigation of extended family members carrying these mutations will help elucidate whether the defective variants contribute to early-onset pediatric inflammatory bowel disease.

The Role of Pyrin On Cell Migaration and The Effect of Colchicine In The Process. *A. Cetinkaya[1], E. Taskiran[2], Y. Akkaya[2], B. Peynircioglu[2], M. Alikasifoglu[1], E. Yilmaz[1,2].* 1) Medical Genetics, Hacettepe University, Ankara, Turkey; 2) Medical Biology, Hacettepe University, Ankara, Turkey.

Familial Mediterranean Fever is an autoinflammatory autosomal recesively inherited disease characterized by inflammatory episodes. The disease is as common as 1:1000 in Mediterranean countries. The drug of choice for the disease is colchicine which both relieves the patient from episodes and prevents late complications like amyloidosis. The abberantly acting protein responsible for the disease is pyrin, shown to have several roles in inflamation control, apoptosis and cytokine secretion. Furthermore pyrin was suggested to have several roles in cell migration through its interaction with well-known regulators of cell migration PSTPIP1 and actin. Appropriate highest concentration of colchicine that would mimic the in vivo colchicine treatment was determined in COS-7 cells through LDH activity measurement, morphological analysis of cells staining of actin-tubulin cytoskeleton and endoplasmic reticulum - Golgi Aparatus. Wound healing assay was used to show the effect of pyrin in transiently transfected HeLa cells. Boyden chamber assays were used to determine the role of pyrin, 3 of its common disease-causing mutants, namely M694V, M680I, V726A and colchicine in transiently transfected COS-7 cells migrating against an insulin gradient. The highest concentration that would mimic colchicine treatment for COS-7 cells was determined as 10ng/ml. In Boyden chamber assays, a significant relationship between wild type pyrin overexpression and increased cell migration was shown, which was not observed in either control group or 3 common disease causing mutants of pyrin. In addition, colchicine treatment would only decrease cell migration in pyrin overexpression group. In wound healing assays, we noted an increased number of pyrin overexpressing HeLa cells neighboring the wound border compared to control group. The data presented here shows direct involvement of pyrin in control of cell migration. This maybe either through pyrin protein's interaction through PSTPIP1 or actin, or a different yet unknown mechanism. Colchicine's cell migration abolorating effects appearing only in the presence of wild type pyrin is also another interesting point to note. Further research in this subject may lead to discovery of novel mechanisms controlling cell migration in inflammatory cells and would result in novel treatment options for inflammatory diseases in general. This study was supported by TUBITAK-109S297 and TUBITAK-109S364.

798T

The Effect of Colchicine on LPS induced MEFV Gene Expression. *E. Yilmaz[1,2], E. Taskiran[1], A. Cetinkaya[2], Y. Akkaya[1], B. Peynircioglu[1].* 1) Hacettepe University, Faculty of Medicine, Department of Medical Biology,Sihhiye, Ankara, Turkey; 2) Hacettepe University, Faculty of Medicine, Department of Medical Genetics,Sihhiye, Ankara, Turkey.

Familial Mediterranean Fever (FMF) is the most common auto-inflammatory disease. It is characterized by recurrent attacks of fever and inflammation. It is caused by mutations in the MEFV (MEditerranean FeVer) gene. The product of MEFV gene, Pyrin, appears to be a regulator of inflammation, though the nature of this regulatory activity remains to be identified. Prophylactic treatment with colchicine, a microtubule toxin, has had a remarkable effect on disease progression and outcome. It has been thought that, inhibition of microtubule polymerization is the main mechanism of action of colchicine. But, the exact cellular mechanism explaining the efficacy of colchicine in suppressing FMF attacks is still unclear. Given the ability of colchicine treatment to be considered as a differential diagnosis criteria of FMF, we hypothesized that colchicine may have a specific effect on gene expression level of MEFV. To test our hypothesis, differentiated THP-1 cells were administered with microtubule non-disrupting concentrations of colchicine and MEFV gene expression was analyzed on both RNA and protein level. Quantitative real-time PCR studies revealed that colchicine caused a dramatic (~6 fold) decrease in MEFV levels compared to DMSO treated control cell. The results of Western blot analysis were similar to real-time PCR data. When differentiated THP-1 cells were treated with 10ng/ml LPS, MEFV expression was up-regulated (~2,5 fold), but in THP-1 cells treated with colchicine containing medium, MEFV levels was not up-regulated by LPS. We observed increasing number of actin stress fibers in THP-1 cells in 200ng/ml and 250ng/ml colchicine containing mediums. We further noted that filopodia was decreased by means of both the average length and the number of filopodia in differentiated THP-1 cells after colchicine treatment. These changes indicate that colchicine causes actin re-organization while it does not disrupt microtubules. Pyrin is an actin-binding protein that specifically localizes with polymerizing actin filaments. Thus, MEFV expression might be affected by re-organization of actin cytoskeleton. The data presented here reveal a potentially important connection between colchicine and MEFV gene which might explain the remarkable efficacy of colchicine in preventing FMF attacks by reducing the mutant protein level in FMF patients. Therefore, our data provide evidence for a pro-inflammatory role of Pyrin. Supported by H.U.BAB-0601101025 and TUBITAK-105S364.

Alternative splicing of MBNL2 transcripts upon C2C12 differentiation. *M. Fardaei, N. Farajzadeh.* Genetics, Shiraz University of Medical Sciences, Shiraz, Iran.

Muscleblind-like protein 2 (MBNL2) has a specific binding affinity for CUG or CCUG expanded repeat transcripts in a length dependent manner. The same as other 2 muscleblind proteins (MBNL1 and MBNL3), MBNL2 protein was also sequestered by nuclear foci of expanded repeats in adult muscle and cultured cells from myotonic dystrophy (DM1 and DM2) patients. This is well accepted that these proteins were diluted from their function in the regulation of pre-mRNA alternative splicing. Previous studies including both knockout mice and zebrafish knockdown model strongly suggested the role of MBNL2 in myotonic dystrophy patients. Alternative splicing of MBNL exons are conserved during embryonic muscle development. In this study we investigated splicing variation of MBNL2 during C2C12 differentiation and in completely differentiated muscle and brain cells in mice. Using RT-PCR, we identified a new splicing form of MBNL2, GQ906534, which encodes a protein with different amino acid sequences at the carboxy terminal end. Also, according to our results the splicing of MBNL2 transcript is changed during C2C12 differentiation, while MBNL2 transcript spliced in one form before differentiation, a bigger isoform also spliced after differentiation in C2C12, muscle and brain cells of mice.

Disease alleles in the general population: HGMD-DM variants in the 1000 Genomes Pilot samples. *Y. Xue[1], Y. Chen[1], N. Huang[1], E.V Ball[2], M. Mort[2], A.D Phillips[2], P.D Stenson[2], D.N Copper[2], C. Tyler-Smith[1], 1000 Genomes Project.* 1) Wellcome Trust Sanger Institute, Cambridge, UK; 2) Institute of Medical Genetics, Cardiff University, Heath Park, Cardiff, UK.

What is the genetic disease allele burden in the general population? In the 1000 Genomes Pilot paper [1], we identified 578 base substitutions from the HGMD database [2] classified as DM (the most severe category) among the 179 individuals sequenced. 72% of these variants showed a disease allele frequency >5%, ~32% were found in the homozygous state in one or more individual, and each person carried 57-80 disease alleles, 9-15 homozygous. We have now investigated further the likely disease implications of these alleles. In some cases, additional literature information was available and indicated that some HGMD-DM alleles were unlikely to be causative, but such information was not available for most variants. However, predictions of the functional consequences of the substitutions were possible for most alleles. We therefore used SIFT [3] and PolyPhen2 [4] to predict the consequences of the ns variants found in (1) the 1000G data only, (2) the HGMD dataset only, and (3) the overlapping set. Assuming that alleles found in set (1) were predominantly “healthy variants”, and that alleles in set (2) were predominantly “disease variants”, we used the distribution of the combined SIFT+PolyPhen scores in “disease variants” and “healthy variants” to calculate a Bayesian posterior probability that each variant caused disease. The majority of overlap set (3) variants had a low posterior probability of being causative, and only 185 variants had >95% probability. In this reduced set, disease alleles were rarer (only 14% >5%), fewer were seen in a homozygous state (22%) and on average each individual carried 15-20 disease alleles, 2-5 homozygous. We also investigated the HGMD-DM indels present in the 1000G data, and found 19. Again, manual curation suggested that the majority were unlikely to be causative, but a single base deletion in PRF1, linked to familial Haemophagocytic lymphohistiocytosis [OMIM: 603553], in the heterozygous state in a single YRI, was perhaps causative. In conclusion, the majority of apparent disease alleles found in the general population are probably not causative and reflect limitations in the original literature reports incorporated into databases. Better disease annotation and functional prediction tools are needed to identify true causative alleles. 1. 1000 Genomes Project Consortium (2010) Nature 467: 1061 2. Stenson et al (2009) Genome Med 1: 13 3. Prateek Kumar et al (2009) Nat Prot 4: 1073 4. Adzhubei et al (2010) Nat Meth 7: 248.

Genomewide Gene Expression Profiling of Monozygotic Twins Discordant for Autism Spectrum Disorder. *E.L. Meaburn[1, 2], C. Wong[1], J. Mill[1], A. Ronald[2], T. Price[1], L.C. Schalkwyk[1], R. Plomin[1].* 1) Psychological Sciences, Birkbeck University, London, United Kingdom; 2) Institute of Psychiatry, King's College London, Denmark Hill, London, SE5 8AF.

Autism Spectrum Disorders (ASDs) are a heterogeneous group of neurodevelopmental disorders that affect approximately 1% of the population. Delineating the etiological basis of ASD will aid diagnosis, prediction, and help develop better treatment and intervention strategies. It is widely recognized that ASD is highly heritable, with identical twin (monozygotic; MZ) concordance rates of about 60%;. However, MZ concordance is far from 100%, illustrating that there is an important - but often overlooked - non-shared environmental component that contributes to the development of ASD. To-date, molecular genetic investigation of ASD has primarily focused on identification of specific genetic risk variants. We sought to interrogate the molecular basis of non-shared environmental influence on the development of ASD. Within the Twins' Early Development study (TEDS) of 6,000 twin pairs, we identified a cohort of MZ twins discordant for ASD traits (N=36 twin pairs), concordant for high-ASD scores (N= 6 twin pairs) and concordant for low-ASD scores (N=11 twin pairs). The selection of MZ twin pairs was based on parental ratings on the Childhood Autism Symptom Test (CAST) when the twins were age 8 years. RNA was extracted from peripheral blood samples and genomewide gene expression was quantified using the Affymetrix GeneChip Human Gene 1.0 ST array platform. Transcripts detected as being differentially expressed (empirical Bayes paired t test) between ASD discordant MZ twins, which did not differ significantly between ASD-concordant or low-ASD concordant control pairs were highlighted as potential candidates under the influence of non-shared environment factors. In order to gain insight into biological themes and enriched processes and pathways, evaluation of the differentially expressed transcript list for previously reported genetic and methylomic ASD risk factors has been undertaken, and gene ontology analyses performed.

The genetics of idiopathic membranous nephropathy elucidated by GWAS. *H. Stanescu[1], M. Arcos-Burgos[2], A. Medlar[1], A. Kottgen[3], D. Bockenhauer[1], S.H. Powis[1], J.M. Hofstra[4], P. Brenchley[5], J. Feehally[6], A.J. Rees[7], H. Debiec[8], J.F.M. Wetzels[4], P. Ronco[8], P.W. Mathieson[9], R. Kleta[1].* 1) University College London, London, United Kingdom; 2) NHGRI, NIH, Bethesda, MD, USA; 3) University Hospital Freiburg, Freiburg, Germany; 4) Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 5) University of Manchester, Manchester, UK; 6) University Hospitals of Leicester, Leicester, UK; 7) Medical University of Vienna, Vienna, Austria; 8) INSERM UMR S702, UPMC Univ-Paris 6, Paris, France; 9) University of Bristol, Bristol, UK.

Idiopathic membranous nephropathy (IMN) is a major cause of nephrotic syndrome and kidney failure, the etiology of which is not fully understood. We investigated the genetic basis of biopsy-proven cases of IMN in Caucasians. Three independent genome-wide association studies (GWAS) utilizing single nucleotide polymorphisms (SNPs) were performed in patients from Caucasian populations (75 French, 146 Dutch, 335 British cases of IMN). Cases were compared with ethnically matched controls; population stratification, quality controls, and statistics were carried out according to standard criteria. In a joint analysis from the 556 cases studied, we identified significant alleles at two genomic loci associated with IMN. Chromosome 2q24 contains the M-type phospholipase A2 receptor gene PLA2R1 (SNP rs4664308, p= 8.6x10-29) shown previously to be the target of an autoimmune response. Chromosome 6p21 contains the human leukocyte antigen complex (HLA) class II gene HLA-DQA1 (SNP rs2187668, p=8.0x10-93). The association to HLA-DQA1 was significant in all three populations (p=1.8x10-9, 5.6x10-27 and 5.2x10-36 in French, Dutch and British, respectively). The odds ratio for IMN with homozygosity for both risk alleles is 79 (35-178 (95% confidence interval)). We sequenced both loci to ascertain the basis for our GWAS findings. An HLA-DQA1 allele on chromosome 6p21 is most significantly associated with IMN in Caucasians. This allele may facilitate an autoimmune response against targets, such as variants of PLA2R1. Our findings, including sequencing of both loci, suggest a basis for the understanding of IMN and illuminate how powerful GWAS can be for the study of a rare disease.

Whole genome gene expression profile of omental adipose tissue in obese Type 2 diabetic African Americans. *A.P. Doumatey, H. Xu, A. Adeyemo, A. Elkahloun, H. Huang, C.N. Rotimi.* Center for Research in Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Type 2 diabetes (T2D) is the most common co-morbidity associated with obesity. Adipose tissue especially omental adipose tissue (OAT) has been shown to play an important role in the pathophysiology of many obesity-related diseases including T2D by oversecreting adipokines and other active biomolecules that are involved in glucose homeostasis and low grade inflammation. Although, a number of studies have explored the differential gene expression profiles in obese T2D, they have focused on: 1) selected set of genes based on a priori biological knowledge and 2) populations of European ancestry. To further understand the genomics of T2D in African Americans (AA), we performed a whole genome gene expression on OAT attained from 20 obese AA. The study consisted of 14 obese subjects with T2D and 6 obese without T2D. Gene expression profiling was done using the whole human genome expression array, U133 Plus 2.0 (Affymetrix), which evaluates the relative expression level of more than 47,000 transcripts and variants, including more than 38,500 well characterized genes and UniGenes. One sample was determined as outlier during quality control and was excluded from subsequent analysis. Analysis of covariance was performed to identify genes differentially regulated between T2D subjects and controls after controlling for the effect of gender. The mean age of the 20 participants was 41.3 ±7.9 years. At a fold-change (FC) threshold >1.5 and false discovery rate <0.05, 130 transcripts were differentially expressed in obese T2D compared to controls. Among them,9 transcripts were upregulated notably HINT3 (FC 2.4),TBRG1 (FC 2.1),COL4A2 (FC 1.7),PPP2R2D (FC 1.51), and the remaining 121 genes were downregulated in obese T2D particularly ABCA9 (FC -2.9),ING3 (FC -2.9) and SEMA4C (FC -1.9).In pathway analysis using Ingenuity database, inflammatory signaling pathways were significantly enriched in the genes differentially regulated between obese T2D and controls, including the actin-based mobility by Rho pathway, Antigen presentation pathway and the Fc. receptor mediated phagocytosis in macrophages and monocytes pathway. In this study, we showed for the first time in a population of African ancestry, significant differential gene expression profiles in OAT of T2D patients, the most active endocrine organ implicated in obesity related diseases. Investigating the biological roles of the identified genes is likely to provide new insight into the patho-biology of T2D.

Adiponectin Q gene harbours risk variants for susceptibility traits of metabolic syndrome. *S. Majid[1], M. Al-Najai[1], E. Andres[1], S. Elhawari[1], M. Vigilla[1], D. Gueco[1], P. Muiya[1], M. Al-shahid[2], N. Dzimiri[1].* 1) Dept. of Genetics, King Faisal Specialist Hosp, Riyadh, Saudi Arabia; 2) King Faisal Heart Institute, King Faisal Specialist Hosp, Riyadh, Saudi Arabia.

Metabolic syndrome (MS) relates to a cluster of risk factors for atherosclerosis and type 2 diabetes mellitus (T2DM) comprising obesity (OB), insulin resistance, hypertension (HTN) and dyslipidemia. Adiponectin (ADIPOQ) is a hormone that modules several metabolic processes and is thought to play an important role in the suppression of the metabolic derangements that may lead to MS. In a preliminary genome-wide linkage study of early onset CAD involving a Saudi family of 11 individuals with predominant heterozygous familial hypercholesterolemia using the Affymetrix Gene Chip 250 sty1 mapping array, we identified several loci, among others, in chromosome 3 region which harbours the ADIPOQ gene. We then pursued a population-based association study for 8 ADIPOQ SNPs with MS risk factors in 4049 Saudi individuals (1584 OB cases versus 2450 controls) using the Applied Biosystems real-time PCR procedure. The rs6773957A>G [Odds ratio(95% Confidence Interval = 1.10(1.01-1.21); p=0.033) and the rs4686804A>G [1.11(1.02-1.22; p=0.021) conferred risk for OB, while the rs2241766G>T [0.88(0.79-0.99; p=0.032) was protective. These associations followed a recessive mode of inheritance. One variant, rs9842733A>T was implicated in both HTN [1.38(0.97-1.95); p=0.070] and T2DM [1.29(0.99-1.68); p=0.058), while another rs1063539 (p=0.07) was further implicated in HTN. These results point to sharing of susceptibility variants by risk traits for the metabolic syndrome.

Surprisingly Low Frequency of Deep Heteroplasmy in Human Mitochondrial DNA (mtDNA); However, Old People Tend to Have more Heteroplasmies but at Lower Levels in Blood. *S. Sommer[1], C. Buzin[1], R. Boles[2], C. Boysen[1], W. Scaringe[1].* 1) MEDomics, LLC, Azusa, CA; 2) Childrens Hospital Los Angeles.

BACKGROUND: Maternal inheritance characterizes the mitochondrial genome mutations that can underlie mitochondrial genome diseases. Mitochondrial genome diseases do not fit the general paradigm of genetic diseases due to the absence of centromeres and the hundreds to thousands of mitochondrial genome copies within a cell. While nuclear mutations at a given position are quantized (generally 2, 1, or 0 per individual), the percentage of mutant DNA, i.e. heteroplasmy level, of mitochondrial genome mutations varies from tissue to tissue and from sib to sib depending on the stochastic and selective factors. Mitochondrial DNA (mtDNA) has a high rate of mutation due to increased free radical exposure and decreased effectiveness of DNA repair, compared to nuclear DNA. New mutations coexist with wild-type mtDNA in the same cells (heteroplasmy). Previous evidence strongly suggested that mtDNA has a very high rate of mutation due to high free radical exposure and little or no available DNA repair mechanisms, predicting that deep heteroplasmy could be common in normal individuals and significantly confound clinical interpretation of mtDNA heteroplasmic variants found in patients with potential mitochondrial disease. METHODS: The entire mtDNA was NextGen sequenced thousands of fold using an Applied Biosystems SOLiD platform in predominantly leukoctye samples (blood or saliva) of 77 subjects. This method has about a 30-fold enhanced sensitivity relative to capillary sequencing. RESULTS: Of 77 patients reveals the majority (39) have zero heteroplasmies at 1% or greater. Within the age categories of 0-12, 13-25, and 25-50 the remaining individuals had 1 or 2 heteroplasmies, while 5 out of 15 of those individuals older than 50 had 3 or more heteroplasmies (p=0.0002). Older people may tend to have a higher number of heteroplasmic variants, but the frequency of those heteroplasmies tends to be lower. For example, 24% (8 of 34) of heteroplasmic variants found in individuals aged 0 to 50 had a heteroplasmic frequency of 10% or greater while 4% (1 of 27) of the heteroplasmic variants found in older people had a heteroplasmic frequency of 10% or more (p=0.03). CONCLUSIONS: The number of heteroplasmic variants at levels of 1% or more within the 16.5 kb genome is low. While more data are desirable, it seems that older individuals tend to have a larger number of heteroplasmic variants, but high frequency heteroplasmic variants are less common.

Integrated transcriptome and enhancer networks during inner ear hair cell regeneration by Next Gen sequence analysis. *Y. Ku, N. Renaud, R. Veile, C. Helms, M. Warchol, M. Lovett.* Genetics, Washington University in Saint Louis, Saint Louis, MO.

Loss of inner ear hair cells is the leading cause of human deafness and balance disorders. Unlike mammals, lower vertebrates such as birds are capable of regenerating new sensory hair cells. We used Next Generation Sequencing technology to derive a comprehensive description of all mRNAs and miRNAs over a 7 day regenerative time course in vitro, following chemical ablation of hair cells within avian inner ear sensory epithelia (SE). We also identified putative enhancer elements activated during regeneration by ChIP-Seq, using an antibody to p300. From mRNA-seq, we detected ~15,000 genes and ~1800 transcripts that reproducibly changed by >2-fold during regeneration, compared to controls. These include previously described components of NOTCH, WNT, FGF, PAX and SOX signaling. We are systematically testing the phenotypic relevance of these and many additional genes by high throughput screening of RNAi knockdowns in utricle supporting cells. Each of these knockdowns is also assessed by RNA-seq to determine downstream transcriptional effects and to computationally build interaction networks for sensory epithelial regeneration. By applying these genomic and bioinformatic approaches we have been able to link together many genes in the regenerative network, including specific components of WNT and NOTCH signaling that influence regeneration. Seventy one avian miRNAs show >2-fold changes in expression during regeneration. We have tested several of these miRNAs by knockdowns and over expression to assess their effects upon regenerative events. For example, a knockdown of miR-34c significantly increased regenerative proliferation, whereas over expression decreased proliferation. Components of the NOTCH signalling pathway are predicted targets of this miRNA and the levels of several of these mRNAs correlate with changes in miR-34c expression. In our enhancer dataset there are many examples of temporal changes in activity. We have built an integrated map of transcription related to flanking putative enhancers/insulators. We are comparing our regeneration data to RNA-seq data from mouse and chicken SE induced to transdifferentiate by gamma secretase inhibitors, to identify similarities and differences in regenerative programs between birds and mammals. The long term goal of our studies is to identify promising therapeutic targets for hair cell replacement and hearing restoration in humans.

Genome-wide gene expression study of peripheral blood monocytes for osteoporosis. *H. Shen[1,2], Y. Chen[2], T. Xu[1,2], C.H. Yi[1], Y.Z. Liu[1,2], H.W. Deng[1,2].* 1) Center for Bioinformatics and Genomics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) School of Medicine, University of Missouri-Kansas City, Kansas City, MO 64108, USA.

Osteoporosis is a disease of bone fragility, with an increased risk of low trauma fracture. The disease has significant impact to the health of the elderly, especially old women. Bone mineral density (BMD) is a key parameter to characterize osteoporosis and genetics plays an important role in BMD variation. An important mechanism for osteoporosis is an excess of bone resorption by osteoclasts over bone formation by osteoblasts. Peripheral blood monocytes (PBMs) are precursors of osteoclasts and play an essential role in osteoclastogenesis by producing cytokines, such as TNF and IL-1. Here we performed a genome-wide gene expression profiling analysis of PBMs in 69 middle-aged Caucasian females (age of 47-53) with extremely high (n=41) or low (n=28) hip BMD. By using Affymetrix Human Exon 1.0 ST arrays, we identified a number of genes showing significant evidence of differential expression between high vs. low BMD subjects. Among these differentially expressed genes, some were previously known to be important factors for osteoclast differentiation (e.g, CTNNBIP1, p= 2.89E-4, fold-change =1.45 between low vs. high BMD subjects) and some have been associated with BMD variation (e.g., C1orf61, p=3.59E-5, fold-change=0.61, and NAMPT, p=6.13E-4, fold-change=1.58). Interestingly, we also identified a number of novel candidate genes for BMD variation, such as CCDC62 (p=2.95E-3, fold-change=0.83), which may act on monocyte-mediated postmenopausal bone loss through estrogen receptor regulation. Our findings, together with the previous evidence, suggested a list of interesting candidate genes for BMD regulation and risk of osteoporosis, which are worth further pursuing with molecular and functional studies.

Admixture mapping of fat mass in African American women identifies region on 3q13.31. *L. Preus[1], L.E. Sucheston[2], J. Wactawski-Wende[1], N. Johnson[3], F. Zakharia[3], H. Tang[3], N. Risch[4], C. Ambrosone[2], C. Carlson[5], C. Carty[5], Z. Chen[6], C. Hutter[5], R. Kaplan[7], C. Kooperberg[5], S. Liu[1], M. Neuhouser[5], U. Peters[5], C. Thompson[8], H.M. Ochs-Balcom[1].* 1) University at Buffalo, Buffalo, NY; 2) Roswell Park Cancer Institute, Buffalo, NY; 3) Stanford University, Stanford, CA; 4) University of California, San Francisco, San Francisco, CA; 5) Fred Hutchinson Cancer Research Center, Seattle, WA; 6) University of Arizona, Tucson, AZ; 7) Albert Einstein College of Medicine, Bronx, NY; 8) Case Western Reserve University, Cleveland, OH.

Obesity is well recognized as a complex phenotype. Body composition phenotypes are particularly appealing for admixture mapping, given the differences in rates of obesity in African American and European American populations. Several studies have shown correlation between global ancestry and body mass index, which is the impetus for our study of more specific adiposity phenotypes. Using dual energy X-ray absorptiometry (DXA) scans available from 842 African American women in the WHI SNP Health Association Resource (SHARe) sample, we performed admixture mapping for the following DXA fat mass phenotypes: total body fat mass, trunk fat mass, ratio of trunk to total body fat mass and whole body percent fat mass. We derived global and local ancestry estimates for each individual from Affymetrix 6.0 data using four reference samples (African, Northern and Western European, East Asian, and Native American). We measured the correlation of DXA phenotypes with African ancestry and used proportion of Northern and Western European ancestry to adjust for population substructure. For each phenotype, we used linear regression to assess the significance of 570,282 SABER estimates of local ancestry (number of African ancestral alleles at each marker) in additive models with adjustment for MET-hrs/week walking, height, weight, smoking, duration of hormone therapy and geographic region. Analyses were performed with and without women who reported a diabetes diagnosis. We found statistically significant covariate-adjusted correlations of whole body fat mass ($p<0.001$) and trunk fat mass ($p<0.04$) with proportion of African ancestry. Genome-wide (admixture) significance ($p<5.5x10-6$) for trunk fat mass was achieved across a 3.3 Mb region on 3q13.31. The five most significant SNPs at this locus showed an inverse association of trunk fat mass and African ancestry ($p=9.4x10-7$). When women with a diabetes history were excluded, we observed a significant inverse association of percent fat mass and African ancestry on 3q24 ($p=4.1x10-6$). After an additional adjustment of the 3q13.31 and 3q24 regions for global ancestry (and multiple testing), both signals were attenuated, with p-values of 2.9x10-4 for trunk fat mass and 1.5x10-4 for percent fat mass. This is the first admixture mapping study of DXA-derived fat mass phenotypes performed to date. Our results suggest that genomic regions in postmenopausal African Americans that contribute to variance in adiposity exist.

Realini[14], J.E. Richards[13], J.S. Schuman[15], K. Singh[16], D. Vollrath[17], R. Weinreb[18], G. Wollstein[15], D. Zach[9], K. Zhang[18], M.A. Pericak-Vance[19], L.R. Pasquale[2], J.L. Haines[5].* 1) Center for Human Genetics Research, Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Ophthalmology, Harvard Medical School, Boston, MA; 3) Departments of Medicine and Ophthalmology Duke University School of Medicine, Durham, NC; 4) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) Center for Human Genetics Research, Vanderbilt University School of Medicine, Nashville, TN; 6) Department of Ophthalmology Duke University Medical School, Durham, NC; 7) Department of Ophthalmology University of Miami Medical School, Miami, FL; 8) National Eye Institute, NIH, Bethesda, MD; 9) Department of Ophthalmology Johns Hopkins University School of Medicine, Baltimore, MD; 10) Eye Doctors of Washington DC; 11) Bioinformatics and Systems Biology Program, University of California at San Diego, La Jolla, CA; 12) Department of Biostatistics, University of Washington, Seattle, WA; 13) Department of Ophthalmology University of Michigan School of Medicine, Ann Arbor, MI; 14) Department of Ophthalmology University of West Virginia School of Medicine, Morgantown, WV; 15) Department of Ophthalmology University of Pittsburgh School of Medicine, Pittsburgh, PA; 16) Department of Ophthalmology Stanford University School of Medicine, Palo Alto, CA; 17) Department of Genetics Stanford University School of Medicine, Palo Alto, CA; 18) Department of Ophthalmology University of California at San Diego, La Jolla, CA; 19) Institute for Human Genomics, University of Miami School of Medicine, Miami, FL.

Primary open-angle glaucoma (POAG) is a common, genetically complex degenerative optic neuropathy that is a leading cause of blindness worldwide. Positive family history of POAG is a strong risk factor, indicating a genetic component to the disease. The NEIGHBOR (NEI Glaucoma Human genetics collaBORation) consortium is a collaborative effort involving 12 institutions throughout the United States, contributing 2,170 cases and 2,347 controls, and constituting the largest collection of POAG cases to date. A genome-wide association study (GWAS) revealed 17 single nucleotide polymorphisms (SNPs) of genome-wide significance. Sixteen are within the *CDKN2BAS* region at chr9p21.3 with a top hit at rs4977756 ($p=7.34x10-16$; OR=0.66). The remaining SNP, rs10483727, is 40 kb 5' from *SIX1* at chr14q23.1 ($p=3.10x10-8$; OR=1.13). Since POAG occurs across a continuum of intraocular pressure (IOP), we stratified our cases by ocular tension status (pretreatment, when available), defining 2 subsets: a normal tension glaucoma (NTG) group with IOP <22 mmHg at or before diagnosis and a high tension glaucoma (HTG) group with IOP ⁄ 22 mmHg. We found the association with *CDKN2BAS* was stronger in our NTG cases (rs4977756; $p= 7.31x10-7$; OR=0.59) than HTG cases ($p=6.61x10-4$; OR=0.78) despite significantly smaller sample size in the former subset (398 NTG; 971 HTG). These data suggest *CDKN2B* SNPs significantly influence susceptibility to glaucomatous optic neuropathy even in the absence of elevated IOP. In addition, the NEIGHBOR consortium has harmonized clinical definitions and genotyping platforms with the Glaucoma Genes and Environment (GLAUGEN) POAG GWAS, which is part of the GENEVA (Gene Environment Association studies) consortium. Combined, the two studies include 3,146 cases and 3,487 controls. A meta-analysis identified a new locus at 8q23 of genome-wide significance in NTG cases (top hit rs284489; $p=8.88x10-10$; OR=1.62). *CDKN2B* is a part of the transforming growth factor-beta signaling pathway (TGFB-p). Furthermore, evidence suggests the SNPs identified at 8q23 influence the expression of *TSC22*, which itself modulates signaling within the TGFB-p. Using the PARIS pathway analysis algorithm, we found the TGFB-p (Kyoto Encyclopedia of Genes and Genomes) associated with POAG in our combined NTG dataset ($p=0.021$). The identification of genetic variation predisposing to POAG is an important step toward understanding its pathophysiology and eventual design of gene-based treatment.

810T

Triplet domain hyper-amplification drove human-lineage specific DUF1220 domain expansion. *M. O'Bleness[1], L. Dumas[1], H. Kehrer-Sawatzki[2], G. Wyckoff[3], J. Sikela[1].* 1) Biochemistry and Molecular Genetics, Univ Colorado Denver AMC, Aurora, CO; 2) Institute of Human Genetics, University of Ulm Albert-Einstein-Allee, Ulm, Germany; 3) Molecular Biology and Biochemistry, University of Missouri, Kansas City, Missouri, USA.

DUF1220 protein domains show the largest human lineage-specific (HLS) increase in copy number of any protein coding sequence in the human genome. From >260 copies in human DUF1220 copy number markedly decreases as a function of a species evolutionary distance with human (125 in chimp; 1 in mouse/rat). Most HLS DUF1220 copies map to 1q21.1 and recently 1q21.1 CNVs that either encompass or flank DUF1220 domains have been implicated in numerous human diseases, including microcephaly, macrocephaly, autism, schizophrenia, mental retardation and heart disease, suggesting a link between this dramatic HLS DUF1220 copy number amplification and the etiology of these disorders. Here we analyze 40 animal genomes and present the most complete portrait to date of the evolutionary history of DUF1220 domains and the genes that encode them (NBPF family). We describe several key events related to DUF1220 evolution, the most striking of which is that the dramatic HLS increase in DUF1220 copy number : from 102 in our last common ancestor with chimp/bonobo to 272 in human (an average of ~28 copies added to the human genome every million years) was driven almost exclusively by domain hyper-amplification involving a 4.7kb, tandemly-repeated three DUF1220 domain unit we have named the HLS DUF1220 triplet. The triplet amplifications lie completely within a unique, recently evolved genomic landscape flanked by the human-specific, large heterochromatic C-band at 1q12, and within an HLS pericentromeric inversion, features which are likely to be key to the sustained rapid expansion of the DUF1220 domain within the human lineage. The data presented here support the view that while the HLS DUF1220 triplet hyper-amplification is among the most striking changes found in the human genome, it has come at an expensive price, having been largely responsible for creating and maintaining one of the most unstable and disease-prone regions of the human genome.

Identification of non-coding elements as candidate sequences associated with diseases. *A. Henrion[1], M. Naville[2], M. Girard[1], C. Mugnier[1], S. Bandiera[1], A. Munnich[1], M. Le Merrer[1], S. Lyonnet[1], H. Roest Crollius[2].* 1) UMR781 INSERM, Paris, France; 2) Dyogen Group, CNRS UMR8197-INSERM U1024, Institut de Biologie de l'Ecole Normale Supérieure (IBENS), Paris, France.

Over three percent of the human genome consists of conserved non-coding elements (CNEs). Those elements are either non-transcribed or transcribed, for instance as microRNAs. In the present work, we considered three groups of genetic diseases: diseases with mapped loci but no known genes (group I), diseases with cloned genes (group II), and diseases with recurrent chromosomal rearrangement (group III). To address the interest of studying non-coding elements in disease-causing genes for which mutations are already known and characterized, we first plotted group II together with the location of microRNAs. Interestingly, we could identify 274 diseases with cloned genes that may still involve microRNAs. In particular, we were able to identify a notable enrichment in monogenic diseases with clinical heterogeneity in this category. By comparative genomics alignments across multiple vertebrate species we then selected possibly functional CNEs. Our aim was to establish functional linkages between these CNEs and their likely target gene by replacing them in an ancestral mammalian genome, and by postulating the maintenance of CNE/target gene physical proximity in ancestral and modern genomes. This approach led to identify 72 disease-causing genes putatively controlled by CNEs and involved in diseases that are listed herein. To increase the specificity and the sensitivity of the analysis we increased the number of species and used the ancestral Boreoeutheria genome as reference. We compiled an atlas of the X-linked diseases that may involve CNEs. Our results provide a source of non-coding elements associated with diseases worthwile interest to sequence in those patients with no mutation previously identified. It also paves the way to unravel sets of CNEs aiming to the concerted phenotypic-specific regulation of a disease-causing gene, otherwise involved in numerous developmental fields.

812T

Development of a novel multiplex assay for major Y haplogroup assignment. *T.D. Parrish[1], A.E. Justice[2], S.M. Johnson[2], K.G. Beaty[2], C. Phillips-Krawczak[3], P. Williams[1], M.H. Crawford[2].* 1) Evogen, Inc, Kansas City, MO; 2) Department of Anthropology, Lab of Biological Anthropology, University of Kansas; 3) Genetics Program, Department of Molecular Biosciences, University of Kansas.

Uni-parentally inherited markers, such as those found on the Y chromosome, are of interest for their utility in determining the ancestry of individuals and reconstructing population history. To accurately assign a region of origin for Y chromosome ancestry it is important to use regionally specific Single Nucleotide Polymorphisms (SNPs). Typically this requires costly and time consuming sequencing of multiple markers or AFLP with expensive kits for haplogroup assignment. This study aims to provide a cost and time efficient means of accurately typing Informative SNPs for Y haplogroup ancestral assignment in a hierarchical fashion. Hybeacons® Probes (Evogen, Inc.) were designed in three multiplex reactions containing a total of 15 SNPs for major Y haplogroup/macrohaplogroup assignment (A, B, C, D/E, F, G, H, I/J, K, L, M, N/O, Q, R, and R1). Hybeacons® Probes use a single primer pair per SNP to amplify the region of interest, normal PCR reagents, and fluorescently-labeled probes in a single PCR reaction. For multiplexing, HyBeacons® were labeled with different fluorescence and staggered by melting temperatures for easy identification of positive SNPs. The difference among melt curves allows the researcher to differentiate among the wild type and the polymorphic SNPs. The multiplexes were used to type descendant and admixed populations from Europe, Africa, Asia, North America, Central America and South America (Peru). Typing was confirmed by sequencing a subset of the samples from each haplogroup/macrohaplogroup and comparing SNP typing to Y STR profiles. The SNP multiplex was successfully employed to obtain ancestral information for paternal lineage identification. The hierarchical fashion of the multiplexes decreased the number of reactions and thus reagent required to complete haplogroup assignment. The SNP multiplex provides a low-cost, high throughput method for typing of Y chromosome haplogroups that will prove useful in the fields of forensics and anthropology.

Alzheimer's disease susceptibility loci: evidence for natural selection and altered gene expression. *T. Raj[1,2,3,4], J.M. Shulman[1,3,4], B.T Keenan[1,3,4], L.B. Chibnik[1,3,4], D.A. Evans[5,6], D.A. Bennett[5,6], B.E. Stranger[2,3,4], P.L. De Jager[1,3,4].* 1) Program in Translational NeuroPsychiatric Genomics, Department of Neurology, Brigham and Women's Hospital, 77 Avenue Louis Pasteur, Boston, MA 02115; 2) Department of Genetics, Brigham and Women's Hospital, 77 Avenue Louis Pasteur, Boston, MA 02115; 3) Harvard Medical School, Boston, MA 02115; 4) Program in Medical and Population Genetics, Broad Institute, 7 Cambridge Center, Cambridge, MA 02142; 5) Departments of Internal Medicine and Neurological Science, Rush University Medical Center, 600 S Paulina St., Chicago, IL 60612; 6) Rush Alzheimer's Disease Center, Rush University Medical Center, 600 S Paulina St., Chicago, IL 60612.

Genome-wide association (GWA) studies have identified a number of susceptibility loci Alzheimer's disease (AD). Many of these loci include genes involved in cholesterol metabolism, immune functions and cell membrane processes, but the contribution of these genes to AD pathophysiology is largely unknown. To dissect the functional consequences of the associated genetic variants, we explored large-scale data sets interrogating the human genome for evidence of positive natural selection and of effects on gene expression in each associated locus (cis-regulatory effects). Using a long-range haplotype test for positive selection, we find that putative AD susceptibility loci including CD2AP, PICALM, EPHA1, MS4A2, CD33 and CR1 harbor haplotypes with evidence of recent selection. For example, the haplotype carrying the AD risk variant rs561655 in PICALM shows strong evidence of positive selection after correction for genome-wide testing. Our results further show that multiple physically interacting proteins (based on protein-protein interaction network) including the genes PICALM, CD2AP, BIN1 and EPHA1 show significant evidence for selection, indicating a possible co-evolution of genetic variants underlying AD pathology, perhaps in response to a single evolutionary pressure. To support the hypothesis that AD susceptibility alleles may influence the function of immune cells, we analyzed gene expression data from monocytes and peripheral blood and identified 4 cis-regulatory effects (PICALM, MS4A2, BIN1 and CD33) in the 10 tested loci, including the rs3826656 variant which is strongly associated with the RNA expression of CD33 in monocytes ($p = 4.07 \times 10^{-17}$) and in peripheral blood ($p = 3.94 \times 10^{-4}$), suggesting that AD susceptibility may act, in some cases, through altered gene expression in immune cells. We have confirmed this effect at the protein level in monocytes: CD33 expression is upregulated on the cell surface relative to the risk allele. Our results provide significant evidence for signatures of recent positive selection acting on several haplotypes carrying AD susceptibility alleles, some of which have cis-regulatory effects on a nearby gene. Taken together, our data suggest several different genes implicated in AD may have worked together in another context to enhance survival over the course of recent human evolutionary history.

Co-existence of Hemoglobin D and IVSII-5 in the same allele of Beta globin gene in Iranian population. *N. Bayat, F. Daneshimehr, S. Jalilnejad, N. Faramarzi, H. Imanian, A. Azarkeivan, H. Najmabadi.* Molecular genetics, Kariminejad-Najmabadi genetic center, Tehran, Tehran, Iran.

The Beta Thalassemia, is one of the most common hemoglobinopathies is Iran as well as Hemoglobin type D (Cd121 G>C). The IVSII-5 beta thalassemia mutation was reported before in a family with Chinese background. And the hemoglobin D Punjab (Also known as Hb D-Los Angeles) has been reported in different places of the world. In this study we have identified these two mutations located in the same allele of Beta globin. The family showing the phenotype of beta thalassemia (maternal side), the HbD phenotype with a little raise of HbA2 in hemoglobin electrophoresis (paternal side) was referred to our lab in case of prenatal diagnosis investigation. They have also had a child with a same phenotype as his father. The DNA was extracted from peripheral blood leucocytes, the beta globin gene was amplified by PCR, and the DNA sequencing was performed to identify the beta mutations. We have determined that the paternal side has two mutations in beta globin gene (HbD and IVSII-5) and the maternal side has only one Beta thalassemia mutation (IVSII-1). Since the maternal and paternal mutations were identified, we would logically look for the same mutations in the child, but the surprising result was that the child has inherited both mutations from his father. In this study we have identified the rare IVSII-5 mutation in Iranian population accompanying the HbD mutation. Also we have shown that these two mutations are located in the same allele, this data is so important for any future pregnancy of this family because they are in a risk of having a child with three beta globin mutations. Also we realized that the Beta globin gene DNA sequencing should be performed for all suspicious cases as well as family study, to identify whether the mutation is located in the same allele and is the person carrying only one mutation or more in the same allele.

815T

Vitamin D Sufficiency Modulates the Effect of Polymorphisms on Bronchodilator Response in Asthmatics. *A.C. Wu[1,2], B.E. Himes[3,4,5,6], K. Tantisira[6], S.T. Weiss[5,6], A. Litonjua[6].* 1) Population Medicine, Harvard Medical School, Boston, MA; 2) Children's Hospital, Boston Division of eneral Pediatrics, Boston, MA; 3) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA; 4) Children's Hospital Informatics Program, Boston, MA; 5) Harvard Partners Center for Genetics and Genomics, Boston, MA; 6) Channing Laboratory, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Low vitamin D levels appear to be associated with asthma, asthma symptoms, and decreased airway responsiveness. Single nucleotide polymorphisms (SNPs) influence bronchodilator response. Thus, we hypothesized that vitamin D could modulate the effect of multiple SNPs on bronchodilator response. We assessed whether vitamin D sufficiency modulates the measured association of SNPs with bronchodilator response in a population of subjects with asthma using a genome-wide association approach. Our primary population is composed of subjects from the Childhood Asthma Management Program (CAMP), a clinical trial that followed asthmatic children for four years. Genome-wide SNP genotyping for 561 Caucasian CAMP subjects and their families was performed on Illumina's HumanHap550 Genotyping BeadChip (Illumina, Inc., San. After excluding SNPs with missing data in more than 5% of subjects, having minor allele frequency (MAF) less than 1%, and having Hardy-Weinberg equilibrium p-values among controls less than 0.001, there were 512,284 SNPs. We conducted a gene by environment analysis in PLINK with vitamin D sufficiency versus insufficiency as the environmental exposure and bronchodilator response as the outcome measure. We found that the SNPs that are most significantly associated with bronchodilator response while accounting for vitamin D sufficiency are in chromosomes 1, 2, 3 and 13. The top 8 SNPs had a gene by environment interaction p-value of <1E-05. Thus, we have identified SNPs that appear to modify bronchodilator response differently depending on Vitamin D levels in the CAMP population. We are replicating these associations in an independent population. This work was supported by.

Keeping it in the Family. *E. Bruford, L. Daugherty, M. Lush, R. Seal, M. Wright.* HGNC, EMBL-EBI, Hinxton, United Kingdom.

The HUGO Gene Nomenclature Committee (HGNC) has assigned unique approved gene symbols and names to over 31,000 human loci to date. Over 19,000 of these are protein coding genes, but we also name pseudogenes, phenotypic loci, genomic features and non-coding RNAs. Our recently updated website, genenames.org, is a searchable repository of HGNC-approved gene nomenclature and associated resources, including nomenclature guidelines and the HGNC Comparison of Orthology Predictions (HCOP) tool. Each locus has an individual “gene symbol report” which can include links to genomic, proteomic and phenotypic information. Approved gene symbols are based on names describing structure, function or homology, and where possible the HGNC also organise these into gene groupings and families, many of which have specialist advisors who are experts in that particular area of biology. HGNC also create web pages for specific gene families, and we are currently in the process of generating more of these pages and expanding their scope using data curated by the HGNC combined with external resources that focus on particular families. These new gene family pages will be sorted into meaningful categories which could include function, structure and homology. We also now provide links from our individual gene symbol reports to our improved gene family resources. If you know of a gene family that you think should be represented please contact us via hgnc@genenames.org or talk to us during this meeting. The work of the HGNC is supported by the NHGRI and the Wellcome Trust.

Very little is known about the genetic etiology of systemic lupus erythematosus (SLE) in individuals of African ancestry - in spite of its higher prevalence, incidence, disease severity, and mortality rates in African Americans (AA). Overproduction of nitric oxide (NO) has been implicated in its pathogenesis and correlated with disease severity, making NO synthases and other reactive intermediate genes biological candidates for disease susceptibility. Here, we report a comprehensive analysis of reactive intermediate genes for their association with SLE in populations of African ancestry. One such population are the Gullah of the Sea Islands of South Carolina: a population isolate with limited and well defined ancestral diversity. Such reduced genetic heterogeneity may increase the power to detect associations in this population. In addition, their higher familial disease prevalence might reflect a stronger genetic component to the disease. We analyzed 279 SNPs from 55 regions in 133 Gullah cases and 112 Gullah controls, as well as in other 1432 AA cases and 1575 AA controls. These and approximately 300 additional ancestry informative markers were genotyped on an Illumina custom array; principal components analysis and admixture estimates were computed and adjusted for in association analyses. While the glutathione reductase GSR (rs2253409, P=0.0014) and paraoxonase PON3 (rs17879114, P=0.0016) were the most significant single-SNP associations in AA, in the Gullah the NADH dehydrogenase NDUFS4 (rs381575, P= 0.0065) and nitric oxide synthase NOS1 (rs561712, P=0.0072) were the most strongly associated with SLE. When analyzed together, GSR remained the most significant effect (rs2253409, P=0.00072). Haplotype analyses revealed a significant 3-SNP haplotype in NOS1 in AA (rs3741476-rs10774909, P=0.00029), as well as in the joint cohorts together (P= 0.00074). Two-loci interaction analysis uncovered significant interactions between NDUFS2 (rs4656993) and the minichromosome maintenance complex component MCM5 (rs4645794) in AA (P=9.74E-05), between the ring finger protein RNF157 (rs11099897) and the toll-like receptor TLR7 (rs5741880) in the Gullah (P=6.61E-05), and between PON3 (rs13226149) and TLR7 (rs1731479) in the joint cohort (P=0.0003). These results suggest that different variants in reactive intermediate genes in different African ancestries may be associated with SLE.

818T

Tailored pathway-based analysis identifies significant enrichment of apoptosis-related genes associated with cardiac manifestations of neonatal lupus. *P. Ramos[1], M. Marion[1], C. Langefeld[1], J. Buyon[2], R. Clancy[2].* 1) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 2) New York University Langone School of Medicine, New York, NY.

Cardiac manifestations of neonatal lupus, comprising atrioventricular conduction defects and cardiomyopathy, occur in fetuses exposed to anti-Ro/SSA antibodies, and carry substantial mortality. Increased recurrence rates, concordance in a third of monozygotic twins, and results from the first published genome-wide association study (GWAS) support a fetal genetic risk. Although several significant associations were identified in individual genes, we hypothesize that there may be a global enrichment of specific pathways that may be overlooked if only the most significant associations are considered. We used the results from this admixture adjusted GWAS (inflation factor 1.026) to search for a potential enrichment of associations in specific pathway-related genes. Based on the finding of exaggerated apoptosis in autopsy studies from affected hearts, we posit that apoptotic responses may promote cardiac injury in these children. We used Ingenuity Pathway Analysis to compile a list with all genes with functions in apoptosis (n=2,283 genes). We then tested for an enrichment of admixture and genomic control adjusted significant P-values in SNPs that met quality control criteria (at alpha=0.05, 0.01, and 0.001). We observed a strong enrichment of significant SNPs (P<1x10-07) at all three significance levels; the enrichment existed whether including (n=16,031 SNPs) and excluding (n=15,935 SNPs) the extended HLA region. These data exhibit highly significant enrichment of association in apoptosis-related genes with cardiac neonatal lupus. We conclude that common genetic variation in genes within this pathway is involved in predisposing to cardiac manifestations of neonatal lupus.

819T

Identification of IL6R and chromosome 11q13.5 as risk loci for asthma. *M.A.R. Ferreira[1], M.C. Matheson[2], D.L. Duffy[1], G.B. Marks[3], J. Hui[4,5,6,7], P. Le Souef[8], S. Baltic[10], G. Background. We aimed to identify novel genetic variants affecting asthma risk, as these may provide novel insights into molecular mechanisms underlying asthma.

Methods. We performed a genome-wide association study (GWAS) in 2,669 physician-diagnosed asthmatics and 4,528 controls from Australia. Seven loci were prioritised for replication after combining our results with those from the GABRIEL consortium (N=26,475), and these were tested in an additional 25,358 independent samples from four in-silico cohorts. Quantitative multi-SNP scores of genetic load were constructed based on results from the GABRIEL study and tested for association with asthma in our Australian GWAS dataset.

Results. Two loci were confirmed to associate with asthma risk in the replication cohorts and reached genome-wide significance in the combined analysis of all available studies (n=57,800): rs4129267 (OR=1.09, combined $P=2.4x10^{-8}$) in the interleukin-6 receptor gene (IL6R) and rs7130588 (OR= 1.09, $P=1.8x10^{-8}$) on chromosome 11q13.5 near the leucine rich repeat containing 32 gene (LRRC32, also known as GARP). The latter was significantly associated with atopic status among asthmatics (OR = 1.33, P = $7x10^{-4}$), suggesting that it is a risk factor for allergic- but not non-allergic asthma. Multi-SNP association results are consistent with a highly polygenic contribution to asthma risk, including loci with weak effects that may be shared with other immune-related diseases, such as NDFIP1, HLA-B, LPP and BACH2.

Conclusions. The IL6R association further supports the hypothesis that cytokine signalling dysregulation affects asthma risk, and identifies a novel target for biological therapies. Results for the 11q13.5 locus suggest that it directly increases the risk of allergic sensitization which, in turn, increases the risk of subsequently developing asthma. Larger or more functionally focused studies are needed to characterise the many loci with weak effects that remain to be identified for asthma.

Association of polymorphisms of the TNIP1 gene with celiac disease. *R. McManus[1], A.W. Ryan[1], M.P. Sperandeo[2], C. Coleman[1], L. Greco[2], G. Turner[1].* 1) Department of Medicine and Institute of Molecular Medicine, Trinity College, St James Hospital, Dublin, Ireland; 2) Department of Pediatrics and European Laboratory for the Investigation of Food-Induced Diseases, University Federico II, Naples, Italy.

Background. Recent whole genome analysis studies have indicated association with celiac disease and numerous regions containing genes whose products act as immune mediators, including T-Cell regulators, and mediators of the inflammatory response, such as TNFAIP3 and C-Rel. TNFAIP3's gene product acts in conjunction with TNIP1 to repress NFkB mediated inflammation. The gene coding for TNIP1 lies within the 5q region, a broad genomic area which has previously shown association with celiac disease in several European populations. We investigated 9 SNPs in the region of TNIP3 selected on a number of criteria, including previous association with inflammatory diseases and potential for regulatory effects due to their potential to disrupt transcription factor binding sites (TFBS) in evolutionary conserved regions (using ECR Browser and rVista software). Six SNPs were situated in conserved TFBSs, two (rs2233292 and rs2233289) were non-synonymous coding sequence polymorphisms and one (rs17728338) had previously been associated with psoriasis. Methods and Results. All 9 selected SNPs were analyzed for allelic, genotypic and carrier status and deviations from HWE. Both of the selected coding SNPs proved to be invariant in the Irish population, as did 3 of the suspected regulatory SNPs. Of the four remaining SNPs, two showed significant association with celiac disease (N>570 cases, >930 controls). rs8177834 was associated with the disease at the allelic level using Fisher's exact test (P=0.0037; OR=1.49 [95%CI, 1.1-2.2), the genotypic level (P=0.009) and dominant/recessive models, with homozygosity for the G allele particularly associated (P= 0.0097; OR=1.45 [95%CI, 1.1-1.9]). rs2017638 was not significantly associated (P=0.067). We replicated these SNPs in an Italian population (N>350 cases, 420 controls) which trended towards, but did not reach, significance. The Cochran-Mantel-Haenszel test was used to test for significance in the combined populations. rs8177834 was significantly associated (P=0.00082; OR=1.4, 95%CI, 1.15-1.71). rs2017638 was weakly associated in the combined populations (P=0.02). Conclusion.The TNIP1 SNP rs8177834 shows evidence of association to coeliac disease in combined Irish and Italian populations. The presence of the major allele completes a consensus sequence for a c-MYB transcription factor binding site which is conserved between mouse and human genomes. We are currently testing this site for function.

Genetic Determinants and Racial Differences in Childhood Asthma. *T. Mersha[1], M. Butsch Kovacic[1], J. Biagini Myers[1], L. Martin[1], M. Lindsey[1], T. Patterson[1], H. He[1], M. Ericksen[1], J. Gupta[1], A. Tsoras[1], A. Lindsley[1], M. Rothenberg[1], M. Wills-Karp[1], N. Eissa[2], L. Borish[3], G. Hershey[1].* 1) pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Department of Medicine, Baylor College of Medicine, Houston, TX; 3) Department of Medicine, University of Virginia, Charlottesville, VA.

RATIONALE Candidate gene case-control studies have identified several single nucleotide polymorphisms (SNPs) that are associated with asthma susceptibility. Most of these studies have been restricted to evaluations of specific SNPs within a single gene and within populations from European ancestry. Recently, there is increasing interest in understanding racial differences in genetic risk associated with childhood asthma. Our aim was to compare association patterns of asthma candidate genes between children of European and African ancestry. METHOD Using a custom-designed Illumina SNP array, we genotyped 1,485 children within the Greater Cincinnati Pediatric Clinic Repository and Cincinnati Genomic Control Cohort for 259 SNPs in 28 genes and evaluated their associations with asthma. RESULTS Fourteen SNPs located in six genes were significantly associated (p-values <0.05) with childhood asthma in African Americans. Among Caucasians, 13 SNPs in 5 genes were associated with childhood asthma. Two SNPs in IL4 were associated with asthma in both races (p-values <0.05). Gene-gene interaction studies identified race specific sets of genes that best discriminate between asthmatic children and non-allergic controls. CONCLUSION For the first time, we identified IL4 as having a role in asthma susceptibility in both African American and Caucasian children. However, while IL4 SNPs were associated with asthma in children with European and African ancestry, the relative contributions of the most replicated asthma-associated SNPs varied by ancestry. These data provide valuable insights into race specific pathways that may predispose to asthma in individuals with European vs. African ancestry.

Whole Genome Sequencing and Rare Variant Analyses of a Multiplex Bipolar Pedigree. *J. Xing[1], C.D. Huff[1], B. Moore[1], R. Robinson[2], J. Ross[3], M.D. Yandell[1], J.A. Badner[4], W. Byerley[3].* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT; 2) Department of Psychiatry, University of Utah, Salt Lake City, UT; 3) Department of Psychiatry, University of California San Francisco, San Francisco, CA; 4) Department of Psychiatry, University of Chicago, Chicago, IL.

Bipolar disorder (MIM 125480) is a complex genetic disorder affecting ~1% of the population. Genome-wide association studies have identified a few common alleles for this disorder, but they all have small effects and together explain no more than 1% of the genetic variance. In contrast to schizophrenia, large CNVs do not appear to play a role in disease etiology. Taken together, these data suggest that a number of large-effect rare variants, many nominal-effect common variants, or both explain a large fraction of disease susceptibility. Large multiplex pedigrees - which are more likely to contain rare variants with large effect sizes - will be a valuable resource for identifying rare variants and distinguish these possibilities. We selected a large multiplex pedigree containing 6 Bipolar Type 1 (BPI) cases. This pedigree was used in a previous linkage study that identified two suggestive signals on chromosomes 4 and 10. Whole genome sequencing of 3 BPI cases from this pedigree was carried out at Complete Genomics. We used a novel analytic tool, VAAST, to characterize variants and prioritize genes. VAAST candidate gene prioritization analysis was performed under both the dominant and recessive inheritance models, assuming an expected allele frequency lower than 0.1% (dominant model) or 1% (recessive model) for the causal variant in the general population, respectively. Genome-wide VAAST analysis identified ~100 rare non-synonymous exonic SNPs including one in the chromosome 4 linkage region (*SORBS2*) and two on the chromosome 10 region (*NEBL* and *CHAT*). We are currently testing for co-segregation of the exonic variants identified in the linkage regions in the pedigree. Because it is not yet financially feasible to perform large-scale case/control whole genome sequencing to map the full range of rare variant loci, whole genome sequencing of pedigrees previously used in linkage studies could be a cost-effective method for mapping rare variants for bipolar disorder.

Genetic variation on inducible gene expression. *H.J. French, K. Hardy, M.F. Shannon, R.B.H. Williams.* Genome Biology, The Australian National University, Canberra, Australian Capital Territory, Australia.

Because activation of the immune response is dependent on extensive changes in gene expression, it is likely that a major component of inter-individual variation in the immune response is ultimately mediated at the level of gene regulation. Here, we examine the influence of genetic variation on inducible gene expression in the murine immune response. We extracted primary CD4+ splenocytes from inbred strains A/J, C57BL/6J, BALB/c, DBA/2J, and 129x1/SvJ (>3 animals/strain) and measured mRNA transcript levels using microarrays in both basal state and four hours after stimulation with PMA/Ionomycin. We defined an expression change occurring during activation as the difference in measured expression intensity between stimulated and basal conditions. We identified genetically influenced genes using a gene-wise single-factor (strain) ANOVA (B-H corrected P<0.05). We identified 2607, 1145 and 506 transcripts whose expression levels are under potential genetic influence in basal state, stimulated state and during activation, respectively. Using previously published data in CHX-treated mouse EL4 cells studied using the same protocol, we confirmed that mRNA levels of both primary response (e.g. Fos, Tnfaip3) and secondary response (e.g. Irf4) genes were subject to genetic influence across activation. These differentially activated genes are ideal candidates for further study into the influence of genetic variation on the mechanisms of gene induction, and provide mechanistic insight into inter-individual variation in the host response to infection.

Genetic variation of FGF-23 gene associates with phosphate homeostasis and bone health in Finnish children and adolescents. *M. Pekkinen[1], H.T Viljakainen[2], R. Mäkitie[1], C. Laine[1], O. Mäkitie[1,2].* 1) Folkhälsan Institute of Genetics, Department of Medical Genetics, University of Helsinki, Helsinki, Finland; 2) Children's Hospital, Helsinki University Central Hospital, Helsinki, Finland.

Fibroblast growth factor 23 (FGF-23), synthesized by osteoblasts and osteocytes, is part of hormonal bone-parathyroid-kidney axis, which is modulated by PTH, 1,25(OH)2-vitamin D, diet and serum phosphorus levels. Several hereditary disorders with inappropriately high serum FGF-23 levels are associated with phosphate wasting and impaired bone mineralization. In the present study we investigated the genetic variation in the FGF-23 gene and its association with parameters of phosphate homeostasis and bone health in Finnish children and adolescents. This school-based study included 183 healthy children and adolescents (110 girls, 73 boys) aged 7-19 years, who were assessed for bone health and its determinants. The genetic variation was detected by direct sequencing of FGF-23 coding exons with flanking intronic regions. The concentrations of plasma/serum Ca, Pi, 25-hydroxyvitamin D (25-OHD), PTH, FGF-23 and the bone formation and resorption markers PINP and ICTP, as well as urine Pi and creatinine concentrations were determined. Bone mineral density (BMD) was assessed with DXA (Hologic Discovery A), and volumetric BMD was measured from non-dominant radius with pQCT (XCT-2000; Stratec). Statistical analyses were performed with PASW18. We detected three different FGF-23 polymorphisms: c.212-37insC (rs3832879) in intron 1 and two SNPs in exon 3, rs7955866 (p.T239M) and rs11063112 (p.P241P). Genotypes among the 183 subjects were for c.212-37insC -/- (78%) and -/C (22%); for rs7955866 G/G (80%) and G/A (20%); and for rs11063112: A/A (47%), A/T (45%) and T/T (8%). Nine different haplotypes were observed: 1 (31.7%), 2 (0.5%), 3 (25.7%), 4 (13.7%), 5 (4.9%), 6 (12%), 7 (2.7%), 8 (3.3)% and 9 (4.9 %). The variation in FGF-23 gene was significantly associated with P-Pi (p= 0.045), total BMD (p=0.038) and cortical volumetric BMD z-scores (p=0.049), but not with stress and strain index z-score (SSI). In boys, but not in girls, FGF-23 gene variation associated with U-Pi/U-Crea (p=0.014). The observed associations between FGF23 haplotypes and plasma and urine Pi, volumetric total and cortical BMD suggests that genetic variation in the FGF23 gene may play a role in mineral homeostasis and bone remodeling.

825T

Known bone mineral density (BMD) associated SNP allele frequencies reflect trends in average population BMD across European, Asian and African populations. *M. Ramsay[1,2], A. Choudhury[1,2].* 1) Division of Human Genetics, NHLS & School of Pathology, University of the Witwatersrand, Johannesburg, Gauteng, South Africa; 2) Wits Bioinformatics, University of the Witwatersrand, Johannesburg, Gauteng, South Africa.

Low bone mineral density (BMD) is correlated with fracture risk and susceptibility to osteoporosis. In GWA studies, 76 SNPs have been significantly associated with BMD in populations of European origin. Sixty four of these are in or near 50 different genes and 12 are intergenic. Many of the genes are represented in the RANKL/OPG, estrogen endocrine and WNT signaling pathways. GWA studies related to bone mineralization phenotypes have not been performed on non-admixed African populations. Average BMD distributions vary widely among populations, being significantly higher in Africans when compared to Europeans, and with intermediate levels in Asians. The aim of this study was to determine which previously associated SNPs have allele frequencies that reflect a cline related to population BMD phenotype and may, therefore, be expected to contribute to BMD in different populations. We used HapMap data to examine this trend. Eight populations were selected from three geographic regions: Africa (YRI, LWK, MKK); Europe (CEU, TSI); and Asia (CHB, CHD and JPT). The 76 SNPs were clustered according to allele frequencies among populations from the three geographic regions and separated into 6 clusters. One cluster showed the expected cline (risk allele for low BMI with the highest frequency in Europeans and the lowest in Africans), and contained 18% of the SNPs. Four of the SNPs in this group showed at least moderate population differentiation (Fst above 0.05) and included one BMD-associated SNP close to the *OPG* gene; rs2062377, with frequencies of 0.47 (European), 0.29 (Asian) and 0.07 (African). Interestingly, 25% of the SNPs showed the opposite cline, including the other four *OPG* associated SNPs. LD structure in and around the *OPG* gene is complex in Europeans and, as expected, is associated with smaller haplotype blocks in Africans (Haploview). The challenge remains to identify the causative variants in LD with the associated SNPs and studies in African populations may provide additional insight. In cases where there are distinct population differences in the prevalence of complex phenotypic traits, genome analysis of data in the public domain (HapMap and 1000 Genomes) may help to identify likely causative genetic determinants across populations.

Combined haplotype sharing analysis and QTL mapping for identification of disease risk alleles. *H. Sadeghi, S. Müller, A. Recke, S. Möller, U. Samavedam, D. Zillikens, SM. Ibrahim, RJ. Ludwig.* Dermatology, UK-SH Universitätsklinikum Schleswig-Holstein, Luebeck, Schleswig-Holstein, Germany.

Epidermolysis bullosa acquisita (EBA) is an autoimmune blistering skin disease, characterized by antibodies to type VII collagen (COL7). Currently, little is known about the genetic basis of EBA. Therefore, we used a multi-step approach to identify genetic loci controlling autoantibody-induced tissue injury (effector phase) in experimental EBA, in mice. First, 16 genetically well characterized inbred strains were tested for EBA susceptibility in an antibody transfer model. A genome-wide association study was then performed using 600,000 SNPs, which are available on public sources. This lead to the identification of 9 quantitative trait loci (QTL) controlling autoantibody-induced tissue injury in experimental EBA. These QTLs were located on chromosomes 1, 6, 8, 9, 11, 12, 15 and 16. For confirmation, antibody-transfer EBA was induced in mice from an advanced 4-way intercross line generated by breeding of 4 different strains (NZM, MRL, BXD2, Cast). Two QTLs located on chromosomes 9 and 12 were confirmed by genotyping the respective single-nucleotide polymorphisms in the mice from the intercross line. Using haplotype-sharing analysis, we then fine mapped QTLs on chromosome 9 and 12 down to 6 Mb (65-71) and 2Mb (92-94) respectively. Overall, we demonstrate that this combined approach allows fast identification of risk alleles.

Integrative Analysis of Genotype and Gene Expression Data from Blood and Sputum Samples Identifies Potential Functional Mechanisms for COPD Genetic Risk Loci. *P. Castaldi[1,3], W. Qiu[1], M. Cho[1,2], J. Riley[4], W. Anderson[5], D. Singh[6], P. Bakke[7], A. Gulsvik[7], A. Litonjua[1,3], D. Lomas[8], J. Crapo[9], T. Beaty[10], B. Celli[2], S. Renard[11], R. Tal-Singer[12], S. Fox[4], E. Silverman[1,2], C. Hersh[1,2].* 1) Channing Laboratory, Boston, MA, USA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 3) Institute for Clinical Research and Health Policy Studies, Tufts Medical Center, Boston, MA, USA; 4) GlaxoSmithKline, Uxbridge, UK; 5) GlaxoSmithKline, Research Triangle Park, NC, USA; 6) Medicines Evaluation Unit, University of Manchester, Manchester, UK; 7) Department of Thoracic Medicine, Haukeland University Hospital and Institute of Medicine, University of Bergen, Bergen, Norway; 8) Cambridge Institute for Medical Research, University of Cambridge, Cambridge, UK; 9) Department of Medicine, National Jewish Health, Denver, CO, USA; 10) Department of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 11) Division of Pulmonary and Critical Care Medicine, University of Nebraska Medical Center, Omaha, NE, USA; 12) GlaxoSmithKline, King of Prussia, PA, USA.

Background: COPD is a major cause of morbidity and mortality. The 4q24 locus has been associated with pulmonary function and COPD susceptibility in genome-wide association studies in multiple population-based and case-control cohorts. However, it is unclear which gene or genes in this region are driving these association signals. Using genome-wide SNP data and gene expression data from blood and sputum from 131 individuals with COPD, we performed an unbiased screen to identify cis eQTL SNPs in whole blood and induced sputum of individuals with COPD. Based on these results, we further interrogated the 4q24 locus to identify potential candidate genes related to COPD in this region. **Methods:** Gene expression profiles from whole blood and induced sputum samples were generated for 131 subjects with COPD from the ECLIPSE study using the Affymetrix HG Plus 2.0 GeneChip. Genome-wide identification of cis eQTLs was performed using a window of +- 50kb from the transcription start site to define potential cis-acting eQTL SNPs. Multiple comparison adjustment was performed by controlling the false discovery rate at 0.05. Identified eQTL SNPs were then tested for association with COPD susceptibility in 4 COPD case-control studies (NETT, ECLIPSE, Norway Genkols, and in first 1000 subjects of COPDGene). eQTL tests were performed using linear regression adjusting for age, sex, and genetic ancestry, and tests of association using logistic regression adjusting for age, pack-years of cigarette smoking, and genetic ancestry were carried out. **Results:** Cis eQTL analysis in COPD cases identified 10,732 eQTL SNPs in whole blood, and 3,298 eQTL SNPs in induced sputum samples. Fifty-eight percent (1900) of the sputum eQTL SNPs were also cis eQTLs in whole blood. When these eQTL SNPs were tested for association with COPD, rs2656069 and rs1051730 were significantly associated with COPD susceptibility as well as transcript levels for IREB2 and CHRNA3/5 in whole blood and sputum. SNP rs4235415, which has previously been associated with lung function measures, was significantly associated with transcript levels for GSTCD in blood, but not sputum. **Conclusions:** Genetic variants near IREB, CHRNA3/5, and GSTCD have been previously associated with COPD susceptibility and/or pulmonary function. We have demonstrated these same genetic variants are associated with expression levels of these genes, suggesting these loci may affect COPD susceptibility through regulatory mechanisms.

Background: Central obesity, measured by waist circumference (WC) or waist-to-hip ratio (WHR), is a marker of body fat distribution and a risk factor for type 2 diabetes, hypertension and cardiovascular disease. Although obesity disproportionately affects minority populations, few studies have reported genome-wide association study (GWAS) results in individuals of predominantly African ancestry. **Methods:** We performed gender-specific meta-analyses of GWA data in up to 5975 men and 17580 women of African-American ancestry, derived from 14 cohorts, seeking to identify loci associated with: a) WC and b) WHR-adjusted for BMI. Approximately 2.5 million typed and/or imputed SNPs across the genome were modeled additively using multivariable linear regression models adjusting for age, age2 and data collection center (within each cohort where appropriate) for both traits. Inverse variance weighted fixed effects meta-analysis was used to aggregate results across studies. We also interrogated SNPs within the ±250kb flanking region of previously reported waist-related loci in populations of European ancestry in our WHR-adjusted-BMI meta-analysis results to compare genetic signals across different populations. **Results:** We detected two genome-wide significant associations with WC in men at PCSK1 (chr2, p=3.8 x10-8) and IL1RL2 (chr2, p=4.0x10-8) and one genome-wide significant signal with WHR in men at MYH11 (chr16, p=3.9 x10-8). None of these three loci were nominally significant in women (all p>0.09). Mutations in PCSK1 have been previously reported to cause monogenic obesity. SNPs in IL1R12 have been demonstrated in association with osteoarthritis, a sequela of obesity. Finally, MYH11 has been previously associated with smooth muscle function and familial thoracic aortic aneurysm. Seven out of fourteen previously reported WHR loci, including GRB14, ADAMTS9, and LY86, were significant in women only, after accounting for the number of interrogated independent SNPs. **Conclusion:** In 23555 samples of African-American ancestry, we identified three genome-wide significant loci in men only. While replication efforts are still underway, these findings demonstrate the similarity of the genetic architecture for WC and WHR among populations of European and African-American ancestry.

829T

A unifying framework for analyzing rare variant quantitative trait associations in selected samples: application to sequence data. *D.J. Liu[1,2], R.C Banuelos[1,2], S.M. Leal[1,2].* 1) Dept Statistics, Rice Univ, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

A large number of exome sequencing studies are currently being performed to understand the etiology of quantitative traits (QT) due to rare variants. In order to reduce sequencing cost and improve power, sequencing individuals with extreme QT is often applied. In addition, many publically available well-phenotyped cohorts (e.g. NHLBI ESP-the exome sequencing project) can be used and jointly analyzed to improve power. Although a number of methods have been developed for analyzing rare variants, they have a variety of limitations: 1.) Most of the methods do not have a valid likelihood model. Therefore it is not possible to adjust for complicated sampling schemes, which are crucial for making powerful inferences, estimating genetic parameters and interpreting identified associations. 2.) Most methods were developed exclusively for the analysis of binary traits. Although QT in selected samples can be dichotomized, ignoring QT values can result in a loss of power. 3.) Some leading methods e.g. the weighted sum statistics (WSS) do not allow for the control of confounders, such as sequence coverage depth and population substructure. Failure to control for confounders will lead to spurious associations which cannot be eliminated by permutations. To overcome these limitations, a unifying method was developed for mapping and interpreting QT associations (UNI-QTL) which can be applied to any studies with known sampling designs. Using a rigorous regression model based likelihood framework, UNI-QTL extends most existing rare variant analysis methods. Testing of associations can be performed using efficient score statistics, which are statistically optimal and numerically stable. Properties of UNI-QTL and the power for different extended rare variant tests were extensively evaluated using datasets generated under realistic population genetic and complex trait models. A sequence dataset from the Dallas Heart Study was also analyzed. For the analysis of QT we show that the power of almost all rare variant tests can be consistently improved, when they are extended in UNI-QTL and applied to analyze full QT information. Although there does not exist a uniformly most powerful test, the extended WSS, variable threshold (VT), and kernel based adaptive cluster (KBAC) methods perform well under most scenarios. With large scale implementation of next generation sequencing, UNI-QTL will be extremely important for mapping rare variant/QT associations using sequence data.

Million Veteran Progam (MVP): Department of Veterans Affairs (VA) Longitudinal Cohort for Genomic and Epidemiologic Research. *S. Muralidhar[1], R. Przygodzki[1], M.J. Gaziano[2,3], J. Concato[4,5], L. D'Avolio[2,7], L. Fiore[2,6], M. Brophy[2,6], T.J. O'Leary[1].* 1) Office of Research & Development, Department of Veterans Affairs, Washington, DC; 2) VA Boston Healthcare System, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) VA Connecticut Healthcare System, West Haven, CT; 5) Yale University School of Medicine, Yale, CT; 6) Boston University, Boston, MA; 7) Brigham and Women's Hospital, Boston, MA.

Background: The goal of the Million Veteran Program (MVP) is to develop a longitudinal cohort of Veterans to study the role of genes, environment, lifestyle and military experience on health. This landmark undertaking will enroll as many as 1 million users of the Veterans Healthcare Administration (VHA) over the next 5-7 years. VHA is the largest integrated healthcare and research system in the United States, with an electronic medical record system and about 7 million enrollees. Veterans who volunteer to participate are asked to: provide a blood sample for future, unspecified research; complete health-related surveys; provide ongoing access to their electronic medical record; and allow for future contact.

Methods: The primary recruitment method is a centralized model; Veterans are invited to participate in MVP via mailings. If interested, they are asked to complete an enclosed Baseline Survey on health, medical history, family history, lifestyle and military experience. Upon receipt of the completed survey, a study visit is scheduled at the local VA hospital, during which the informed consent process, HIPAA authorization, and a blood draw takes place. Participants also receive an optional, more detailed Lifestyle Survey. Veterans can also enroll by calling the MVP Information Center and scheduling a study visit, or as walk-ins at the hospitals. The blood samples are shipped to the VA Central Biorepository and processed to extract 10-15 μg of DNA and to store two 1ml aliquots of plasma and one aliquot of buffy coat; samples are stored at -80 °C. Phenotype and biosample data as well as analysis results are stored in the Genomic Information System for Integrated Science (GenISIS) and will be made available to researchers in a secure, scientific computing environment.

Results: The pilot phase was launched in January 2011 at nine Vanguard sites. An additional eighteen sites will begin enrollment in June 2011. Plans are underway to expand to 50 VA medical centers within a year. Recruitment rate at the Vanguard sites is 19%. Results of the recruitment strategies and the first application for a genomic study will be discussed.

Conclusion: The early recruitment rate indicates feasibility of meeting the enrollment target and developing one of the largest cohorts/databases of its kind in the world for genomic and epidemiologic research.

831T

Determining the genomic factors of sickle cell disease severity among West African children. *J. Quinlan[1], Y. Idaghdour[1], E. Gbeha[1], A. Sanni[2], M.C. Rahimy[3], P. Awadalla[1].* 1) Ste-Justine Research Center, University of Montreal, Montreal, Quebec, Canada; 2) Biochimie et Biologie Moleculaire, Universite d'Abomey-Calavi, Cotonou, Benin; 3) National Sickle Cell Disease Center, Centre National Hospitalier et Universitaire de Cotonou, Universite d'Abomey-Calavi, Cotonou, Benin.

Although sickle cell disease (SCD) is classically thought to be a simple mendelian disease, there is considerable heterogeneity in the clinical expression of the disease, with little understanding on the mechanisms underlying this. By integrating quantitative data from many biological sources, we took a systems biology approach to investigate the factors that explain variation in disease severity and clinical status of 400 SCD patients aged 6 months to 5 years with different degrees of disease severity from a cohort of 2000 children at the National Sickle Cell Center in Cotonou, Benin. We recruited children diagnosed with various SCD severities, plus ethnically matched controls, and obtained peripheral blood samples in order to perform gene expression profiling, genome-wide genotyping, and hematological profiling. Gene expression profiles were compared using various statistical approaches that take into account disease status and various clinical and biochemical covariates, including complete blood count and hemoglobin levels. Unsupervised clustering analysis of the data identified distinct groups of individuals with similar profiles. Principal component (PC) analyses of the transcriptomes indicates that approximately 40% of the variation in the data is contained in the first three PCs. Variance component analysis shows that SCD phenotype and clinical state explain the majority of the observed variance. An analysis of covariance identified several hundred differentially expressed transcripts that are associated with disease status. Out of the differentially expressed transcripts that were significant, we identified enrichment in biological pathways associated with clinical categories. These differentially expressed transcripts were used in a stepwise linear discriminant analysis in order to identify transcripts that can accurately identify each category. “Leave one out” cross validation confirmed these results. Finally, given our large cohort, and coupled with data from a control sample in the same region, we performed the first genome wide association of gene expression traits for SCD and identified several hundred expression single nucleotide polymorphisms (eSNPs). Our study identifies specific transcripts associated with SCD status and demonstrates the power of joint analysis of gene expression and genotyping data in systems biology.

832T

Who will be the biggest loser? GWAS reveals clues about response to gastric bypass. *E. Rinella[1], C. Still[2], Y. Shao[3], G.C. Wood[2], X. Chu[2], G. Gerhard[2], H. Ostrer[1].* 1) Human Genetics Program, New York University Langone Medical Center, New York, NY; 2) Geisinger Obesity Research Institute, Geisinger Clinic, Danville, PA; 3) Division of Biostatistics, New York University Langone Medical Center, New York, NY.

Purpose: Bariatric surgery offers an effective treatment for obesity and obesity-related complications when other interventions fail. However, despite its success, many patients do not achieve and/or maintain sufficient weight loss following bariatric surgery. Roux-en-Y Gastric Bypass (RYGB) is one of the most effective bariatric procedures but does have potentially significant short and long-term risks. Our ultimate goals are to identify clinical and genetic factors that are associated with favorable and unfavorable outcomes following bariatric surgery. In order to better understand the long-term response to RYGB we designed a case-control genome-wide association study (GWAS) to examine the genetic variation between those that lost the least and those that lost the most weight as a result of RYGB. **Method:** We studied a discovery cohort of 175 patients receiving RYGB intervention for obesity (BMI > 35). 86 cases and 89 controls were selected based on those who had the least excess body weight loss (< 50% EBWL-regainers) and those who lost the most (>90% EBWL-losers), respectively, at 2 years post-surgery. DNA from whole blood was used for genotyping using the Affymetrix 6.0 SNP array. Significant SNPs were tested in a replication cohort of 333 RYGB patients, 164 regainers and 169 losers. **Results:** Confirming previous studies, we found that pre-surgery BMI was strongly associated with response to RYGB, those at <50 kg/m^2 losing the most weight and those at >50 kg/m^2 losing the least amount of excess body weight. We also identified 111 SNPs in the discovery cohort, many clustering within the same genes, whose frequencies were significantly different between regainers and losers (χ^2-test p<10-4). Linear regression of percent excess body weight remaining at 2 years post-surgery revealed 14 SNPs that were validated in the replication cohort (p<0.05). These SNPs cluster in or near several genes with potential biological relevance including a gene previously shown to be associated with antipsychotic drug related weight gain, appetite, adiposity and energy balance. **Conclusions:** We conclude that there are genetic components associated with response to RYGB and that further studies are needed to reveal the function of these SNPs and their predictability in determining who should undergo such procedures.

Does Predisposition to Unhealthy Eating Behavior Share Genetic Variants with Genes Influencing Obesity? A Genome-Wide Association Study on Eating Behavior and Obesity Indices. *Y. Yang[1], D.H. Lee[1], M. Lee[1], Y.M. Song[2], J. Sung[1].* 1) Department of Epidemiology, School of Public Health and Institute of Health and Environment, Seoul National University, Seoul, South Korea; 2) Department of Family Medicine, Samsung Medical Center, and Center for Clinical Research, Samsung Biomedical Research Institute, Sungkyunkwan University School of Medicine, 50 Ilwondong, Gangnamgu, Seoul 135-710, South Korea.

Backgrounds: Growing evidence indicates that eating behavior may be a predictor of obesity independent of dietary measurements. Both behavior and body mass index (BMI) have genetic influences, and recent genome-wide association (GWA) studies identified a list of genetic variants related to obesity. The specific hypothesis of the study is that some of the single nucleotide polymorphisms (SNPs) influencing obesity may be mediated by eating behavior. The authors attempted to test the hypothesis to explore shared genetic variants, by comparing the GWA studies on DEBQ measures and obesity traits. **Method:** This study involves 3077 adult individuals (1217 men) who have participated in the Healthy Twin study Korea. DEBQ measured three domains of eating behavior; restrained eating(RE), emotional eating(EmE) and external eating(ExE). Obesity level was measured by; Body Mass Index (BMI), waist circumference (WC), total body fat (toFat%) and trunk fat (trFat%) proportion measured by Dual-energy X-ray absorptiometry (DXA) . The Affymetrix GeneChip Array version 6 (1 million SNPs) platform was used for generating genetic marker information. The GWA study was conducted by combining p-values of transmission test (FBAT) and population mean effects using founders (PLINK). We listed obesity-related genes from HuGE Navigator website (www.hugenavigator.net), and compared the GWA findings for DEBQ and obesity indices to the list. **Results;** Each of DEBQ domains and obesity index showed significant genetic influences, with heritability ranging from 0.17(EmE) to 0.30(RE) for DEBQ and from 0.53(WC) to 0.65(BMI) for obesity indices. From GWA analysis on DEBQ measures several candidate loci were identified; “RE” 11q23.3, p=1.27E-6; “EmE” 18q23, p=8.33E-7; and “ExE” 9p24.1, 15q22, p=7.42E-6. Candidate loci associated with obesity indices were; “BMI” 10p14, p=1.52E-7; “toFat%” 18q11.2, p=2.75E-6; “trFat%” CAP2 on chromosome 13, p=1.72E-6; and “WC” 15q24, p=1.03E-7. We compared associated genes of the most significant SNPs of DEBQ measures to obesity-related genes list; several genes were shared; “RE” APOB (p=4.8E-5) and RGS6(p=8.6E-5), “EmE” FAAH(p=1.3E-5), “ExE” ADRA2A (p=1.5E-5). **Conclusion:** GWA study on DEBQ and obesity indices suggested that a part of genetic variants are shared by certain unhealthy eating behavior and obesity.

A Genome-wide Screen of Gene-Gene Interactions for Osteoporosis Susceptibility. *F.P. Zhao[1], T.L. Yang[2], Y. Guo[2], H. Shen[1], Q. Tian[1], H.W. Deng[1].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA 70112, USA; 2) Xi'an Jiaotong University, Xi'an 710049, P. R. China.

Osteoporosis is a typical complex disease determined by both actions and interactions of multiple genes. Bone mineral density (BMD) is the most important risk phenotype for osteoporosis. Recent genome-wide association studies (GWAS) identified several genes for their independent effects on osteoporosis. However, no studies have been performed to identify gene-gene interactions in GWAS analyses. Here, we performed a genome-wide gene-gene interaction analysis for osteoporosis susceptibility in two independent US Caucasian populations. Sample 1 consisted of 916 unrelated subjects with extreme hip BMD values (458 high and 458 low) selected from a cohort of 2286 subjects. Sample 2 consisted of 400 unrelated subjects with extreme hip BMD values (200 high and 200 low) selected from 1000 subjects. Combing results from these two samples, we detected one SNP-interaction pair (rs8047431 and rs1975460) significantly associated with hip BMD after FDR adjustment for multiple testing, with the original P value of 1.88E-10. SNP rs8047431 is located at WW domain-containing oxidoreductase (WWOX) gene, which encodes a tumor suppressor. WWOX functionally suppressed RUNX2 transactivation ability in osteoblasts, and Wwox knockout mice exhibited a delay in bone formation and developed metabolic bone disease. The evidence suggested that WWOX might be a potential candidate gene for BMD variation. SNP rs1975460 is located at 16q23 and the nearest gene is ribosomal protein L36a pseudogene (RPL36AP46). In addition, we detected some other interaction pairs of SNPs showing suggestive association with osteoporosis susceptibility (P = 3.77E-8 to 4.85E-9), such as SNPs in LNX1 and TMEM132D, and SNPs in SOX6 and HAUS6. In summary, our findings suggest that gene-gene interactions may play a role in osteoporosis susceptibility.

Genome-wide Association Study of Early-Onset Myasthenia Gravis: Identification of TNIP1 and evidence for multiple autoimmune loci. *R. Kosoy[1], M.F. Seldin[1], A. Lee[2], J. Lamb[3], N. Wilcox[4], F. Piehl[5], R. Pirskanen[5], J.J.G.M. Verschuuren[6], M. Titulaer[6], J. Sussman[3,7], D. McKee[3,7], A. Maniaol[8], A. Elsais[8], C. Tallaksen[8], B.A. Lie[8], H.F. Harbo[8], B. Tackenberg[9], M. Pütz[9], H-J. Garchon[10], A. Melms[11], L. Hammarstrom[5], P.K. Gregersen[2], Myasthenia Gravis Genetics Consortium.* 1) Dept Biological Chemistry, Univ California, Davis, Davis, CA; 2) The Robert S. Boas Center for Genomics and Human Genetics, Feinstein Institute for Medical Research, North Shore LIJ Health System, Manhasset, NY; 3) Centre for Integrated Genomic Medical Research, Manchester Academic Health Science Centre, University of Manchester, Manchester, UK; 4) University of Oxford, Oxford, UK; 5) Karolinska Institutet, Stockholm, Sweden; 6) Leiden University Medical Center, Leiden, Netherlands; 7) Greater Manchester Neuroscience Centre, Salford Royal Hospital; 8) Departments of Neurology and Medical Genetics, Oslo University Hospital, Oslo, Norway; 9) Klinik für Neurologie, Philipps-Universität, Marburg, Germany; 10) INSERM U1016, University Paris Descartes, Paris, France; 11) Tübingen University Medical Center, Tubingen, Germany.

We report the first genome-wide association study for myasthenia gravis (MG). MG is a relatively uncommon disease (prevalence 1-2/10,000) characterized by antibodies directed against the muscle motor end-plate and results in severe muscle weakness. Previous studies have reported associations with HLA and PTPN22. To reduce potential genetic heterogeneity our study focused on early-onset MG (EOMG) in European patients meeting restricted entry criteria (anti-AChR antibody +, onset age >10 and <40 without known thymoma or < 45 with thymic histology showing hyperplasia without thymoma). The study was conducted in two phases using EOMG matched 1:4 with population controls selected from >8900 subjects using principle components analyses (discovery, 400 EOMG cases, 1600 controls; replication, 249 cases, 996 controls). Association tests (adjusted for residual substructure) for HLA, PTPN22 and TNIP1 met replication criterion with the following combined results for the strongest associated SNPs (HLA, rs7750641, p = 1E-92, OR = 6.3; PTPN22, rs2476601, p = 4E-10, OR = 1.71; TNIP1, rs4958881, p = 3E-10, OR = 1.73). For TNIP1 (TNFAIP3-interacting protein 1), a novel association for EOMG, multiple SNPs achieved thresholds for association (p < 5E-08) and each associated alleles was found on a common haplotype (p values > 0.05 after conditioning on rs4958881). The TNIP1 OR is the largest reported for any autoimmune disease and the haplotype was the same as that for SLE and disparate for psoriasis. For HLA, most of the association was also due to a single haplotype (peak near MHC Class 1 region, and part of HLA B 8.1 haplotype). However, after conditioning on rs7750641 a second associated haplotype was uncovered (including rs1265109, p =0.49 prior to conditioning, p = 4.31E-10 after conditioning). The peak association for this haplotype was near HLA class I and suggested definition of a more limited region of ~150 kb. Other autoimmune disease susceptibility loci were also over-represented in SNPs with suggestive evidence for association (7 of 151 loci with p values < 5E-04). Of 71 autoimmune loci examined, STAT4, IKZF1, IRF5, NKX2-3, ORMDL3, CD226 and PTTG1 met Bonferroni corrected criterion (p < 7E-04). A SNP for TRAF3, a gene critical to multiple B and T cell signaling pathways also showed suggestive association (rs4906269, p = 2.25E-05). Together these data suggest that a unique combination of autoimmune loci and haplotypes are critical to the etiopathogenesis of EOMG.

836T

Association of SLE specific susceptibility alleles with ANA production or transition to disease. *P. RAJ[1], DR. KARP[1], QZ. LI[1], P. DOSHI[1], N. OLSEN[1], K. MOSER[2], JA. KELLY[2], EK. WAKELAND[1].* 1) IMMUNOLOGY, UT SOUTH WESTERN MEDICAL CENTER, UNIVERSITY OF TEXAS, DALLAS, TX; 2) Oklahoma Medical Research Foundation, 825 North East 13th Street, Oklahoma City, Oklahoma 73104, USA.

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by the production of IgG autoantibodies directed towards nuclear antigens. The production of IgG anti-nuclear autoantibodies (ANA) is virtually uniform in SLE patients, and found in about 5% of the normal population. Genetic predisposition is a strong component of SLE susceptibility, and more than 30 SLE susceptibility loci have identified and replicated. Recently, a consortium of investigators produced a SNP array consisting of 196,524 SNPs that provide a dense coverage of susceptibility loci associated with a variety of autoimmune diseases, including SLE. To assess the role of individual SLE susceptibility loci in ANA production versus the transition to disease pathology, we assessed the association of SLE susceptibility loci in 372 European ANA negative normal controls (ANA-), 206 ANA positive normal controls (ANA+), and 134 SLE patients (SLE). These samples were obtained from the DRADR collection at UT Southwestern and the LRR collection at the Oklahoma Medical Research Foundation. Association analysis comparing ANA- and SLE patients identified 141 SNPs in 14 SLE-associated genes with chi-square p value ≤10-5. Association analyses were performed which compared these SNPs between ANA- and ANA+ controls, and separately between ANA+ and SLE patients. The results indicated that genetic variations in genes predominantly affecting pathways in adaptive immunity, such as BLK, LYN, and TNFSF4, may predispose to autoantibody production, and hence may be involved in the loss in immune tolerance that mediates the transition of normal individuals from ANA- to ANA+. On the other hand, variations in TNIP1, XKR6 and UBE2L3 are significantly associated with SLE in comparison to either ANA+ or ANA- individuals, which suggests that these variations may be functional drivers of the transition from ANA positive to full SLE phenotype. Other genes i.e. STAT4, VDR, IRAK1 and MECP2 appeared to be involved in both, ANA production as well as progression to SLE. We are currently expanding this analysis to ultimately encompass > 4000 patients and controls. These results, though performed on a small set of samples, indicate that individual susceptibility alleles contributing to SLE may specifically influence the initial autoantibody production or the subsequent transition from high ANA to full SLE disease.

Direct assessment and validation of allele-specific transcription factor binding in the human genome. *A. Schiavi[1,2], V. Adoue[1,2], S. Busche[1,2], B. Ge[2], T. Kwan[1,2], T. Pastinen[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada.

Characterization of human genetic variation, which effects gene expression, has focused on expression quantitative trait loci (eQTL) mapping; however, direct assessment of *cis*-regulatory variation necessitates allele-specific approaches. Measuring allelic expression (AE) on a genome-wide scale is more powerful as environmental and trans-acting influences are minimized. Results indicate that allele-specific differences among transcripts within an individual can affect up to 30% of loci. These variants can be identified by mapping differences in AE on Illumina Omni-1M/2.5M BeadChips. Over 50% of population variance in AE is explained by mapped *cis*-rSNPs. Studies show that these *cis*-rSNPs have been implicated in differences in transcription factor binding, suggesting a strong genetic component that needs to be further investigated. Combination of multiple GWAS datasets, eQTLs in osteoblasts, AE in primary fibroblasts and DHS-seq from mesenchymal stem cell lineage (MSC) allowed determination of a single SNP >200kb upstream of the *WNT4* gene. Consistent with a cell type restricted chromatin signal, we observed the regulatory association only in fibroblasts, indicating that the SNP alters gene regulation in MSC lineage and therefore is directly relevant to bone disease. Numerous loci contributing to bone mineral density and osteoporosis risk have been described by GWAS; however, the underlying biological effect of many of these variants remains unknown. Bioinformatic analysis of the *cis*-rSNP indicates that it alters a *SNAI1* binding site. We have shown in vitro allele-specific EMSA signals in nuclear extracts from MSC lineage and are now pursuing in vivo validation of *SNAI1* binding in living cells by carrying out ChIP with allele-specific readouts, as well as, *SNAI1* knockdown by RNAi with monitoring of its consequences in *WNT4* allelic expression phenotype. Consistent inhibition (85%) of *SNAI1* using RNAi in transfection studies has been observed. We are pursuing allelic expression imbalance assessment of *WNT4* in cells heterozygous for this *cis*-rSNP and treated with efficient *SNAI1* RNAi. These approaches will be generically extended to other allele-specific transcription factor binding and the consequences of these gene knockdowns will be monitored in a genome-wide manner. In progress is work on the *NF2B* transcription factor that has been shown to be involved in the immune response and where the *NF2B* motif is enriched in lymphoblastoid cell lines.

Evaluation of oral samples and tracheal fluid collection from premature newborns as a source of DNA for genotyping. *J. Niles[1], V. Biran[2], R.M. Iwasiow[1].* 1) DNA Genotek Inc., Ottawa, Ontario, Canada; 2) Service de Pédiatrie et Réanimation Néonatales Hôpital Robert Debré, APHP, Université Paris 7, France.

Newborn screening is an important procedure in which newborn infants are screened for a list of treatable diseases. The standard procedure is to sample whole blood from the heel of the infant and blot it on a specially designed filter paper. Recently it has been suggested that screening dried blood spots for some infections, such as congenital cytomegalovirus (CMV), may not be suitable and that other specimen types, such as oral sample and tracheal fluids, should be explored. In the current study oral sample and tracheal fluid, both non-invasive collection methods, were evaluated for suitability of DNA collection from premature newborns for genotyping purposes. The oral samples were collected using sterile rayon swabs to collect sample from the mouth of the premature newborn and cutting the heads of the swab into an Oragene.DNA device containing preservation solution. Paired tracheal fluid was also collected by rinsing a tracheal tube with saline (between 300 and 500 μL) and added to the Oragene.DNA collection devices. The samples were taken from premature newborns as young as 24 weeks. Oragene.DNA is a non-invasive collection device that is intended for collection and stabilization of DNA from saliva for extended periods at room temperature, thus enabling transport through regular mail. The performance of the extracted gDNA was assessed by evaluating different markers using PCR based genotyping methods. The results indicate good quality and quantity of DNA can be extracted from both tracheal fluids and oral samples collected into Oragene.DNA devices. The oral samples had an average concentration of 8.90 ng/μL ranging between 4.52 and 23.23 ng/μL and tracheal fluid average concentration was 10.23 ng/μL ranging between 0.99 and 19.02 ng/μL. The average total yields for these samples were 1.78 μg (oral) with a range of 0.90 to 4.65 μg and 2.49 μg (tracheal fluid) with a range of 0.23 to 4.26 μg. Each sample demonstrated 100% genotyping call rates with a 100% concordance of results between oral and tracheal fluid samples.

Rare functional variants in CFH, LIPC, and TLR3 segregate with severe bilateral AMD in multiplex families negative for known risk alleles. *J. Ayala-Haedo[1], A.G. Martinez[1], W. Cade[1], I. Konidari[1], A. Agarwal[2], S.G. Schwartz[3], J.L. Kovach[3], G. Wang[1], W.K. Scott[1], J.L. Haines[4], M.A Pericak-Vance[1].* 1) Hussman Institute Human Genomics, Univ Miami Miller Sch Med, MIAMI, FL; 2) Vanderbilt Eye Institute, Vanderbilt University Medical Center, Nashville, TN; 3) Bascom Palmer Eye Institute, University of Miami School of Medicine, Miami, FL; 4) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN.

Age-related macular degeneration(AMD)has multiple associated genetic risk factors. Of these, gene variants in the CFH and ARMS2 loci are the most prevalent and strongest risk factors. However, some individuals negative for susceptibility variants in CFH and ARMS2 still develop severe disease (bilateral grade 5 or neovascular AMD). The purpose of this study is to identify new, potentially damaging and rare variants in loci previously associated with AMD using next generation whole-exome sequencing of families with multiple AMD cases. We selected 4 multiplex families for our study. Each family was composed of at least two affected siblings; families had two, three or five affected individuals. At least one affected individual with bilateral neovascular AMD in each family was negative for both the CFH402H and ARMS69S risk alleles. In addition, two families had one individual with the known genetic risk factors in CFH and ARMS2 without disease manifestation. Exome capture was performed using Agilent SureSelect and sequencing done on the Illumina HiSeq 2000 platform. Sequence alignment and variant calling were carried out using MAQ and variants were annotated with SeattleSeq. We focused primarily on missense, splice junction, frameshift and nonsense mutations in 48 loci previously reported as associated with AMD. Variants were filtered using dbSNP and Hapmap databases assuming these multiplex families have novel and possibly family-specific variants that follow Mendelian inheritance. We found 6,137 novel and rare variants overall and 11 rare and probably damaging variants in 8 genes previously associated with AMD that were only present in the 12 cases and absent in the 3 controls. We confirmed by Sanger sequencing two rare variants in CFI, LIPC and four variants in CFH, HCMN1, CX3CR1,TLR3 predicted to probably be damaging by the Polyphen program that may potentially have an influence on disease pathogenesis. Of particular interest is the potentially damaging gene variant in the CFH gene found in all affected individuals of one family that are negative for the primary CFH genetic risk factor and the variants in LIPC and TLR3 that were shared by multiple families. By applying whole exome sequencing to our four multiplex families, we identified several potential damaging and rare variants in previously reported loci offering an interesting application of next generation sequencing (NGS) in discovering additional genetic factors contributing to AMD pathogenesis.

Using Genomic Markers to Stratify Risk for Prostate Cancer: A Case Study and Literature Review. *J. Davies[1], A. Lionel[2, 3], L. Velsher[1], R. Singal[1, 4], J. Aw[1].* 1) Medcan Clinic, Toronto, Ontario, Canada; 2) University of Toronto, Toronto, Ontario, Canada; 3) The Hospital for Sick Children MaRS Centre, Toronto, Ontario, Canada; 4) Toronto East General Hospital, Toronto, Ontario, Canada.

Current guidelines for prostate cancer screening are controversial and largely inconsistent across different countries. This is mainly due to suboptimal value of PSA alone as a screening tool as well as the indolent nature of prostate cancer in many men. There are also inconsistencies in criteria used for prostate cancer biopsies. Recent GWAS studies have implicated several SNP loci in prostate cancer risk. Patient genotypes at these loci could potentially provide predictive information beyond that of PSA and could thus be clinically relevant in helping classify patients into different levels of cancer risk. Here, we review previous studies of the clinical utility of SNP genotype data in prostate cancer screening, and go on to further investigate this issue in a new clinical dataset. The dataset comprises 400 men over the age of 35 from the Medcan Clinic, who underwent Personal Genome Testing, which includes a detailed review of their family history, results from Navigenics' genome-wide SNP microarray test (including 9 specific SNP markers associated with prostate cancer risk) and in-person genetic counseling. In addition to genomic and family history data, we also have access to phenotype data from each patient's annual health assessment at Medcan, including PSA, review of genitourinary symptoms and digital rectal examination (DRE) results. We will analyze this unique combination of clinical, genomic and family history data, particularly in the context of individuals who are not known to have prostate cancer. Medcan uses a comprehensive screening algorithm for prostate cancer prediction (nomogram), but this does not currently use SNP genotype data. By incorporating this data into the nomogram, we hypothesize that we will obtain additional predictive value for categorizing patients into low/high risk screening groups. To test this hypothesis, we will systematically compare the relative contribution of the SNP genotypes with those of risk factors currently part of the nomogram, such as PSA, family history and DRE. This study will help to assess the clinical utility of using SNP genotype information as an early screening tool for prostate cancer to determine eligibility for additional surveillance and/or biopsy. This information is particularly useful as the cost of whole genome sequencing continues to decline, thereby increasing feasibility of using genetic markers for risk prediction on a population screening level.

Genome-wide association study for the personality trait in Korean women. *H. Kim[1], S. Kim[1], C. Hong[2], E. Lee[2], Y. Sung[3], H. Chung[4], J. Lee[2], H. Kim[1].* 1) Dept Biochem, Sch Med, Ewha Womans Univ, Seoul, Korea; 2) Center for Genome Science, Korea National Institute of Health, Korea Centers for Disease Control and Prevention, Seoul, Korea; 3) Dept Internal Medicine, Sch Med, Ewha Womans Univ, Seoul, Korea; 4) Dept Obstetrics & Gynecology, Sch Med, Ewha Womans Univ, Seoul, Korea.

Personality traits are heritable components, influence major life outcomes and strongly link to psychiatric disorders. To identify genetic factors influencing personality traits, we performed a genome wide association study in 1,119 individuals from the Young Women cohort constructed with the PCOS study in Korea. Participants were between the ages of 17 to 40 years old. Personality traits were measured by the Korean version of the Revised NEO Personality Inventory (NEO-PI-R), items measure of the five dimensions of personality (Big5 personality). The Korean version of NEO-PI-R showed good psychometric properties: The factor structure replicated the American normative structure; internal consistency reliabilities ranged from 0.75 to 0.86. Participants' scores on Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness were tested for genome-wide association with 636,870 autosomal SNPs after Quality Control. Four newly identified loci were strongly associated with variation in Openness (P value from 9×10^{-8} to 9×10^{-9}). The newly identified loci, along with several additional loci with suggestive associations, were involved in important neuronal processes. Although none of the SNPs for the other dimensions except Openness to Experience did not achieve genome-wide significance (P value < 7.85×10^{-8}), several strong signals within or near genes previously implicated in psychiatric disorders or behavior disorders were found. Our results are the first significantly positive report of genome-wide association study for Big5 personality traits and meaningful because the interval of age is narrow, though the small sample size. These variants can be expanded the insight for influence of genetic factors on human personality as well as personality disorder, psychiatric disorder and other behaviors. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (2010-0026606) and Center for Genome Science, Korea, National Institute of Health research contract (4845-301).

Genome-wide Association Study of Systemic Lupus Erythematosus Specific Autoantibodies to Sm B', Sm D1 and 60 kD Ro Peptide Epitope in European Americans. *C.P. Lin[1], I. Adrianto[1], J.A. Kelly[1], K.M. Kaufman[1,2,3], J. Anderson[1], L. Curley[1], S.B. Glenn[1], J.B. Harley[4,5], P.M. Gaffney[1], K.L. Moser[1,2], J.A. James[1,2], C.G. Montgomery[1].* 1) Arthritis and Immunology, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) US Department of Veterans Affairs Medical Center, Oklahoma City; 4) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 5) U.S. Department of Veterans Affairs Medical Center Cincinnati, Cincinnati, OH.

Systemic lupus erythematosus (SLE) is a prototypic systematic autoimmune disease characterized by multi-organ-system involvement and the production of autoantibodies that can lead to tissue inflammation, destruction and even end-organ damage. Further, studies of SLE support the contribution of environmental exposure to the development of disease. Multiple studies have found the presence of temporal sequence of specific immune targets of autoantibodies years prior to clinical diagnosis and in the early years following diagnosis. Curiously, these autoantibodies are closely related to the antibodies that arise in some lupus patients to viral infection, specifically Epstein-Barr Virus (EBV) nuclear antigen 1 (EBNA-1). To better determine how genes influence the production of these early autoimmune structures and how that response might be related to infection, we conducted a genome-wide association study (GWAS) of the three initial antigenic epitopes of anti-Sm B' (PPPGMRPP), anti-Sm D1 (a Gly-Arg repeat) and anti-60kD Ro (amino acids 169-180) in a study population of 703 independent SLE patients of European descent. Tests of association between the quantitative traits and the genetic variants were performed using linear regression under an additive model adjusted for gender and global ancestry. We identified several single-nucleotide polymorphisms (SNPs) exceeding suggestive significance ($p<1x10^{-4}$) for each of the three antigenic epitopes, with the most significant SNP at rs7531957 ($p=1.95x10^{-6}$), rs7576105 ($p=1.06x10^{-5}$) and rs9882901 ($p=1.72x10^{-6}$) for anti-Sm B', ant-Sm D1 and anti-60kD epitopes respectively. SNPs concentrated in previously implicated SLE genes were also evident in the findings, emphasizing the potential power gained by examining more precise phenotypes. Overall, our study presents the first evidence of genetic associations to early lupus autoimmunity. It highlights the importance of examining sub-phenotypes of a complex disease and hence defines the involvement of gene by environment interaction toward initiating specific lupus autoimmune responses.

Rapid Identification of Mutations Responsible for Mendelian Disorders. *J. Majewski, J. Schwartzentruber, E. Lalonde, R. Koenekoop, E. Shoubridge, N. Jabado, D. Rosenblatt, RaDiCAL.* Dept Human Genetics, McGill Univ, Montreal, PQ, Canada.

Exome sequencing has ushered in a new era in Mendelian genetics. In contrast to linkage and positional cloning approaches, which typically involved a large number of individuals and took years to complete, we can now routinely sequence the coding exons of even single individuals affected with rare recessive disorders and identify the causative mutations. In many cases, the process takes around two weeks, starting from sample reception at a sequencing centre, through data analysis, to producing a short candidate list, or a single causative mutation. A number of international and Canadian initiatives now aim at large scale investigation of a variety of Mendelian disorders. At McGill University, we have formed the RADICAL (Rare Disease Consortium for Autosomal Loci), bringing together local clinicians and international collaborators who provide phenotypically well characterized DNA samples from patients affected with rare recessive disorders, and a technology and bioinformatics analysis support group. Our goal is to sequence the exomes of single individuals, small families, or multiple unrelated patients, and identify as many new disease genes as possible. To date, we have sequenced over 50 disorders, and have achieved about 25% success rate in identifying the causative genes using this approach. Here, we describe our detailed approach and successes including finding genes responsible for blindness, mitochondrial disease, methylmalonic acid metabolism, and immune deficiency.

Wactawski-Wende[2].* 1) Department of Cancer Prevention and Control, Roswell Park Cancer Institute, Buffalo, NY; 2) Department of Social and Preventive Medicine, State University of New York at Buffalo, Buffalo, NY; 3) Department of Biostatistics, State University of New York at Buffalo, Buffalo, NY; 4) Department of Genetics, Stanford University, Stanford, CA; 5) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 6) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 7) College of Public Health, The University of Arizona, Tucson, AZ; 8) Department of Biological Chemistry and Medicine, Rowe Program in Human Genetics, University of California, Davis, Davis, CA; 9) Department of Family Medicine, Case Western Reserve University, Cleveland, OH; 10) Division of Endocrinology, Diabetes and Metabolism, College of Medicine, The Ohio State University, Columbus, OH.

STATEMENT OF PURPOSE: With aging, decline in bone mineral density (BMD) places individuals at greater risk for diseases such as osteoporosis. Both genes and environment have been implicated in determining BMD in individuals of European ancestry, however few studies have been conducted among other races or ethnicities, and even fewer in older individuals. In this report, we present results from the first genome-wide admixture scan, to date, of dual-energy X-ray absorptiometry (DXA) derived BMD measurements in African American (AA) post-menopausal women. METHODS: DXA scans were performed on 842 AA women in the WHI-SHARe cohort to obtain BMD measurements of the total body, hip (total, trochanter, femoral neck, inter-trochanter) and spine (L2-L4). The Affymetrix 6.0 platform was used for genotyping with appropriate quality control to remove poor quality samples and SNPs. Four populations, capturing African, Northern and Western European, East Asian, and Native American ancestry, were used as reference groups to estimate global ancestry proportions for each individual. Locus-specific ancestry estimates for 570,282 markers were obtained using an extension of the method implemented in SABER software. This new approach accounts for haplotype structure and long range SNP correlations. Each local estimate of ancestry was included in crude and covariate adjusted genome-wide regression models of BMD phenotypes. Regression was also performed on a set of 3731 highly informative SABER derived local ancestry estimates. RESULTS: For both panels, genome-wide (admixture) significance (p<6e-6) for femoral neck (FN) BMD was achieved on 5.2 Mb region on 19q13. The most significant markers showed a direct association between an increasing number of African alleles and higher FN BMD (p=5.3x10e-7). A direct association between greater hip BMD and increasing copies of African alleles was also seen on 14q21 using the reduced SNP panel. Possible candidate genes in 19q13 include CKM, CYP2A and TGFB1 and ESR2 in 14q21. CONCLUSIONS: CKM/19q13 was previously associated with BMD in a Hispanic population and ESR2/14q21 was associated with BMD in European-American (EA) cohorts. TGFB1 variants have shown no association with BMD in a previous meta-analysis of EAs, however SNPs in this gene have not been tested for association in women with predominantly African ancestry. Our results suggest that there are genomic regions in postmenopausal AA women that contribute to variance in BMD.

845T

DNA methylation in early-stage non-small cell lung cancer. *N. Tonisson[1,8], K. Kirotar[1], T. Vooder[1,2], R. Kolde[3], K. Välk[1], R. Roosipuu[4], L. Milani[5,6], K. Fischer[5,6], M. Solovjova[1], T. Annilo[1], A. Metspalu[1,5,6,7].* 1) IMCB, University of Tartu, Tartu, Estonia; 2) Lung Clinic, Tartu University Hospital, Estonia; 3) Institute of Computer Science, University of Tartu, Estonia; 4) Dept. of Pathology, Tartu University Hospital, Estonia; 5) Estonian Genome Center, University of Tartu; 6) Center for Translational Genomics, University of Tartu, Estonia; 7) Estonian Biocentre, Tartu; 8) United Laboratories, Tartu University Hospital, Estonia.

Background: Despite of intense research, there is still a lack of biomarkers for the reliable detection of early-stage malignant tumours, including non-small cell lung cancer (NSCLC). DNA methylation changes are common in various cancers, and might be used as diagnostic or prognostic biomarkers. Methods: We performed DNA methylation profiling of samples from 48 patients with stage I NSCLC and 18 matching cancer-free lung samples using HumanMethylation 27 microarrays (illumina, Inc.) that cover the promoter regions of more than 14,500 genes. The DNA methylation changes discovered were correlated with gene expression levels and survival analysis performed. Results: We observed hypermethylation of 496 CpGs in 379 genes and hypomethylation of 373 CpGs in 335 genes in NSCLC. Methylation differences were also present in two major histological types of NSCLC, adenocarcinoma and squamous cell carcinoma. A majority of these CpG sites showed the expected inverse correlation between CpG site methylation and gene expression levels. As a result of a survival analysis, we found 10 CpG sites in 10 genes, in which the methylation level differs in different survival groups. Conclusions: We have identified a set of genes with altered methylation in NSCLC and descibed their correlation with gene expression levels. We also found a number of genes that associated with the survival of the patients. These newly-identified marker candidates will need further analysis in order to determine their clinical utility.

Whole exome sequencing of populations of African ancestry. *A. Adeyemo[1], D. Hernandez[2], J.R. Gibbs[2], A. Doumatey[1], H. Huang[1], D. Shriner[1], J. Adeleye[3], W. Balogun[3], J. Zhou[1], O. Fasanmade[4], T. Johnson[4], J. Oli[5], G. Okafor[5], A. Amoah[6], B. Eghan[7], K. Agyenim-Boateng[7], J. Acheampong[7], C. Adebamowo[8], A. Singleton[2], C. Rotimi[1].* 1) CRGGH, NHGRI/NIH, Bethesda, MD; 2) Laboratory of Neurogenetics, NIA//NIH, Nethesda, MD; 3) University of Ibadan, Ibadan, Nigeria; 4) University of Lagos, Lagos, Nigeria; 5) University of Nigeria, Enugu; 6) University of Ghana Medical School, Accra, Ghana; 7) University of Science and Technology, Kumasi, Ghana; 8) University of Maryland, Batimore, MD & Institute of Virology, Abuja, Nigeria.

The application of high throughput sequencing approaches to human exomes and whole genomes promises to provide new insights into population variation, disease mapping and evolutionary biology. African populations play a unique role by virtue of belonging to some of the oldest human lineages and exhibiting the greatest genetic diversity of any continental population. In the present study, we conducted whole exome sequencing of ten individuals of African ancestry, comprising Ghanaians (three Akan, two Gaa-Adangbe), Nigerians (two Yoruba and one Igbo) and African Americans (two individuals from the Washington DC region). To our knowledge, this is the first time that individuals from three of the ethnic groups (Akan, Gaa-Adangbe, Igbo) are undergoing whole exome sequencing (WES). Sequence enrichment was done using Nimblegen SeqCap EZ Exome v2.0 which targets a total of ~30,000 coding genes (~300,000 exons, total size 36.5 Mb, 44.1 Mb target region). Sequencing was done on an Illumina HiSeq 2000. Reads were mapped and aligned, then aligned data files were converted, sorted, and indexed using Samtools and Picard. The sequence quality scores were recalibrated with the Genome Analysis Toolkit (GATK). After identification and removal of duplicate reads, variants were identified with GATK's UnifiedGenotyper and DINDEL tools. The single-nucleotide variants were then filtered for the removal of low-quality variant calls with GATK's VariantFiltration walker. Mean coverage per sample was ~88X. The number of sites in the covered regions that differed from the NCBI Build 36 (hg18) reference ranged from 25,911 to 35,394 per individual. The number of novel SNPs fell from ~5500 per person with reference to dbSNP129 (the last pre-1000 Genomes version) to ~1600 per person (with reference to dbSNP132). This represents a ~70% reduction in the number of novel variants, demonstrating the enormous contribution of the 1000 Genomes Project and other large-scale sequencing projects. The individuals represented by the newly sequenced groups (Akan, Gaa-Adangbe, Igbo) had variants that were absent from the 1000 Genomes YRI reference. This suggests that more samples from more African populations would prove useful in characterizing genetic variation and utilizing this variation to map disease genes. New and ongoing genomic initiatives in Africa (e.g., H3Africa and MalariaGen) will benefit from strategic integration of whole exome and whole genome sequencing technologies.

Exome sequencing is rapidly becoming a standard technique for identification of alleles responsible for inherited genetic disorders. Despite several early successes, there are a number of examples of inherited diseases for which likely alleles have not been elucidated using existing exome sequencing technologies. To increase the probability of allele identification, we have developed two technologies which can be utilized in combination to comprehensively characterize the coding portion of the human genome for a fraction of the cost, time, and data analysis requirements of whole genome sequencing. The first is a comprehensive exome capture technology that targets 62Mb of exonic and other functional content that includes the nearly complete coding exons of the RefSeq, CCDS, Vega, and Gencode, databases, ACESscan predictions that overlap with UCSC genes, as well as mirRBase v16, and additional miRNAs, snoRNAs and miRNA binding sites from USCS. Secondly, copy number variation of coding exons is also an important contributor to alleleic variation, but has proven difficult to measure at the exon level using exome sequence. We have developed a new 4.2 million probe whole genome comparative genomic hybridization (CGH) array that allows copy number to be determined at ~1 Kb resolution, sufficient to identify deletions and amplifications of individual exons. We are applying these technologies to identify the mutation alleles responsible for a number of hereditary cancer syndromes which have been clinically evaluated and current genetic diagnostics have not revealed a mutation in a known cancer susceptibility gene. This includes gastric and colorectal cancer syndromes which have so far eluded a specific genetic diagnosis. The resulting data from extended pedigrees will be used to identify loci and the specific mutation that appropriately segregate with affected family members.

Patterns of indel variation in 202 drug target genes from >14,000 individuals. *N. Bing[1], K.C. Huang[2], E.Y. Liu[3], J. Li[4], D. Fraser[1], J. Aponte[1], X. Liu[5], H. Zhang[5], A. Slater[1], P. Woollard[1], S.L. Chissoe[1], J.C. Whittaker[1], V.E. Mooser[1], M.G. Ehm[1], S. Zöllner[6], J. Novembre[7], Y. Li[8, 2], M.R. Nelson[1].* 1) Quantitative Science, GlaxoSmithKline, RTP, NC, USA; Upper Merion, PA, USA; and Stevenage, UK; 2) Biostatistics, University of North Carolina, Chapel Hill, NC, USA; 3) Computer Science, University of North Carolina, Chapel Hill, NC, USA; 4) Human Genetics, University of Michigan, Ann Arbor, MI, USA; 5) BGI, Shenzhen, China; 6) Biostatistics, Psychiatry, University of Michigan, Ann Arbor, MI, USA; 7) Ecology and Evolutionary Biology, University of California, Los Angeles, CA, USA; 8) Genetics, University of North Carolina, Chapel Hill, NC, USA.

Short insertion and deletion variants (indels) are an important and yet poorly studied fraction of genetic variation. With the advancement of high-throughput sequencing technology and improvement of indel calling algorithms, it is increasingly feasible to systemically measure indels, describe their variation within and among populations, and assess their influence on human traits. We have investigated the quality and patterns of indel variation within the exons of 202 drug target genes sequenced in over 14,000 individuals, predominantly of European origin. Indels were called from the short read data using Dindel, GATK, and a novel method developed at BGI. Among these methods, Dindel had the highest duplicate heterozygous concordance: 83% for uncommon (minor allele frequency [MAF] < 5%), 89% for common variants. Genotype validation of all indels with MAF > 0.5% from all three methods and capillary sequence validation for a sample of rare indels is ongoing. Analysis of the Dindel genotypes identified 4,529 unique indels, 42% consisting of a single base and only 17% with a length of more than 5 bases. Most indels were rare: 66% were singletons and doubletons, and 88% had MAF < 0.1%. Deletions were enriched among rare and insertions were enriched among common indels. The indel density varied substantially across gene regions, with 1.6/kb in coding regions, compared to 9.0 and 9.8/kb in introns and UTRs, respectively. The bias against coding indels was evident even amongst singletons (1.1/kb versus ~5/kb outside coding regions). Amongst coding indels, we observed approximately two frameshift indels for every in-frame variant within singletons and doubletons, but a ratio less than one for more frequent variants. There were no frame-shift indels with MAF > 1%. Our results demonstrate the strong effect of purifying selection on protein coding indels. This study estimates the accuracy of indel calls with current algorithms, presents the previously undescribed pattern of rare indel variation, and provides insight into the selective pressures on short insertions and deletions.

Whole-exome and transcriptome sequencing of families with Primary Immunodeficiencies. *F. Casals[1,2], Y. Idaghdour[1,2,4], I. Fernández[1,3], V. Bruat[1], T. de Malliard[1], E. Haddad[1,3], F. Le Deist[1,3], P. Awadalla[1,2,4].* 1) Centre de Recherche, Université de Montréal, Montréal, Québec, Canada; 2) Département de Pédiatire, Université de Montréal, Montréal, Québec, Canada; 3) Département de Microbiologie et Immunologie, Université de Montréal, Montréal, Québec, Canada; 4) CARTaGENE, Montréal, Québec, Canada.

Primary immunodeficiencies (PID) constitute a heterogeneous group of disorders with defects in one or more components of the immune system. Although these diseases have a wide spectrum of clinical manifestations, they are mainly characterized by unusually increased susceptibility to infections, autoimmunity and malignancies. Although PIDs are mostly rare, cumulatively they have an overall incidence of 1 in 5,000 newborns, and this number is increasing with the improvement of diagnostic tools. However, the molecular basis for many of these immune deficiencies remains unknown. To understand the molecular mechanisms underlying these immunodeficiencies we have integrated full exome sequencing, RNAsequencing of leukocytes and clinical data from over 15 families with different uncharacterized immunodeficiencies. These families include both sporadic as well as cases having some family history for the PID. SNPs and indels calling were performed in the context of pedigrees, where each variant discovered in patients can be validated with the information obtained in its relatives. We obtained an initial list with less than fifty candidate genes for each patient, according to a compound heterozygote model for the disease. Functional classifications coupled with an in-house algorithm for prioritizing mutations generated a shorter list of candidate genes for each patient. We also used RNASeq analysis to identifiy candidate genes with significant differences in expression levels between patients and healthy individuals and to characterize variation in allelic expression and RNA editing. We estimated the frequencies for the different RNA editing changes using the comparison of whole exome and full transcriptome sequencing in the same individuals. Integrative statistical analysis of sequencing, comparison to our cohort of French-canadian controls, gene expression and clinical data helped narrow down the list of candidate causal genes and mutations, to a list of few candidate genes that might be involved in the etiology of the disease. Functional validation of candidate genes will be performed to test their role in the molecular origin of the disease.

850T

A Comprehensive Comparison of Whole Human Genome and Exome Sequencing Technologies. *M.J. Clark[1], R. Chen[1], H. Lam[1], M. O'Huallachain[1], K. Karczewski[1], G. Euskirchen[1,2], P. Lacroute[1,2], M. Snyder[1,2].* 1) Department of Genetics, School of Medicine, Stanford University, Stanford, California, U.S.A; 2) Center for Genomics and Personalized Medicine, Stanford University, Stanford, California, U.S.A.

Whole human genome (WGS) and exome sequencing (exome-seq) has become a reality in research and disease diagnosis. As the per-base cost of sequencing has decreased, the demand for sequencing in research, medicine and personalized genomics has increased. There are numerous approaches for WGS and exome-seq in competition with one another. Here we present a comprehensive comparison of genome and exome sequencing technologies. We have sequenced the whole genome of a single individual using both Illumina HiSeq and Complete Genomics Inc. (CGI). We analyzed the Illumina sequence data with an academic pipeline developed by our lab and compared it to the processed data reported by CGI. Using our pipeline to process Illumina data, we detected 3.64 million SNPs, and with CGI we detected 3.4 million SNPs. We found that the majority of SNPs (>3.3Mb) were detected by both platforms, but a number of platform-specific SNPs were found. We have investigated the nature of these differences. We also found differences in copy number and structural variation calls generated by the two pipelines. CGI detected 1,573 SVs, but our Illumina pipeline detected 44,781 SVs. These findings demonstrate significant differences in variants detected by each technology. We have also performed exome-seq on the same sample using three commercial exome enrichment platforms (Agilent SureSelect 50M, Nimblegen EZ Exome 2.0 and Illumina TruSeq Exome) sequenced on the HiSeq. Each of these platforms targets and enriches specific (sometimes different) parts of the exome. They also take different approaches to tiling (Nimblegen—overlapping baits, Agilent—adjacent baits, Illumina—spaced baits). The Nimblegen has >2.1M baits and targets only 44Mb while the Agilent has 656k baits and targets 51.5Mb and the Illumina has 340k baits and targets 62Mb. We found that denser tiling improves targeting efficiency. However, this occurs at the expense of target size. The higher density platforms capture fewer total bases and therefore fewer variants. We found high concordance between variants called by each platform, but we also noted a significant subset of variants uniquely called by each platform, suggesting biases related to bait density and target choice. We also find differences between calls in overlapping regions covered by exome and whole genome sequencing. We present these findings to inform the genomic research and diagnosis communities about the benefits and drawbacks of each of these technologies.

Whole Genome Analysis of Clinical Samples using Omicia's Genome Annotation System. *E. Coonrod[1], R. Margraf[1], P. Ridge[1,2], S. Guthery[3], J. Durtschi[1], E. Lyon[1,4], L. Jorde[5], M. Yandell[5], A. Russell[6], S. Chervitz[6], E. Kiruluta[6], M.G. Reese[6], K.V. Voelkerding[1,4].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT; 2) Department of Biology, Brigham Young University, Provo, UT; 3) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT; 4) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 5) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah School of Medicine, Salt Lake City, UT; 6) Omicia Inc., Emeryville, CA.

Whole genome sequencing (WGS) for clinical research and diagnostics is expanding as technical complexity and costs decline. It is now possible to diagnose inherited disorders based on WGS of affected and unaffected relatives. To facilitate the use of WGS as a diagnostic tool for identifying genetic causes of disease, novel informatics tools are needed that are capable of fast and accurate clinical annotation of detected variants. In this study, we describe the performance of Omicia's Genome Annotation System (GAS), a new software tool for variant annotation and analysis. A family of four comprised of a male proband with autoimmune enteropathy of unknown but suspected genetic origin, an unaffected brother, and both parents, were studied. WGS was performed on each family member using an Illumina HiSeq 2000 with 100 bp paired-end reads. Reads were aligned using BWA and variant detection was performed with SAMTools. Variants were annotated using an early-access beta-testing program with the GAS software pipeline which cross-correlates the variants with several databases including dbSNP, OMIM, LSDB, PharmGKB and HGMD. From the 3.5 million variants called with SAMTools, the GAS software annotated approximately 1.3 million variants in introns, exons, and 1kb upstream regions for each genome. From this list, variants of interest were further prioritized to as few as 35 and at most 42 per individual genome by filtering out variants that are common in the population and keeping only non-synonymous variants with a potentially pathogenic association. Other filtering options include showing only homozygous changes, stop gain/loss, insertion/deletion variants, or variants with OMIM evidence or other known potentially pathogenic associations. Features of high utility for diagnostic purposes include disease and drug filters and a viewer that displays the individual's variant location within the gene compared to known variants as well as cDNA and amino acid changes. Accuracy is also important for WGS analysis, so we searched for known exonic variants in the RET gene in these individuals and found that all variants queried were accurately classified by the GAS software. Omicia's GAS software is a fast and easy to use method for annotating WGS data. Inherent multiple filtering options are useful to limit lists of candidate genes and ongoing analyses are focused on using the GAS software to compile a list of potentially disease-causing variants.

Comparison of Library Construction Methods and Evaluation of Whole Exome Capture Products for Next-Gen Sequencing. *B. Craig, K. Hetrick, B. Marosy, J. Romm, H. Ling, E.W. Pugh, K.F. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. As the demand for custom targeted and whole exome capture sequencing increases, multiple technologies have emerged designed to produce viable library constructions and capture these regions of interest. We evaluated the Agilent© SureSelectXT library preparation and 50Mb Human All Exon capture products and the Illumina® TruSeq™ DNA sample preparation and 62 Mb Exome Enrichment products. There are a number of differences between the 2 products (Agilent vs. Illumina respectively) that are of interest to compare and determine the impact, if any, on quality of the sequencing data and use in a production scale service. Input DNA requirements (3ug vs. 1ug) and average shearing size range (150-200 vs. 200-300 base pairs) differ as well as master mix creation type (manual vs. pre-made), point of sample pooling (post vs. pre capture), bait type (RNA vs. DNA), hybridization time (One 24hr vs. Two 24hr capture events) and sequencing run length recommended for each platform (75bp vs. 100bp paired-end on the HiSeq 2000). Analysis of these data will show if there is any impact on library complexity, capture efficiency or SNV detection as well as any benefit to lab workflow time or automation and effect on the quality, cost and throughput of the sequencing data. We processed 4 HapMap samples using the most recent protocols at the time for each of the platforms except for the size selection in the Illumina protocol. Here, we replaced gel purification with a modified SPRI bead cleanup to select for the 300-400 bp size range. The samples were sequenced with the recommended run length parameters and repeated using the parameters recommended for the other platform. Experiments were analyzed, in brief, with BWA and SAMtools (refer to the CIDRSeqSuite abstract). Comparing the Agilent and Illumina products resulted in, respectively; 16%|28% duplicate molecules, 69%|55% capture efficiency, 99.7%|99.8% concordance with a genotyping array, 3.1|3.0 Transition/Transversion ratio on exon, 32,210 (on bait)| 43,310 SNVs (on target), 94%|94% SNVs in dbSNP 131 and 3.5%|0.6% targeted exonic regions with no coverage.

853T

Whole-genome medical annotation of admixed genomes reveals ancestry-related ascertainment biases in variants of clinical significance. *F. De La Vega[1,2], A. Moreno-Estrada[1], A. Russell[2], J.K. Byrnes[1], J.M. Kidd[1], S. Gravel[1], M.G. Reese[2], C.D. Bustamante[1].* 1) Department of Genetics, Stanford University Medical School, Stanford, CA; 2) Omicia, Inc., Emeryville, CA.

Due to colonialism, slave trade, and more recently, the easy access to modern means of transportation, populations of recent mixed genetic ancestry are widespread throughout the world. Understanding how to analyze and interpret admixed genomes will be critical for enabling trans and multi-ethnic medical genetic studies. Here, we analyzed the genomes of admixed individuals from North America previously genotyped by the International HapMap 3 project: five of African-American descent (ASW), five of Mexican-American descent (MXL), and two of Puerto Rican decent (PUR). Two of these genomes where sequenced with the SOLiD™ System, and the rest are part of a set released to the public domain by Complete Genomics. To infer continental ancestry for each individual across the genome, we utilized a PCA-based admixture deconvolution approach that assigned segments of the paternal and maternal haplotypes to three potential ancestral populations: West African, European, or Native American. Intersection of the variants from each genome with the OMIM, HGMD, PharmGKB, NHGRI GWAS, and locus specific databases using the Omicia Genome Analysis System identified an average of ~70 non-synonymous coding alleles per genome which are annotated to have an effect on human phenotypes. We show that in spite of lower heterozygosity expected for the segments of Native American ancestry, there is an under-annotation of alleles of medical significance in these as compared with European descent segments. In addition, we observe variants that appear in admixed genomes that otherwise are rare in the origin population fall within segments derived from a different ancestral population (e.g. an allele that confers susceptibility to immunoglobulin A nephropathy which is rare in Europeans and Hispanics, but common in Africa appears in an African-ancestry segment in a MXL sample). This demonstrates that, on an individual level, the average proportion of the genome derived from a given ancestry is less informative a metric than the specific ancestry assignment at a given genomic position. Our results also underscore the need to consider local genomic ancestry in interpreting medical genetic studies, and makes it critical that efforts to map the genetic basis of common disease undertake variant discovery and association mapping in individuals of diverse ancestries relevant to the population of medical genetic interest.

Phased whole genome genetic risk in a family quartet. *F.E. Dewey[1], R. Chen[1], S.P. Cordero[1], K.E. Ormond[1], C.C. Caleshu[1], K.J. Karczewski[1], M.W. Carrillo[1], M.T. Wheeler[1], J.T. Dudley[1], J.K. Byrnes[1], O.E. Cornejo[1], J.W. Knowles[1], M. Woon[1], K. Sangkuhl[1], L. Gong[1], C.F. Thorn[1], J.M. Hebert[1], E. Capriotti[1], S.P. David[1], A. Pavlovic[1], A. West[2], J.S. West[3], C.D. Bustamante[1], M.P. Snyder[1], R.B. Altman[1], T.E. Klein[1], A.J. Butte[1], E.A. Ashley[1].* 1) Stanford University, Stanford, CA; 2) The Harker School, San Jose, CA; 3) ViaCyte, Inc., San Diego, CA.

Whole genome sequencing harbors unprecedented potential for characterization of individual and family genetic variation. Here, we develop a novel synthetic human reference sequence that is ethnically concordant and use it for the analysis of genomes from a nuclear family of four with history of familial thrombophilia. In doing so we demonstrate that prior population mutation rate estimates are biased upwards by the reference sequence, and estimate a Watterson's theta of 7.8 x 10-4. We infer recombination sites to a median resolution of less than 1000 base pairs, show equal male and female recombination frequency, consistent with RNF212 haplotypes, and high recombination hotspot usage, consistent with PRDM9 haplotypes. We use family inheritance state analysis to control sequencing error and inform family-wide haplotype phasing, allowing quantification for the first time of genome-wide compound heterozygous risk alleles and reduction of genotype error rates by ~90 percent. We develop a sequence-based methodology for Human Leukocyte Antigen typing that utilizes long range phased haplotypes from short read sequencing. Finally, we advance methods for analysis of disease and pharmacogenomic risk across the coding and non-coding genome that incorporate phased variant data. We show these methods capable of identifying multigenic risk for inherited thrombophilia in the family quartet involving the genes F5, MTHFR, and HABP2, and drug dosing predictions for the anticoagulant warfarin that are consistent with steady state dosing derived empirically. These ethnicity-specific, family-based approaches to interpretation of genetic variation represent the next generation of genetic risk assessment using whole genome sequencing.

855T

Evaluation of Mitochondrial DNA Alignment Data in Illumina HiSeq Whole Genome Sequencing for Quality Control Monitoring. *J.D. Durtschi[1], R.L. Margraf[1], P.G. Ridge[1,2], K.V. Voelkerding[1,3].* 1) ARUP Institute for Clinical and Experimental Pathology, Salt Lake City, UT 84108; 2) Department of Biology, Brigham Young University, Provo, UT 84602; 3) Department of Pathology, University of Utah School of Medicine, Salt Lake City, UT 84108.

Massively parallel sequencing with the Illumina HiSeq 2000 instrument allows whole genome sequencing (WGS) for research and clinical applications. Sequencing data quality must be monitored to insure the accuracy of resulting variant identification. Error and bias enter the sequencing process from initial library preparation through data post processing and lead to increased variant miscalls in the complex and moderate coverage alignments of WGS. Metrics generated with sequencing, alignment and variant call data can indicate data quality. A standard DNA sample such as phiX is typically spiked into a sample library or sequenced in a separate lane to monitor base call error rate. The goal of the current study was to evaluate whether mitochondrial DNA (MT) sequences, inherently generated during WGS, could be used as an alternative to phiX. Six whole genome libraries were prepared using Covaris fragmentation followed by Illumina library generation on the Beckman SPRI-TE platform. WGS was performed using an Illumina HiSeq 2000 with 100 bp paired-end reads. Alignment to the whole genome including the MT reference followed by variant identification was performed with BWA and SAMtools. QC metrics were generated with tools including the Illumina HiSeq RTA software, FastQC and the GATK suit. All sequence data sets had between 86 and 91% of reads passing the Illumina filter. PhiX aligned error rates ranged from 0.37 to 0.8%. Average alignment coverage for each of the six full genomes was approximately 30 while average coverage of only the MT sequence regions ranged from 1250 to 1600. After filtering MT alignments to remove homozygous variants and those due to apparent misalignments, MT average error rates for five of the six genomes ranged from 0.29 to 0.7%, similar to phiX. In one of the six genomic samples, average MT error rates were 3.7% and the source of this higher error rate is under investigation. Trends observed in other QC parameters including base quality, read mapping quality, coverage variability and ti/tv ratio appeared unrelated to MT error rates. MT sequencing error data appears to be a potentially useful QC tool to complement spiked control samples such as phiX as the MT data is integral to the sample experiencing similar storage and processing steps.

Rapid detection of the ACMG/ACOG recommended 23 CFTR mutations using Ion Torrent semiconductor sequencing. *A. Elliott, J. Radecki, B. Moghis, X. Li, A. Kammesheidt.* Dept R&D, Ambry Genetics, Aliso Viejo, CA.

Cystic fibrosis (CF) is one of the most commonly diagnosed autosomal recessive diseases in the Caucasian population. To date over 1500 causative mutations have been detected in the cystic fibrosis transmembrane conductance regulator (CFTR) gene responsible for CF; however, the majority of these account for ≤ 0.1% of CF cases. For general population CF carrier screening The American College of Medical Genetics (ACMG)/American College of Obstetricians and Gynecologists (ACOG) have recommended a core panel of 23 mutations that will identify ~88% of carriers in Caucasians. Using a genotyping technology that can rapidly identify disease causing mutations is important for high-throughput general population carrier screening, confirming clinical diagnosis, determining treatment options, and prenatal diagnosis. Here we describe a proof of principle study to determine if the IonTorrent Personal Genome Machine™ Sequencer can reliably identify all ACMG/ACOG-23 CFTR mutations. DNA specimens representing all 23 CFTR mutations, which had previously been verified by Sanger and Illumina next generation sequencing, were selected and Ion Torrent specific fusion primer libraries were constructed. Amplicons representing the mutations of interest were sequenced bi-directionally on the Ion Torrent 314 chip, and data was analyzed using a custom script. We were able to correctly identify all the selected mutations except c.2184delA. An intrinsic limitation of flow-based sequencing is that the signal strength in homopolymers is only linear up until ~5-6 nucleotides. The mutation c.2184delA lies in a homopolymer stretch of 7 adenines and therefore cannot be accurately detected due to homopolymer length sequencing errors. Based on our study, we believe Ion Torrent sequencing may be a suitable method for identifying CFTR mutations in the future. However, due to the high rate of base calling errors within homopolymer stretches, mutations within such regions may need to be sequenced using an alternative method.

Exome sequencing has identified the causes of several Mendelian diseases, although it has rarely been used in a clinical setting to diagnose the genetic cause of a disorder in a single patient. We performed exome sequencing on a pedigree with several members affected with attention deficit/hyperactivity disorder (ADHD), in an effort to identify candidate variants predisposing to this complex disease. While we did identify some rare variants that might predispose to ADHD, we could not prove causality for any of them as of yet. However, over the course of the study one subject was discovered to have idiopathic hemolytic anemia (IHA), which was suspected to be genetic in origin. Analysis of this subject's exome readily identified two rare non-synonymous mutations in PKLR as the most likely cause of the IHA, although these two mutations had not been documented before in a single individual. We therefore confirmed the deficiency by functional biochemical testing, consistent with a diagnosis of red blood cell pyruvate kinase deficiency. Our study implies that exome and genome sequencing will certainly reveal additional rare variation causative for disease even in already well-studied classical Mendelian diseases, while also revealing variants that might play a role in complex diseases. Furthermore, our study has clinical and ethical implications for exome and genome sequencing in a research setting: how to handle unrelated findings of clinical significance, in the context of originally planned complex disease research, remains a largely uncharted area for clinicians and researchers.

Title: Identifying potentially life-threatening variants in an unscreened population using whole exome sequencing. *S.G. Gonsalves[1], D. Ng[1], J.J. Johnston[1], F.M. Facio[1], S.L. Ruppert[1], C. Krause[1], J.K. Teer[1,2], J.C. Mullikin[1,2,3], L.G. Biesecker[1,2], National Institutes of Health Intramural Sequencing Center, NIH, Bethesda, MD.* 1) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Background: Malignant hyperthermia (MH) is a potentially lethal, genetically heterogeneous disorder of skeletal muscle calcium metabolism, triggered by anesthetics and depolarizing muscle relaxants. Whole exome sequence (WES) from an unselected *ClinSeq™* cohort was screened for MH susceptibility variants. Methods: WES was performed on 401 *ClinSeq™* participants. Variants in RYR1 and CACNA1S were annotated using an algorithm that filtered results based on mutation type, frequency, and information in locus-specific mutation databases (LSDB). Variants with low genotype quality were scored 0; the remainder were scored on a pathogenicity scale of 1-5 based on published criteria (Plon et al., 2008). Medical histories and pedigrees were reviewed for MH and related disorders. Clinically relevant results will be returned to participants for medical management. Results: We identified 53 RYR1 and 41 CACNA1S sequence variants in 401 exomes. Variants with a heterozygous frequency >1% or a most probable genotype (MPG) score/coverage value of <0.5 were excluded. Forty-seven RYR1 and 32 CACNA1S variants passed the quality/frequency metrics and were further analyzed. One CACNA1S variant p.Arg498His was listed in LSDB as pathogenic without supporting literature and defined as a variant of uncertain significance (score 3). Eight RYR1 missense variants were listed in the Human Gene Mutation Database as disease causing variants (MH, central core disease, and multi-minicore disease). RYR1 p.Arg614Cys, and p.Asn2342Ser were found in two participants without medical or family histories of MH. One *ClinSeq™* participant with an unpublished missense variant p.Arg3498Gly was found to have a three-generation family history of MH. Several affected relatives in the pedigree had positive in-vitro muscle contracture tests consistent with MH. Conclusions: We found 3 out of 401 (0.0075) participants in *ClinSeq™* carrying an RYR1 variant associated with MH susceptibility or an MH related disorder. This is an extraordinarily high frequency and exceeds the highest published incidence of MH (1/2000). Possible explanations include: 1) penetrance of the disease is lower than previous estimates; 2) self-selection in the *ClinSeq™* cohort; 3) some of the disease associated RYR1 variants are actually common, benign polymorphisms. Identified participants will be further evaluated with a focused family history, genotyping of relatives for co-segregation studies, and muscle contracture testing.

Leveraging off-target sequence reads for more precise inference of local ancestry and haplotypes from exome sequence data. *Y. Hu, Y. Lo, G. Abecasis, H. Kang, 1000 Genomes Consortium.* Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor, MI.

Deep sequencing of exomes allows us to comprehensively understand the profile of common and rare coding variations potentially causative to Mendelian disorders and complex diseases. When analyzing exome sequences of admixed samples, local ancestry information around the locus of interest allows us to decompose the between- and within-population genetic variations to better understand the genetic architecture of the disease traits. However, typical analyses of exome sequence data focus only on protein-coding regions, which represent only a few percent of the genome. The local ancestry inference only from sparse coding variants is likely less precise than the inference using genome-wide data.

We are motivated by the fact that a substantial amount of exome sequence data comes from off-target regions of the genome due to imperfect capturing of targets in current technologies. While off-target reads are uninformative for the purpose of understanding coding variations, they can increase the precision of local ancestry mapping by providing shallow but wide coverage across the genome. For example, only 2.4% of OMNI 2.5M SNP chip sites reside in on-target region of exome data in the 1000 genomes project. However, > 54% of Omni SNPs have coverage in a typical exome sequence sample, mostly at shallow depths supported by the off-target reads.

We propose a sequence-based Hidden Markov Model (HMM) approach to precisely estimate the local ancestry from both on- and off-target exome sequence reads. Our method utilizes sequence reads at a wide range of known variant sites to model the likelihood of sequence reads given the HMM state. We apply our method to the exome sequence of admixed individuals in the 1000 Genomes project. Compared to the approach using only on-target sequence reads, we demonstrate that the proposed method provides more precise inference of local ancestry which is more concordant to independent inferences from whole-genome sequence data or high-density genotype data of the same sample. Finally, we also evaluate how much the off-target reads are informative in inferring haplotypes, especially when genome-wide array or sequence data is not readily available.

Multi-pronged Approach to Highly Accurate, Highly Comprehensive Complete Human Genomes. *S. Jacobs, J. Baccash, C. Tian, S. Ghosh, G. Nilsen, K.P. Pant.* Complete Genomics, Mountain View, CA.

Complete human genome sequencing studies offer the promise of elucidating the genetic architecture of a wide spectrum of simple and complex diseases. Such studies require a very low error rate: billions of nucleotides are assembled for each genome, and the number of errors needs to be small compared to the number of causal variations within any class of interest. Complete Genomics offers a service for complete human genome sequencing using DNA nanoarrays and a non-sequential, unchained read technology that generates 70-base paired end reads. The reads are assembled using methods that have recently been optimized for more sensitive detection of variants of low allelic fraction, as would occur in aneuploid or heterogeneous tumor genomes. Approaches adopted to ensure a highly accurate and sensitive representation of each genome sequenced will be described. A new and comprehensive analysis of the error rate in the genomes of an extended pedigree has also been performed. This analysis, which uses both Mendelian inheritance consistency and phasing within the pedigree to identify errors, will also be discussed.

Development of an automated sample preparation and quality control pipeline for high throughput sequencing applications. *J. Lambert, A. Barry, S. Cohen.* Caliper Life Sciences, Inc., Hopkinton, MA.

Recent advances in data generation capacity for high throughput sequencing technologies has resulted in new bottlenecks for upstream sample preparation and downstream data processing. Leveraging recent advancements in microfluidic and automation technologies, an automated pipeline has been developed that integrates sample preparation, quality assessment, and quantification to improve overall yields, sample to sample consistency, and reduce the need for amplification. The pipeline also incorporates sample tracking and LIMS compatibility. The system includes methods for DNA library preparation, RNA-Seq, and exome capture protocols, including Roche Nimblegen's SeqCap, Illumina's TrueSeq, and Agilent's SureSelect, and can process up to 96 samples in parallel. Detailed workflows and data demonstrating improved yields from optimization will be presented.

862T

Exome sequencing identifies mutations in *PDE4D*, encoding phosphodiesterase 4D, in acrodysostosis. *H. Lee[1], J.M. Graham[2], D.L. Rimoin[1,3,4,7,8], R.S. Lachman[2], S.F. Nelson[1,9], D. Krakow[1,5], D.H. Cohn[1,5,6].* 1) Human Genetics, Univ California, Los Angeles, Los Angeles, CA; 2) Clinical Genetics and Dysmorphology, Cedars-Sinai Medical Center, Los Angeles, CA; 3) Medical Genetics Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 4) Pediatrics, Cedars-Sinai Medical Center, Los Angeles, CA; 5) Orthopaedic Surgery, Univ California, Los Angeles, CA; 6) Molecular, Cell and Developmental Biology, Univ California, Los Angeles, CA; 7) Pediatrics, Univ California, Los Angeles, CA; 8) Medicine, Univ California, Los Angeles, CA; 9) Psychiatry, Univ California, Los Angeles, CA.

Acrodysostosis is a dominantly-inherited, multisystem disorder with neurological, endocrine and skeletal abnormalities. Mental retardation is a consistent but variable feature, and endocrine abnormalities include hypogonadism, hypothyroidism and irregular menses. Skeletal features include brachycephaly, midface hypoplasia with a small upturned nose, brachydactyly, spinal stenosis and osteoporosis. To identify the molecular basis of acrodysostosis, exome sequencing was carried out in four genetically independent cases. Exome sequences were also determined for the unaffected parents in two of the cases, facilitating filtering the variants to identify new mutations. Mean oversampling of bases was 107X and at least 93.9% of the ~33.4 Mb of protein coding sequence defined by RefSeq was read to at least 10X depth. A single plausible mutational target was identified genome-wide. Distinct missense mutations in *PDE4D*, which encodes cAMP-specific phosphodiesterase 4D, were identified in three of the cases. The parental exome sequences demonstrated that two of the mutations had occurred de novo, providing strong genetic evidence of causation. Each missense change altered an evolutionarily conserved residue in the encoded protein, further suggesting that the mutations are pathogenic. The acrodysostosis-like phenotype of the *Pde4d* knockout mouse which, in the homozygous state, exhibits neurological abnormalities, infertility and poor growth, imply that the mutations lead to reduced PDE4D-mediated phosphodiesterase activity. *PDE4D* is the human orthologue of the *Drosophila* gene *dunce*, which has been shown to play a role in learning and memory in flies. Thus an evolutionarily conserved neurological pathway is disrupted by PDE4D deficiency. Many clinical findings in acrodysostosis are similar to the phenotype of Albright's hereditary osteodystrophy (pseudohypoparathyroidism type IA), which also results from defects in cyclic nucleotide metabolism and results in resistance to parathyroid hormone (PTH). Our data therefore implicate PDE4D as a component of the PTH signaling pathway. We conclude that acrodysostosis can result from missense mutations in *PDE4D*, and that the wide variety of phenotypic consequences of PDE4D deficiency underscores the exquisite sensitivity of many tissues to alterations in cAMP homeostasis.

Low DNA input optimization using Agilent SureSelect XT Library Prep and Whole Exome Selection for Next Generation Sequencing. *B. Marosy, B. Craig, K. Hetrick, KF. Doheny.* Center for Inherited Disease Research (CIDR), Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality next-gen sequencing (NGS), genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. CIDR has developed a NGS lab using the Illumina® HiSeq™2000 platform in conjunction with the Agilent© SureSelect™XT library prep and target enrichment kits. Historically, sample requirements for a variety of targeted selection and NGS platforms have been a limiting factor for investigators. Recently, the Broad institute published automation and optimization methods for library prep and solution hybrid selection capture, including a reduction in the DNA input. CIDR has adapted these optimizations for use with the Agilent SureSelectXT library prep and target enrichment kit. Two HapMap samples with DNA inputs of 3ug, 1ug and 100ng were processed in parallel using 1) the standard XT protocol adapted for plate processing; and 2) the optimized low input protocol adapted for the XT reagents, which includes the `with bead' clean up. Further comparisons were made between samples in which the library preps were constructed using the optimized low input protocol (2) and subsequently processed post capture in parallel using 3) the standard Agilent capture protocol adapted for plate processing; and 4) the optimized post capture protocol which includes the `off Bead catch'. Samples were hybridized using 500ng of constructed library and the SureSelect 50Mb Human All Exon library for 24hrs. Samples were then clustered for sequencing using the Illumina cBOT Cluster Generation system. Seventy-six bp paired-end sequencing was performed on the HiSeq2000. Estimated total DNA, using the Agilent 2100 BioAnalyzer, after the pre-capture PCR yielded >1.5ug for the 3ug input samples using the standard methods (1). By comparison, the 1ug and 100ng samples had estimated total DNA yield of >2ug and ~1ug, respectively using the optimized library prep method (2). Preliminary sequencing data analysis of the 100ng input experiment using the optimized library prep and post capture methods (4) yielded 91.4% of the baited bases covered >= 8X depth, an estimated selection library size of 208 million, and a molecular duplication rate of 15%. This should be compared to 81.8%, 123 million and 13.2% respectively for the optimized library prep with standard post capture methods (3).

Whole-exome sequencing in multiplex families with multiple sclerosis. *J.L. McCauley[1], A.H. Beecham[1], A. Hadjixenofontos[1], P.L. Whitehead[1], I. Konidari[1], A. Aviram[1], Y. Pasco[1], S.L. Hauser[2], J.R. Oksenberg[2], D.J. Hedges[1], J.M. Vance[1], J.L. Haines[3], M.A. Pericak-Vance[1].* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Department of Neurology, School of Medicine, University of California, San Francisco, CA, USA; 3) Center for Human Genetics Research, Vanderbilt University Medical Center, Nashville, TN, USA.

Multiple sclerosis is a common neurodegenerative disease affecting more than 1.3 million individuals worldwide. Since the first genome-wide association study (GWAS) of MS was published in 2007, over 20 genetic loci have demonstrated undisputable evidence for association to this disease. Moreover, comprehensive follow-up, meta-analyses, and second generation GWAS continue to identify additional loci. Despite this progress toward understanding the genetics of MS, the genes identified thus far represent only a fraction of the inherited susceptibility. The importance and success of the GWAS approach to identifying loci underlying MS cannot be overlooked. However, alternative hypotheses concerning the genetic architecture of MS must be explored, including the multiple rare variant (MRV) hypothesis. The MRV hypothesis states that susceptibility to common diseases may be determined in part by a large number of rare variants with higher penetrance. Given the number of multiplex families found in MS, it is plausible that rare variants may be found to directly contribute to MS in these families. To test this hypothesis, we have employed next-generation sequencing technologies to scan multiplex families for evidence of rare variants involved in MS. We have used a targeted-enrichment capture approach (50Mb Agilent exome enrichment kit) to selectively capture and subsequently sequence (Illumina HiSeq2000) the exomes of 110 individuals spanning 27 multiplex MS families. Using BWA, 85% of the target is covered at a read depth of 8X or greater. At this stage of our analysis, these data are filtered on quality (GQ⁄ 30), and non-synonymous coding variations. Additional filters include conservation scores as well as polyphen prediction of damaging versus benign amino acid changes. As an example, the sequencing of one multiplex family, containing 8 individuals (2 unaffected parents; 4 affected and 2 unaffected children), found 11,107 non-synonymous coding variants. Thirty-one variants followed an autosomal recessive model; three of these (found in *LIPA*, *FAM35A*, and *SMYD4*) show strong conservation, are predicted to be damaging, are not found in the unaffected siblings, and have not previously been associated with MS. In general, these results will help to address whether rare variants of strong main effect are present within MS. Moreover, our whole-exome approach will allow us to examine both established and novel MS loci and to explore putative pathway analyses.

A nucleic acid fractionation solution for high throughput sequencing applications. *I. Meek[1], E. Wong-Ho[2], J. Molho[2].* 1) Caliper Life Sciences, Inc., Hopkinton, MA; 2) Caliper Life Sciences, Inc., Alameda, CA.

The LabChip XTe provides rapid (<30 minutes), reproducible, and economical fractionation and isolation of nucleic acids. Recent assay and software improvements have expanded the platforms use into different sequencing chemistries and application areas, including ChIP-seq, microRNA-seq, and targeted resequencing. Data will be presented to demonstrate how this microfluidics-based platform increases average read lengths and ensures diversity with higher sample recovery.

866T

Multiplex exome enrichment with a new system from pooled barcoded libraries yields efficient variant detection on the SOLiD™ System. *G. Meredith, G. Bee, M. Dudas, L. Pickle, C. Adams, W. Zhang, M. Allen, J. Bishop, Y. Sun, G. Marnellos, M. Storm, J. Ichikawa, R. Bennett.* R & D, Life Technologies Corp, Carlsbad, CA.

The identification of genetic variation associated with human disease requires the development of a robust and cost-effective approach for systematic resequencing of candidate regions in the human genome. Even though the cost of sequencing a human genome continues to drop, the demand for high sample throughput continues to increase. Higher sample throughput is considered necessary to enable larger patient cohort studies which hold the key to identifying rare disease-related alleles. Thus, scalable and automatable workflows for target enrichment and sequencing are needed to facilitate cancer and other genetic disease research. Described here is a targeted resequencing workflow that employs pooled barcoded fragment libraries, multiplexed exome enrichment and multiplexed sequencing on Applied Biosystems® SOLiD™ 4.0 and 5500xl Systems. To validate the performance of this multiplexed workflow, barcoded fragment libraries were automatically constructed, using an AB Library Builder™ System, from either HapMap sample NA12878 or HuRef genomic DNA. Resulting libraries were then pooled in multiples of 4 for exome capture with the TargetSeq™ Exome Enrichment System. This new system for solution-phase hybridization-based exome enrichment targets exons from VEGA, CCDS, RefSeq, and miRBase and covers > 20,000 gene models within a 45.1 Mb probe footprint. The design was developed in conjunction with a team from the Human Genome Sequencing Center at the Baylor College of Medicine (manuscript submitted). As an example, data obtained from 5.8 Gb of raw SOLiD sequencing of the NA12878 exome yielded an average depth of coverage over the targets of 49X with an on-target rate of 68.5%. For this same dataset, only 5.4% of bases were not covered, 91.3% were covered at 5X, 87.0% at 10X and 75.1% at 20X. Likewise for this set, more than 42,900 SNP calls (26,240 homo and 16,703 het) were made with the BioScope™ 1.3 targeted resequencing analysis pipeline with agreement to dbSNP of 94.2%. Overall, good barcode balance, similar mapping efficiencies and similar SNP/indel calls are observed for 4-plex exome capture samples. Data will also be presented on single-tube exome enrichment of DNA from patient-matched breast tumor vs normal tissue obtained with the 5500xl SOLiD™ System. The combination of multiplexed exome enrichment and SOLiD™ Systems provides an efficient and economical solution for the high-throughput detection of genetic variation in multiple human genomes.

867T

Characterization of non-unique insertion content in the mouse genome using next-generation paired-end sequencing. *N. Parrish, F. Hormozdiari, E. Eskin.* Department of Computer Science, UCLA, Los Angeles, CA., USA.

Genome resequencing techniques have proven effective in characterizing single-nucleotide polymorphisms (SNPs) in an individual genome. However, large-scale structural variations (SVs) are difficult to characterize using resequencing. While SVs have been shown to play an important role in genetic disorders, few methods have been developed to determine the content of the SVs within an individual. Previous methods to determine the content of large inserted sequences have used paired-end sequencing information and de-novo assembly tools, but focused solely on novel sequences. Our recently developed method utilizes additional information gathered during resequencing to assemble both novel and copied insertion content. By looking for patterns in both the overall depth of coverage and the distance between read pairs, our method is able to identify reads which were likely sampled from an inserted region. These reads, along with unmapped reads, are then assembled into contigs using a custom assembly technique referred to as segment extension. Segments of the genome bordering identified insertion locations are progressively extended using the identified reads and mate-pair information. Building on our previous paper, we apply our method to the 129S1/SvImJ and DBA/2J strains of the mouse genome data from the Sanger Institute, and report our findings of assembled insertions common between the two strains and an analysis of the differences.

868T

Optimized automation of next-generation, multiplexed DNA sequencing. *E.A. Phillips, S.R. Austin, A.N. Gracien, M.R. Annable, C.E. Igartua, B.P. Munson, M.B. Mynsberg, K.M. Sawatzki, M.L. Tackett, L.A. Urquhart, B.W. Paeper, J.D. Smith, E.H. Turner, M.J. Rieder, D.A. Nickerson.* Genome Sciences, University of Washington, Seattle, WA.

We have adapted our automated, 96-well library preparation method to pool libraries into a composite, multiplexed sample for sequencing without the need for manual sample handling. While exome sequencing has proven a cost-effective method for sequencing and analyzing the coding regions of the human genome, recent improvements in sequencing technology and methods for custom target capture of smaller regions of the genome make running individual samples inefficient. With our current library preparation and exome capture methods (Roche/Nimblegen EZCap v2 - 36 Mb), a single lane of paired-end, 50bp sequencing on an Illumina HiSeq2000 using the latest V3 chemistry and flowcells with provides an average of 90M unique read pairs (~82% passing >Q30 filter) for a single lane of sequencing (~200X coverage for a single sample). This level of data production necessitates the implementation of pooling or multiplexing strategies to improve the per sample cost of sequencing. We have developed automated approaches to process samples in a 96-well format using a liquid handling robot. 8-base barcodes are added to the samples during the library preparation phase prior to capture. Post capture, the libraries are normalized to 10nM using qPCR, and pooled into a single tube for sequencing. An initial flowcell is run on the pool, and automated QC analysis is performed to provide information on individual library quality and complexity as well as balance of library representation within the pool. Based on this information, libraries are the automatically re-queued within our LIMS system, regrouped and repooled, to eliminate libraries that show unbalanced representation across the target area or exhibit poor capture efficiency. These newly balanced pools can then be sequenced to completion. This strategy allows us to complete 2-4 exomes per lane of sequence run, or even larger multiplexed sample configurations for smaller capture targets, thereby increasing overall efficiency and lowering costs per exome. By adopting multiplexed DNA sequencing as our primary workflow we have decreased costs and optimized high throughput next generation sequencing.

869T

The Totalome ,Towards a Complete Description of a Sample. *M. Rhodes[1], M. Storm[1], Y. Sun[1], N. Fong[1], J. Ichikawa[1], G. Meredith[2], C. Adams[2], B. Nutter[1], A. Tobler[1].* 1) Life Technologies, Foster City, CA; 2) Life Technologies, Carlsbad, CA.

It is now over 25 years since the advent of routine automated sequencing, and 10 years since the sequencing of the Human Genome. Since then there has been a radical change in the number and types of sequencing technologies, with rapid platform and chemistry development driven by the desire to increase throughput and decrease costs. The ability to generate in excess of 50 gigabases of sequence data in a single run has enabled the analysis of both the genome and transcriptome. It is now possible to contemplate collecting all the information on a sample in a single run on a 5500xl Genetic Analyzer. In order to validate this a sample consisting of MCF7 DNA and RNA was run on 2 slides on a 5500 Genetic Analyzer. RNA was analyzed via a whole transcriptome poly A+ selected library as well as a small RNA library. Methylation was analyzed by carrying out a pulldown of the methylated regions using MethyMiner™ Kit and two different salt concentrations. Protein binding was analyzed via a series of ChIP-seq experiments in which a range of Protein DNA binding regions were captured with a variety of antibodies (targets included POL1). In order to increase efficiency the smRNA and ChIP-seq, samples were barcoded so that they could be loaded into the same lane. The whole genome was analyzed by paired end sequencing (the two ends of the same molecule are sequenced , the distance between the two tag sequences being ~250 bases , in order to overcome the challenges of repeat regions Mate Pair sequencing was carried out with 3 kilobases between the two sequenced Tags The true power of the totalome is achieved during analysis, although each technique provides valuable information on its own by combining data will enable significant improvements in analysis. This ranges from the simple, by knowing the SNP present in the genomic sequence, it becomes possible to more efficiently observe allelic bias in the Transcriptome data. More complicated data analysis enabled us to correlate the transcription levels to the binding of RNA polymerase as well as methylation. As well as showing the results of this experiment data for a “mix and match” approach will be presented, this will allow a user to tune the experiment so that only the needed information is collected, for example by choosing the number of transcriptome reads the user can choose the sensitivity required, the same can be done for ChIP-seq, methylation, genome sequencing, thus a custom experiment can be designed.

870T

Combining short (Illumina) and long (PacBio) NGS reads to improve de novo genome assemblies of rice and Saccharomyces cerevisiae genomes. *M. Schatz, M. delaBastide, M. Muller, L. Gelley, E. Antoniou, R. McCombie.* Cold Spring Harbor Laboratory, 1 Bungtown Road, Cold Spring Harbor, NY.

Several large genomes have been sequenced using next generation sequencers. However, the completeness of these genome assemblies is limited by the short size of the sequencing reads. The goal of this project is to assess the potential improvement in genome assemblies when using a mix of short (Illumina HiSeq) and long reads (PacBio RS). We used SOAPdenovo to assemble sequences produced by the Illumina HiSeq and BLASR to align PacBio reads. The analysis described below is preliminary and will evolve as the coverage of long reads increases and we learn how to best process this type of sequencing data. We generated over 200x coverage of the yeast genome in 2x100bp with 275bp inserts (Illumina). The PacBio RS was used to get the following coverage; 38x if every read is included, 33x for reads > 500bp, 17x for reads > 1kbp, 5.7x for reads > 2kbp, and 1.7x for reads > 3kbp. The max read length is 8,495bp. The average accuracy is ~83% relative to the reference, with errors dominated by insertions errors (11.5%), deletions (3.4%) and substitutions (1.4%). Using only short reads, the scaffold N50 is 81kbp and the contig N50 is 64kbp. There are 151 scaffolds pairs linked by at least 2 PacBio reads. Using all reads, the scaffold N50 is improved by 54% to 125kbp, and the number of scaffolds (> 1kbp in size) is reduced by 28% to only 210. For the rice genome, we sequenced a mix of 2x100 PE reads (134bp and 270bp inserts), plus 2x100 mate reads (1.8kbp inserts) for a total coverage over 100x. The scaffold N50 is 28.8kbp and the contig N50 is 5.2kbp. PacBio coverage again depends on read length; 10.8x considering every read, 9x for reads > 500bp, 5.6x for reads >1kbp, 2x for reads >2kbp and .6x for reads >3kbp. The longest read is 10,008bp.There are 14,890 scaffold pairs linked by PacBio reads. The hybrid genome assembly is ongoing. We also started a project to investigate the usefulness of the PacBio RS to validate SNPs detected by Illumina reads. The PacBio RS can sequence short inserts multiple times to improve accuracy and the cost would be well below the cost of Sanger sequencing the same number of fragments. The mean insert size of our initial library is 182bp and the mean mapped read length is 2,241bp. Initial evaluation using the SMRT view browser shows very few instances of the same sequencing error present on multiple reads when coverage is <10 sequences/position. Additional analyses are required to assess to accuracy of the consensus sequences.

871T

An updated assembly model for the human reference genome. *V.A. Schneider[1], P. Flicek[2], T. Graves[3], T. Hubbard[4], D. Church[1] for the Genome Reference Consortium and the NCBI Genome Annotation Team.* 1) NCBI, Bethesda, MD 28092; 2) EBI, Hinxton, Cambridge, CB10 1SD, U.K; 3) The Genome Institute at Washington University, St. Louis, MO 63108; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1SA, U.K.

From the time of its draft release a decade ago, the human reference assembly has played critical roles in basic research and clinical advances. However, many of the discoveries this resource enabled now demonstrate that the assembly model initially used to represent the genome is insufficient in its ability to successfully capture the extent of human genomic variation and to represent the more complex regions of the genome. The Genome Reference Consortium (GRC), responsible for updates and improvements to the human reference genome since 2007, has developed a new assembly model, used for the current reference version (GRCh37), to address these issues. Alternate representations for variant regions of the genome are represented on scaffolds known as alternate loci, which exist as distinct sequences from the reference chromosomes. The GRC provides alignments of these scaffolds to the reference chromosomes, enabling users to place alternate loci in chromosome context. We will show how inclusion of alternate loci improves alignments of short read sequences by reducing mapping errors, thus curtailing false variant predictions. The new assembly model also provides users with timely access to assembly updates without the disruptive coordinate changes that occur in full assembly releases. The GRC releases updates as patches, which like the alternate loci, are standalone scaffold sequences with alignments to the reference chromosomes. Fix patches reflect changes in the existing assembly sequence, and will be incorporated into the chromosomes at the next full assembly release. Novel patches add new sequences, such as allelic variants, and will become alternate loci in the next assembly version. To date, quarterly patch releases to GRCh37 have included 37 fix patches and 55 novel patches, many of which include corrections or additions to clinically relevant genomic regions. We will show how these patches have added a significant amount of the sequence declared as “novel” in several individual genomes to the reference assembly. NCBI provides bioinformatics support for the GRC and annotates the human assembly, including alternate loci and patches, as part of its genome annotation pipeline. Additionally, NCBI supports mapping of features from one assembly to another, or from an assembly to clinical references such as RefSeqGene. We will present data from the NCBI annotation of the most recent GRCh37 patch release.

Extensive genomic diversity identified through massively parallel sequencing of eighteen Korean individuals. *J. Seo[1,2], Y. Ju[1,2], J. Kim[1], S. Kim[1], D. Hong[1], S. Lee[1], H. Park[3], C. Lee[3].* 1) Genomic Med Inst, Medical Research Center, Seoul National Univ, Seoul, Korea; 2) Macrogen, Inc., Seoul, Korea; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts 02115, USA.

Massively parallel sequencing technologies have identified broad spectrum of diversity of human genome. Here, we sequenced 18 genomes of Korean individuals to an average of 26.1 fold coverage using Illumina GA IIx platform. The majority of the short-reads were sequenced from both ends with 76 to 151 bp read lengths. We aligned the short reads to the NCBI human reference genome build 36.3. Upon applying a set of bioinformatic filter conditions, we identified 3.45 million - 3.73 million SNPs from each whole-genome sequenced. The SNPs clustered into a non-redundant set of 8.37 million SNPs, 21.9 % (1.83 million) of which were considered to be novel when compared to dbSNP131. Specifically, of these 1.83 million novel SNPs, 73.9 % (1.36 million) were found as singletons among the 10 individuals studied, suggesting a large proportion of these novel variants are rare. Each individual genome has approximately 130,000 of these putative rare SNPs, consistent with the understanding that many rare variants still remain to be identified. We identified 28,179 genomic variants influencing protein sequences. Of these, 8,130 (28.6%) are novel. A subset of the nsSNPs showed remarkably high allele frequencies among the Koreans studied, compared to other populations, including Europeans and West Africans represented in the HapMap project. For example, the rs4961 SNP in the ADD1 gene, the rs17822931 SNP in the ABCC11 gene and the rs3827760 SNP in the EDAR gene are known to be associated with common salt-sensitive hypertension, dry type ear wax and thick hair morphology, respectively. A subset of genes was found to be highly enriched for nsSNPs, herein called super nsSNP genes. Among the 86 super nsSNP genes, 49 (57.0 %) are associated with sensory and immunological function, such as olfactory receptors and HLA related genes. The deep sequencing of Korean genomes also enabled us to assess the relationship between Korean common nsSNPs (allele frequency > ~10%) and previously known SNPs. Indeed, 53.4% of novel but common Korean nsSNPs showed insufficient LD (r2 <0.8) with currently known SNP variants within a distance of 20kb. This finding suggests that current GWA studies, based on common tagging SNPs observed in other ethnic groups (e.g. Caucasians) may have fundamental limitations for detecting common nsSNPs in other populations, that may be capable of having a functional role in the etiology of complex human diseases.

Elevated lipid and glucose levels together constitute part of the spectrum of “metabolic syndrome” and are a risk factor for cardiovascular disease and type 2 diabetes (T2D). Recent genome-wide association studies have unequivocally implicated multiple loci associated to lipid/glucose levels. To identify variants that may directly affect levels of these quantitative phenotypes, we performed resequencing of 79 genes at 17 loci previously implicated as associated with lipid or glucose levels, in over 5,000 persons from the 1966 Northern Finnish Birth Cohort (NFBC) and 919 T2D cases and 919 normal glucose tolerant controls from the Finland-United States Investigation of NIDDM Genetics (FUSION) study. Exons and splice sites comprising 270kb of target were captured using the WU-cap method developed at The Genome Institute at Washington University and were sequenced using paired-end Illumina sequencing. The first data release for 1,941 NFBC subjects identified 895 variant sites in target regions, 32% of which are present in dbSNP. Newly identified variants include 15 nonsense and 208 missense variants that were predicted to be deleterious by PolyPhen-2. Variants associated with lipid and glucose levels in these samples are candidates for statistical and functional follow-up, and additional analyses are underway. At the time of abstract submission, sequencing is complete for nearly 5,500 samples, and we anticipate the sequencing of 79 genes in the full set of 6,965 samples will be complete by the end of summer 2011.

874T

TARGETED RESEQUENCING OF SLE SUSCEPTIBLE LOCI. *E.K. Wakeland[1], E. Rai[1], B. Wakeland[1], C. Liang[1], N. Olsen[1], D. Karp[1], G. Wiley[2], K. Kaufman[2], J. Harley[2], P. Gaffney[2].* 1) Department of Immunology, The University of Texas Southwestern Medical Center, dallas, TX, USA; 2) Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma, USA.

Susceptibility to systemic lupus erythematosus (SLE) is impacted by both genetic and environmental factors. Six SLE GWAS reported >30 SLE susceptible loci, however, the causal variants responsible for these associations are largely unknown. We have developed a high throughput sequencing technology to perform targeted resequencing of 90 SLE susceptible LD segments (~10.4 Mb genomic sequence) implicated by association mapping or/and play roles in developing murine lupus. 335 Caucasian (184 SLE cases and 151 controls) were sequenced using combined method of SureSelect array capture (Agilent) and Paired End sequencing protocol from Illumina. High quality non redundant reads were assembled and variations were called using GATK and VCFtools. Of the targeted bases, an average of ~99% bases was captured by at least one non-redundant read and ~94.5% bases by at least eight non-redundant reads, yielding average fold coverage of ~60 fold. We have identified >90,000 variations (SNPs and Indels), of which ~35% were novel (not in dbSNP 132). A significant proportion of our novel variations were rare. Of the total variations, ~20% were localized to gene segments that potentially impacted function. The distribution of potentially functional variations constituted ~10% non-synonymous; ~11% synonymous; ~23% UTR; ~2% deleterious (including nonsense, frameshift, probably/possibly damaging and essential splice); ~2% splice and the rest were regulatory and conserved. Most of the non-synonymous and deleterious variations were rare, suggesting that either they are newly evolved or have been subjected to purifying selection. Interestingly, we have seen a high accumulation of novel potentially functional variations in the loci reported to have major effect on SLE susceptibility or informative in animal models (C1Q; TREX1; TLR9 etc). To explore the degree of functional variation that was associated with alleles tagged by SNPs strongly associated with SLE, phylogenic networks were drawn using haplotypes formed by potentially functional SNPs in complete LD with SLE associated SNPs. This analysis identified a specific CLADE of alleles containing multiple SLE associated SNPs in ITGAM and identified extensive variations in functional SNPs among families of alleles that carried disease associated SNPs for many other genes. These results suggest that many disease-associated SNPs actually identify a cluster of functional variants, rather than a single disease allele.

875T

Exome Sequencing in Autism Spectrum Disorder. *S. Walker[1], A. Prasad[1], C.R. Marshall[1, 2], S.L. Pereira[1], L. Lau[1], J. Foong[1], E. Cheran[1], J. Howe[1], O. Buske[3], M. Dzamba[3], M. Fiume[3], B. Thiruvahindrapuram[1], M. Brudno[3], S.W. Scherer[1, 2].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, Research Institute, The Hospital for Sick Children, Toronto, Canada; 2) McLaughlin Centre, Faculty of Medicine, University of Toronto, Canada; 3) Department of Computer Science, University of Toronto, Toronto, Canada.

Autism Spectrum Disorder (ASD) is neurological condition characterised by limited communication skills, impaired social interaction and repetitive behaviours. There is a strong but complex genetic etiology with perhaps hundreds of contributing risk loci, some of which are now known (eg. *SHANK2*, *SHANK3*, *NRXN1*, *PTCHD1*, 16p11.2). Recently, Next Generation Sequencing technologies have proven powerful tools for identifying mutations underlying Mendelian diseases and their application to more heterogeneous disorders may discover novel sequence variants, identifying new loci and verifying previously implicated genes. With the aim of discovering rare genetic variants associated with ASD, we are carrying out high throughput exome sequencing in a cohort of 1000 Canadian patients. All individuals have previously been genotyped using a high resolution microarray (more than one million probes) and thorough copy number variant (CNV) analysis conducted. We are currently focusing on individuals carrying potentially pathogenic large CNVs under the hypothesis that there may be additional sequence changes or other contributing loci. We are using the Agilent 50Mb whole exome SureSelect target enrichment protocol with Life Technologies' SOLiD platform for sequencing. We have developed an analysis pipeline using alignment tool SHRiMP2 and the Genome Analysis Toolkit (GATK) genotyper, followed by filtration through dbSNP and data from the 1000 genomes project with functional annotation using SIFT and PolyPhen. Variants of interest identified in this discovery stage are being validated and segregation patterns examined. From the first 100 sequenced exomes, we typically detect approximately 15,000 single nucleotide variants per individual in exonic regions, 3000-5000 of which are novel. We have identified numerous distinct, potentially pathogenic sequence changes in genes previously associated with ASD susceptibility. Inherited missense and nonsense variants have been discovered in genes such as *NRXN1*, *RPGRIP1L*, *EFHC1* and *CEP290* among others and appear to segregate with the phenotype. Further characterisation will be achieved by assessment of frequencies in independent case and control populations and through functional studies. We speculate that sequencing of these individuals will yield novel genes and variants influencing ASD susceptibility and shed light on the broader issues of allelic architecture, variable penetrance and phenotypic heterogeneity in complex disorders.

Long Range Sequence Scaffolding of Large Genomes using the Argus™ Optical Mapping System. *N. Xiao[1], R. Ptashkin[1], T. Anantharaman[1], B. Zhu[1], D. Sweeney[1], X. Xun[2], J. Henkhaus[1].* 1) OpGen, Inc., Gaithersburg, MD; 2) Beijing Genome Insitute, Shenzhen, China.

Despite the continued improvements in DNA sequencing technologies, whole genome sequencing of large complex organisms remains a significant bioinformatics challenge, particularly when trying to discern the order and orientation of the hundreds or thousands of sequencing scaffolds typical in these projects. Optical Mapping is a single molecule technology that generates de novo, ordered, high-resolution restriction maps. Whole genome Optical Maps are assembled from collections of single molecule restriction maps, and are routinely used in comparative genomics, sequence assembly and sequence finishing of microorganisms. Recent improvements in data throughput and data quality suggest that the Argus™ Optical Mapping System can be practically applied to large complex genomes such as plants and animals, including the human genome. In order to understand the utility of Optical Mapping in sequencing large genomes, we conducted proof-of-concept studies on the human and goat genomes. With this approach, sequencing information and Optical mapping data were used in combination where Optical Mapping linked otherwise unordered scaffolds into much larger, super-scaffolds. For both the human and goat genomes, millions of single molecule restriction maps that typically ranged from 250Kb to 1 Mb in length were obtained from the Argus Optical Mapping System. In an iterative fashion, these molecules were then aligned to sequence scaffolds to extend the ends with de novo Optical Mapping data. Scaffolds that shared overlapping mapping information were then joined. For the human genome, a test data set was used where artificial gaps of known size (10 - 200 Kb) and position were incorporated into existing human genome sequence (NCBI Build 37). Optical Mapping was performed directly from human blood. The goat genome involved an active de novo sequencing project where whole-genome, shotgun sequence information was obtained using the Illumina platform. Optical Mapping was independently performed directly from frozen, epithelial cells. Results from the human test set successfully joined >90% of the gaps; the error rate (mis-join rate) was < 2%. For the goat genome, scaffold N50 was improved nearly 8-fold (from 2.2 Mb to 16.9 Mb). The N90 was similarly improved from 0.5 Mb to 2.8 Mb. These results indicate that the Argus Optical Mapping System can facilitate sequence finishing of large complex genomes, reduce the bioinformatics burden and improve the overall sequence quality.

Whole genome sequencing of one 100-year old and one discordant MZ twin pair. *K. Ye[1], M. Beekman[1,2], E. Lameijer11, J. Houwing-Duistermaat[3], D. Kremer[1], K. Raine[4], B. Blackburne[5], S. Potluri[6], R. van der Breggen[1], R. Westendorp[7], P. t' Hoen[8], J. den Dunnen[8], G. van Ommen[8], G. Willemse[9], D. Cox[6], Z. Ning[4], D. Boomsma[9], E. Slagboom[1,2].* 1) Leiden University Medical Center, Leiden, Leiden, Netherlands; 2) Netherlands Consortium for Healthy Ageing; 3) Medical Statistics and Bioinformatics, Leiden University Medical Center, Leiden, the Netherlands; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge CB10 1SA, UK; 5) Faculty of Life Sciences, University of Manchester, Michael Smith Building, Oxford Road, Manchester M13 9PT, UK; 6) Pfizer Inc., South San Francisco, US; 7) Gerontology and Geriatrics, Leiden University Medical Center, Leiden, the Netherlands; 8) Human Genetics, Leiden University Medical Center, Leiden, the Netherlands; 9) Department of Biological Psychology, VU University, Amsterdam, The Netherlands.

Monozygotic (MZ) twins develop from one zygote that splits and forms two embryos. Genomic studies and recent whole genome sequencing efforts all tend to conclude that MZ twins are genetically identical. However, very old MZ twins may accumulate somatic mutations and phenotypically discordant MZ twins may carry germline variants. Therefore, we investigated whether we could detect genetic differences within MZ twin pairs by applying next generation sequencing from two platforms. We identified the oldest living Dutch MZ twin pair of 100 years old. These twins were collected as part of the Leiden Longevity Study (LLS) and they are highly concordant for a range of metabolic phenotypes. In contrast, a 40-year old MZ twin pair from the Netherlands Twin Register (NTR) discordant for BMI from an early age onwards. To identify somatic and germline discordant variants, the whole genomes of both MZ twins were sequenced on Illumina GAII sequencers. We first compared the nucleotide base counts per location between the co-twins to generate a list of potentially discordant base substitutions. After filtering the data on the basis of the distance among these base substitutions, the distance to other identified variants (indels and structural variants) and the coverage, we prioritized a list of 1,349 potentially discordant base substitutions between the co-twins for both pairs (LLS 690 and NTR 659). We validated a first set of top 485 sites using Sequenom MassArray. Between the phenotypically discordant NTR co-twins we did not confirm any of the single base discordancies whereas in the centenarian LLS MZ twin pair we confirmed three single base discordances, which were further confirmed by Sanger sequencing. For the centenarian LLS twin pair, whole genome sequencing data were also generated using the Complete Genomics platform. We observed 19 potentially discordant base substations supported by the data from both Illumina and Complete Genomics sequencing platforms, 17 variants additional to the ones described above. We are investigating these additional potential variants by Sanger sequencing and sofar confirmed 7 of them. In summary, so far there was no evidence for discordant single base substitution in the BMI-discordant MZ twin pair. This could indicate that epigenetic variation may contribute to the discordancy in phenotype. In contrast, we confirmed a modest number of somatic single base substitutions in the very old MZ twins.

878T

Identification of novel loci for hereditary cataract in dogs. *S. Ahonen[1,2,3], SL. Ricketts[4], C. Mellersh[4], H. Lohi[1,2,3].* 1) Dept Med Gen, Univ Helsinki, Helsinki, Finland; 2) Dept. of Molecular Genetics, the Folkhälsan Institute of Genetics, Helsinki, Finland; 3) Dept. of Veterinary Biosciences, University of Helsinki, Finland; 4) Centre for Preventive Medicine, Animal Health Trust, Newmarket, Suffolk, UK.

Dogs suffer from many of the same hereditary eye diseases as humans including hereditary cataract (HC), which is the leading cause of blindness in both species. Cataract is defined simply as an opacity of the lens and there are many causes of cataract in both species, including accompanying ocular disorders, metabolic disease, senility, trauma and inherited defects. In humans about 10 % of congenital cataracts are caused by hereditary cataract and to date 25 genes have been associated with the development of cataract. However, there are many patients for whom a molecular diagnosis is unavailable, indicating that there are many additional genes involved with the development of cataract. In dogs it is estimated that around 100 breeds are affected with HC. Thus far only one gene has been associated with HC in dogs. Characteristics such as age of onset, rate of progression and position of the opacities vary between breeds, whereas inherited cataracts usually exhibit marked intra-breed specificity, indicating their genetic homogeneity within a breed. Due to the genetic homogeneity, dogs may be useful animal models to map novel cataract genes, which can then be screened in humans patients with similar phenotype. We have established a large sample cohort for posterior polar subcapsular cataract in the Siberian Husky, Alaskan Malamute and Samoyed breeds and for posterior polar subcapsular and posterior polar cortical cataract in the Karelian Beardog (KBD). We have performed a genome-wide association study (GWAS) with Illumina's 173K canineHD SNP array to attempt to map HC-associated loci in each breed. GWAS identified a shared HC-associated locus in the Siberian Husky and Samoyed on canine chromosome 18 (CFA18) (Praw=4.6 x 10^{-7}, Pgenome =0.01). A tentative association was identified in Karelian Beardogs on CFA11 (Praw=2.66 x 10^{-6}, Pgenome =0.18). No association was identified in the Alaskan Malamute possibly due to overall homozygosity. However, it is suspected that the Alaskan Malamute may share the same genetic background due to its close ancestral relationship with the Siberian Husky. Further studies will include re-sequencing of the associated loci in the Siberian Husky and replication study of the KBD locus in a larger sample cohort. This is likely to reveal novel canine cataract genes. Mapping new causative genes for canine HC will enable important new insights into the molecular pathogenesis of hereditary cataract in both dogs and humans.

879T

A genome-wide association meta-analysis reveals new childhood obesity loci. *J.P. Bradfield[1], S.F.A. Grant[1,2] on behalf of the Early Growth Genetics Consortium.* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia Research Institute, Philadelphia, Pennsylvania 19104, USA; 2) Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104, USA.

A number of genetic determinants of adult obesity have already been established through large scale meta-analyses of genome wide association studies (GWAS), several of which were also confirmed in the context of childhood obesity. However, less progress has been made to establish genetic influences specific to childhood obesity though similar approaches. To identify novel genetic factors that influence early-onset obesity, we performed a meta-analysis of genome-wide genotyped datasets from 14 study sites consisting of 5,447 cases (≥ 95th percentile of BMI achieved any time from age 2 to 18 years old) and 8,185 controls (<50th percentile of BMI consistent throughout all measures during childhood) of European ancestry. Following the meta-analysis of ~2.54 million SNPs (directly genotyped or imputed), variation at seven loci yielded association at the level of genome wide significance ($P < 5x10^{-8}$). All these loci have been previously reported in the context of adult BMI GWAS (*FTO*, *TMEM18*, *POMC*, *MC4R*, *FAIM2*, *TNNI3K* and *SEC16B*). *FTO* yielded the strongest evidence for association while *TNNI3K* and *POMC*, which were only detected in adult studies when using hundreds of thousands of participants, were readily detected in our relatively small sample size. We elected to take forward all novel signals yielding association with $P < 5x10^{-6}$ (n = 8) in order to test for replication in independent datasets. We observed two loci that yielded a genome wide significant P-value when combined with the discovery cohort, namely near keratoconus gene 6 (*KC6*) on 18q12 (rs17697518; combined $P = 9.05x10^{-10}$) and near olfactomedin 4 (*OLFM4*) on 13q14 (rs9568856; combined $P = 2.03x10^{-8}$). By also exploring association with the inclusion of extreme childhood obesity, we further confirmed the locus near OLFM4 (rs9568856; combined $P = 1.00x10^{-8}$). In summary, as a consequence of extensive North American-Australian-European collaborative meta-analyses of genome-wide genotyped datasets on children, we have uncovered at least two novel obesity loci.

880T

The Axiom® Genomic Database and the Axiom® Design Center: Designing custom genotyping arrays made easy. *J. Burrill, J. Bleyhl, Y. Lu, D. Le, R. Shigeta, W. Short, A. Tracy, R. Wheeler, B. Wong, Y. Zhan.* Affymetrix, Inc, Santa Clara, CA.

The Axiom® Genomic Database (AGD) and the Axiom® Design Center (ADC) have been created to facilitate marker selection for inclusion on SNP genotyping arrays. The AGD is a collection of more than 11M markers, annotation information, and genotype information across three major populations (CEU, ASI [comprised of CHB and JPT], and YRI). Linkage disequilibrium (LD) was computed across the database, enabling LD-based selection methods in the ADC. The database contains two types of markers: Axiom-validated markers and "taggable" markers. Axiom-validated markers have been shown to genotype with high accuracy and call rate in the Axiom Assay, and the minor allele was seen in more than two individuals. Taggable markers can be reliably tagged in at least one population by a validated marker. The ADC is a web-based tool, accessible at www.affymetrix.com/designcenter, that enables users to query the AGD to create custom microarray designs. The selection of markers is divided into two steps: defining the target set and choosing the selection method. Researchers can utilize the AGD as a target set, or use lists of markers, regions, or genes to define their target set. Users can then filter the available markers by their relationship to transcripts (*e.g.,* cSNPs) or minor allele frequency in a population. Four methods are available to select markers for the design; a different method can be used for each set of target markers. The direct selection method includes all of the Axiom-validated markers in the target set. The best tag method first performs a direct selection, then selects the validated marker with the highest r^2 value for each taggable marker. The greedy tag method "greedily" selects validated markers that cover the most target set markers at a user-defined r^2 threshold. Finally, the physical density method uses a "gap-filling" strategy to obtain uniform physical coverage across the region. The ADC processes the marker group queries (target set and selection rule) and generates reports and BED files detailing the markers selected by each query and for the overall design.

The Axiom Genomic Database and the Axiom Design Center were successfully used internally to create several array plates, including the Axiom Genome-Wide CHB 1 and YRI Arrays. Together, the Axiom Genomic Database and Design Center provide an easy-to-use, web-based tool that enables the rapid selection of markers for custom array designs.

A Genome-Wide Search for Non-UGT1A1 Markers Associated with Unconjugated Bilirubin Level Reveals Significant Association with a Polymorphic Marker in a Gene of the Nucleoporin Family. *S. Datta[1], A. Chowdhury[2], M. Ghosh[3], K. Das[2], P. Jha[4], R. Colah[5], M. Mukerji[4], P.P. Majumder[1,6].* 1) Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India; 2) Department of Gastroenterology, S.S.K.M. Hospital, Kolkata, India; 3) Department of Haematology, N.R.S. Medical College & Hospital, Kolkata, India; 4) Institute of Genetics & Integrative Biology, New Delhi, India; 5) Institute of Immunohaematology, Mumbai, India; 6) National Institute of Biomedical Genomics, Kalyani, India.

Background & Aims.Variants in *UGT1A1* gene and its promoter are known to determine levels of unconjugated bilirubin (UCB), but do not explain all cases of unconjugated hyperbilirubinemia. We undertook a genome-wide association study with unconjugated bilirubin level to discover associations with variants in genes other than *UGT1A1*.

Methods.We recruited 200 participants to cover the entire range of quantitative variation in UCB level. Genome-wide scans were performed using 512349 polymorphic markers. Quantitative trait locus (QTL) association analyses were performed with these markers and UCB level adjusted for effects of age, gender and genotype at the dinucleotide (TA) insertion locus in the promoter of *UGT1A1* that is known to significantly modulate UCB level.

Results.Association analysis performed with age- and gender-adjusted UCB level, but without adjusting for the effect of the dinucleotide insertion in the *UGT1A1* promoter, revealed statistically significant associations with polymorphic markers in *UGT1A1*, *UGT1A6*, *UGT1A10*, *NUP153*, and *FAM155A*. When further adjustment for genotype effect of the dinucleotide insertion was done, the significant association of a polymorphic marker (rs2328136) in the *NUP153* gene (which produces a 153 kDanucleoporin) was sustained.The frequency of the variant allele (A) at the rs2328136 locus in our study population is 9.95%, similar to European populations. *NUP153* is associated with the transport of biliverdinreductase, which is important for bilirubin conjugation.

Conclusions.In addition to *UGT1A1*, the nucleoporin gene *NUP153*, whose product is a major regulatory factor in bidirectional transport of biomolecules across nucleus to cytosol, is important in the regulation of unconjugated bilirubin level.

Genome-wide association analysis of lactose consumption measured longitudinally identifies a novel variant 500kb downstream of the LCT gene region. *K.M. Eny[1], S.B. Bull[2,3], A.J. Canty[4], L. Sun[3,5], A.P. Boright[6], S.M. Hosseini[1], P.A. Cleary[7], J. Lachin[7], A.D. Paterson[1,3], DCCT/EDIC Research Group.* 1) Genetics & Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Prosserman Centre for Health Research, Toronto, Canada; 3) Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 4) Department of Mathematics and Statistics, McMaster University, Hamilton, Ontario, Canada; 5) Department of Statistics, University of Toronto, Canada; 6) Department of Medicine, University of Toronto, Toronto, Canada; 7) The Biostatistics Center, The George Washington University, Rockville, Maryland.

Lactase non-persistence occurs due to the decrease in lactase activity post-weaning, resulting in the inability to digest lactose in adulthood. rs4988235, 14 kb upstream of the lactase (*LCT* Chr 2q21) gene first discovered in a Finnish linkage study, showed complete co-segregation and association of the CC genotype with lactase non-persistence, and was later associated with lower lactose consumption in young Finnish adults. *In vitro* functional studies demonstrated differential enhancer activity of the *LCT* promoter by rs4988235, suggesting this SNP to be the causal variant in Europeans. However, given the long-range linkage disequilibrium (LD) known to occur in this region, it is conceivable a variant other than rs4988235 could be the causal polymorphism. To date, no genome-wide association study (GWAS) has been conducted on lactase non-persistence or lactose consumption. We therefore conducted a GWAS of lactose intake assessed using a diet history questionnaire in 1304 white participants with type 1 diabetes from the Diabetes Control and Complications Trial. Given that repeated measures may improve power, we used mean lactose intake measured an average of 3.6 (range: 1-6) times per subject over a mean of 6.5 years. To detect significant loci for lactose consumption, we applied linear regression examining the association of 841,342 SNPs with mean lactose intake transformed into a normal score. Several SNPs in the *LCT* region were associated in an additive manner with mean lactose intake. The top SNP identified, rs1561277, () ±SE =-0.23±0.04, p= 1.2e-8) is located in the *ZRANB3* gene, 517kb centromeric from rs4988235 () ±SE=-0.21±0.04, p=1.8e-7) with pairwise r^2=0.77. The lambda statistic for the full GWAS analysis was 1.06, reducing to 1.04 when a 2MB region around the LCT gene was removed. In analysis of rs1561277 with rs4988235, the association of rs4988235 was diminished (p=0.68), while the effect at rs1561277 was attenuated, but not completely diminished () ±SE =-0.20±0.09, p=0.02). This suggests that rs1561277 or another variant in linkage disequilibrium with it are alternative causal variants. In cross-sectional analysis, the effect at rs1561277 was mildly attenuated () ±SE = -0.21±0.04, p=2.2e-7), indicating that use of longitudinal measures of lactose intake may be more powerful than use of a single measure. Taken together, our GWAS identified a novel variant associated with lactose consumption and demonstrates the value of longitudinal trait measures.

Identification of candidate genes of complex diseases through an integrated analysis of genome-wide association studies and expression quantitative trait loci. *C.K. Fuller, X. He, H. Li.* Integrative Program in Quantitative Biology, University of California, San Francisco, CA.

Genome-wide association studies (GWAS) have successfully identified many loci for a range of complex diseases, but there have been relatively few functional studies of these loci to date. Association studies of molecular traits, such as gene expression level, could greatly facilitate such functional studies by directly linking genetic variants to their putative functional consequences. In this work, we propose a general strategy for integrating association data of complex diseases and molecular traits. Our approach is based on the idea that if a molecular trait has a causal relation to a complex phenotype, then any genetic variation (whether in cis- or trans-) that affects this molecular trait will likely affect the phenotype as well. We translate this intuition into a novel Bayesian statistical method to identify genes and gene networks involved in the phenotype. We test our method on GWAS data of Crohn's disease, using gene expression as the molecular trait. Genes predicted by our method are highly enriched with putative causal genes of Crohn's disease, including those already confirmed by recent studies or those known to play an important role in regulating immune functions. Compared with earlier studies that utilize expression quantitative trait loci (eQTL) data for interpreting GWAS results, our method is capable of leveraging the information in all gene expression SNPs (not just those in cis-), can distinguish causality from coincidence, and is generalizable to any molecular trait (e.g. metabolite level). With the coming explosion of genomic sequencing and molecular phenotyping data, we believe integrative methods such as what we describe here are essential for determining the mechanistic basis of complex diseases.

Implication of European-derived adiposity loci in African Americans. *J. Hester[1,2,3], J. Li[1,2], P. Hicks[1,2,4], C. Langefeld[5,6], B. Freedman[7], D. Bowden[1,2,4,7], M. Ng[1,2].* 1) Center for Diabetes Research, Wake Forest University School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC; 3) Molecular Genetics and Genomics Program, Wake Forest University School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest University School of Medicine, Winston-Salem, NC; 5) Department of Biostatistical Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 6) Division of Public Health Sciences, Wake Forest University School of Medicine, Winston-Salem, NC; 7) Department of Internal Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

Recent genome-wide association studies (GWAS) have identified multiple novel loci associated with adiposity in European-derived study populations. Limited study of these loci has been reported in African Americans. Here we examined the effects of these previously identified adiposity loci in African Americans. 74 representative SNPs in 47 loci that were previously reported in GWAS in Europeans (including *FTO* and *MC4R*) were genotyped in 4992 subjects from six African American cohorts. These SNPs were tested for association with BMI after adjustment for age, gender, disease status, and population structure in each cohort. Meta-analysis was conducted to combine the results. Meta-analysis of 4992 subjects revealed eight SNPs near five loci including *NEGR1*, *NISCH/STAB1*, *TMEM18*, *SH2B1/ATP2A1*, and *MC4R*, showing significant association at $0.005 < P < 0.05$ and had effect sizes between 0.04 and 0.06 SD units (or 0.30 to 0.44 kg/m^2) of BMI for each copy of the BMI-increasing allele. The most significantly associated SNPs (rs9424977, rs3101336, and rs2568958) are located in the *NEGR1* gene ($P = 0.005$, 0.020 and 0.019, respectively). We replicated association of variants at four loci in six African American cohorts that demonstrated a consistent direction of association with previous studies of adiposity in Europeans. These loci are all highly expressed in the brain, consistent with an important role for central nervous system processes in weight regulation. However, further comprehensive examination of these regions may be necessary to fine map and elucidate for possible genetic differences between these two populations.

Toward a deep catalog of results from >1,000 genome-wide association studies. *A. Johnson, R. Leslie, C. O'Donnell.* Division of Intramural Research, NHLBI's Framingham Heart Study, Framingham, MA.

Purpose: We previously reported on a catalog and analysis of results from 118 genome-wide association studies (GWAS). We report the ongoing construction of a catalog of >1,000 GWAS. **Method:** Controlled search terms were used to construct a list of GWAS. QUOSA was used to automate article retrieval. All referenced supplemental files were additionally downloaded. Each significant SNP association ($P<0.05$) was extracted manually, in semi-automated or automated fashion. Custom programs were used to remove redundant associations. Phenotypic labels were assigned to each study to facilitate cross-study queries. Due to privacy concerns we conducted a temporal survey of all results publicly available from 11/1/02 to 7/1/10 to assess community standards for release of GWAS results. **Results:** At the time of submission 1,055 GWAS were identified. We conducted interim analysis of 650 GWAS; cataloguing of further studies is ongoing. This catalog differs from the NHGRI catalog in having more studies, multiple SNP-phenotype associations allowed per SNP per study, and including all results with $P<0.05$. Differences with the NHGRI catalog are due to search strategies and several criteria for inclusion. Major phenotypic divisions are: Neurological (n= 257), Cardiovascular disease (broadly-defined CVD [n=53], diabetes [n= 55]) and its risk factors (total n=225), Blood-related (n=148), Cancer-related (n=139), and Drug/treatment-response (n=77). In our prior survey of 118 GWAS we predicted regions of pleiotropic effect. In interim prospective analysis of 650 subsequently published GWAS we find further evidence of pleiotropic effects for predicted regions (e.g., OAS1 at 12q24.13 which mediates immune response to viral infections). **Discussion:** Our temporal survey shows historical shifts with increased results disclosure over time, but a parallel increase in protected access modes. To our knowledge this is the largest genetics results database constructed to date (currently >2.5 million SNP entries with $P<0.05$ from 768 GWAS). While many entries are expected to be false positives or correlated markers this database has features important for data mining including depth of results, SNP result redundancy (retaining results in linkage disequilibrium), standardized annotation and exact source references for each result. A deeply annotated results catalog will facilitate hypothesis generation and help genomic scientists identify cross-dataset opportunities for mining and collaboration.

Fine Mapping and Biological Functional Study of 14q24.1 Breast Cancer Susceptibility Locus. *P.S. Lee[1], YP. Fu[1], J. Figueroa[2], L. Prokunina-Olsson[1], S. Chanock[1], The Cancer Genetic Markers of Susceptibility (CGEMS) Consortium.* 1) NCI-DCEG, Gaithersburg, MD; 2) NCI-DCEG, Rockville, MD.

A single nucleotide polymorphism (SNP) marker, rs999737, which maps to the last intron of the RAD51-like 1 (RAD51L1) gene coding region, has been associated with breast cancer risk in a genome-wide association study. Located within the 14q24.1 region, RAD51L1 coding region is composed of 13 exons and at least three mRNA splicing variants. The protein has been proposed to promote homologous recombination repair and to maintain genome integrity; another RAD51-paralog has also been associated with breast cancer risk. Our experiments further elucidate the biological relationship between rs999737, RAD51L1, and breast cancer risk. First, we fine mapped the 14q24.1 region to determine whether additional SNPs can pose as targets of additional interest for our biological validation work. We imputed a 3.93MB region flanking rs999737 for Stages 1 and 2 of the Cancer Genetic Markers of Susceptibility study (5,692 cases, 5,576 controls, and 11,268 SNP markers) using the combined reference panels of the HapMap 3 and the 1000 Genomes Project. Single-marker association testing and variable-sized sliding-window haplotype analysis were performed, and for both, the tagging SNP rs999737 exhibited the strongest association with breast cancer risk. Investigation of contiguous regions did not reveal evidence of an additional independent signal. We concluded that rs999737 was an optimal tagging SNP for common variants in the 14q24.1 region and should be the focus of further biological validation studies. We hypothesize that rs999737 alters the RAD51L1 mRNA splicing patter due to its location within the coding region. To examine this hypothesis, we performed Rapid Amplification of cDNA Ends (RACE) experiments to determine the 3' ends of RAD51L1 mRNAs in T47D and Hs578Bst cells, a breast tumor cell line heterozygous for the risk allele and a normal breast cell line homozygous for the risk allele, respectively. We cloned and then sequenced the results from the 3' RACE experiments and observed mRNA with a terminal site located within intron 12, but only in the T47D cell line. This preliminary finding suggests that either the RAD51L1 splice pattern varies among cancer and non-cancer samples, or, that the genomic element tagged by rs999737 is associated with variation in mRNA splicing in the 3' terminal of RAD51L1. As the preliminary RACE experiment data were encouraging, we plan to expand the RACE and sequencing experiments to additional tissue RNA samples.

887T

Genome-wide Association Study Identified 3q13 and 6p12 as Candidate Loci for Childhood Eczema. *T.F. Leung[1], H.Y. Sy[1], S.S. Wang[1], A.P.S. Kong[2], I.H.S. Chan[3], L.Y. Tse[1], W.C. Chan[1], G.W.K. Wong[1], J.C.N. Chan[2], K.L. Hon[1].* 1) Department of Pediatrics, The Chinese University of Hong Kong, Hong Kong, Hong Kong; 2) Department of Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong; 3) Department of Chemical Pathology, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Rationale: Eczema is the commonest chronic skin disease in children. It is caused by complex interactions between multiple predisposition genes and environmental factors. The only published genome-wide association study (GWAS) found single-nucleotide polymorphisms (SNPs) on 11q13.5 locus to be associated with eczema in German children (Esparza-Gordillo JA, et al. Nat Genet 2009), but such findings have not been replicated in other ethnic groups. We performed a multi-stage GWAS for eczema in Hong Kong Chinese children. **Methods:** Over 590K SNPs were genotyped in 264 patients (151 males; mean [SD] age: 10.7 [4.2] years) with early-onset, moderate-to-severe eczema using Illumina HumanHap 610-Quad BeadChips. Genotypic data was compared with those of 1000 random non-diseased Chinese controls by PLINK, adjusted for relatedness by dividing χ^2 statistic by the genomic inflation factor 1.594. Significant SNP signals were replicated in an independent population using TaqMan or Sequenom platforms, and results were analyzed by multivariate logistic regression. Interactions between SNPs for eczema were analyzed by generalized multifactor dimensionality reduction (GMDR). **Results:** 458K SNPs with genotyping call rate⁄ 99.9% satisfied quality control criteria. Sixty-two SNPs reached *P*-value threshold of 4.75×10^{-5}. Three clusters of SNPs could be identified: 15 on chromosome 3q13.32, three on 6p21.3 and nine on 6p12.1. Their respective odds ratios for eczema diagnosis were 1.67-1.80 ($P = 3.96 \times 10^{-5}$-8.48×10^{-6}), 1.95-2.17 ($P = 2.09 \times 10^{-5}$-2.22×10^{-6}) and 1.88-2.22 ($P = 1.91 \times 10^{-5}$-2.29×10^{-7}). No association was found between eczema and 11q13.5. Chromosome 6p21.3 being in the HLA locus was not replicated because of its known effects on allergies. Findings for 24 SNPs on 3q13.32 and 6p12.1 were replicated in another 992 patients (mean [SD] age: 11.7 [4.5] years) and 1022 controls, especially for the phenotypes of early-onset disease and moderate-to-severe eczema. No functional gene could be mapped within 1-megabase of the signals on 3q13.32, and bioinformatics analyses revealed possible epigenetic influences due to abundance of non-coding RNAs in this intergenic locus. The 6p12.1 locus contains two genes, namely *GFRAL* and *HMGCCL1*. GMDR did not reveal any interaction between SNPs on 3q13.32 and 6p12.1. **Conclusion:** Chromosomal regions 3q13.32 and 6p12.1 are putative susceptibility loci for eczema in Chinese children. **Funding:** RGC General Research Fund (469908), Hong Kong SAR.

A Replication Study of Two Genetic Variants for Bone Mineral Density Variation in Caucasians. *J. Li[1], L.S. Zhang[2], H.G. Hu[2], Y.J. Liu[1], P. Yu[1], F. Zhang[3], T.L. Yang[3], Q. Tian[1], Y.P. Zheng[2], Y. Guo[3], H.W. Deng[1,2,4].* 1) Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA, 70112; 2) College of life sciences and bioengineering, School of Science, Beijing Jiaotong University, Beijing 100044, P R China; 3) The Key Laboratory of Biomedical Information Engineering, Ministry of Education and Institute of Molecular Genetics, School of Life Science and Technology, Xi'an Jiaotong University, Xi'an 710049, P R China; 4) Center of System Biomedical Sciences, Shanghai University of Science and Technology, Shanghai, PR China.

A recent genome-wide association study in a Korean population suggested two SNPs, rs7776725 and rs1721400, were significantly associated with bone mineral density (BMD) variation at the radius, tibia and calcaneus. In this study, we aimed to test whether the association of these two genetic variants with BMD can be replicated in Caucasians and whether the association can be extended to BMDs at other skeletal sites that are more clinically relevant to osteoporotic fractures. We tested these two SNPs for association with BMD in two independent US Caucasian cohorts, including a cohort of 2,286 unrelated adults living in Kansas City area, and a cohort of 1,000 unrelated adults living in Omaha and its surrounding areas. We found significant association of rs7776725 with wrist BMD (p=1.42E-16) and suggestive association of rs1721400 with wrist BMD (p=0.017). In addition, rs7776725 was also associated with BMDs at hip, spine and whole body (p=0.013-1.26E-8). The SNP rs7776725 is located in the FAM3C gene. Interestingly, several additional FAM3C SNPs (e.g., rs4727922, rs1803389, and rs718766) also showed association with BMD variation, independent of the effect of rs7776725, which further highlights the potential importance of the FAM3C gene for BMD variation. Our results demonstrated that the SNPs rs7776725 and rs1721400 are associated with BMD variations at multiple skeletal sites in Caucasians. Further in-depth re-sequencing study and functional assays are necessary to elucidate the underlying mechanisms.

Genome Wide Association Study of Hematological Traits among African American Children. *J. Li[1], P. Sleiman[1], C. Kim[1], C. Hou[1], J. Glessner[1], F. Mentch[1], H. Zhang[2], Y. Guo[1], S.L. Furth[3], H. Hakonarson[1].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Office of Biostatistics and Epidemiology, Center for Biologics Evaluation and Research, U.S. Food and Drug Administration, Rockville, MD; 3) Division of Nephrology, School of Medicine, University of Pennsylvania, Philadelphia, PA.

Hematological traits, such as the number and volume of red blood cells, white blood cells, and platelets, are important diagnostic factors for a variety of diseases. Several studies have been carried out to address the question of what genetic loci are associated with blood cell traits in Caucasians adults. However, little is known about the genetic determinants among African American children. We performed a genome-wide association study of eight hematological traits among 6208 African American children as the discovery cohort and additional 1796 African American children as our replication cohort. The hematological traits that we studied include hemoglobin concentration (Hgb), hematocrit (Hct), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC) , red blood cell count (RBC), white blood cell count (WBC) and Mean platelet volume (MPV). We also carried out a meta-analysis of the discovery and replication cohorts. Our results indicate a locus on chromosome 11p15.4 (HBE1) is significantly associated with Hct, Hgb and RBC. Two loci on chromosome 3p14.3 (ARHGEF3) and 10q21.3(JMJD1C) reached genome-wide significance for MPV and a locus on 16p13.3 (C16orf35, LUC7L) is significantly associated with MCV, MCH and MCHC. Thus multiple previously reported hematological loci among Caucasians were replicated among our cohorts of African American children. Interestingly, the locus on 16p13.3 shows a more significant association among African American children than it does among Caucasians adults.

Winkler[1].* 1) Basic Science Program, SAIC, NCI-Frederick, Frederick, MD; 2) Chaire de Bioinformatique, Conservatoire National des Arts et Metiers, Paris 75003, France; 3) Université Paris 12, INSERM U955, Créteil 94010, France; 4) ANRS Genomic Group (French Agency for Research on AIDS and Hepatitis), Paris 75013, France; 5) Department of Experimental Immunology, Sanquin Research, Landsteiner Laboratory, Center for Infectious Diseases and Immunity Amsterdam (CINIMA) Academic Medical Center, University of Amsterdam, Amsterdam 1105 AZ, Netherlands; 6) Laboratory of Genomic Diversity, National Cancer Institute-Frederick, Frederick, MD 21702, USA; 7) Laboratory of Genomic Diversity, SAIC-Frederick, Inc., National Cancer Institute-Frederick, Frederick, MD 21702, USA; 8) Rudolf Magnus Institute of Neuroscience, Department of Neurology, University Medical Center Utrecht, Utrecht 3584 CX, The Netherlands; 9) San Francisco Department of Public Health, HIV Research Section, San Francisco, CA 94102, USA; 10) Department of Epidemiology, the Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD 21205, USA; 11) Departments of Ophthalmology and Medicine, the Mount Sinai School of Medicine, New York, NY 10029, USA; 12) UMR CNRS 8090, Institut Pasteur de Lille, Lille 59000, France; 13) Genomic Medicine, Hammersmith Hospital, Imperial College London, London SW7 2AZ, UK.

To date only mutations in *CCR5* have been shown to confer resistance to HIV-1 infection and these explain only a small fraction of the observed variability in HIV susceptibility. We therefore performed a meta-analysis between two independent European genome-wide association studies, each one comparing HIV-1 seropositive cases with normal population controls known to be HIV uninfected, to identify SNPs associated with the HIV-1 acquisition phenotype. A single highly significant association with the chromosome 8 SNP rs6996198 was revealed ($P = 8.91 \times 10^{-6}$) and this SNP was moved forward for a second stage analysis in two independent USA cohorts of European descent: rs6996198 was replicated in both stage 2 cohorts ($P = 1.77 \times 10^{-2}$ and $P = 2.80 \times 10^{-3}$). Among the four groups, the rs6996198-T allele was significantly associated with a reduced risk from HIV-1 infection, and this protective allele was correlated to a higher *CYP7B1* gene expression. Overall, the meta-analysis between the four independent groups reached the genome-wide significance: $P_{combined} = 7.76 \times 10^{-8}$. In conclusion, we provide strong evidence of association for a common chromosome 8 variant with HIV-1 acquisition in populations of European ancestry. This signal is the first association with protection against HIV-1 infection identified outside the CCR5 nexus. It provides a putative new molecular mechanism of resistance potentially involving the *CYP7B1* gene, encoding a member of the cytochrome P450 family which has been reported to impact inflammation, apoptosis, and regulation of IgA levels.

Genome-wide Association Study in the GAIT Project Disclose Sex-specific Regulation of Mitochondrial DNA Levels. *S. Lopez[1], A. Buil[1], J.C. Souto[2], J. Casademont[3], J. Blangero[4], A. Martínez[1], L. Rib[1], J. Fontcuberta[2], L. Almasy[4], J.M. Soria[1].* 1) Genomics of Complex Diseases, IIB - Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; 2) Haemostasis and Thrombosis Unit, Department of Haematology, Hospital de la Santa Creu i Sant Pau, Universitat Autonoma de Barcelona, Barcelona, Spain; 3) Internal Medicine Department, Hospital de la Santa Creu i Sant Pau, Universitat Autonoma de Barcelona, Barcelona, Spain; 4) Department of Population Genetics, The Texas Biomedical Research Institute, Sant Antonio, TX, USA.

An increasing number of common diseases in humans, such as cancer, diabetes, cardiovascular diseases and neurological disorders, are associated with altered mitochondrial DNA levels. These altered mtDNA levels affect normal mitochondrial function. There is great interest in defining the factors that control mitochondrial biogenesis, especially the genes that regulate the mtDNA copy number. We searched for genetic variants that influence mtDNA levels using a genome-wide association (GWAS) method and families from the Genetic Analysis of Idiopathic Thrombophilia Project (GAIT). MtDNA levels were measured by quantitative real-time PCR in 386 individuals from 21 extended Spanish families. A GWAS using the Illumina infinitum 317 Beadchip was performed to detect single nucleotide polymorphisms (SNPs) associated with variation of mtDNA levels. The first GWAS was carried without regard for sex. In addition, association analyses were performed with individuals according to their sex. Also, we fine-mapped three linkage regions, which were sex-specific and that were reported previously in the same individuals. Twenty-two SNPs showed significant association with mtDNA levels (p value ≤ 1e-6). We grouped the SNPs according to sex-specificity, since 6 SNPs showed strong statistical significance in males only, 6 SNPs were strongly associated only in females and 10 SNPs showed significant associations with mtDNA levels independent of sex. These three mitochondrial-related genes *MGC25181*, *MRPL37* and *PARK2* harbour some of the SNPs with significant associations without regard for sex, in males only or in females only, respectively. Interestingly, fine-mapping within the male-specific linkage region that was reported previously (in GAIT) revealed the most significant SNP association with mtDNA levels, which was located in *MRPL37* when analyzed in males only. Our study demonstrates the potential to find genes using GWAS with families. This approach could help to identify genes that affect variation of mtDNA levels. Our objective was to dissect the sex-specific architecture of mtDNA and to describe the mechanisms involved in the control of this quantitative trait. However, our findings require replication and functional validation.

Genome-wide association study of juvenile idiopathic arthritis identifies novel susceptibility loci associated with early disease onset. *M. Marion[1], P. Ramos[1], M. Sudman[2], M. Ryan[2], M. Tsoras[2], S. Kramer[2], M. Wagner[2], D. Glass[2], C. Langefeld[1], S. Thompson[2].* 1) Department of Biostatistical Sciences and Center for Public Health Genomics, Wake Forest School of Medicine, Winston-Salem, NC; 2) Division of Rheumatology, Children's Hospital Medical Center, Cincinnati, OH.

Juvenile idiopathic arthritis (JIA) is the most common chronic childhood rheumatic disease in the Western world. It is comprised of several clinically heterogeneous groups of arthritides with onset before the age of 16 years. Given its early disease onset, JIA may have a stronger genetic contribution than other adult onset disorders. Our goal was to identify genetic risk factors associated with early age of onset in JIA. We performed a genome-wide association study (GWAS) in 771 Caucasian children with oligoarticular and polyarticular rheumatoid factor negative forms of JIA, using the Affymetrix SNP Array 6.0. Tests for association were adjusted for potential confounding effects of population structure by including principal components derived from the GWAS as covariates in logistic regression models. The strongest associations were in the nitric oxide synthase 1 adaptor protein (NOS1AP; rs10753784, P=4.0E-06), the chemokine ligand 2 (CXCL2; rs11815919, P=5.6E-06), and between the dendritic cell-derived BTB/POZ zinc finger (ZBTB20) and the T cell immunoreceptor with Ig and ITIM domains (TIGIT) genes (rs9837270, P=5.8E-06). None of these immune-related genes herein associated with early JIA onset have been associated with the presence of JIA. Current efforts are focusing on replication of top results. These results may help explain the genetic basis of JIA's clinical heterogeneity, and provide tools to aid in a more specific genetic-based phenotypic classification of the disease.

893T

A three-stage genome-wide association study in progressive multiple sclerosis. *F. Martinelli Boneschi[1], P. Brambilla[1], F. Esposito[1], H. Abderrahim[2], M. Rodegher[1], B. Colombo[1], L. Moiola[1], V. Martinelli[1], J. Hillert[3], E. Lindstrom[3], H.F. Harbo[4], A.B. Oturai[5], J. Wojcik[2], D. Booth[6], T.J. Kilpatrick[8], G. Stewart[6], J. Stankovich[7], J. Rubio[8], G. Comi[1].* 1) Department of Neurology, Scientific Institute of San Raffaele, Milan, Italy; 2) Merck-Serono Genetics Research Center, Geneva, Switzerland; 3) Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden; 4) Department of Neurology, Hospital and University of Oslo, Oslo, Norway; 5) The Danish Multiple Sclerosis Center, Department of Neurology, Copenaghen University Hospital, Rigshospitalet, Copenaghen, Denmark; 6) Westmead Millennium Institute, University of Sydney, Australia; 7) Menzies Research Institute, University of Tasmania, Tasmania, Australia; 8) Centre for Neuroscience, University of Melbourne, Melbourne, Australia.

Objective: To identify genetic susceptibility loci associated with the risk of progressive multiple sclerosis (PrMS). Methods: We conducted a genome-wide association study (GWAS) in 197 patients affected with primary progressive (PP), progressive-relapsing (PR) and single attack progressive (SAP) multiple sclerosis (MS) and 234 age- and sex-matched controls of Italian origin. We tested 20 SNPs with suggestive evidence of association in the GWAS study ($p \leq 10^{-4}$) in two independent sets of PPMS cases and healthy controls. Results: We identified a risk-associated SNP in the HLA region in linkage-disequilibrium (LD) with the DRB1*1501 and DQB*0602 loci with evidence of genome-wide significance (rs3129934T, pcombined= 6.7×10^{-16}, OR=2.34, 95% CI=1.90-2.87), and a novel locus on chromosome 7q35 with suggestive evidence of association (rs996343G, pcombined=2.4×10^{-5}, OR=0.7, 95% CI=0.59-0.83) present in an intergenic region which resides within a human endogenous retroviral (HERV) element, belonging to the HERV16 family. The new locus did not appear to have a “cis” effect on RNA expression in PBMCs, but pathway analyses of “trans” effect point to a regulation of the expression levels of genes involved in neurodegeneration, including glutamate metabolism (p<0.02) and axonal guidance signalling (p<0.03) . Conclusions: We performed a three-stage GWAS study in PrMS cases. We confirmed that the association of the HLA-DRB/DQB loci locus with MS is independent of disease course, while the second strongest signal was found for rs996343 which is in an intergenic region on chromosome 7 and could play a regulatory role.

894T

Evaluating genomic copy number variations in a Brazilian population of adult sickle cell anemia patients with and without stroke complication. *F. Menaa[1,2], MA. Bezerra[3], A. Silva Araujo[3], G. Ananina[1], P. Rodrigues Souza da Cruz[1], G. Pereira Gil[1], F. Ferreira Costa[2], M. Barbosa de Melo[1,2].* 1) Center of Molecular Biology and Genetic Engineering (CBMEG), Laboratory of Human Molecular Genetics, State University of Campinas, Campinas-São Paulo, Brazil; 2) Department of Hematology and Hemotherapy - HEMOCENTRO, School of Medical Sciences, State University of Campinas, Campinas-São Paulo, Brazil; 3) Department of Hematology and Hemotherapy-HEMOPE, Recife-Pernambuco, Brasil.

Background - Sickle cell anemia (SCA), an autosomal recessive disorder caused by a missense mutation (Glu6Val) in the beta polypeptide chain of hemoglobin, displays distinct clinical complications that suggest a complex etiology. To the best of our knowledge, little is known about the submicroscopic genomic alterations (e.g., SNPs, CNVs) among Brazilian SCA patients (SS), especially those with stroke-associated complication. The main purpose of our study was to identify, classify and compare the copy number variations (CNVs) in a cohort-case of Brazilian SS patients, in order to determine possible genomic regions associated with the risk of this critical complication. Material and Methods - Two independent groups of unrelated adult Brazilian SS patients - one with stroke and one without stroke - were enrolled in this study. The patient stratification was performed in accordance to eligibility criteria based on patient's information as well as clinical, laboratorial and imaging data when available. Genomic DNA was isolated from 2 ml of peripheral blood collected from each informed consent patient. CNVs were screened using the Genome-Wide Human SNP Array 6.0 (Affymetrix Inc., CA, USA) according to the manufacturer's instructions. Our comparative CNV analysis first focused on large events (> 100 kbps). Results - Comparing SS patients with stroke versus SS patients without stroke defined as reference, we observed an average of 13.22 ± 3.72 events per patient. The number of gain events was about 2.7 times higher than the number of losses. The de novo CNVs represented an average of 1.56 ± 1.51 per patient. This number of de novo CNVs could change, depending on the size of genomic fragments analyzed. We further observed genomic regions of major differences (e.g., 4q13.2, 14q11.2 or 15q11.1) containing known coding proteins (e.g., olfactory receptor family member). Current investigation of those CNV regions against our Brazilian healthy group population as well as against available HapMap populations, is providing a better understanding about the meaning of such genomic variations. Conclusions - Genome wide-association studies (GWAS) are opening new frontiers in the comprehension of some diseases. This study in the Brazilian population is getting extended to a much larger number of Brazilian samples and will be validated using other techniques (e.g., qPCR) and population groups. Financial support - FAPESP.

Translation of genomic medicine : Use of GWAS studies for drug repositioning. *V. Mooser[1], P. Agarwal[2], M. Barnes[2], L. Cardon[1], P. Sanseau[2].* 1) Genetics, GlaxoSmithKline, King of Prussia, PA; 2) Computational Biology, GlaxoSmithKl.ine, King of Prussia, PA.

The promises that GWAS studies would lead to novel therapeutics haven't materialized yet. This is due in part to the 10+year lag time between the time a new drug target is identified and the discovery and development of novel medicines modulating this target. One way to accelerate the translation from GWAS studies into clinical benefits is to use GWAS results to identify unsuspected indications for existing molecules. That is, some GWAS loci contain the target of existing drugs; if the conditions these loci are associated with differ from the diseases considered for these drugs, such mismatches may point to alternative indications for these drugs. To capture these opportunities, we first looked at the overlap between known drug targets and GWAS hits. The list of drug targets was derived from PharmaProjects; this database listed 3,613 marketed therapeutics and 10,093 drugs under development, which together target 1,191 human gene products. The list of GWAS hits was derived from the NHGRI database; on 02/03/11, this database reported 796 publications and 4,818 associations between a trait and a locus. We excluded associations with p > 10E-7, anthropometric traits and unreplicated associations, leaving 991 items. The overlap, consisting of GWAS hits containing genes for which there is a drug, consisted of 155 genes. For 49 genes (e.g. HMGCOaR), the drug (e.g. statins) indication (i.e. LDL-lowering) matched the GWAS trait (e.g. LDL-cholesterol). The remaining 106 associations were manually evaluated. We removed 57 GWAS traits which do not represent strong unmet medical needs (like platelet volumes) and GWAS hits containing several genes with ambiguous association with target genes. This left 49 potential repositioning opportunities. Thirty eight (78%) mismatches correspond to immunology target genes. An example is JAK2, an active drug target for Rheumatoid Arthritis, which is associated in several GWAS studies with Crohn's Disease. As such, these GWAS observation strongly support very recent trials designed to develop JAK2 inhibitors for Crohn's. In conclusion, GWAS studies have the potential to identify well-validated alternative indications for marketed medicines or molecules in development, especially for drugs designed to modulate immunology targets. These repositioning opportunities shall provide a much faster route to clinical utility for GWAS studies than the ab initio discovery and development of drugs targeting novel GWAS-derived loci.

A genome-wide association study identifies the association of HLA-DP locus with chronic hepatitis B and viral clearance. *N. Nishida[1, 2], H. Sawai[1], Y. Mawatari[1, 2], M. Yamaoka[1], A. Koike[3], K. Matsuura[4], Y. Tanaka[4], M. Sugiyama[2], k. Ito[2], M. Mizokami[2], K. Tokunaga[1].* 1) Dept Human Genet, Univ Tokyo, Tokyo, Japan; 2) Research Center for Hepatitis and Immunology, NCGM, Ichikawa, Japan; 3) Central Research Laboratory, Hitachi Ltd., Kokubunji, Japan; 4) Department of Virology & Liver unit, Nagoya City University, Nagoya, Japan.

In 2009, a genome-wide association study identified a significant association of chronic hepatitis B with a region including HLA-DPA1 and HLA-DPB1 using 179 Japanese individuals with chronic hepatitis B and 934 control individuals (Kamatani et al. 2009). We conducted a genome-wide association study, using an independent set of 181 Japanese individuals with chronic hepatitis B (CHB), 184 controls and 185 individuals who were recovered from HBV (HBsAg-negatibe and anti-HBc-positive), to identify the host genetic factors related with protective effects for CHB and/or viral clearance. All samples were genotyped using the Affymetrix Genome-Wide Human SNP Array 6.0 including more than 906,600 SNPs and more than 946,000 probes for the detection of CNVs (copy number variations). The genotype calls of a total of 906,600 SNPs were determined using the Birdseed algorism using the genotyping data with >95% QC call rate. The SNP filtering was performed using the following criteria: (i) SNP call rate≧95%, (ii) minor allele frequency (MAF)≧1% and (iii) deviation from Hardy-Weinberg equilibrium (HWE) P≧0.001 in control samples. We identified significant associations of chronic hepatitis B with 5 SNPs in a region including HLA-DPA1 and HLA-DPB1 in a GWAS using 181 individuals with chronic hepatitis B and 184 controls (rs3077; $P = 1.01 \times 10^{-7}$, OR=2.41 and rs3117229; $P = 3.25 \times 10^{-8}$, OR=2.41). We also found strong associations of chronic hepatitis B with SNPs in the same region in a GWAS using 181 individuals with CHB and 185 HBV-recovered individuals (rs3077; $P = 1.91 \times 10^{-6}$, OR=2.21 and rs3117229; $P = 2.88 \times 10^{-5}$, OR=1.97). In addition, we found several candidate genetic regions with $P<10^{-5}$ in the single-point association data based on allele frequency, which would be expected to be associated with viral clearance. Our findings confirmed the significant association of CHB with the HLA-DP locus using an independent set of Japanese individuals. In addition, the HLA-DP locus would be associated with clearance of hepatitis B virus with several other genetic factors. Further investigations are necessary to clear the molecular mechanism by which the HLA-DP locus and/or other genetic factors confer the risk of chronic hepatitis B and lead viral clearance. URLs. The results of the present GWAS will be registered at a public database: https://gwas.lifesciencedb.jp/cgi-bin/gwasdb/gwas_top.cgi.

Kawasaki disease (KD; OMIM 611775) is an acute systemic vasculitis syndrome of infants and young children. Previously we performed a genome-wide linkage study of affected sib pairs of KD and mapped several candidate loci for susceptibility genes. From these loci, we have identified SNPs in *ITPKC* at 19q13.2 and *CASP3* at 4q35 which confer risk for KD in the Japanese and Caucasian children. To identify additional KD risk loci, we performed a GWAS. We genotyped 447 KD cases for 551,767 tag SNPs on Illumina Human Hap550v3 BeadChip. As a control population, we used 3397 individuals constituted by 906 healthy adults and 2,491 adults with various common diseases unrelated to KD and genotyped them for 620,480 tag SNPs on Illumina Human610-Quad DNA Analysis BeadChip. After quality control, we compared frequencies of 463,883 autosomal SNPs in 438 KD cases and 3397 controls by Cochrane-Armitage trend test. Association with genome-wide significance ($P < 1.0 \times 10^{-7}$) was observed at two SNPs; $P = 8.0 \times 10^{-12}$ for SNP 1 and $P = 3.3 \times 10^{-8}$ for SNP 2, respectively. For validation of these two SNPs and following up of other marginally associated SNPs, we prepared two case-control panels (panel 1; 470 KD cases and 378 controls, panel 2; 284 KD cases and 569 controls) independent from those used in GWAS and genotyped them for the top 100 SNPs showing P values smaller than 6.3×10^{-5}. In both panels, SNP 1 showed association with KD and the P value in a meta-analysis was 2.0×10^{-21}. Initial association of SNP 2 was not replicated in either of the panels. Association of genome wide significance level was additionally achieved at five loci including those of *ITPKC* and *CASP3* in combined data analyses of GWAS and follow up studies. Thus we identified four novel susceptibility loci for KD. We believe further investigation of these loci will foster better understanding of the pathogenesis and pathophysiology of the disease.

GWAS in Neurofibromatosis Type 1 (NF1): progress update. *A. Pemov[1], H. Sung[2], A.F. Wilson[2], D.R. Stewart[1].* 1) NIH/NCI/DCEG, Bethesda, MD; 2) NIH/NHGRI/IDRB, Baltimore, MD.

Background. NF1 is known for phenotypic variable expressivity and limited correlation between genotype and phenotype. However, the cause of such variability is unknown. We hypothesize that this variable expressivity is genetically determined, in part, by elements other than variants in coding regions at the *NF1* locus. We tested this hypothesis with a genome-wide association study (GWAS) of quantitative NF1 phenotypes. **Methods.** A single observer quantified severity in multiple NF1 sub-phenotypes, including head circumference (OFC), and the number of café-au-lait macules (CALM), cutaneous neuorofibromas (cNF), Lisch nodules (LN) and cherry hemangiomas (CH). Germline DNA was hybridized on the Illumina Human OmniQuad-1M SNP genotyping array for 117 Caucasians (82 families, average family size = 1.4). Traditional test of association, ignoring family structure was performed on 605,630 SNPs (MAF >= 0.10) on the 22 autosomal chromosomes in an attempt to identify non-NF1 variants associated with sub-phenotypes. Each sub-phenotype was adjusted for selected covariates such as age, gender and eye color. **Results.** Several SNPs were identified for each studied NF1 clinical sub-phenotypes at a significance level of 10^{-5} reflecting the modest sample size. Significant SNPs for CH and LN sub-phenotypes resided in gene-free regions of the genome, while the SNPs for CALM, cNF and OFC were found inside *RPS6KA2*, *KCNJ6* and *FOXP2* genes, respectively. *RPS6KA2* encodes p90 ribosomal S6 kinase, which, like *NF1*, is a part of MAPK and mTOR pathways. *KCNJ6* encodes one of the subunits of inward rectifier potassium ion channels; it has been shown that inactivation of *NF1* in Schwann cells leads to increased levels of cAMP and as consequence to increased outward K+ current and cell proliferation. *FOXP2* is a transcription factor that controls expression of ~300 human genes and is highly expressed in developing brain; this gene is required for proper development of speech and language regions of the brain during embryogenesis **Conclusions.** We expect that GWAS of quantitative traits in NF1 to be a useful first step in understanding NF1 phenotypic diversity. Future analyses will include other NF1-related traits. Principal component analysis will be performed on these phenotypes to identify independent phenotypic components for analysis.

Genome-wide association of structural MRI data identifies variants associated with amygdala volume. *P.M.A Sleiman[1], T. Satterthwaite[2], K. Ruparel[2], C. Kim[1], R. Chiavacci[1], J. Richard[4], M.E. Calkins[5], R.C Gur[3], J. Loughead[2], R.E Gur[3], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Brain Behavior Laboratory Neuropsychiatry Section Department of Psychiatry University of Pennsylvania Philadelphia, PA 19104; 3) Department of Psychiatry University of Pennsylvania Philadelphia, PA 19104; 4) Director, Computerized Neurocognitive Testing/Research Data Manager Department of Psychiatry/ Neuropsychiatry Section University of Pennsylvania Medical Center 10th Floor Gates 3400 Spruce Street Philadelphia, PA 19104; 5) Schizophrenia Research Center and Brain Behavior Laboratory Department of Psychiatry, Neuropsychiatry Section University of Pennsylvania School of Medicine 9 Maloney, 3600 Spruce Street Philadelphia, PA 19104.

We carried out a genome-wide association study of cortical and subcortical brain volumes derived from the structural MRI data of 374 individuals, comprising 189 Caucasians and 185 African Americans, all were between the ages of 8 and 21. All samples were genotyped on either Illumina HH550 or HH610 arrays, SNPs common to both were carried forward after standard quality controls. Genetic ancestry was determined by principal component analysis. Volumetric data for whole brain, grey matter, white matter and individual subcortical regions was scaled to account for differences in intracranial volume and tested for association as quantitative traits in linear models. After multiple testing correction, variants at one locus on chromosome 11p15 remained significantly associated with amygdala volume ($P = 1.6x10^{-8}$). All associated variants mapped to a single gene, NAV2, that is highly expressed in the nervous system in both developing embryos and adults. Previous work suggests the gene is a cytoskeletal-interacting protein that functions in neurite outgrowth and axonal elongation. Interestingly, homozygous mouse mutants have previously been shown to exhibit reduced cerebellar volume, which resulted from a reduction in the number of cells undergoing proliferation, limiting the expansion of the cerebellar primordium during development. We will therefore report on the identification of the first genetic variants associated with amygdala volume in both Caucasians and African Americans using subcortical volumetric data derived from structural MRI. There is intense interest in the volume of the human amygdala and its asymmetry between the hemispheres in relation to a broad range of phenotypes including fearfulness, emotion recognition, neuropsychiatric conditions such as autism, schizophrenia and bipolar, normal ageing and neurodegenerative disorders such as Alzheimer's and even obesity and cardiovascular disease. The identification of common variants that influence normally developing human amygdala volume could therefore inform research across a broad range of phenotypes.

A Genome-Wide Association Study Examining Obese Factors in an Arab Family with a History of Type 2 Diabetes. *G. Tay[1], H. alsafar[2], H. Cordell[3], S. Jamieson[4], K. Khazanehdari[5], R. Francis[4], J. Blackwell[4,6], alsafar.* 1) Centre for Forensic Science, The University of Wes, Perth, Australia; 2) Khalifa University of Science, Technology and Research; 3) Institute of Human Genetics, Newcastle University, Newcastle upon Tyne, United Kingdom; 4) Telethon Institute for Child Health Research, Centre for Child Health Research, The University of Western Australia, Subiaco, Western Australia; 5) Molecular Biology and Genetics, Central Veterinary Research Laboratory, Dubai, United Arab Emirates; 6) Cambridge Institute for Medical Research and Department of Medicine, School of Clinical, Medicine University of Cambridge, Cambridge, United Kingdom.

ABSTRACT Overweight and obesity are major risk factors for a number of chronic diseases, including Type 2 Diabetes (T2D), cardiovascular disease and cancer. In the United Arab Emirates (UAE), it has been estimated that some twenty percent of adults suffer from obesity. The incidence of T2D in the UAE population is also among the highest in the world. To identify factors that result in obesity, and its association with T2D, we conducted a Genome-Wide Association Study (GWAS) and specifically assessed genetic associations with “Body Mass Index” (BMI) and “Waist Circumference” (WC). GWAS analysis of 178 individuals in an extended family of Arab descent revealed four loci that reached genome-wide significance, two of which were found in previous studies. The previously described association between the Single Nucleotide Polymorphism (SNP) at position rs2793823 within the ADAM30 locus (identified through meta-analysis of a GWAS study of subjects of Caucasian descent) was also shown to be associated with the disease in Arabs (p = 1.86E-8). Our study also confirmed the association between SNPs within the JAZF1 loci and BMI, WC and T2D as reported in other studies. Two novel associations were noted in our study: (1) a novel locus on chromosome 16 within the FBXO31 locus (rs9308437, p = 7.5E-7) was shown to be associated with the WC phenotype, and (2) the SNP (rs7120774) in GALNTL4 of chromosome 11 was found to be associated with BMI (p =1.82E-10). FBX031 is a candidate gene for breast cancer, whereas GALNTL4 plays a role in insulin stimulated glucose transport in muscle. Work continues to replicate the two latter findings in independent cohorts to confirm the involvement of FBXO31 and GALNTL4.

London, Institutes of Health, Department of Health and Human Services, Research Triangle Park, North Carolina, USA.

Lung function measures are heritable traits that predict population morbidity and mortality and are used in the diagnosis of chronic obstructive pulmonary disease. Recently, two large meta-analyses of genome-wide association studies (GWAS), each of them with sample sizes over 20,000 individuals of European ancestry, discovered novel loci associated with lung function. To increase the power to detect genetic variants of modest effect sizes we undertook a larger meta-analysis including a total of 23 lung function GWAS in Stage 1 (n=48,201) and followed-up potentially novel loci in 17 studies in Stage 2 (n=46,411). In each study, forced expiratory volume in 1 second (FEV1) and the ratio of FEV1 to forced vital capacity (FVC) were adjusted for age, sex, height and ancestry principal components, and inverse normal transformed. Additive genetic models stratified for ever/never-smoking status were used to test the association of approximately 2.5 million genotyped or imputed SNPs with the adjusted traits. Inverse variance weighting was used to meta-analyse the smoking strata within studies first and then to obtain the pooled estimates across studies in Stage 1 and 2. Ten previously discovered loci (*TNS1, FAM13A, GSTCD/NPNT, HHIP, HTR4, ADAM19, AGER, GPR126, PTCH1,* and *TSHD4*) showed genome-wide significance (P<5x10^{-8}) in our Stage 1 data. We also describe novel loci reaching genome-wide significance after meta-analysing Stage 1 and 2 and the relation of these loci to other complex traits. These new loci may provide insight into the molecular mechanisms regulating pulmonary function and into molecular targets for future therapy to alleviate reduced lung function.

902T

Genome-wide association analysis of rare variants with Type 2 Diabetes. *M.E. Travers[1], R. Magi[2], J. Chen[2], K. Gaulton[2], A.L Gloyn[1], M.I McCarthy[1,2], I. Prokopenko[1,2], A.P Morris[2].* 1) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Genome-wide association studies (GWAS) of common variants have been successful in identifying novel type 2 diabetes (T2D) susceptibility loci. However, the joint effects of these common variants account for no more than 15% of T2D heritability. The aim of this study was to assess the evidence for association of T2D with rare genetic variation, defined here to have minor allele frequency (MAF) less than 0.01 (1%), through imputation from existing GWAS genotyping data.

We performed imputation in 1,926 T2D cases and 2,942 controls of European descent genotyped using the Affymetrix 500K GeneChip. Imputation was undertaken using the European reference panel from the 1000 Genomes Project (August 2010 release). We tested for association of T2D with accumulations of minor alleles at rare variants within genes. The analysis was performed using GRANVIL, which models disease status as a function of the proportion of rare variants at which an individual carries a minor allele in a logistic regression framework.

The strongest signal of association was observed for *BMP2* (p=1.0x10-6, genome-wide significant correcting for 30,000 genes). Common variants within this gene are associated with height and body mass index. The gene contained 36 rare variants (mean MAF = 4.3x10-3), with odds ratios of 1.26 (1.15-1.38) per minor allele. Strong evidence of association (p<10-5) was also observed for *IGFL4* (p=2.4x10-6) and *CLK3* (p=6.4x10-6). *IGFL4* belongs to a family of signalling molecules that play crucial roles in cellular energy metabolism and in growth and development.

We have designed and validated assays to genotype nine of the most strongly associated variants, and our validations have confirmed presence of the expected rare variants in samples with the highest confidence imputation. Further genotyping will assess the overall accuracy of imputation using this reference panel, as well as the impact of replication genotyping upon disease association strength. Our analysis has demonstrated strong evidence of association of T2D with rare variation in three genes. Our results highlight the potential for the identification of rare variant associations using existing GWAS genotyping data, supplemented with imputation from high-density reference panels, without the need for costly re-sequencing experiments.

Genome-wide Association (GWAS) Results in dbGaP. *Z. Wang, Y. Jin, M. Xu, Y. Shao, M. Kimura, R. Bagoutdinov, N. Popova, J. Paschall, N. Sharopova, S. Pretel, A. Sturcke, L. Hao, L. Ziyabari, L. Phan, S. Sherry, M. Feolo.* Information Engineering Branch, National Center for Biotechnology Information, NLM/NIH, Bethesda, MD 20892, United States.

A huge investment in genome-wide association studies (GWAS) in the past few years have produced billions of associations between genetic variants and phenotypic or exposure variables or biomarkers. In most cases, the volume of generated data is so large that only the associations with the lowest p-values are reported in manuscripts. Consequently, many genetic association results are not accessible to public even though they may account for a non-trivial fraction of variance contributing to an inherited trait. Since 2006, NCBI's dbGaP has been populated with over 3100 analysis datasets, including 2808 allelic association and/or linkage scans from approximately 1000 traits in the Framingham Cohort and ~300 other result sets spanning 44 different dbGaP studies. These submitter-produced results are curated, linked to existing NCBI resources, and included as controlled access components available to researchers authorized to download data for that study. Public users can visit the dbGaP Association Results Browser website: http://www.ncbi.nlm.nih.gov/projects/gapplus/sgap_plus.html and efficiently query for significant results by SNP identifier (rs#), chromosomal location, gene, or phenotype trait (MeSH term). Users can explore dbGaP association results using dbGaP interactive genome display, where testing statistics such as p-value, effect size (OR and Beta) and the coding allele (QTL), genotype quality (call rate and p-value from HWE test) are shown on a sequence view that contains recombination rates, genes, proteins and neighboring markers in that region. The locus positions, feature orientations and alleles are updated with successive Genome and dbSNP builds. The data presented in the browser for each analysis are downloadable from the public dbGaP ftp site. The original submission, including genotype counts and allele frequencies, are fully accessible through NCBI Controlled Access system. This presentation will describe the current association results, use of tools to explore and download the results, and future development of GWAS results data at dbGaP.

904T

A New Reference Dataset for Imputing Common and Uncommon SNPs. *Z. Wang[1,2], K.B. Jacobs[1,2], M. Yeager[1,2], A. Hutchinson[1,2], J. Sampson[1], M. Tucker[1], S.J. Chanock[1].* 1) Core Genotyping Facility, SAIC-F/NCI, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD.

Statistical imputation of SNP genotype data is a commonly used technique in the analysis of genome-wide association studies. This approach is used to infer additional genetic variants to test for association with medically-relevant states, to remove missing data from dense datasets to add statistical power or to apply methods that are intolerant of missing data, and most importantly to allow the combined analysis of genotype data obtained from different SNP assays and assay versions. The accuracy of genotype imputation depends on the size, data quality and population representation of the imputation reference panels. We have developed a dataset that, in combination with data from HapMap and 1000 Genomes Project, is a novel set for performing genotype imputation of common and uncommon SNPs (MAF greater than 1%): (1) ~750 cancer-free individuals of European descent from three large prospectively sampled cohort studies genotyped on the Illumina HumanHap1M, HumanOmni1M, HumanOmni2.5 arrays; (2) 75 African American individuals and 75 Chinese individuals genotyped on the HumanOmni2.5 array; and (3) 441 HapMap samples genotyped on the HumanOmni2.5 array. The cleaned and harmonized dataset contains approximately 3.1 million SNPs and 1,300 individuals. Using this reference set, we explore different imputation scenarios starting from datasets genotyped using the Illumina HumanHap660W and HumanOmniExpress assays. We show a substantial improvement in imputation accuracy when using our reference panel to impute all 3.1 million SNPs versus the standardly used combination of 1000 Genomes and HapMap data for both scenarios using the IMPUTE2 and BEAGLE software. We also demonstrate several interesting results on the power of imputation analysis when the reference population does not precisely match that of the inference set and for hybrid genome-wide scans that combine data from the Illumina HumanHap660W and OmniExpress assays. This reference dataset will be shared with the scientific community through the NCBI dbGaP portal and be provided as conventional genotype data files, preformatted for use with the IMPUTE2, Beagle and MACH software. An upcoming version of the dataset will include Affymetrix 6.0 array data and additional data from non-European populations. Funded by NCI Contract N01-CO-12400.

Genome-wide association study identifies novel susceptibility candidates for Kawasaki disease. *J. Wu[1], Y. Lee[1], F. Tsai[2], L. Chang[1], Y. Liu[1], Y. Chen[1], C. Chen[1], Y. Chen[1].* 1) Institue Biomedical Sci, Academia Sinica, Taipei, Taiwan; 2) Department of Medical Genetics, Medical Research and Pediatrics, China Medical University Hospital, Taichung, Taiwan.

Kawasaki disease (KD) is an acute systemic vasculitis syndrome that primarily affects infants and young children with epidemiological observations suggesting a substantial genetic contribution to disease susceptibility. Taiwan has the third-highest incidence of KD in the world, after Japan and Korea. To investigate novel mechanisms that might predispose individuals to KD, we conducted a genome-wide association study (GWAS) in 622 KD patients and 1107 controls in a Han Chinese population residing in Taiwan, and further validated our findings in an independent Han Chinese cohort of 261 cases and 577 controls. Three loci with most strongly associated single-nucleotide polymorphisms (SNPs) were detected, of which two novel loci were identified and a COPB2 locus previously identified in GWAS was confirmed. The first novel locus is associated with the tolerance mechanisms of B cells; the second locus is involved in stimulatory signal of immune response. Both regions were previously identified associated with several other autoimmune diseases. These findings have implications for understanding the immune activation in KD pathogenesis.

906T

In search of genetic attributors of handedness. *M. Xu[1], G. Pare[4], P. Kraft[1], E.B. Rimm[1,2], D.J. Hunter[1,2], D. Chasman[4], J. Han[1,2,3].* 1) Epidemiology, Harvard School of Public Health, Boston, MA; 2) Channing Laboratory, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston; 3) Clinical Research Program, Department of Dermatology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 4) Division of Preventive Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

About 10% of humans are left-handed and it has previously been estimated from twin studies that the heritability of handedness is around 24.64%. Left-handedness has been shown to be associated with pathological conditions such as lower birth weights, higher incidence of schizophrenia. We conducted genome-wide association studies (GWAS) of genotyped and imputed 2.54 million SNPs (data set 1) on handedness with 9,428 subjects and another GWAS in an independent population with 18,994 subjects (data set 2) followed by a meta-analysis of these two GWASs. The rs16879276 SNP on chromosome 6 had the smallest p-value 2.8 x 10-7, which is 64kb upstream of ATXN1, a gene that is associated with schizophrenia and ataxia (inability to coordinate muscle movements). GWAS with data set 1 identified a SNP rs6719499 on chromosome 2 with p-value = 1.04 x 10-6 in the CTNNA2 gene region previously reported to be associated with handedness and schizophrenia, and the p-value of this SNP is 0.0013 in the meta-analysis. To investigate the role of common variants in handedness heritability, we used 151,154 SNPs genotyped in data set 2 and either genotyped or imputed with R-squared greater than 0.99 in dataset 1 to estimate additive genetic contribution to handedness and found these SNPs explain 14.7% (95% CI 0, 35.3%) variance. After adjusting for the top 4 eigenvectors, these SNPs explain 4.22% (95% CI 0, 26.9%) variance, suggesting the strong influence of population stratification on handedness for either genetic or cultural implications. Analyses on the eigenvectors found the Jewish groups have significantly higher incidence (10.8%) of left-handed people than other religious groups (7.0%). The low percentage of variance explained by commons SNPs suggests a large portion of handedness heritability may come from other genetic factors such as rare SNPs, imprinting, and copy number variation whose information is not contained in the common genetic variants.

907T

Bimodality filtering to prioritize genes for eQTL analysis of allelic imbalance. *K. Azad[1,2], B. Ge[4], T. Pastinen[4,5], C.M.T. Greenwood[1,2,3].* 1) Lady Davis Institute for Medical Research, Montreal, QC, Canada; 2) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, QC; 3) Department of Oncology, McGill University, Montreal, QC; 4) McGill University and Genome Quebec Innovation Centre, Montreal QC; 5) Department of Human Genetics, McGill University, Montreal, QC.

Introduction: eQTL analysis usually involves many tests looking for associations between cis-SNPs and gene expression levels. However, severe corrections for multiple testing are necessary due to the number of tests performed. Here, we are investigating a two-stage process to prioritize genes for eQTL analysis of allelic imbalance, by first identifying genes showing evidence for bimodal distributions of allelic imbalance. Association tests at bimodal genes are then given higher priority. We expect this strategy to lead to increased specificity.

Methods: High-density SNP genotype data for 11,365,000 markers, after imputation, was extracted for the 56 YRI samples from HapMap. We use a Tukey-biweighted mean of allelic imbalance across all heterozygous SNPs within each gene to obtain a measure of differential allelic expression. We then use three indexes of bimodality, variance reduction score (VRS), bimodality index (BI), and the dip test (DIP) of unimodality, to identify a subset of genes whose distributions seem to support a two-component mixture model. In this subset, we look for cis associations between allelic imbalance and nearby SNPs in a window around each gene +/-50kb.

Results: Among 5005 full-length transcripts on chromosome 1, bimodality could be evaluated for all but 29. Intraclass-correlation (ICC) was high (0.7) for VRS and BI, but DIP agreed poorly with the other two (ICC of all three measures: -0.4). On chromosome 1, we selected the genes with top 2% evidence for bimodality by any of the 3 measures, obtaining 282 bimodal genes. For 48 of these bimodal genes, at least one nearby SNP was associated with allelic imbalance with a p-value less than 0.001.

Conclusions: It is interesting that a large proportion of these genes demonstrating evidence of bimodality are not associated with a nearby common SNP. We anticipate that additional power to detect cis-SNPs will be obtained by this 2-stage strategy combined with stratified false discovery rate estimation.

908T

A linear complexity HMM phasing method for unrelateds and nuclear families. *O. Delaneau[1,2], J. Marchini[2], J.F. Zagury[1].* 1) Chaire de Bioinformatique, Conservatoire National des Arts et Métiers, Paris, France; 2) Department of Statistics, University of Oxford.

Phase information in diploid sequences is of crucial interest in genetic studies of human disease and population genetics. However, experimental methods to determine this information are still in development, making statistical alternatives widely used in practice. With datasets ever increasing in the number of markers, samples and diversity of populations from which samples originate, as highlighted by the 1000 Genomes Project, it is important to develop accurate, fast and flexible statistical phasing methods. Here we describe a phasing method called SHAPEIT, that relies on the same Gibbs sampler scheme used by methods such as PHASE, IMPUTE or MACH, but differs in the way that each individual's haplotypes are updated conditional upon the other haplotypes in the sample. We have made two improvements to this core step. First, we build a graph representation of the full list of the conditioning haplotypes on which we can derive a compact hidden Markov model (CHMM) similar to the Li & Stephens model but with a limited number of states. Second, we use a separate graph per individual to represent the space of possible haplotypes consistent with each individual's genotypes. The transition probabilities between nodes of this graph are quickly computed using the CHMM and then pairs of haplotypes consistent with each genotype can be efficiently sampled. This new method has several notable features (1) it scales linearly in the number of haplotypes used in each iteration, which leads to improved accuracy and speed, (2) it can handle mixtures of unrelated samples and small nuclear families, (3) it can be run efficiently on whole chromosomes at once, and (4) phasing uncertainty is captured within the graph constructed for each individual. We illustrate the improved performance of the method compared to IMPUTE, BEAGLE, FASTPHASE and MACH on several real datasets with both European and African ancestries.

RNA Polymorphisms: Impact on the Transcriptome and on Complex Traits. *E.R. Gamazon[1], D.S. Park[2], N.J. Cox[1].* 1) University of Chicago, Chicago, IL; 2) Columbia University, New York, NY.

RNA editing characterizes a wide variety of molecular phenomena in which nucleotide information in an RNA molecule is modified, causing a difference between the amino acid sequence of the encoded protein and the predicted sequence from the template genomic DNA. The mechanisms by which these differences between DNA template and RNA product arise remain to be elucidated, and their biological implications are little understood. Recent advances in assaying the genome and the transcriptome at single nucleotide resolution may facilitate studies of RNA editing and promise to expand our understanding of this relatively novel form of gene regulation. While studies of disease susceptibility and drug response have focused on DNA sequence polymorphisms or mRNA expression variability, RNA sequence polymorphisms are likely to contribute to the etiology of at least certain complex traits. In this study, we set out to clarify the biological impact of DNA and RNA sequence differences. Using RNASeq data from samples of European and African ancestry, we uncovered loci with high coverage where the DNA and RNA sequences show a consistent type of nucleotide difference in multiple individuals within each population and across populations. Through the use of an independent gene expression assay, we found that genes with RNA editing sites are significantly enriched for the most differentially expressed genes across a range of p value thresholds. We conducted a systematic study of the genes identified as harboring such RNA editing sites for their role in pharmacologic phenotypes. Our findings strongly support the hypothesis that identified and validated DNA-RNA differences have biological significance and their inclusion in studies of complex traits are likely to advance our understanding of etiology.

910T

TAG-PCR allows rapid high-throughput sequencing of targeted genomic regions in pooled barcode-labeled samples. *G. Haller, C. Cruchaga, A. Goate.* Department of Psychiatry Washington University 660 S. Euclid Ave. St. Louis, MO 63110.

We demonstrate the use of Tagged, Adapter-ligated Genomic DNA (TAG) fragments as template for the amplification and sequencing of targeted genomic regions in pooled samples using next-generation technology. Individual DNA samples were prepared for Illumina sequencing using single-end barcoded adapters. Samples were then pooled and used as the template for PCR amplification of targeted genomic regions using one primer complimentary to the adapter used for Illumina sequencing and one region-specific primer with a 5' overhang complementary to the second adapter and ending with a biotin molecule. The product of this reaction was then purified with streptavidin-coated magnetic beads and sequenced on an Illumina GAIIx. Using this method, we sequenced the entirety of the *TAS2R16* gene in 96 individuals. We obtained ~20 million reads from one lane of single-end 36bp Illumina sequencing. These reads were first separated based on barcode, allowing a total of ~19 million reads (95%) to be unambiguously assigned to one of the 96 sequenced individuals. Barcodes were specifically designed to differ from all other barcodes at a minimum of 2 sites, allowing even those reads containing one misincorporated base to be assigned. Reads for each individual were then aligned to the reference sequence using MAQ. Greater than 30% of individual assigned reads aligned to amplified regions. This figure will likely improve with changes to the PCR protocol as well as primer characteristics, however. Individual genotypes were then determined at all sites with at least 8-fold coverage. Variant calling was possible at an average of 95% of sequenced sites across the sequenced individuals. We then validated a subset of sites found to be polymorphic using previously obtained genotyping results. All chosen predicted polymorphic sites were confirmed. Dideoxy-sequencing of 10 sequenced individuals across the entirety of *TAS2R16* verified the absence of variants not identified by pooled sequencing. Additionally, TAG-PCR utilizes DNA samples prepared and pooled before amplification, reducing reagent costs substantially, allowing for rapid sequencing of future loci of interest within the same pooled sample and providing the flexibility to sequence hundreds of loci in a single individual or a single locus in hundreds of individuals.

911T

High-throughput single molecule DNA mapping in nano-channels. *E.T. Lam[1], A. Hastie[2], D.S. Ehrlich[1], D. Somas[2], M.D. Austin[2], P. Deshpande[2], C. Lin[1], H. Cao[2], M. Xiao[2], P.-Y. Kwok[1].* 1) Institute of Human Genetics, University of California, San Francisco, San Francisco, CA; 2) Bionanomatrix, Philadelphia, PA.

Many genomes from normal and diseased individuals have recently been sequenced by short-read technologies. The advancement in sequencing has led to better characterization of single-nucleotide variants. Despite the explosion of data, mapping of short reads relies on the reference genome sequence, and de novo genome assembly using short reads remains difficult. Also, structural variants and long-range haplotypes are inferred from short sequencing reads by computational means with great uncertainty. In-depth analysis of structural variants requires laborious methods such as PCR and fluorescence in situ hybridization. Here, we present an optical mapping approach that complements short-read data in sequence assembly and analysis of structural features. Silicon-based nano-channels are fabricated for uniform DNA linearization. Labeling of sequence-specific sites and subsequent high resolution imaging of DNA molecules enable analysis of individual DNA molecules of several hundred kilobases (kb) in a linear, single haplotype form. To illustrate the utility of our method in mapping, we have used previously mapped bacterial artificial chromosomes (BACs) to reconstruct the major histocompatibility complex (MHC) region, a gene-rich and highly polymorphic region important for immune functions and known to be structurally complex. 49 BACs from the PGF library and 46 BACs from the COX library were analyzed as single BACs and as mixtures. An automated pipeline was used for unsupervised clustering of molecules with different labeling patterns, deriving consensus optical maps, and assembly. Molecules from individual BACs were recovered, and labels of more than 2 kb apart could be clearly resolved. In parallel, the BACs were sequenced using the Illumina HiSeq 2000 for comparison of short-read sequencing and our method for assembly of the MHC region. Our approach will enable high-throughput assembly of structurally complex regions and characterization of structural variants.

Genomic Analysis of 15q Duplication/Deletion Disorders Reveals Differential Regulation of Genes with FOXP1 and NF-Y Binding Sites. *L. Reiter[1,2,3], T.J. Bischell[4], W. Taylor[2,5], N. Urraca[1].* 1) Dept Neurology, UTHSC, Memphis, TN; 2) Dept. of Anatomy and Neurobiology, UTHSC, Memphis, TN; 3) Dept. of Pediatrics, UTHSC, Memphis, TN; 4) Vanderbilt Kennedy Center, Vanderbilt University, Nashville, TN; 5) Molecular Resource Center, UTHSC, Memphis, TN.

Angelman syndrome (AS) and interstitial duplication 15q autism (int dup(15)) are two reciprocal genomic disorders caused by maternal allele deletion or duplication of the 15q11.2-q13 region. Although AS is caused by maternal loss of the *UBE3A* gene most AS patients have a more complex phenotype, in part due to the deletion of additional genes at the 15q locus. Maternal duplications of this region cause an autism phenotype, while paternal duplications do not, clearly implicating the maternally expressed *UBE3A* gene in the autism phenotype. Although *UBE3A* is not imprinted in peripheral blood mononucleocytes (PBMC), UBE3A protein levels are elevated in blood. We investigated both chromatin and gene expression changes in blood from three int dup(15) Class II and three reciprocal AS deletion Class II subjects to identify global genomic and gene expression changes that may influence the AS and autism phenotypes. Using whole genome sequencing combined with formaldehyde-assisted isolation of regulatory elements (FAIRE) we identified 1104 regions of differential open chromatin in AS deletion and 2344 regions int dup(15) indicating global changes in chromatin could influence gene expression in these regions. Microarray analysis from PBMC revealed 1236 genes that were elevated in AS deletion PBMC vs int dup(15) and 981 genes that were elevated in int dup(15) vs AS deletion PBMC (pval<0.05). As expected, significant differences in expression were found for genes in the duplicated/deleted locus like *UBE3A*, *ATP10A* and *HERC2*. Among the 981 genes elevated in int dup(15) there was a significant enhancement for genes with binding sites for transcription factors NF-YA and FOXP1. Although we expected to find peaks indicative of open chromatin at loci for differential gene expression, we actually found a large set of genes with FAIRE peaks in AS deletion but increased transcription in Int dup(15) subjects. Among these were genes involved in chromatin remodeling, DNA repair and neurogenesis. This combined chromatin and microarray analysis provides the first insights into transcriptional changes which may be mediated by the transcriptional co-activation function of the UBE3A protein unveiling new sets of genes and pathways contributing to both AS and int dup(15) autism pathogenesis.

Extensive characterization of NF-2B binding uncovers non-canonical motifs and advances the interpretation of genetic functional traits. *D. Wong[1], A. Teixeira[1], S. Oikonomopoulos[1], P. Humburg[1], I.N. Lone[3], D. Saliba[2], T. Siggers[5], M. Bulyk[5,6,7], D. Angelov[3], S. Dimitrov[4], I. Udalova[2], I. Ragoussis[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Kennedy Institute of Rheumatology, Imperial College, 65 Aspenlea Road, London W6 8LH, UK; 3) Université de Lyon, Laboratoire de Biologie Moléculaire de la Cellule, CNRS-UMR 5239/INRA 1237/IFR128 Biosciences, Ecole Normale Supérieure de Lyon, 46 Allée d'Italie, 69007 Lyon, France; 4) Université Joseph Fourier - Grenoble 1; INSERM Institut Albert Bonniot, U823, Site Santé-BP 170, 38042 Grenoble Cedex 9, France; 5) Division of Genetics, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA; 6) Harvard-MIT Division of Health Sciences and Technology (HST), Harvard Medical School, Boston, MA 02115, USA; 7) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA.

Genetic studies have provided ample evidence of the influence of non-coding DNA polymorphisms on trait variance, particularly those occurring within transcription factor binding sites (TFBSs). Protein binding microarrays and other high-throughput platforms that map TFBS with great precision have enhanced our understanding of how a single nucleotide polymorphism (SNP) can alter binding potential allowing for a prediction of its effect on a TFBS. When used in conjunction with ChIP-Seq, these enable allele-specific analyses of expression and DNA-TF interactions on a genome-wide scale. We have used both arrays and Electrophoretic Mobility Shift Assay-Sequencing (EMSA-Seq), a deep sequencing based method we developed to analyze the DNA binding preferences of 9 distinct NF-2B TF-dimers. Despite this TF-family being one that has been extensively studied, our understanding of its DNA binding preferences is largely limited to the consensus motif, GGRRNNYYCC which was first described 25 years ago. We highlight differences in the binding preferences of NF-2B family members and also, put under the spotlight non-canonical motifs that are bound by NF-2B dimers and that may be found within genomic regions in which a canonical motif is not evident. When overlaid onto a dataset describing the binding of NF-2B RELA immunoprecipitated from lymphoblastoid cells across eight individuals (Kasowski *et al*., 2010), our binding affinity data enhances the interpretation of TF-binding across 1405 genomic regions laden with SNPs. The overall approach is equally applicable to other TFs and is a relevant resource for immunologists, geneticists and systems biologists and the wider scientific community.

Characteristics of an Online Consumer Genetic Research Cohort. *J.Y. Tung, N. Eriksson, A.K. Kiefer, J.M. Macpherson, B.T. Naughton, A.B. Chowdry, C.B. Do, D.A. Hinds, A. Wojcicki, J.L. Mountain.* 23andMe, Inc, Mountain View, CA.

The increasing availability of internet access and the decreasing costs of generating genetic information have created a new group of individuals who are active internet users with access to their own genetic information. We hypothesized that these individuals would be interested in sharing their genotypic and phenotypic information for research if given the opportunity to do so by providing data online, thus removing any geographic restriction for participating in a study. All customers of 23andMe, a direct-to-consumer genetic testing company, were recruited for an ongoing research project entitled 23andWe. We evaluated consent rate, demographics (including sex, age, education, self-identified race, and genetic ancestry), and research questionnaire response rate in this cohort. Most customers consented to participate in 23andWe, and the majority of those further agreed to have their saliva sample banked and also potentially used for future research. Over half of participants answered at least one research question, with an average of 10 questionnaires completed, and 75 singular "Research Snippet" questions answered. Despite the fact that the majority of customers did not obtain the 23andMe service in order to participate in research, we have found that most are willing to contribute their data for research and that more than half actively contribute additional phenotypic data online, suggesting that tapping into consumer interest in genetics and research is a viable method for conducting large-scale studies.

Simultaneous Evaluation of Small RNA, Whole Transcriptome, Whole Genome and Targeted Resequencing on Next Generation Sequencing Platforms. *C. Patel, N. Fong, J. Briggs, Q. Doan, M. Storm, Y. Sun, P. Kinney, R. Padilla, H. Shepherd, L. Joe, T. Burcham.* Life Technologies, Foster City, CA.

Researchers are using Next Generation Sequencing platforms to support more and more applications. It is critical for such platforms to be flexible enough to support many applications at the same time while maintaining low cost, high quality and high throughput. In this study we describe the development of an end to end solution from sample prep to analyzing the sequencing run. The test was to interrogate up to six independent samples simultaneously on a single run. In a single run we sequenced two lanes with single-plex human long mate pair sample, a multi-plex of universal human reference whole exome, ChIP-Seq sample, a kinome enriched sample, and a whole transcriptome sample. Each sample type used required a different sequencing run, yet with this new process they all were run together saving time, reagents, and freeing the researcher from having to wait to collect sample of the same type to run together.

Enhancer mixture for amplifying genes with CpG islands in PCR. *F. DE LA CRUZ-RUIZ, M.C. MARTINEZ-LOPEZ, J.L. CORTES-PEÑALOZA, D. CADENA-SANDOVAL, E. ZAMARRON-LICONA.* LABORATORIO DE DIAGNOSTICO MOL, Universidad Juárez Autónoma de Tabasco (UJAT), VILLAHERMOSA, TABASCO, Mexico.

Summary Background: Several biological additives have been used to make sure polymerization in GC-rich DNA sequences Objective: To design a PCR enhancer mixture for amplifying genes with CpG islands. Methods: Fragments of IRS2 and HNF1(; genes were analyzed using EMBOSS CpG Report software, Primers were designed with the Primer3 software and were tested with e-PCR. Three additives were used: BSA (0,1 µg/µl), DMSO (5%) and Formamide (5%), in five assays of PCR, two using one additive, two combining two additives and one with all additives. DNA sequences were amplified with the enzymes: Taq native, recombinant and platinum. Amplicons quality was tested by sequencing. Results: HNF1(gene were amplified only with the three enzymes with no additives, however sequence was not pure. IRS2 gene sequences achieved pure amplification in all fragments with the whole enzymes package and DMSO-BSA-Formamide mixture addition. Conclusion: DMSO-BSA-Formamide mixture can be used to obtain GC-rich DNA amplicons with such a high quality that generates pure chromatograms during sequencing.

917T

Non-invasive specimen collection for molecular diagnostics and point-of-care testing. *C. Dobbin, M. Abdalla, M. Elmogy, W.-S. Kim, Y. Haj-Ahmad.* Norgen Biotek Corp, Thorold, Ontario, Canada.

Blood has traditionally been the specimen of choice for various molecular diagnostic analyses of disease-specific biomarkers. However, there are a number of drawbacks when using blood for diagnostics, including: 1) it is complicated to collect, requiring highly trained personnel; 2) it is infectious and poses a risk to technicians performing the collection; 3) it is invasive and painful for the patient; 4) collections must be performed into filling tubes with additives, such as anti-coagulants, which may affect downstream assays; 5) blood is a very complex media and contains inhibitory compounds known to interfere with molecular assays such as PCR and; 6) there is also a substantial risk to neonates or young children who risk becoming anemic by repeated blood collections. As a result Norgen Biotek is now focusing on the use of non-invasive specimens as a source of biomarkers for disease diagnostics. Much research has now accumulated which has unveiled a number of disease biomarkers in these biological fluids for the diagnosis of microbial and systemic disease. The advantages of using biological specimens such as saliva, urine or sputum for disease diagnostics include: 1) ease of access; 2) noninvasive sample collection; 3) increased acceptance by patients; 4) reduced risks of infectious disease transmission and; 5) lower costs. Whereas blood exists in the circulation for several days, passing through organs that can potentially alter biomarkers that are present, saliva is a "real-time" fluid since the salivary glands are exocrine glands that produce biomarker profiles indicative of the individual's status at the moment of collection. In addition, specimens such as urine are abundant and allow for repeated samples to be collected. As saliva, urine and sputum can be collected non-invasively, by untrained personnel they have also gained widespread interest as a diagnostic specimen for rapid point-of-care testing. The objective of this research was therefore to develop a universal diagnostic solution for a complete, ready-to-use system for the isolation and detection of disease from non-invasively collected samples. In particular, the rapid isolation of total nucleic acids (DNA & RNA) and proteins from various specimen types (urine, saliva or sputum) using Norgen's proprietary resin. Preservation and detection of the collected specimens for sensitive detection assays will also be discussed.

918T

Measuring the chronology of technology transfer of molecular genetic discoveries. *F. Rousseau[1, 2, 3], C. Lindsay[2, 3], Y. Giguère[1, 2, 3], J. Jbilou[2, 4], R. Landry[2, 5], N. Amara[2, 5].* 1) Biol Medicale, Univ Laval, Quebec, PQ, Canada; 2) APOGEE-Net/CanGèneTest Network on Genetic Services and Policy, International; 3) URGHM, Centre de recherche du CHUQ, Hôpital St-François-d'Assise, PQ, Canada; 4) Dept of Public administration, University of Moncton, NS, Canada; 5) Dept Management, University Laval, PQ, Canada.

Purpose:The process of technology validation and transfer of new molecular diagnostic tools towards the clinic faces challenges and needs to be improved. Albeit massive investments in genomic research, molecular genetic tests represents <0.05% of all diagnostic laboratory tests in many Western countries. There is no empirical measure of the process nor of the pace of technology transfer of molecular genetic discoveries. We studied the chronology and pace of technology transfer for 28 different molecular genetic test discoveries with the objectives to 1)provide estimates of the timeframe between discovery and complete clinical implementation, and 2)compare the trajectories between different new tests to identify common patterns and bottlenecks. Methods:We developed a list of 11 publicly available "timestamps" for the technology transfer process. 28 different well known molecular genetics tests (with different characteristics) were selected. For each test selected, public databases were searched in order to identify available timestamps and dates. Trajectories of individual tests, including chronology, were plotted and compared using standard statistics. Results:There is much variability in the chronology of transfer from test to test. The mean time between discovery and clinical test offer was 10 years (minimum 2). There was a mean time of 11 years between discovery and publication of the first health technology assessment report (minimum 2 years). A mean of 15 years spanned between test discovery and FDA approval (minimum 9), and it took a mean of 17 years between discovery and the availability of a certified reference material (minimum 13). Our analysis revealed variability between different molecular tests in terms of trajectory. Indeed the sequence of events is not always identical between tests, as well as the time between individual timestamps. Further, all steps are not present for all tests. Short time spans were typically observed for molecular tests with clear clinical utility, filling a need, or replacing a poorly performing test, amongst other factors. Conclusion:New molecular genetic tests seem to take significant time between discovery and clinical implementation. However, the trajectory and pace of transfer appears to be very variable and influenced by tests characteristics and performance. Further work is needed to pinpoint key factors, including policy and organization factors, that may allow for improving and streamlining this process.

DUNES Environment: A Suite of Tools and Software to Support Data Harmonisation and Synthesis. *D. Doiron[1], V. Ferretti[2], F. L'Heureux[1], M. Naccache[1], I. Fortier[3].* 1) Public Population Project in Genomics (P3G), Montreal, Quebec, Canada; 2) Ontario Institute for Cancer Research, MaRS Centre, Toronto, Ontario, Canada; 3) Research Institute - McGill University Health Centre, Montreal Quebec, Canada.

Very few individual studies provide the statistical power needed to thoroughly investigate complex interactions between environmental and genetic factors in chronic disease etiology. It is therefore necessary and increasingly common to pool information collected from participants across several studies to increase the sample sizes available for statistical analyses. However, ensuring the quality of pooled information requires a formal and rigorous approach and specialized data harmonisation tools and software. Such an approach must not only ensure that pooled data is measured well but that the information each study conveys is effectively compatible. Impelled by a growing demand from epidemiology consortia and networks around the world, DUNES Environment has been launched to consolidate existing data harmonisation tools and methodologies developed under the umbrella of the Public Population Project in Genomics (P3G) and its partner projects. As a framework to support data harmonisation, DUNES Environment has established a five-step approach which is supported by a suite of web-based software. As a first step, the scientific objectives and scope of a cross-study harmonization initiative must be defined and its participating studies should be well documented. That is, study designs and sampling protocols, calendar times of exposures and outcomes, data access policies, as well as all relevant information describing data collected by participating studies (e.g. questionnaires, data dictionaries, SOPs) is properly catalogued. Second, target variables to be shared between studies are defined and annotated. Third, the harmonisation potential between the data collected by participating studies and the variables targeted by the harmonisation project is evaluated. Fourth, processing algorithms are developed and implemented to transform original study data into a common compatible format. Lastly, pooled data is disseminated to investigators and appropriate statistical analyses are conducted. For each step, open-source web-based software has been developed to streamline the entire process. Among these, the P3G Catalogues, DataSHaPER, Opal, and Mica software are being made freely accessible to the scientific community. DUNES Environment ultimately aims to facilitate collaborative research by offering a centralized web-based infrastructure that facilitates the harmonisation process and ensures the validity and compatibility of pooled data.

Miniaturization and Automation of One-step Gene Expression using the Access™ Laboratory Workstation and the Echo® liquid handler. *R. Dyer, C. Glazer, S. Datwani, J. Barco, T. Allison.* Labcyte Inc., Sunnyvale, CA.

As gene expression workflows are pushed to the next step of miniaturization, sample preparation techniques must evolve. The Labcyte Echo liquid handler utilizes tipless, touchless, transfer of samples and reagents to enable the highest precision and accuracy at nanoliter volumes. With a seamless addition of automated plate handling, the Access workstation transforms the Echo platform into a walk-away solution tailored for gene expression. This poster illustrates the ability to prepare a one-step RT-qPCR reaction as low as 300 nl, directly from cell lysates, in both 384- and 1536-well plates. The automated workflow, along with the consistency and accuracy of these reactions are discussed. With the Access workstation, high throughput gene expression screens using more relevant cell models including primary cells can replace less sensitive cell-based reporter assays.

921T

Sequencing of expanded CGG repeats in the *FMR1* gene. *E. Loomis[1], J. Yen[2], J. Major[2], F. Tassone[3], P.J. Hagerman[1,3].* 1) Univ. of Calif. Davis School of Medicine, Biochemistry and Molecular Medicine, Davis, CA; 2) Pacific Biosciences of California Inc., Menlo Park, CA; 3) Univ. of Calif. Davis School of Medicine, MIND Institute, Sacramento, CA.

The 5' untranslated region (5' UTR) of the fragile X mental retardation 1 (*FMR1*) gene contains a CGG-repeat element that, when expanded beyond ~200 CGG repeats, generally undergoes methylation-coupled transcriptional silencing, giving rise to fragile X syndrome (FXS); smaller expansions (55-200 CGG repeats) result in elevated levels of *FMR1* mRNA, which is now thought to be responsible for the late-onset neurodegenerative disorder, fragile X-associated tremor/ataxia syndrome (FXTAS). Previous DNA sequencing methodologies have been unable to sequence cleanly through more than ~100 CGG repeats, thus limiting the ability to precisely characterize such disease-causing alleles. The recent development of single molecule, real-time sequencing (Pacific Biosciences) represents a novel approach to DNA sequencing that couples the intrinsic processivity of DNA polymerase with the ability to read polymerase activity on a single-molecule basis. Furthermore, the accuracy of the method is improved through the use of closed circular templates, such that each molecule can be read multiple times to produce a circular consensus sequence (CCS). We have succeeded in generating CCS reads representing multiple passes through both strands of large expanded CGG repeats (>400 CGGs) flanked by native *FMR1* sequence. This application will allow us to fully characterize the previously intractable CGG repeat sequence, leading to a better understanding of the distinct FXS and FXTAS molecular pathologies.

Next-Gen Sequencing of HLA class I and class II exons with GS GType HLA Primer Sets on the GS Junior System. *C.S. Teiling[1], C. Holcomb[2], B. Hoglund[2], P. Moonsamy[2], B. Simen[3], E. Blake[3], K. McGowan[3], H.A. Erlich[2].* 1) Roche Applied Science, Indianapolis, IN; 2) Roche Molecular System, Pleasanton CA; 3) Roche/ 454 Sequencing, Branford CT.

Inherited DNA sequence variation in the HLA region on human chromosome 6 significantly influences the risk for autoimmune diseases and the host response to pathogenic infections. Collecting allelic sequence information at the HLA class I and class II genes is critical for studying hematopoietic stem cell transplantation for genetic association studies, but is complicated due to the high degree of polymorphism across the major histocompatibility (MHC) antigen region. Next-generation sequencing offers a cost-effective alternative to Sanger-based sequencing, which has been the standard for HLA typing, with the new GS GType HLA Primer Sets. The GS GType HLA Primer Sets together with the GS FLX Instrument or the benchtop GS Junior Instrument enable high- and medium-resolution genotyping of the class I and II loci of the HLA genes. The clonal, high-throughput, long reads generated by these 454 Sequencing systems provide a direct, unambiguous assignment of phase for linked polymorphisms within exons. This enables third-party genotyping software, such as the Conexio Genomics Assign ATF 454 software, to consolidate reads and, by comparing sequences to the IMGT HLA sequence database, assign alleles automatically. As shown by the data presented, in a typical run of 5 to 6 samples, the concordance of genotype assignments at 8 loci using the GS Junior Instrument and Conexio software was 100% and unambiguous allele assignment was 59%. 454, 454 SEQUENCING, GS FLX, GS JUNIOR, and GTYPE are trademarks of Roche. All other product names and trademarks are the property of their respective owners.

Genetic modification of cancer cells using non-viral, episomal S/MAR vectors for in vivo tumour modelling. *S.P. Wong, O. Argyros, R. Harbottle.* Molecular Medicine, Imperial College London, London, Greater London, United Kingdom.

The development of genetically marked animal tumour xenografts is an area of ongoing research to enable easier and more reliable testing of cancer therapies. Genetically marked tumour models have a number of advantages over conventional tumour models, including the easy longitudinal monitoring of therapies and the reduced number of animals needed for trials. Several different methods have been used in previous studies to mark tumours genetically, however all have limitations, such as genotoxicity and other artefacts related to the use of integrating viral vectors. Recently we have generated an episomally maintained plasmid DNA (pDNA) expression system based on Scaffold/Matrix Attachment Region (S/MAR), which provides permanent genetic modification and persistent transgene expression in tumour cells. Here we describe the use of this pDNA vector to create stable genetically marked human hepatoma (Huh7), pancreatic carcinoma (MIA PaCa-2) and Birt-Hogg-Dube Syndrome folliculin knockout (UOK 257) cell lines. These modified cells were xenografted into NOD-SCID mice and monitored longitudinally over time. Each cell line exhibited the permanent episomal maintenance of the vector and sustained long-term transgene expression. Importantly, each formed tumours showing the pathological characteristics of hepatocellular carcinoma, pancreatic carcinoma and renal cancer respectively. This is the first demonstration that a non-viral, replicating, non-integrating pDNA vector can confer sustained transgene expression in various murine tumour models. We believe that this system provides great utility and advantages over currently used technologies and will be a useful resource to the field of cancer research.

High throughput validation of next generation sequencing results from lung cancer samples using a novel custom genotyping platform. *R. Selzer[1], K. Lo[1], J. Patel[1], M. Watt[1], X. Zhang[1], T. Richmond[1], M. You[2], P. Liu[2], T. Albert[1].* 1) Roche NimbleGen, Inc., Madison, WI; 2) Medical College of Wisconsin, Milwaukee, WI.

Massively parallel sequencing technologies have revolutionized the way we conduct genomics research by providing an unbiased and comprehensive method of detecting novel single nucleotide polymorphisms (SNPs), insertions-deletions (Indels) and structural rearrangements within complex genomes. As sequencing cost declines, sequencing is fast becoming the method of choice for discovery. However, due to massively parallel nature of these novel technologies, even miniscule error rates can translate into hundreds or thousands of false discoveries. Thus, downstream validation is essential to ensure reporting accuracy. Today, Sanger sequencing remains the de facto gold standard for downstream validation but suffers from low throughput and high cost. Mass spectrometry based methods, such as Sequenom, improve upon throughput but are still limited to hundreds of putative SNPs. Genotyping arrays, such as Illumina iSelect HD, provide up to 1 million SNPs for validation but require steep up-front costs. The need for a high throughput and low cost validation method remains unmet. We have developed a novel SNP validation assay which utilizes both hybridization and on-array enzymatic reactions to provide enhanced specificity for SNP validation. The probe is specifically designed to provide discrimination between perfect match and mismatch by combining a long hybridization oligonucleotide with a hairpin. Stringent hybridization of genomic DNA to an array is followed by flap endonuclease (FEN) treatment, which provides the first layer of discrimination. The tripartite structure of the hairpin complexed with the hybridized genomic DNA is recognized by FEN, resulting in the cleavage of the 5' end overhang of the genomic DNA. Additional discrimination is provided by DNA ligase, which does not catalyze the ligation when a mismatch of the 5' end of the newly cleaved substrate is present. Covalent attachment of genomic DNA to the probe occurs when the probe sequence matches the cleaved genomic DNA sequence perfectly. In this study, we validated 13,500 SNPs from the DNA of 11 pairs of matched lung cancer and normal tissues that were previously exome-capture sequenced to an average depth of 86X using the Illumina paired end library prep protocol on an Illumina Genome Analyzer II sequencer. Overall, accuracy of 95.4% was achieved, demonstrating this method as an accurate and high-throughput solution to validating sequencing results.

925T

Single-Step Capture and Sequencing of Natural DNA for Detection of BRCA1 Mutations. *J. Thompson, J. Reifenberger, E. Giladi, K. Kerouac, J. Gill, E. Hansen, A. Kahvejian, P. Kapranov, T. Knope, D. Lipson, K. Steinmann, P. Milos.* Res & Development, Helicos Biosci, Cambridge, MA.

Genetic testing for disease risk is an increasingly important component of medical care. However, testing can be expensive which can lead to patients and physicians having limited access to the genetic information needed for medical decisions. To simplify DNA sample preparation and lower costs, we have developed a system in which any gene can be captured and sequenced directly from human genomic DNA without amplification, using no proteins or enzymes prior to sequencing. Extracted whole-genome DNA is acoustically sheared and loaded in a flow cell channel for single-molecule sequencing. Gene isolation, amplification, or ligation is not necessary. Accurate and low cost detection of DNA sequence variants is demonstrated for the BRCA1 gene. Disease-causing mutations as well as common variants from well-characterized samples are identified. Single-molecule sequencing generates very reproducible coverage patterns and these can be used to detect any size insertion or deletion directly, unlike PCR-based methods which require additional assays. Because no gene isolation or amplification is required for sequencing, the exceptionally low costs of sample preparation and analysis could make genetic tests more accessible to those who wish to know their own disease susceptibility. Additionally, this approach has applications for determining genomic sites of integration for gene therapy vectors, transposons, retroviruses, and other mobile DNA elements in a more facile manner than possible with other methods.

Enhanced Multiplexing Capabilities Using the Agilent Technologies SureSelect*XTII* Target Enrichment System for Fast and Easy Pre-Capture Indexing. *B. Arezi[1], A. Giuffre[2], S. Joshi[2], H. Ravi[2], M. McCarthy[1], K. Chen[1], J. Ong[2], B. Novak[3], M. Visitacion[3], M. Hamady[3], C. Pabón-Peña[3], F. Useche[3], E. Lin[3], W. Liu[3], S. Hunt[3], D. Roberts[3], S. Happe[2], E. Leproust[3].* 1) Agilent Technologies, La Jolla, CA 92037; 2) Agilent Technologies, Cedar Creek, TX 78612; 3) Agilent Technologies, Santa Clara, CA 95051.

Massively parallel sequencing technologies have enabled scientists to discover rare mutations, structural variants, and novel transcripts at an unprecedented rate. Nevertheless, it remains cost-prohibitive to sequence entire genomes from large sample cohorts. To meet the demand for fast, inexpensive and accurate genome analysis method, Agilent Technologies has developed the SureSelect*XT* platform, an in- solution hybrid selection technology for systematic re-sequencing of candidate regions in the genome. To further reduce costs and take advantage of the increasing capacity of next-generation sequencers, we highlight the ability to pre-capture multiplex DNA samples in a single sequencing lane/slide while maintaining the coverage necessary to confidently make SNP calls. We demonstrate an automation-friendly, easy to use protocol where gDNA libraries are uniquely “tagged” and then combined pre-capture, to allow for maximum multiplexing (up to 96 indices). We also introduce the more streamlined SureSelect*XTII* kit that utilizes reagent master mixes for faster, easier, and more user-friendly preparation of samples for multiplex sequencing. We show high performance, as measured by capture efficiency, uniformity and reproducibility. The multiplexing capabilities of our kit extend to both small (<1Mb) and large (>50Mb) libraries. SureSelect captures maintain performance when sequenced alone in one lane/slide or multiplexed in a pool with other samples. When multiplexing HapMap samples, >98% concordance between SureSelect resequencing results and previously-determined genotype is observed. The unique 8bp 96 index show uniform performance across different bait sizes. Additionally, there are no dropouts and coverage and index representation is uniform. In summary, the SureSelect pre-capture indexing kit provides the ability to combine targeted enrichment with multiplexing, thus maximizing the number of samples that can be sequenced at one time, providing optimum time and cost savings without sacrificing performance.

Automating high-throughput production of libraries for massively parallel sequencing platforms. *J. Bishop, M. Allen, W. Zhang, D. Mandelman, M. Landers, A. Harris, R. Bennett.* Life Technologies, Carlsbad, CA.

Advances in the capabilities of massively parallel sequencing platforms have outpaced methods for constructing sequencing libraries, which do not scale well to the tremendous speed and throughput capabilities of the sequencers. We describe here a set of protocols, robotics scripts, reagents and instrumentation developed to automate the simultaneous production of up to 96 high quality sequencing libraries. Methods for creating sequencing libraries are slow, tedious, prone to error and variation, and generally not optimized for automation. For robust, high throughput library creation, we describe here the development of robotic scripts for simultaneously producing 1-96 sequencing libraries on commonly used robotic fluidic-handling platforms. These automated protocols provide uniquely optimized adaptor concentrations and bead-based clean-up techniques to increase by several fold the yield of libraries from small amounts of input. The protocols accept 10-5000 ng of sheared DNA input, calculate and dilute barcode adaptors for each library, automate all intermediate processing and cleanup steps, and deliver purified libraries for amplification off-instrument. An additional script enabling post-PCR purification of the libraries is also provided. We further describe an alternative automation process for lower-throughput needs. Our analysis of sequencing data shows that libraries produced by all of the above procedures remove excess adaptors which interfere with quantitation and pooling, are unbiased, free from cross-contamination and of high complexity.

Next Generation Sequencing High-throughput Solution for Illumina Fragment Library Sample Preparations. *M.E. Blair, K.L. Marshall, R. Zhang, A. Jackson.* Genomics, Beckman Coulter, Indianapolis, IN.

Illumina library sample preparation for Next Generation Sequencing (NGS) is a long and complicated process that can also require precise fragment size selection through agarose gel separations in order to obtain high quality sequencing results. Beckman Coulter has already released SPRIworks chemistry for low-throughput using the SPRI-TE Nucleic Acid Extractor and has now developed chemistry for high-throughput (HT) automation using Biomek® liquid handlers for Illumina compatible NGS library sample preparation. The HT solution can produce up to 96 libraries in a 96-well format with minimum hands on time and uses Solid Phase Reversible Immobilization (SPRI) paramagnetic beads to offer various fragment sizes selection (150-350 bp, 250-450 bp, 350-550 bp, and 150 bp up) with high accuracy as shown by bioanalyzer data. Downstream processes, including PCR reaction setup and cleanup, qPCR setup, and normalization, have been automated to create a suite of methods. This suite of automation methods has a single user interface (UI) to allow for easy selection of options.

A Stream-lined Process for Amplicon Resequencing using Ion Torrent's Personal Genome Machine coupled with Fluidigm's Access Array. *J. Boland[1,2], D. Roberson[1,2], J. Bacior[1,2], V. Lonsberry[1,2], A. McCary[1,2], A. May[3], M. Pieperzyk[3], M. Yeager[1,2], K.B. Jacobs[1,2], A.A. Hutchinson[1,2], S.J. Chanock[1,2].* 1) Core Genotyping Facility, NCI Frederick, Bethesda, MD; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Rockville, Maryland USA; 3) Fluidigm Corporation, South San Francisco, California USA.

A multiplexed approach to sample processing is essential to maximize data return of a single run on a next generation sequencing platform. Using Fluidigm's Access Array and Ion Torrent's PGM, we have streamlined both our regional resequencing and follow-up validation for familial whole exome studies, with the ability to process hundreds of targets of interest across hundreds of samples in a single day. This presentation will focus on the sequencing of a region of chromosome 10 that was found to be associated with prostate cancer risk by genome-wide association studies (GWAS). This 97kb region, which includes *MSMB* and *NCOA4*, has also been resequenced using both the Illumina HiSeq 2000 and the 454 FLX platforms, providing ample comparative data. The ability to process hundreds of samples per day will undoubtedly lead to faster discovery of underlying genetic markers for many of today's current diseases. This project has been funded in whole or part with federal funds from the NCI, NIH under contract HHSN261200800001E.

"Genetics, Meet Genomics": Using SNPs to Guide Variant Discovery in Sequencing Data. *R. Daber[1], S. Mulchandani[1], J. Ganesh[1], M. Mennuti[2], E.A. Tsai[1], H.C. Lin[1], B.A. Haber[1], P.F. Whitington[3], L.K. Conlin[1], H. Hakonarson[1], N.B. Spinner[1].* 1) Children's Hospital of Philadelphia, Philadelphia, Pa; 2) University of Pennsylvania, Philadelphia, Pa; 3) Children's Memorial Research Center, Northwestern University, Chicago, IL.

Next generation sequencing holds the promise of elucidating the cause of many genetic disorders. While various groups have had success in identifying new disease causing mutations associated with a variety of phenotypes, incorporation of next generation sequencing into routine variant discovery for genetic disorders remains challenging. Two major barriers that remain are the costs per individual genome and the difficulty in interpreting the meaning of the large number of variants that are found. To overcome these two challenges we have developed an analysis pipeline that utilizes traditional genetic approaches based on family history and genome-wide SNP arrays to reduce the number of samples that must be sequenced as well as the number of variants that need to be interpreted and subsequently validated. Depending upon the family history and availability of familial samples, genotype information is collected on SNP arrays and is used to determine allelic phase. Difference maps of allelic inheritance among affected and unaffected family members is then used to reduce the genome to chromosomal regions which are consistent with a model of inheritance displayed in the family history. In our first application, we compared genotypes of two affected siblings with their unaffected brother to define regions of shared inheritance following both a dominant and recessive model. This allowed us to sequence a single affected individual and instantly reduce the sequence data set to those reads found in the defined regions. When a dominant model of inheritance was assumed in this family, the number of genes analyzed for variants was reduced from 38,047 to fewer than 12,500. Under a recessive model the number of genes dropped even further to 6,173. This reduction of sequence search space by nearly 85% was completed well before the first base was even sequenced and reduces both the computational demands of analysis and the number of variants needing interpretation. In a second family where the disease was tracking through the maternal lineage, the genomes of two affected siblings were further filtered to only the regions of shared maternal inheritance. Thus, by incorporating information on the biological inheritance of chromosomal regions determined from SNP arrays, variant discovery by sequencing can be reduced to a single sample and variant interpretation is limited to only the regions that are biologically relevant.

931T

Real-time data quality feedback for next generation sequencing of a breast cancer whole transcriptome library. *R. Fish, S. Ngola, M.-Y. Shen, L. Jones, J. Ziegle, N. Fong, K. Perry, S. Chang, L. Lua, L. Liu, M. Mariano, A. Vadapalli, L. Xu, S. Yerramalli, E. Wang, C. Yang, L. Joe.* Life Technologies, Foster City, CA.

A large number of genes have been implicated in breast cancers when their expression is improperly or no longer regulated. With the advent of massively parallel sequencing in next generation sequencing systems, researchers have a powerful tool to study genome-wide changes in RNA expression. MCF-7 is a breast cancer cell line that has served as a model system for investigating the genome and transcriptome of a cancer cell. In order to study genetic variants and expression differences accurately, next generation sequencing samples and instrument runs have to be of high quality. Therefore, any feedback regarding sample and run quality is greatly beneficial to users. In order to address this need, the 5500 Series Genetic Analysis Systems incorporate sequencing control beads as a small percentage of the total sample population. As they represent less than one percent of the total beads, the overall impact on run throughput is negligible. The control template sequences contain a unique identifier that discriminates these beads from sample beads. The beads are comprised of a set of synthetic sequences that will support all run sample types from both DNA and RNA libraries, including mate pair and paired end sequencing. In this study, we show sequencing of a whole transcriptome library from MCF-7 in the presence of sequencing control beads. The same library was sequenced on multiple instruments, allowing an assessment of instrument to instrument and sample bead to sample bead differences by investigating the behavior of the sequencing control beads. As the run progresses the sequencing control provides real time comparison of the sequencing quality of the sample beads compared to the control beads. The sequencing control and associated software provide a powerful tool for monitoring and determining run quality and performance.

932T

Targeted Resequencing on Illumina's MiSeq: Methods for Rapid Validation and Cost Effective Extension Studies of Putative Genetic Variants. *S. Fisher, C. Russ, J. Flannick, N. Burtt, M. DePristo, W. Winckler, M. Carneiro, M. Parkin, J. Abreu, R. Hegarty, D. Perrin, T. DeSmet, M. Coole, J. Meldrim, C. Nusbaum, R. Nicol, S. Gabriel.* Broad Institute, Cambridge, MA.

Over the past several years whole exome or whole genome sequencing of significant number of samples from a wide variety of diseases has become common practice for identifying putative disease linked variants. However, follow up work to validate the large number of potential mutations identified in these studies and extending the study of specific subsets of targets across larger sample cohorts has been to date time consuming and costly. Here we present two approaches for targeted re-sequencing of small subsets of target regions using the Illumina MiSeq sequencer.

The first approach allows for rapid validation of target variants in less than 8 hours from PCR amplification to data analysis. In a proof of principle experiment, PCR amplicons approximately 600bp in length, for ~300 SNP containing targets, were designed, ordered and received within 48 hours. PCR was performed across eight samples and resulting amplicons were pooled by sample. Using Epicentre's Nextera transposon based library construction approach, amplicon pools were transformed into sequence ready libraries in under an hour. To enable sample multiplexing, a molecular barcode was added during the final library amplification step. Finally all eight sample libraries were pooled and sequenced on a single 36 base paired-end Illumina MiSeq run.

The second approach offers a cost effective method for extending studies to larger sample cohorts while examining small subsets of targets. Using Illumina's TruSeq Custom Amplicon kit, which enables highly multiplexed amplicon sequencing e.g. [700 amplicons of 250 bp in size], exonic regions totaling approximately 67Kb of sequence were selected and sequenced using 151 base paired-end reads on both Illumina's HiSeq2000 and MiSeq instruments. The resulting validation and extension data will be presented.

933T

Automation Method Suite for NGS Downstream Applications: PCR Cleanup, Real-Time qPCR Quantification, Normalization and Pooling Using Biomek FXp Laboratory Automation Workstation. *A. Jackson, R. Zhang, K. Marshall, M. Blair, J. Schlitz.* Application, Beckman Coulter, Inc., Indianapolis, IN.

Quality next generation sequencing (NGS) data depends on precise sample quantification. However, quantitation and normalization (Quant and Norm) are often the most time consuming and error prone processes in the laboratory. With the automation of library construction for higher throughput (HT), quant and norm has quickly become the bottleneck with the requirement for individual per-well volumes for sample and diluent. Once normalized, the NGS libraries are often pooled for sequencing, where uniform concentrations are critical. Using the Biomek FXP Laboratory workstation, PCR Clean-up using AMPure XP, and real-time qPCR Setup were automated in the 96-well plate format in addition to separate Norm and Pooling method. KAPA Biosystems Library Quantification Kits were used for real-time qPCR setup and provide easy to use standards. This suite of methods includes an intuitive user interface (UI) that enables simple entry of method defining information. There's flexibility to select specific samples to process for PCR clean-up, real-time qPCR setup, normalize and pooling samples. The Norm method utilizes Biomek Software's ability to interact with Microsoft Excel spreadsheets to allow the user to view the concentrations of the samples, select and note outliers and visually check sample volumes prior to normalization and pooling for better error handling and control of samples for downstream processing. Our preliminary real-time qPCR data has shown CVs <10% per plate, with +/-0.5 Ct from sample to sample variations. For sample tracking the UI assigns a plate ID that is tracked throughout the process with date and time processed. The user can also assign a unique ID manually through a barcode scan. All samples volumes of diluent transferred are displayed in the Quant/Norm spreadsheet and can be saved for note booking. This suite of methods is simple, fast, and convenient. It can be applied to NGS and other similar applications. Note: Beckman Coulter, the stylized logo, and Biomek are trademarks of Beckman Coulter, Inc., and are registered in the USPTO.

Target enrichment for Human Kinome RNA and DNA sequencing. *E. Lin[1], A. Giuffre[2], B. Novak[1], M. Visitacion[1], M. Hamady[1], F. Useche[1], V. Kulkarni[1], W. Liu[1], T. Fjelsted[1], C. Pabón-Peña[1], S. Hunt[1], D. Roberts[1], S. Happe[2], E. Leproust[1].* 1) Genomics, Agilent Technologies, Santa Clara, CA; 2) Genomics, Agilent Technologies, Cedar Creek, TX.

Deep sequencing technology has revolutionized the discovery of rare polymorphisms, structural variation, and novel splice variants. To meet the demand for fast, cost-effective, and accurate genome and transcriptome analysis methods from small scale studies to large sample cohorts, Agilent Technologies has developed the SureSelect Target Enrichment System - a highly robust, customizable, and scalable system that focuses analyses on specific genomic loci or expressed transcripts by in-solution hybrid capture. Both RNA and DNA enrichment demonstrate excellent performance as measured by capture efficiency, uniformity, and reproducibility of sequence coverage. This enables the accurate detection of common and rare SNPs, indels, CNVs, allelic expression, and gene fusions. SureSelect for RNA-seq also retains relative transcript amounts after capture for accurate gene expression. In collaboration with the Netherlands Cancer Institute (NKI), 2 sets of probes were designed targeting over 500 kinases and a subset of clinically-relevant cancer genes (the “Kinome”) for use with DNA-seq and RNA-seq, respectively. We profiled a set of 6 cell lines and 2 tumor/normal pairs utilizing the each of the Kinome enrichment kits. The RNA-seq dataset will provide specific examples of allelic expression variance, differential splicing, and the capture of known disease mutations will be highlighted. The DNA-seq dataset from the same samples allows correlation of transcript, SNP, and indel information back to the genome, as well as identification of structural variants.

935T

Advanced Capture-Sequencing: New Designs and Multiplexing for Whole Exome and Regional Capture Sequencing Applications. *D. Muzny[1], I. Newsham[1], M. Wang[1], Y. Wu[1], C. Kovar[1], A. Sabo[1], R. Chen[1], J. Reid[1], M. Bainbridge[1], E. Boerwinkle[2], T. Albert[3], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) University of Texas Health Science Center at Houston, School of Public Health, Houston, TX 77030; 3) Roche NimbleGen, Inc., 1 Science Court, Madison, WI 53719.

Since the initial report of targeted-enrichment (Albert et al, 2007) we have been evolving the design and utility of capture reagents and methods, taking advantage of the parallel advances in sequencing platforms. New exome designs target a comprehensive set of coding exons from 6 different gene databases, as well as computationally predicted coding and non-coding elements: regulatory regions, and conserved UTRs. These reagents have shown that different regions of the exome have different capture qualities, and that variant densities from targeted exome regions outside CCDS, are 2X higher than the CCDS. Library automation, reduction of DNA input samples, capture hybridization multiplexing and application of faster read mapping tools such as BFAST and BWA, together allow a rate of >1500 libraries/captures per month, with >10,000 exome and regional capture libraries already completed. For regional capture designs (0.5-2 Mb target region), up to 48 barcoded samples have been pooled for capture hybridization with equal representation of samples and >90% of the target regions at 20X coverage with ~400Mb of raw sequence. Capture applications have also been developed for the Ion Torrent platform using a custom design (~1Mb), targeting all 167 known retinal disease genes. Excellent coverage was achieved with 85% of the target regions at 20X coverage from 200Mb of sequence and high concordance (99.1%) to known genotype calls was observed. Exome co-capture has now been implemented in production routinely achieving 90% coverage of targeted regions at 20X, from 10Gb of total sequence. Up to 12 samples have been pooled for exome capture hybridization, showing equal representation of samples. Future applications will include SNP validation and screening for genetic disorders and cancer mutations in clinical settings.

936T

Rapid Illumina Library Quality Assessment Using MiSeq. *D. Perrin[1], I. Rasolonjatovo[2], D. Dionne[1], T. Fennell[1], M. Costello[1], S. Humphray[2], T. DeSmet[1], J. Meldrim[1], S. Fisher[1], R. Nicol[1].* 1) Genome Sequencing Platform, Broad Institute, Cambridge, MA., USA; 2) Illumina, Inc.

Increased yields from the Illumina HiSeq 2000 have enabled large scale multiplexing of a variety of sample types. At the Broad Institute, we routinely pool sets of 96 barcoded libraries and run the pools across multiple HiSeq lanes. Uneven barcode representation or poor library quality can be costly and time consuming to fix. Here we demonstrate the utility of the Illumina MiSeq in an inexpensive, rapid, accurate, highly reproducible QC method for both libraries and pools of barcoded libraries that can be run prior to sequencing at high coverage on HiSeq. Running a library on a single MiSeq run enables the calculation of key performance indicators such as estimated library size, percent duplication, and insert size distribution, as well as GC bias and targeted sequencing metrics. In addition, running a pool of barcoded libraries on a single MiSeq run enables assessment of the evenness of representation of libraries within the pool, as well as the frequency of orphaned reads (reads for which a barcode cannot be confidently assigned). Finally, MiSeq cluster density can also be used to predict HiSeq cluster density, reducing rework and maximizing yields on HiSeq flowcells.

937T

Scaling with the flow: advantages of a MapReduce-based scalable and high-throughput sequencing workflow. *L. Pireddu[1], S. Leo[1], F. Reinier[1], R. Berutti[1,2], R. Atzeni[1], G. Zanetti[1].* 1) CRS4, Pula, CA, Italy; 2) Dept. of Biomedical Sciences, University of Sassari, Sassari, Italy.

The continuous increase in sequencing throughput imposes a new generation of tools for data processing. The alternative is to continue suffering scalability problems in processing workflows and IT infrastructure. We evaluate the advantages that the CRS4 Sequencing and Genotyping Platform (CSGP), equipped with 6 Illumina sequencers, gained by replacing its conventional workflow with a new one based on Seal (http://biodoop-seal.sf.net) and Hadoop. The former was a standard pipeline that demultiplexed samples, aligned reads with BWA, removed duplicates with Picard and recalibrated base qualities with GATK. It parallelized computation through concurrent jobs, using a centralized file system to share data. This implementation showed weaknesses as the workload increased: low parallelism; I/O bottleneck at central storage; failure of entire analyses due to node failures or transient cluster problems. The new workflow is a custom, distributed pipeline based on the open-source Seal suite, which provides a set of tools (including a distributed BWA aligner) that run on the Hadoop MapReduce framework, leveraging its functionality for genomic sequencing applications. By switching to a Seal-based workflow we have acquired computational scalability out-of-the-box. Therefore, we can now easily meet the demands imposed by the growing sequencing platform by adding more computing nodes. In addition, the much-increased parallelism has improved overall computational throughput by taking advantage of all available computing power. Notably, we drastically sped up alignment and duplicates removal by 5x without adding computation nodes; adding nodes would result in additional throughput. Moreover, the effort required by our operators to run the analyses has been reduced, since Hadoop transparently handles most hardware and transient network problems and provides a friendly web interface to monitor job progress and logs. Finally, we eliminated the need for our expensive shared parallel storage devices. Our tests reveal that Seal is efficient, achieving close to 70% of the theoretical maximum throughput per node (measured with a single-node version of the workflow on a small data set) and scales linearly at least up to 128 nodes. In summary, this case study suggests that the MapReduce programming model, Seal and Hadoop provide considerable benefits in the genomic sequencing domain. Seal now includes our new workflow as a downloadable sample application.

Automated Pyrosequencing using Digital Microfluidics. *M.G. Pollack, D.J. Boles, J.L. Benton, G.J. Siew, M.H. Levy, M.A. Sandahl, J.L. Rouse, L.C. Perkins, V.K. Pamula, V. Srinivasan, A.E. Eckhardt.* Advanced Liquid Logic, Inc, Research Triangle Park, NC.

Most DNA sequencing technologies employ large instruments incapable of functioning outside of laboratory environments. Advanced Liquid Logic's (ALL) digital microfluidics technology represents a novel means of liquid handling, streamlining molecular workflows in a broad range of settings. By automating a series of assay steps, complex molecular biology procedures (or techniques) can be performed by personnel with minimal training. Meeting these criteria for the automation of DNA sequencing would provide a tool for a range of research, clinical and forensic applications including microbial identification and DNA fingerprinting. Pyrosequencing is a sequencing-by-synthesis method by which nucleotides are sequentially added to a template-of-interest. Incorporation of nucleotides into the template complement is monitored by the release of pyrophosphate. ALL has tested the feasibility of implementing pyrosequencing chemistry within droplets using electrowetting-based digital microfluidics. The digital microfluidic cartridge is composed of an array of electrodes patterned on a printed-circuit board, bonded to a plastic top-plate containing various reagents which are programmably dispensed based on software commands. The cartridge is inserted into an analyzer, which houses detection systems, heaters and magnets for various processes. Using this system, a three-enzyme protocol was developed in which individual droplets containing enzymes, dNTPs, and DNA templates were combined to perform the pyrosequencing reaction. DNA templates were anchored to magnetic beads, enabling thorough washing between nucleotide additions. Reagents and protocols were optimized to maximize signal over background, linearity of response, cycle efficiency, and wash efficiency. As an initial demonstration of feasibility, a 229 bp Candida parapsilosis template was sequenced using both a de novo protocol and a resequencing protocol. Up to 67 bp of sequence was obtained with 100% sequence accuracy based on raw pyrogram signals. Excellent linearity was observed for homopolymers (2, 3, or 4 nucleotides) contained in the C. parapsilosis sequence and control experiments demonstrated the possibility of extending the linear response to at least 8 nucleotides. With improvements in microfluidic design, it is expected that longer reads, higher throughput and improved process integration (i.e. “sample-to-sequence” capability) could be achieved using this droplet-based platform.

939T

High Accuracy Genome Sequencing on the Illumina HiSeq Platform. *S.R. Rawlings[1], S. Humphray[1], K. Maisinger[1], V.P. Smith[1], J. Gordon[2], S. Tanner[2], C. Tregidgo[1], G. Smith[1], K. Hall[1], D. Bentley[1].* 1) Illumina UK, Chesterford Research Park, Little Chesterford, Nr Saffron Walden, Essex, United Kingdom; 2) Illumina Inc, 9885 Towne Centre Drive San Diego, CA 92121 USA.

Illumina Sequencing platforms have been instrumental in transforming the use of sequence information in a wide range of genomic, genetic and biological studies. Applications include whole genome and targeted sequencing, de novo genome assembly, RNA sequencing, functional and epigenetic studies. Together the range of applications and launch of the complementary fast-turnaround MiSeq platform enable integrated studies in both the research and clinical setting. Common to all the sequencing platforms is a simple sample preparation workflow that enables preparation of DNA fragments to form high density random arrays of clusters that are then sequenced using reversible terminator chemistry. Single- or paired-read datasets (read length 35-150 bases) are generated either for de novo assembly or alignment to a previously known reference. Recent developments in chemistry, hardware and software have resulted in higher accuracy, improved genome coverage (low GC bias), longer reads and faster cycle times. Major improvements to image analysis algorithms, analysis software and base calling calibration tables have contributed to greater accuracy, density and hence yield, with paired 100-base runs regularly providing >600 Gb per run and >80% of base calls with quality values >Q30 (>99.9% raw read accuracy at each base) on all platforms. When the sequencing or detection accuracy of SBS is isolated from errors introduced during sample prep, it is found to be compatible with overall system base-quality scores of Q60 or greater. Whole genome sequencing (WGS) has been widely adopted during the past year for the analysis of germ line and somatic mutations in human disease, with a particular focus on cancer. A recent study of a time-series on chronic lymphocytic leukaemia (CLL) patients enabled characterisation of the changing profiles of somatic mutations during cycles of treatment, remission and relapse. Tumour heterogeneity and subclonal populations were defined using deep targeted sequencing of somatic mutations. The CLIA-certified, CAP-accredited WGS laboratory has expanded activity particularly in patient sequencing in response to an increased number of requests from physicians and we anticipate progress in the direct clinical application of whole genome and targeted sequencing in personalised medicine.

Optimizing DNA Shearing Utilizing Bulk Lateral Ultrasonic™ Energy. *S. Sharma, K. Dev, v. Vivek, J. Shieh, B. Jamieson.* Microsonic Systems, San Jose, CA.

As Next-Gen sequencing throughput continues to accelerate, a serious sample preparation bottleneck is emerging, calling for a higher throughput DNA shearing technique. The solution must not compromise the quality of the sheared fragments and should not add to the existing high cost of sample prep kits. Microsonics has pioneered the use of a unique, new ultrasonic technology "Bulk Lateral Ultrasonic™ Energy" and implemented a core building block "The Microprocessor for Life Sciences" to commercialize this exciting new technology, making possible a multi-channel DNA shearing device that is scalable to any number of simultaneous shearing channels.

This poster will reveal the most critical parameters and explain how this new form of ultrasonic energy can be optimized for DNA shearing, including: 1.The effect of ultrasonic energy power level and shearing time, 2. The effect of the starting sample size and source of DNA, 3. The effect of starting sample volume, 4. DNA concentration independence and then provide a comparative chart to highlight the advantages of BLU over other technologies like probe sonication, pressure differential, nebulization, enzymatic and focused acoustics.

Careful optimization of these critical parameters has led to a successful implementation of Bulk Lateral Ultrasonic energy for high throughput DNA shearing, sufficient to meet the needs of current and emerging Next-Gen sequencing throughput demands.

941T

De novo Assembly and Haplotype Sequencing from Short Sequencing Reads. *F. Steemers[1], S. Amini[1], N. Pignatelli[1], C. Turk[1], I. Goryshin[2], T. Royce[1], M. Ronaghi[1], K. Gunderson[1].* 1) Advanced Research, Illumina, San Diego, CA; 2) Research, Illumina, Madison, WI.

Next-generation sequencing is transforming the field of genomics. With a growing list of assembled genomes, these technologies are enabling a wide range of applications including genomic re-sequencing, RNA-seq, and ChIP-seq. However, some applications are limited by the shorter read lengths involved in next-generation sequencing. De novo assembly can be facilitated by mate-pair libraries to enable scaffolding of assembled short read contigs, but generating these libraries can be time-consuming and can require large amounts of DNA. Limitations in read length can also create challenges for mapping reads to highly variable and repeat regions. Furthermore, some previous short read technologies were unable to reassemble molecular haplotypes — information that has significant medical importance. The completeness and accuracy of these assemblies are critical to the information extracted from genomes. We propose a revolutionary new sequencing approach that enables the rapid and accurate assembly of sequencing reads into long meta-reads by preserving order and contiguity information during fragmentation. During library preparation, each fragment is automatically tagged with information to identify neighboring sequences in the original DNA molecule. Simple look-up tables enable neighboring sequences to be reassembled bioinformatically, removing the necessity of a reference genome for assembly. This unique molecular tagging also enables haplotype reconstruction at the single-molecule level. Metagenomics can also benefit by simultaneously assembling reads from multiple unknown and diverse microorganisms. This new approach facilitates accurate de novo genome assembly, haplotype sequencing, sequencing of previously uncharacterized genomes, and metagenome sequencing.

942T

Automated Library Preparation for Next Generation Sequencing using Digital Microfluidics. *A.P. Sudarsan[1], J.L. Rouse[1], R.R. Dhopeshawrkar[1], A. Rival[1], A.E. Eckhardt[1], N. Mushero[2], M. Weiand[2], B. Minie[2], P. Cahill[2], M.G. Pollack[2].* 1) Advanced Liquid Logic, Inc., Research Triangle Park, NC; 2) Broad Institute of MIT and Harvard, 320 Charles St. Cambridge, MA.

The preparation of fragment libraries for next generation sequencing remains a cost and labor intensive bottleneck in most genomics laboratory workflows. Advanced Liquid Logic (ALL) and the Broad Institute have teamed to develop a cost-effective automation solution for library preparation, using ALL's proprietary "digital microfluidics" technology. ALL's system consists of an instrument and cartridge, the latter of which contains a network of liquid handling electrodes. Using the "electrowetting" effect as a motive force, fluid droplets are manipulated on the electrode network based on a predefined set of software commands. The instrument component of the system houses electronics, thermal management equipment and magnet arrays. To date, capabilities for sequential end-repair, A-tailing and adapter ligation have been demonstrated, with additional on-cartridge workflow components under development. Because specific protocols are defined in the system's software, new protocols and enhancements to existing protocols can be rapidly incorporated. The flexibility of the ALL system enabled the examination of both published and novel library preparation protocols for use with next generation sequencers. Data will be presented regarding the quality of the DNA libraries prepared, resulting sequencing data, as well as ease-of-use and cost-effectiveness metrics.

Complete Solution for Next-Generation Sequencing Sample Preparation of Roche's GS FLX Titanium Series Kits. *R. Zhang.* Application, Beckman Coulter, Inc., Indianapolis, IN.

This poster presents a suite of high-throughput (HT) NGS sample preparation methods that automated the Roche 454* GS FLX Titanium* Series Kits in a 96-well plate format with samples starting from random sheared gDNA to the enriched emPCR beads that are ready-to-load onto the Roche FLX Genome Sequencer. It consists four major applications: (1) Preparation of up to 96 libraries using Roche GS FLX Titanium* Rapid Library Preparation Kit (< 3 hours). (2) NGS Library Quantification and Normalization using Rapid Library (RL) Standard and PicoGreen Assay Kit (Invitrogen) (< 1 hour). (3) emPCR Reaction Setup using Roche GS FLX Titanium* LV and SV emPCR Kits (1-1.5 hours). (4) Large Volume (LV), Medium Volume (MV) and Small Volume (SV) emPCR enrichment and sequencing primer annealing processes (~ 4 hours). Random sheared DNA (500 ng) samples from clonal isolates of Daphnia pulex provided by Indiana University were used to generate libraries for sequencing on the Roche/454 Life Science* platform. The data shows that compared to libraries prepared manually, libraries prepared using automation were proportionally equal across libraries but the yield was slightly higher, and the size distribution of DNA fragments prepared using automation fit within acceptable boundaries, but with a slightly shortened average length of the reads (361 bp automated vs. 391 bp manual). Note: Beckman Coulter, the stylized logo, and Biomek are trademarks of Beckman Coulter, Inc., and are registered in the USPTO.

Molecular analysis of mutations in *COL4A3* gene, in Mexican patients with Alport syndrome. *B. Rodriguez-Espino[1], A. Sanchez-Boiso[2], R. Garcia-Vazquez[1], A.M. Hernandez-Sanchez[1], L.M. Ortiz-Vaquez[1], M.I.P. Garcia-Roca[1], B. Romero-Navarro[1], Y. Fuentes-Velasco[1], M. Medeiros-Domingo[1].* 1) Investigacion en Nefrologia, HIMFG, Mexico, D.F., Mexico; 2) Departamento de Genetica, , HIMFG, Mexico, D.F., Mexico.

Introduction. Alport syndrome is a genetic disorder characterized by glomerulo-nephritis, endstage kidney disease, and hearing loss. Alport syndrome is caused by mutations in *COL4A3*, *COL4A4*, and *COL4A5*, collagen biosynthesis genes. Mutations in any of these genes prevent the proper production or assembly of the type IV collagen network, which is an important structural component of basement membranes in the kidney, inner ear, and eye. In most cases with Alport syndrome, the condition is inherited in an X-linked pattern, due to mutations in the *COL4A5* gene. However, it is possible an autosomal recessive inherit, if both copies of the gene *COL4A3* and *COL4A4*, located on chromosome 2, have been mutated. There are many mutations reported in Alport syndrome, but most cases are unique to each family and there are no records in the Mexican population. Aims. To determine the type of mutations in the *COL4A3* gene in four positive Mexican index cases for Alport syndrome. Methods. Genomic DNA was isolated from patients and a control group of healthy individuals. The coding regions of *COL4A3* genes were analyzed by DHPLC and direct sequencing, and compared against international data bases. Results. In one patient was detect the mutation [*c*.1141-1142G/C], this produce a missense change of the amino acid G327P. In a second patient, was found [*c*.IVS17 + 35G/T] in the intronic sequence, which prevents adequate RNA splicing. In two different patients more, we observed the insertion of a nucleotide [*c*.1141_1142insN], this produces a framework shift in the polypeptide translation. Conclusions. It is the first molecular study of *COL4A3* gene in Mexican population, which reported four new mutations associated with Alport syndrome. These studies together with clinical data, can support the family genetic counseling of affected individuals and also to identify the molecular variables of the Alport syndrome in the Mexican population.

945T

Overlapping features of Mehes and Potocki-Lupski syndromes: Report of an adult patient with Mehes phenotype and 17p11.2 duplication. *P. Sarda[1], K. Hollody[2], M. Vincent[1], M. Girard[1], A. Schneider[1], G. Lefort[1], J. Puechberty[1], D. Genevieve[1].* 1) Dept Med Gen, Arnaud de Villeneuve Hosp, Montpellier, herault, France; 2) Department of Paediatrics, University of Pécs, Pécs, Hungary.

We describe a 24-year-old woman presenting with delayed speech development, mild developmental delay, facial dysmorphism with asymmetry, strabismus and transverse earlobe creases. All these features are reported in patients with Mehes syndrome. The patient has mild mental retardation associated with psychiatric troubles not defined as autistic syndrome. Adaptive functioning was uniformly low with a complete lack of social skills and autonomy for daily life activities and the inability to have any independent work activity at an adult age. Microarray analysis found a de novo duplication of chromosomal region 17p11.2 confirming diagnosis of Potocki Lupski syndrome. We looked for 17p11.2 duplication by interphase FISH in the four patients with Mehes syndrome published by K. Hollody (2005) and found no duplication. This new observation of a patient with “delayed speech development associated with facial asymmetry, strabismus and transverse earlobe creases” confirms the existence of this association, but this entity is certainly heterogeneous. Our observation shows an overlap between the phenotypes of Mehes and Potocki-Lupski syndromes. Consequently it seems important to look for a chromosome 17p11.2 duplication using a specific probe in patients with this phenotype. It also appears that the diagnosis of Potocki Lupski syndrome is difficult to evoke through the sole observation of dysmorphic traits. This diagnosis should be considered in patients with severe language delay associated with particular behavioural difficulties including some or all traits of the autism spectrum. In these patients, the non-specific and variable dysmorphic traits present in Potocki-Lupski syndrome will then suggest cytogenetic analysis to look for a 17p11.2 duplication.

946T

22q11 deletion syndrome at Siriraj Hospital, Bangkok, Thailand - 16 years review (1995-2011). *A. Sathienkijkanchai, N. Vatanavicharn, P. Wasant.* Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand.

Background: 22q11 deletion syndrome is the most common microdeletion syndrome in humans, affecting 1 in 4,000 live births. It has variable phenotypes, including congenital heart disease (CHD), facial dysmorphism, palatal anomalies, immune deficiency, hypocalcemia, and learning difficulties. This syndrome is diagnosed in individuals with a submicroscopic deletion of chromosome 22 detected by Fluorescence *in situ* Hybridization (FISH).

Methods: Retrospective study included all children clinically diagnosed with 22q11 deletion syndrome, DiGeorge syndrome, or velocardiofacial syndrome who were seen in the Genetics clinic, Department of Pediatrics, Siriraj hospital between1995-2011. Children who had no FISH analysis done were excluded from the study.

Results: A total of 20 new cases with the deletion of chromosome 22q11 confirmed by FISH analysis were seen in the clinic. Eight cases (40%) were referred by pediatric cardiologists due to CHD with facial dysmorphism. Four cases (20%) presented with seizures resulting from hypocalcemia. The rest of them were referred because of developmental delay, or facial dysmorphism. 75% of patients (15/20) had CHD, e.g. ventricular septal defect (5/20), MAPCA/VSD/PDA (major aortopulmonary collaterals) (4/20), tetralogy of Fallot (3/20), interrupted aortic arch typeB (1/20). Two patients died from CHD at very young age. Hypocalcemia was found in 8 patients (40%), and 5 of them had seizures due to hypocalcemia. Eight patients had laboratory analysis of immune function performed which revealed that 2 of them had T-cell defect. 45% of patients (9/20) had palatal anomalies. More than half of patients (11/20) had failure to thrive.

Conclusion: Most of the clinical findings in this study reflect previous report. However, we found a higher incidence of MAPCA/VSD/PDA in our patients. This is a hospital-based study, so further studies on a national scale are warranted to better elucidate clinical features of 22q11 deletion syndrome in Thai population.

947T

Molecular confirmation of Costello syndrome in siblings and use of allelic specific amplification to determine parent of origin in a cohort of patient with *HRAS* germline mutations. *K. Sol-Church.* Dept Biomedical Res, Alfred I duPont Hosp Children, Wilmington, DE.

Here we report on the identification of an HRAS mutation c.34G>A, predicting a p.G12S amino acid substitution, in the surviving brother of a previously reported sibling pair, and documentation of the same change in autopsy material from his deceased sister. This represents, to our knowledge, the first molecularly confirmed Costello syndrome in siblings. Using single nucleotide polymorphic markers and allele specific amplification, we clearly identified the mutation in the surviving sibling to be of maternal origin. While we cannot exclude two independently occurring de novo mutations, the complete sharing of polymorphic markers around the mutation site in both siblings supports maternal germ cell mosaicism. We also report of parental origin using Allelic speaific amplification in additional families with costello syndrome.

948T

Analysis of deletions in 22 Brazilian cases of Williams-Beuren syndrome. *D.H. Souza[1], M. Yoshimoto[2], L.R. Martelli[3], J.A. Squire[2], D. Moretti-Ferreira[1].* 1) Genetic, São Paulo State University - UNESP, Botucatu, São Paulo State, Brazil; 2) Queen's University, Kingston, Ontario, Canada; 3) Dept. Genetics, University of São Paulo, Ribeirao Preto, SP, Brazil.

Williams-Beuren syndrome (WBS) is a developmental genomic disorder with an incidence of 1/7,500 [Strømme et al., 2002]. WBS has multisystemic manifestations, mainly characterized by vascular stenosis (predominantly supravalvular aortic stenosis), distinctive craniofacial features, mental retardation with a characteristic neurocognitive profile, short stature and some endocrine and connective tissue abnormalities. The WBS syndrome is caused by a heterozygous deletion of contiguous genes at chromosomal region 7q11.23. The common deletions in WBS patients span a genomic region of ~1.5 (94%) or ~1.8 (5%) megabase pairs (Mb), encompassing approximately 28 genes (Frohnauer et al., 2010). Deletions occur due to nonallelic homologous recombination (NAHR) in a region of chromosome 7 containing blocks of unstable low copy repeat, with high sequence homology, that predispose to rearrangements during meiosis. There is considerable heterogeneity in deletion locations within this cytoband, as NAHR can occur within any of the blocks of low copy repeats that cluster to the WBS region. Furthermore, a genotype-phenotype correlative study of patients with WBS requires that the complexity of the pattern of genomic imbalance within this region be considered In this study an integrative clinical, cytogenetic and high-resolution array Comparative Genomic Hybridization (CGH) map of 7q11.23 deletions in 22 Brazilian patients with WBS has been performed, to compare the pattern of genomic imbalance with variations in the WBS phenotype. In all patients normal karyotype (550 band level) was observed, but analysis by FISH (probe LPU 011 - Cytocell) showed that all 22 cases, had a deletion of the WBS region. To analyze and precisely map the position of each deletion in this region array CGH (60K x 8 platform Agillent oligonucleotides) was performed. In 18 cases of the deletions had a minimal region of loss of 1.5 Mb (Type I deletions) and in 4 cases genomic losses were more extensive, approaching 1.8 Mb (Type II deletions). Direct correlations of phenotypical characteristics with the genomic mapping data failed to detect a significant differences between these two deletion classes of WBS patients. This is the first comprehensive high resolution genomic deletion analysis of WSB in Brazilian patients. The use of array-CGH technology allowed better delineation of the deletion maps that may be helpful for the patient prognosis.

949T

Refinement of the Jacobsen syndrome critical region for thrombocytopathy by aCGH. *D.J. Stavropoulos[1], Y. Diab[2], W.H. Kahr[2], R. Babul-Hirji[3], D. Chitayat[3].* 1) Department of Paediatric Laboratory Medicine; 2) Division of Haematology/Oncology; 3) Division of Clinical and Metabolic Genetics, Department of Paediatrics, The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada.

Jacobsen syndrome (JS) is a rare contiguous gene disorder characterized by a deletion within distal 11q ranging in size from 7 to 20 Mb. The clinical symptoms include dysmorphic features, growth and psychomotor delays, and congenital anomalies involving the brain, heart, kidneys and gastrointestinal systems. Some of the cases have transient neonatal thrombocytopenia and occasional pancytopenia that resolves over time, and persistent thrombocytopathy. The phenotype varies depending on the deleted segment. Recent studies of cases with partial deletions of 11q have implicated the FLI1 gene as a strong candidate for the haematological manifestation of this disorder. We present a 4-year-old girl with clinical symptoms of JS who was found to have a 2.899 Mb deletion at 11q24.2-11q24.3, with haploinsufficiency of the OMIM Morbid Map genes KIRREL3 (OMIM 607761), FLI1 (133450) and KCNJ1 (OMIM 600359), as well as MIR3167, ETS1, KCNJ5, C11orf45, TP53AIP1, ARHGAP32, and BARX2 genes. She had normal platelet counts but her platelet ATP release was significantly decreased and platelet electron microscopy revealed markedly decreased numbers of dense granules and the presence of giant alpha granules, likely caused by the haploinsufficiency of FLI1, as supported by previous studies. The BARX2 gene has been suggested as a candidate for the dysmorphic features and craniosynistosis due to its expression pattern, and her small deletion is supportive of that hypothesis. This deletion further refines the critical region associated with JS.

950T

A novel FOXG1 mutation causing congenital Rett syndrome presenting with lactic acidosis. *M. Strenk[1], A. Atherton[1], C. Saunders[2], B. Heese[1].* 1) Department of Pediatrics, Children's Mercy Hospitals and Clinics, Kansas City, MO; 2) Department of Pathology, Children's Mercy Hospitals and Clinics, Kansas City, MO.

Introduction: In the last few years, several variants of Rett syndrome (RTT) have been identified, both due to mutations in MECP2, as well as CDKL5 (variant RTT) and FOXG1 (congenital RTT). Features associated with RTT caused by FOXG1 mutations include hypotonia, acquired microcephaly, impaired motor development, and hypoplasia of the corpus callosum. At this time, 26 patients (19 females, 7 males) with FOXG1 mutations have been described in the literature. To our knowledge, none have presented with elevated lactic acid levels. Case History: We present a 21 month old Caucasian male with lactic acidosis, developmental delay and regression of skills following frequent illness. Other than feeding difficulties shortly after birth, his development was apparently normal until about four months, at which time he experienced frequent respiratory illness associated with loss of skills. He had laryngomalacia, GERD, abnormal sleep study, neutropenia, and seizures. Feeding difficulties and poor growth eventually necessitated placement of a G-tube. At 5 months of age, an initial metabolic work up included plasma amino acids that revealed an elevated alanine level of 636 umol/L (ref <439). Lactic acid was found to be elevated (8.4 mmol/L and 6.1 mmol/L (ref <2.1)) on two occasions. Comprehensive metabolic and genetic testing, including chromosomes, microarray, and methylation studies for Angelman syndrome, was otherwise negative. Prior to a planned biopsy to proceed with evaluation of pyruvate metabolism, the patient was found to have a de novo c.506delG mutation in FOXG1. Conclusion: Our patient has a novel FOXG1 mutation associated with a congenital RTT phenotype. His clinical picture is interesting given his elevated lactate, which lead to initial concerns for mitochondrial dysfunction. There are several reports in the literature of classical RTT (due to mutations in MECP2) associated with mitochondrial dysfunction. It has also been suggested that FOXG1 may share molecular pathways with MECP2 during brain development. This raises the possibility that FOXG1 mutations may also be associated with mitochondrial dysfunction. We recommend consideration of congenital Rett syndrome in patients who present with developmental delay/regression and lactic acidosis or clinical findings suggestive of mitochondrial dysfunction.

951T

Müllerian anomalies should be considered a component of the clinical phenotype of 16p11.2 deletion syndrome. *R.D. Susman[1], R.M. Kimble[2].* 1) Genetic Health Queensland, Royal Brisbane and Women's Hospital, Brisbane, QLD, Australia; 2) Department of Obstetrics and Gynaecology, Royal Brisbane and Women's Hospital, Brisbane, QLD, Australia.

With the increasing use of array comparative genomic hybridisation (aCGH), 16p11.2 deletion syndrome is becoming increasingly recognised. The recurrent ~550kb deletion (from 29.5-30.1Mb) is associated with variable clinical phenotypes including delayed language development, intellectual disability, autism, and congenital anomalies. Some people with this deletion have a normal phenotype. We report a 16 year old girl with multiple problems including intellectual disability, speech and language impairment, epilepsy, and Müllerian anomalies who has a 16p11.2 deletion. We will present further details of her phenotype and review the literature.

952T

A Novel Frame-Shift Mutation in the NHS Gene Associated with Significant Dental and Behavioural Phenotypes in Females in a Family with Nance Horan syndrome. *M. Szybowska[1], A. Levine[2], A. Toutain[3], C. Li[1].* 1) Clinical Genetics Program, McMaster University Medical Centre, Hamilton, ON, Canada; 2) Department of Ophthalmology, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 3) Service de Genetique, Hopital Bretonneau, Tours Cedex, FRANCE.

Nance Horan syndrome (NHS) is a rare X-linked recessive condition typically characterized by bilateral congenital cataracts and abnormal dentition in males with milder lens opacities and dental issues in females. Mental retardation, behavioural issues and dysmorphic features have also been documented. NHS is caused by mutations in the NHS gene on Xp22.13 whose protein product is thought to be involved in the development of the eye, teeth, brain, face, and skull. The overwhelming majority of reported mutations in NHS are nonsense, although microdeletions and missense mutations have also been observed. We report on a family with two sons clinically diagnosed NHS and their mother and two sisters. A novel frameshift mutation in NHS [c.2393dupC; p.Gly799TrpfsX34] that causes a premature stop codon was found in this family. Features of NHS in our family include not only congenital bilateral cataracts and dental anomalies in the two affected males but also very significant dental anomalies in the three affected females including: diastema, positional anomalies, persistence of deciduous teeth, tapering incisor crown, “screwdriver shaped teeth”, incisal notching, enamel hypoplasia, caries, and pulp anomalies. Indeed the dental phenotypes observed in the females are more severe in certain aspects than in the males in this family. One of the females is confirmed to have sutural cataracts and ophthalmology assessments are pending for the other two women. Additionally, the male and female siblings have difficulty with attention span but do not have mental retardation. Our report draws attention to a new frameshift mutation as well as the fact that significant dental and behavioural issues can manifest in females to the same degree as in males with NHS.

953T

Palate abnormalities in Chilean patients with chromosome 22q11 microdeletion syndrome. *M. Vasquez[1], M. Palomares[2,3], M.L. Guzman[1], G. Lay-Son[1,3,4], G.M. Repetto[1,4].* 1) Genetics, Clinica Alemana-Universidad del Desarrollo, Santiago, RM, Chile; 2) Fundación Gantz, Santiago, Chile; 3) Hospital Calvo Mackenna, Santiago, Chile; 4) Hospital Padre Hurtado, Santiago, Chile.

Chromosome 22q11 microdeletion syndrome (del22q11) has complex clinical features involving several organs and systems. The findings include structural anomalies such as cleft palate and cardiac malformations among others, as well as developmental and neuropsychiatric manifestations. It is the most frequent microdeletion syndrome in humans, with an estimated incidence of 1/4000 and is a common identifiable cause of cleft palate. We characterized the palatal abnormalities in a large cohort of Chilean patients with del22q11. Two hundred and one patients with the deletion were evaluated by geneticists and speech pathologists, including nasopharyngoscopy when indicated. The average age at the time of the study was 12.2 years, ranging from 1.4 to 49 years. Males represented 48% of the group. Nine cases (4.5%) were inherited from an affected parent. Palate abnormalities were diagnosed in 141 patients (70%). The most frequent findings were submucous cleft palate and velopharyngeal insufficiency, seen in 112 patients (59% of the total group). Overt cleft palate was seen in 21 patients (11%) and cleft lip and palate in 5 (2.6%). Patients with or without palate anomalies had similar gender distribution. Patients with palate anomalies were older at the time of diagnosis of the deletion compared to those without palate abnormlaties (average 5.9 vs 4.4 years, respectively). Congenital heart disease was seen in 48% of patients with palate abnormalities and in 70% of patients with normal palates (p 0.002, Fisher's exact test). Our data show a high frequency of palate abnormalities, similar to other published series, but no evidence of association was found with gender, in contrast with other reports. Heart disease was more frequent in patients with normal palates. The most common types of palate defects seen in this series are usually not evident on physical examination and thus require a high index of suspicion and active evaluation through nasopharyngoscopy. Funded by Fondecyt-Chile grant #1100131.

The Pitt-Hopkins syndrome: report of 20 new patients and proposal of a clinical score for the molecular test. *M. Zollino, S. Ricciardi, D. Orteschi, S. Lattante, M. Murdolo, G. Marangi.* Institute of Medical Genetics, Università Cattolica del Sacro Cuore, Roma, Italy.

Pitt-Hopkins syndrome (PTHS) is an emerging condition characterized by severe mental retardation, typical facial gestalt and additional features, such as breathing anomalies. Following the discovery of the causative haploinsufficiency of TCF4, about 60 cases have been reported. Because of the overlapping phenotype of severe mental retardation with absent speech, epilepsy, microcephaly, large mouth and constipation, differential diagnosis of PTHS with respect to Angelman (AS), Rett (RTTS) and Mowat-Wilson (MWS) syndromes represents a relevant clinical issue, and many patients are currently undergoing genetic tests for different conditions that are assumed to fall within the PTHS clinical spectrum. We performed a search for TCF4 mutations in 72 patients with a suspected PTHS by means of both quantitative genome analyses and/or direct gene sequencing. Haploinsufficiency of TCF4 was identified in 17 patients, as a consequence of complete gene deletions (2 patients), gene mutations (14 patients) and a t(14q;18q) balanced translocation disrupting TCF4 (one patient). By evaluating clinical features of these patients, we noticed that, in addition to the typical facial gestalt, the PTHS phenotype results from the various combination of the following characteristics: mental retardation with severe speech impairment, normal growth parameters at birth, postnatal microcephaly, breathing anomalies, motor incoordination, ocular anomalies, constipation, seizures, typical behaviour and subtle brain abnormalities. We assigned specific score to each signs, and a clinical checklist driving a first choice molecular test for Pitt-Hopkins syndrome is proposed and discussed. We found that patients with a proven TCF4 mutation reached scores significantly different from those of 16 patients with a proven mutation causing AS and of 13 patients with MECP2 mutation associated with RTTS. This checklist allowed the enrolment into the genetic test, with positive results, of three patients lacking the typical PTHS facial gestalt. On the same basis, a diagnosis of PTHS was made clinically in three patients who had normal TCF4. Although it was considered that PTHS evolves as a differential diagnosis to several encephalopathies with severe mental retardation and microcephaly, including Angelman and Rett syndromes, we observed that a molecular test of choice for PTHS is possible on a standardized clinical evaluation.

955T

***JARID2* isolated deletion is associated with velo-palatal insufficiency, hypotonia and developmental delay.** *T. Zvi, Y. Yaron, A. Orr-Urtreger, S. Ben-Shachar.* The Genetic Institute Tel-Aviv Sourasky Medical Center.

Palatal anomalies are amongst the most common major congenital anomalies. They include an array of defects such as cleft palate and velo-palatal insufficiency. The etiology of cleft palate is usually complex and believed to be associated with both genetic and environmental factors. However, many palatal anomalies are associated with chromosomal aberrations or monogenic disorders. Velo-palatal insufficiency without clefting has been reported in some genetic conditions as well. We report a 4-year-old male with speech delay, hypotonia, and a nasopharyngeal abnormality leading to velo-palatal insufficiency. Array based comperative genomic hybridization (aCGH) analysis, that was performed in Signature Genomics (Spokane, WA), revealed a ~220Kb deletion in chromosome 6p22-23, containing a complete heterozygous deletion of a single gene, *JARID2*, with no other annotated genes located in the deleted region. The deletion was confirmed by fluorescence *in situ* hybridization (FISH). Parental FISH analyses did not reveal the deletion. Neither deletions/duplications nor disease causing mutations have previously been described in *JARID2* gene. However, genome-wide-association studies have previously shown that *JARID2* mutations are associated with isolated cleft palate. We suggest, therefore that *JARID2* heterozygous isolated loss-of-function is a cause of congenital palatal abnormalities as well as intellectual disability. Furthermore, it is possible that *JARID2* intragenic mutations may be associated with cleft palate and/or intellectual disability as well.

Mosiac trisomy 22 and normal developmental outcome: Report of two cases and review of the literature. *D. Abdelgadir[1], C. Li[2], M.J.M. Nowaczyk[2, 3].* 1) Department of Pediatrics, Pediatric Residency Program, McMaster Univesity Hamilton, Ontario, Canada; 2) Department of Pediatrics, McMaster University, Hamilton, Ontario, Canada; 3) Department of Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada.

Mosiac trisomy 22 is known to be compatible with prolonged survival. However, there are fewer than 20 reports in the literature of live born children with minimal information about their neurodevelopmental outcome. We report 2 girls with mosaic trisomy 22 with dysmorphic features, but documented normal development at ages 3 and 5 years, respectively. Case 1 was diagnosed at 30 weeks gestation because of IUGR and cardiac abnormalities. Amniocentesis at that time showed mos 47,46,XX,+22[6]/46,XX,[11]. Analysis of skin fibroblasts showed mos 47,XX,+22[16]/46,XX,[5]. ASD and pulmonary stenosis were repaired in the newborn period, she also had LV non-compaction, but her cardiac function was normal. At age 5 years she presented with growth parameters <3rd centile, left-sided hemihyperplasia associated with hypomelanosis of Ito, and normal developmental milestones except mild gross motor delays. Case 2 presented antenatally at 18 weeks gestation with IUGR and tetralogy of Fallot. At birth, peripheral karyotype was normal, 46,XX, but cytogenetic testing of umbilical cord fibroblasts showed mos 47,XX,+22[4]/46,XX[4]; mosaic karyotype was also found in cardiomyocytes. At age 5 years she presented with normal social, language and fine motor skills. She had left-sided hemihyperplasia, but all her growth parameters were <3rd centile. Both girls had characteristic dysmorphic features including flat nasal bridge, preauricular pits, epicanthic folds and 5th finger clinodactyly. Approximately 50% of reported mosaic trisomy 22 cases had normal development. Prenatal and postnatal growth failure were the most common complications. Skeletal abnormalities including body asymmetry and 5th finger clinodactyly were also common. It is possible that children with trisomy 22 mosacisim, minimal physical findings and normal development are not diagnosed. Missing these mildly involved patients would lead to skewing of the prognosis for the final development outcome in this population. Appropriate information regarding developmental outcome is necessary for genetic counseling, especially in prenatal situations.

957T

A complex de novo 4 cell line mosaic with gains of 4p15.32pter and 12p13.31pter in a patient with intellectual disability, scoliosis and foot abnormalities. *S. Ahmed, K. Reddy.* Genetics department, Kaiser Permanente Southern CA.

A child with a complex mosaic karyotype had additional material on chromosomes 4 or 12, a dicentric 4, 12 and a normal cell line. A decade and a half later FISH characterized each of the abnormal cell lines to have duplications of 4p15.32pter and 12p13.31pter. The size of these gains and genes involved were defined using aCGH. After confirming this mosaicism in the buccal epithelial cells by iFISH we were able to proceed with confidence to draw a genotype to phenotype correlation.

958T

A de novo 4.7 Mb deletion 6p21.2p21.31 and an insertion of chromosome 6p23p21.31 into chromosome 3q26.32 with a pericentric inversion 3p25q26.32. *D. Broome, K. Reddy.* Dept Gen, Kaiser Permanente, Anaheim, CA.

A well adjusted, independent teenager who had attained menarche also had mild facial dysmorphism, developmental delay and mild intellectual impairment. Her childhood karyotype showed an apparent translocation between chromosomes 3 and 6. On revaluation at high resolution banding the chromosome 3 involved a pericentric inversion of 3p25q26.32 and an inverted insertion of 6p23p21.31 into 3q26.32. By array CGH a subtle de novo loss of 4.7 Mb from chromosome 6 short arm, arr 6p21.31p21.2 (35,597,487-40,283,968)x1 was identified and confirmed using FISH. A complete understanding of the 5-break, complex abnormality was possible because of combining the multiple techniques, which in turn provided an accurate recurrence risk. Because of the high risk, Genetic counseling included possible PGD diagnosis for any future pregnancy. The phenotype associated with a proximal 6p deletion, del(6)(p21.2p21.31) is described for the first time.

959T

Characterization of the derivative X chromosome resulting from Xq;Yq translocation in a female with recurrent abortion. *E.Y. Choi[1], D.E. Lee[1], B.Y. Lee[1], J.Y. Park[1], I.S. Kang[2], H.M. Ryu[2], S.Y. Park[1].* 1) Laboratory of Medical Genetics, Cheil Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea; 2) Department of Obsterics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Kwandong University College of Medicine, Seoul, Korea.

We present a cytogenetic and molecular cytogenetic study of a phenotypically normal female with an X;Y translocation. In this particular case, the breakpoints were located at the distal portions of the long arms on the X and Y chromosomes. Translocations between the Xq and Yq chromosomes occur rarely in humans. Chromosome analysis by G-banding showed a slight difference between the long arms of the two X chromosomes in a 28 year-old female with recurrent spontaneous abortion. Result of the fluorescent in situ hybridization revealed that there was Y chromosome material on the Xq. X inactivation study by R banding showed that the derivative X chromosome was late replicated in all 100 cells. Although the patient has a regular menstrual cycle to date, the Xq deletions have been known as a cause of premature ovarian failure. We have tried to localize the breakpoint positions of the X and Y chromosomes through methylation specific Southern blot analysis for FMR1 gene, multiplex PCR of Y-specific sequence tagged sites and array CGH.

960T

Mosaicism for deletion 8p22-p21.2, duplication 8p21.2-p12, and loss of the Y chromosome in an adult male with de novo robertsonian translocation 13;14. *D. Copenheaver[1], J. Meck[2], S. Aradhya[2], P. Tanpaiboon[1].* 1) Children's National Medical Center, Division of Genetics and Metabolism Washington, DC 20010; 2) GeneDx, Gaithersburg, MD 20877.

A cognitively impaired 28-year old male with a reported balanced robertsonian translocation between chromosomes 13 and 14, diagnosed at the time of amniocentesis, was referred to Genetics for re-evaluation. A whole genome oligonucleotide array CGH was requested to determine whether the translocation was truly balanced. The results instead revealed an 11.5 Mb mosaic interstitial deletion of 8p22-p21.2, an immediately adjacent 10.4 Mb mosaic duplication of 8p21.2-p12, and mosaic loss of the Y chromosome. There were no copy number abnormalities involving chromosomes 13 or 14. Both parents were phenotypically and karyotypically normal and neither had the copy number aberrations found in their son. The patient now presents with cognitive impairment, impulsive talking and bilateral hearing impairment requiring hearing aids, with the latter perhaps due to a lifelong history of recurrent ear infections. The patient has progressive bilateral keratoconus that may require bilateral corneal transplantation. At the age of 25, he started experiencing rapid hair loss. Physical examination revealed no dysmorphism except for simple, low set ears. This constellation of findings has not been previously reported in conjunction with duplication or deletion of 8p and/or mosaic 45,X/46,XY. Patients with full, non-mosaic 8p21.2-p22 deletion typically present with dysplastic ears, cognitive impairment, and microcephaly. Features of full, non-mosaic duplication of 8p similar to that found in our patient are markedly variable and do not constitute a distinct phenotype. The only consistent finding is mental retardation. Clinical findings in individuals with postnatally diagnosed mosaic 45,X/46,XY range from Turner syndrome to mixed gonadal dysgenesis, male pseudohermaphroditism, or a normal male phenotype. This proband had an unexpected number of chromosome abnormalities including a de novo balanced robertsonian translocation, a mosaic deletion/duplication abnormality of 8p, and mosaic loss of the Y chromosome. The mosaic nature of the unbalanced aberrations likely explain this unusual phenotypic presentation. Given the patient's de novo robertsonian translocation, investigation for possible uniparental disomy 14 should also be performed since this could contribute to the phenotype. Furthermore, the findings may represent the natural history of an individual with imbalance of genetic material of chromosome 8 and/or Y, since most reports describe phenotypes in children.

961T

Unexpectedly Variable Phenotype of a Combined Chromosomal Disorder of 18p Monosomy and 18q Partial Trisomy: Autopsy Findings. *M. Doi[1], H. Kuniba[1], S. Miura[2], M. Nakashima[3], T. Hayashi[4], A. Yamashita[1], A. Yanai[1], M. Obatake[5], K. Mochizuki[5], H. Moriuchi[1].* 1) Dept Pediatrics, Nagasaki University Hospital, Nagasaki, Japan; 2) Tissue and Histopathology Section, Division of Scientific Data Registry, Atomic Bomb Disease Institute, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 3) Dept Tumor and Diagnostic Pathology, Atomic Bomb Disease Institute, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 4) Dep Pathology, Nagasaki University Hospital; 5) Dept Pediatric Surgery, Nagasaki University Hospital, Nagasaki, Japan.

Introduction 18p deletion syndrome is characterized by mild to moderate mental retardation, speech delay, short stature, and characteristic face. While patients with holoprosencephaly-type defect usually have a poor prognosis, patients without severe brain malformations are believed to have unimpaired life expectancy. We herein report a fatal case of 18p depletion syndrome with unexpectedly variable clinicopathological manifestations and a unique combination of chromosome 18 abnormalities. **Case report** A 40-year-old woman (gravida 4, para 3, spontaneous abortion 1) underwent ultrasound examinations at 12 weeks of gestation, which showed fetal hygroma. Chromosomal analysis by amniocentesis at 16 weeks of gestation revealed 18p monosomy. The female baby was born at 39 weeks of gestation, weighing 2064 g. Soon after birth, she developed respiratory failure requiring mechanical ventilation. Her face looked “coarse”with a protruding forehead, low-set malformed ears and a low nasal bridge. She also suffered from heart failure, hyperbilirubinemia, panhypopituitalism, normocytic anemia, increased susceptibility to infection and feeding difficulty with continuous abdominal distention. Although she was intensively treated with mechanical ventilation, various medications, and enteral nutrition with duodenal tube for 3 months, she died of shock associated with sudden deterioration of paralytic ileus, adrenal insufficiency and severe anemia. Autopsy revealed that aplasia of the pituitary gland (empty sella), lung saccular hypoplasia characterized by failure to terminally differentiate alveolar sacs, non-compaction of the ventricular myocardium, hypoganglionosis of the ileum and cecum, myelodysplastic dysplasia, liver hemochromatosis, thymic hypoplasia, and hypoplasia of pancreatic) -cell within the islets. Array-comparative genomic hybridization (CGH) with Agilent 1M platform detected 18q partial duplication (18q22.3 - q23, 5.0-Mb) in addition to 18p deletion (18p11.32 - p11.21, 14.8-Mb). **Discussion** Our patient showed a variety of clinicopathological manifestations apparently different from those known for 18p monosomy. Little has been known about clinicopathological characteristics in patients with a combined chromosomal disorder of 18p monosomy and 18q partial trisomy. The correlation between those unique features proven by autopsy and the karyotype identified with array-CGH in details will shed light on the functional mapping of chromosome 18.

962T

Duplication of 10q associated with multiple congenital anomalies, dysmorphism, cognitive impairment and autism. *H. El-Shanti[1], Y. Al-Sarraj[1], R. Taha[1], H. Khair[2], Z. Hamed[2], I. Shafeeullah[2], B. Saleh[2], J. Alami[1].* 1) Shafallah Medical Genetics Center, Doha, Qatar; 2) Shafallah Center for Children with Special Needs, Doha, Qatar.

Characterizing chromosomal rearrangements at the molecular level is an often successful approach to identify monogenic disorder genes, as well as susceptibility loci for complex disorders. Autism spectrum disorders (ASD) are characterized by language impairment, social deficits, and repetitive behaviors and are associated with cognitive impairment in a fraction of affected individuals. Genetic factors play a significant role in the etiology of cognitive impairment, as well as ASD. Several studies have shown that DNA copy number variants (CNV) are associated with cognitive impairment, as well as ASD. We describe a 20 year old young man with multiple congenital anomalies including cleft palate and microphthalmia, dysmorphism including marfanoid habitus, prominent lips and prognathism, severe cognitive impairment and ASD. He has severe cognitive impairment with poor verbal and non-verbal communication skills. He talked at the age of 7 year but never acquired phrase speech. His ASD evaluation denotes a Pervasive Developmental Disorder Not Otherwise Specified (PDD-NOS). Cytogenetic analysis of his chromosomes revealed an unbalanced chromosomal abnormality with an additional chromosomal material attached to the short arm of chromosome 14. The chromosomal analysis of the parents was normal. The techniques employed for the molecular analysis included multiplex ligase-dependent probe amplification (MLPA), real-time PCR (RT-PCR) and SNP genotyping on an Illumina platform. The MLPA provided evidence that there are three copies of chromosome 10q subtelomeric sequences, which was confirmed by RT-PCR on two genes, *TUBGCP2* and *VENTX*, which are centromeric to 10q subtelomeric sequences. The Illumina SNP genotyping showed duplication of the telomeric 30 Mb of the long arm of chromosome 10. The RT-PCR refined the breakpoint to show that it does not disrupt any gene sequences but is present between *NT5C2* (2 copies) and *HCG* (3 copies). The duplicated region contains hundreds of genes. In conclusion, we describe a young adult with multiple congenital anomalies, dysmorphism and cognitive impairment and ASD, who carries a *de novo* duplication of the telomeric 30 Mb of the long arm of chromosome 10.

963T

Prenatal Somatic Overgrowth and Postnatal Growth Deceleration in Pallister Killian syndrome: Phenotypic and Mechanistic Overlap with Beckwith-Wiedemann syndrome. *K. Izumi[1], M. Kaur[1], L. Conlin[2], N. Spinner[2], A. Wilkens[1], Z. Zhang[3], I. Krantz[1].* 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Bioinformatics, Children's Hospital of Philadelphia, Philadelphia, PA.

Pallister Killian syndrome (PKS) is a multi-system developmental disorder typically caused by tetrasomy 12p mosaicism. Clinical manifestations in PKS includes craniofacial dysmorphia, clefts, ophthalmologic, audiologic, cardiac, musculoskeletal, diaphragmatic, gastrointestinal, gentiourinary, cutaneous anomalies, intellectual disability and seizures. Growth parameters are often normal to elevated at birth with deceleration of growth postnatally. The purpose of this presentation is 1) to further delineate the growth pattern of PKS, 2) to suggest PKS as an important differential diagnosis for Beckwith-Wiedemann syndrome (BWS), and 3) to discuss the potential mechanism of overgrowth in PKS. We conducted a retrospective chart review of 60 probands with PKS enrolled in the PKS study cohort at the Children's Hospital of Philadelphia. Birth weight was available on 50 probands and was greater than 90th centile in 18 probands (36%). Birth weight was greater than 50th centile in 42 probands (84%). None of the probands had birth weight of less than 10th percentile. Birth length was available on 45 probands and was greater than 90th centile in 17 (37%). Birth head circumference was available on 22 probands and was greater than 90th percentile in 11 (50%). Postnatal growth pattern was analyzed in 15 probands with birth weights greater than 90th centile. Weight and height usually drops within first year of life, with the exception of a single proband who maintained a weight greater than 97th percentile at 6 years. In addition to macrosomia, additional findings overlapping with BWS in this cohort included umbilical hernia and ear pits, and 2 PKS probands were clinically misdiagnosed with BWS, one of whom exhibited limb asymmetry. Our data demonstrates a unique growth pattern for PKS which consists of macrosomia at birth and subsequent growth deceleration after birth. Genome-wide expression array analysis revealed dysregulated expression of insulin-like growth factor binding proteins (IGFBPs). Upregulation of IGF2 activity is thought to play a pivotal role in the pathogenesis of BWS, suggesting a mechanistic connection between these two diagnoses.

964T

VCP mutations associated with varied phenotypes in the dominant and homozygous state. *V. Kimonis[1], A. Nalbandian[1], E. Dec[1], S. Donkervoort[1], H. Yin[2], G.D. Watts[3], B. Martin[4], C. Smith[4], V. Caiozzo[5], A. Wang[2], T. Mozaffar[2], J. Weiss[2].* 1) Division of Genetics, Department of Pediatrics, University of California Irvine, CA; 2) Department of Neurology, University of California, irvine, CA; 3) School of Medicine, Health Policy and Practice, University of East Anglia, Norwich, Norfolk, UK; 4) Department of Neurology, University of Kentucky Medical School, Lexington, KY; 5) Department of Orthopedic Surgery, University of California, Irvine, CA.

Hereditary inclusion body myopathy associated with Paget's disease of bone and frontotemporal dementia is an increasingly recognized disorder caused by VCP mutations and is now identified in 2% of familial amyotrophic lateral sclerosis. VCP is at the crossroads of many cellular functions including ubiquitin proteasome-mediated degradation, and p62-associated autophagy. Pathology includes ubiquitin and TDP-43 positive inclusions also seen in ALS and other proteinopathies. Genotype-phenotype correlations reveal marked intrafamilial variations and varied phenotypes including cardiomyopathy, ALS, Parkinson's, myotonia, cataracts and anal incompetence. Our studies in this fascinating disorder in patients, myoblasts and the knock-in VCP R155H mouse model adds some insight in the disrupted pathways in VCP disease. Our R155H VCP knock-in heterozygous mice demonstrate progressive muscle, bone, and brain pathology. Spinal cords show typical ALS pathology which increases with the age of the mice. Preliminary studies with our homozygous mice produce fewer than the 25% homozygous pups expected. The mice are small and die by 14-21 days of age. There is a decrease in muscle mass, wide variation in muscle fiber size and angulated myofibers, increase in nuclei and lymphocytes. The heart depicts marked bilateral hypertrophy and dilated vascular channels. Electron microscopy identifies abnormal mitochondrial structure in the homozygote tissue and immunohistochemistry studies implicate abnormal autophagy. Understanding the pathogenesis of VCP disease has implications for potential therapeutic targets in more common related progressive muscle, bone and brain diseases.

965T

19p13.3 pure duplication. *K. Kurosawa[1], A. Ishikawa[1], K. Enomoto[1], M. Tominaga[1], N. Furuya[1], M. Masuno[2].* 1) Kanagawa Children's Med Ctr, Yokohama, Japan; 2) Kawasaki University of Medical Welfare, Kurashiki, Japan.

19p13.3 aberration has been rarely described, and published reports are so limited. With the advent of array CGH, the newly recognized microdeletion/duplication syndromes have been emerging. We described a girl with 19p13.3 pure duplication caused by unbalanced translocation der(10)t(10;1-9)(qter;p13.3). She was born to non-consanguineous healthy parents. At the 28th weeks of pregnancy, severe IUGR was diagnosed. Due to fetal distress, a cesarean section was performed at 35 weeks of gestation. Her birth weight was 1216g, length 36.5cm, and OFC 28cm. APGAR were 4/9. She was referred at age 3 years for evaluation of a severe developmental and growth delay, dysmorphic facial appearance, and cardiac failure caused by pulmonary hypertension and mitral valve abnormalities associated with endocardial cushion defect. The detailed examination revealed left renal agenesis, scoliosis, strabismus, and dislocation of hip joints. Standard GTG is normal. Subtelomere screening by FISH with subtel probes showed cryptic translocation of 19pter to 10qter, but the 10qter signal was retained. Both parents had normal karyotype. Array CGH (Agilent, SurePrint G3, 60K) identified 5.7Mb duplication of 19p13.3 (arr 19p13.3(327,273-6,106,229)x3dn). FISH with BAC clones also confirmed the range of duplication. Only 3 cases with pure duplication 19p13.3 were reported, but the range of duplication varied. The common clinical features are developmental and growth delay. Chromosome 19 has the highest gene density among all chromosomes. Further analyses are required for genotype-phenotype correlation in the 19p13.3 duplication syndrome.

966T

Clinical Characteristics of Chromosome 18 Deletion Anomalies. *J. Lin[1], S. Wang[1], F. Lo[2].* 1) Division of Medical Genetics, Department of Pediatrics, Chang-Gung Memorial Hospital, Chung Gung University College of Medicine, Taoyuan, Taiwan; 2) Division of Pediatric Endocrinology, Department of Pediatrics, Chang Gung Memorial Hospital, Chung Gung University College of Medicine, Taoyuan, Taiwan.

Chromosome 18 abnormalities, including deletion of 18q, deletion of 18p, and ring chromosome 18, are among the most frequent autosomal anomalies, together occurring in approximately 1/40,000 live births. We retrospectively reviewed the chromosome 18-deletion patients in our hospital and compared them with previous reports. There were two patients with 18p deletion, four with 18q deletion and 6 with ring chromosome 18. Our patients had a higher proportion of ring 18 than 18q deletion. Mitotic instability for ring 18 was also noted. This might contribute to the clinical manifestation changes in future life. Malignancies, behavioral problems and thyroid functions should be carefully assessed when ring 18 patients were followed up.

967T

Duplication of GPC3 in the boy with growth retardation and developmental delay. *N. Nakashima, T. Yamagata, M. Saito, Y. Nozaki, M. Y. Momoi.* Dept Pediatrics, Jichi Medical Univ, Tochigi, Japan.

GPC3 mutations and deletion were reported to be responsible for Simpson-Golabi-Behmel syndrome (SGBS) that is one of the over growth syndrome such as Beckwith-Wiedemann syndrome (BWS). A boy with severe growth retardation and multiple anomalies had duplication on Xq26 including clusters of *glypican (GPC) 3* and *GPC4*. (Case report) The patient was a four-year-old boy. He was born at 35 weeks of gestation, and his height and weight at birth were 36cm and 1,440g, respectively. At four years of age, his height and weight were 75.8cm (-5.7SD) and 7.558g (-4.1SD), respectively. He also had severe mental retardation, double-outlet right ventricle, narrow palpebral fissures, micrognathia, cleft palate, hearing difficulty, low set ear, overlapping fingers, micropenis, etc. And he often showed fasting hypoglycemia. The secretion of thyroid hormone, growth hormone, ACTH and cortisol were all retained. No patient with *GPC3* duplication was reported, thus far. (Results) On his array CGH analysis using Agilent Human genome CGH 244K, about 4.6MB duplication on Xq25-q26 was detected. Main genes involved in this duplicated region were *ARHGAP36*, *IGSF1*, *MST4*, *RAP2C*, *HS6ST2*, *TFDP3*, *GPC4*, *GPC3*, *PHF6*, etc. and microRNAs. (Discussion) Among these genes, loss of function of *GPC3* causes SGBS which shows overgrowth with high stature, obesity and large head. Addition to that SGBS shows mild to moderate mental retardation, cardiac anomalies such as VSD, PA, TGA, etc, down slanting palpable, large mouth and gnathia, cleft palate, hearing difficulties, syndactyly skeletal abnormalities, etc. And *GPC4* may contribute to SGBS. Members of the glypican family, including *GPC3*, are heparan sulfate proteoglycans that bind to the exocytoplasmic surface of the plasma membrane and regulate the signaling of WNTs, Hedgehogs, fibroblast growth factors, and bone morphogenetic proteins. It was considered that over expression of *GPC3* causes growth retardation opposite to over growth induced by disruption of *GPC3*, like *IGF2* where over expression of *IGF2* induced BWS and suppression of *IGF2* induced intrauterine growth retardation. The fact that many anomalies in this patient and SGB were common organs and tissues also suggested that *GPC3* contributed to this patient.

968T

Interstitial duplication of 1p13.3-p22.3: Report of a patient and review of the literature. *I. Ohashi[1], T. Sasaki[1], T. Kusaka[2], Y. Shimanouchi[1], M. Masuno[3], S. Itoh[2].* 1) Pediatrics, Mitoyo General Hospital, Kanonji, Kagawa, Japan; 2) Pediatrics, Kagawa university, Miki-cho Kita-gun, Kagawa, Japan; 3) Graduate School of Health and Welfare, Kawasaki University of Medical Welfare , Kurashiki, Okayama, Japan.

Chromosome duplications of 1p are rare, and less than 20 such patients have been reported. We describe a three-year-old girl with an interstitial duplication of the short arm of chromosome 1 [46,XX,dup(1)(p13.3p22.3)]. The patient presented with some clinical findings, such as postnatal growth retardation, developmental delay, mild sensorial hearing impairment, dolichocephaly, epicanthus, telecanthus, sparse eyebrows, downturned corners of the mouth, soft cleft palate, and clinodactyly of the fifth fingers. She was born at 36 weeks of gestation by normal vaginal delivery with an Apgar score of 10 at 5 min. Her parents were nonconsanguineous. During gestation, her mother did not receive medication or radiation. There had not been intrauterine growth retardation; birth weight was 2,680 g and length was 46 cm. The family history was unremarkable. During the neonatal period, she demonstrated feeding problems and marked growth retardation. At the age of one year old, she also demonstrated developmental delay, especially that of language due to cleft palate and mild hearing impairment. She began to walk independently at 18 months. At the age of three years, chromosome study on peripheral blood was performed by GTG banding and showed a 1p duplication. Her karyotype was 46,XX,dup(1)(p13.3p22.3). At the age of three and half years, her height was 81.8cm (-2.6 S.D.) and weight was 9.0kg (-2.6 S.D.). Her mental development was equivalent to about two years of age. There were no cardiac or urogenital complications. Only 3 cases demonstrating a similar duplication of 1p have been reported, but the range of duplication varied: dup(1)(p13.1p22.1) [Lo et al., 1998], dup(1)(p13.3p22.1) [Utkus et al., 1999], dup(1)(p13.3p21.2) [Piccione et al., 2010]. Clinical manifestations are quite variable among these 4 patients including the present patient. A patient with dup(1)(p13.3p22.1) demonstrated Kabuki make-up syndrome [Lo et al., 1998]. However, our patient did not show any of the typical features of Kabuki syndrome. In another paper, the microduplication of 1p21.2-p13.3 was detected using array CGH technique and the patient was diagnosed as having autism spectral disorder [Piccione et al., 2010]. In this case, we should monitor her mental development, especially for signs of autism spectrum. Further analyses using array CGH are required for genotype-phenotype correlations in 1p13-p22 duplication patients.

MLPA and Cytogenetic Microarray: Utility in Evaluation of Mental Retardation. *S. Phadke[1], V. Boggula[1], R. Kumar[2].* 1) Dept Med Genetics, Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India; 2) Department of Pediatrics, Chhatrapati ShahujI Maharaj Medical University, Lucknow.

Identification of etiology of developmental delay / mental retardation (DD / MR) continues to remain a challenge for clinicians as well as scientists. With new molecular cytogenetic techniques there is improved diagnostic yield. We applied these techniques to study the cases of DD /MR without identified etiology after evaluation by a clinical geneticist and appropriate investigations like traditional karyotype, neuroimaging, fragile X study and other investigations like Fluorescent in situ hybridization, evaluation for genetic metabolic disorders as per clinical situation. One hundred and seventy four cases of DD /MR with or without malformations and dysmorphism were studied by Multiplex Ligation Probe Amplification (MLPA) using P245 kit by MRC, Holland for common microdeletion syndromes. One hundred and seventy four cases were studied by MLPA using kits for subtelomeres (P70 and P36 - MRC, Holland). Sixty males with DD /MR were studied by kit for X linked genes for DD /MR. Cytogenetic Microarray (CMA) analysis was carried out in 49 cases of idiopathic DD /MR and 2 cases of unbalanced karyotypes detected by MLPA and traditional karyotype. Out of 49 cases 7 genomic imbalances were detected and in 2 other cases CMA provided additional information. Two of these deletions could have been detected by MLPA as well. MLPA for common microdeletions identified imbalances in 13 out of 174 cases (7.4%) and kit for subtelomeres identified abnormalities in 4 out of 174 cases (2.3%). No abnormality was detected using the MLPA kit for X linked genes for MR/ DD. The molecular cytogenetic techniques improve the diagnostic yield of cases with DD/ MR and help greatly in genetic counseling. The choice of first test at present depends on the availability of the test and relative cost.

Identification of deletions in patients with cleft palate and/or velopharyngeal insufficiency without a definitive diagnosis. *L.A. Ribeiro-Bicudo[1], R.M.C. Sandri-Souza[2], N.C. Lorenco[1], R.M. Zechi-Ceide[1].* 1) Genetics, Hospital for Rehabilitation of Craniofacial Anomal, Bauru, Sao Paulo, Brazil; 2) Center for Human Genome Studies - Institute of Biosciences/USP, Sao Paulo, Brazil.

Aberrations of the 22q11 region are amongst the most common constitutional chromosomal abnormalities, with an incidence of around 1 per 4000. The resulting varied and complex phenotypes make these disorders a significant health problem. Congenital conotruncal cardiac defects, immune deficiency, palatal abnormalities, characteristic facial features, learning disabilities, and psychiatric symptoms present as the most common features. Although most individuals with 22q11 deletion syndrome (22q11DS) are considered to have a “common 3MB deletion” that contains more than 45 known genes, 8% show a 1.5Mb deletion, and a minority has smaller overlapping and non-overlapping 22q11.2 deletions. Thus, a molecular test that could identify deletion variants is relevant not only for increasing diagnostic rates, but also for identifying specific genes that could be involved in different 22q11DS phenotype. MLPA is a technology based on simultaneous hybridization of 40 DNA sequence-specific probes enabling the detection and delineation of deletions and duplications in the 22q11 region. MLPA kit is a cost-effective, rapid, and sensitive method effective for not only detecting, but also sizing the recurrent deletions and duplications in proximal 22q11. In the present work we evaluated a sample of 35 individuals presenting cleft palate and/or velopharyngeal insufficiency features without definite diagnosis by the MLPA technology. The results, confirmed by the use of positive and normal controls identified that 13 individuals had deletions in the region under study. The MLPA technique has been implemented successfully demonstrating that their inclusion in the diagnosis of chromosomal abnormalities in certain clinical conditions, such as the 22q11 microdeletion, can significantly increase the detection rate and therefore a more appropriate genetic counseling. We believe that a definitive diagnosis of 22q11DS helps the team predict the future needs of the patient and aids early intervention and allocation of the appropriate resources.

971T

Analphoid supernumerary marker chromosome characterized by high resolution array: a *de novo* 3q26.32-q29 duplication in a child with pigmentary mosaicism of Ito. *C.E. Steiner[1], K.S. Cunha[1], M. Simioni[1], T.A.P. Vieira[1], V.L. Gil-da-Silva-Lopes[1], M.B. Puzzi[2].* 1) Department of Medical Genetics, State University of Campinas Medical School, Campinas, Sao Paulo, Brazil; 2) Skin Cell Culture Laboratory, State University of Campinas Medical School, Sao Paulo, Brazil.

Pigmentary mosaicism of Ito is a skin abnormality often characterized by hypopigmentation of the skin following, in most cases, the Blaschko lines, usually associated with extracutaneous abnormalities, especially of the central nervous system. Here we report a sporadic case of a four year old girl presenting with developmental delay, speech abnormalities, congenital cardiac defects, umbilical hernia, high arched palate, cubitus valgus, short metacarpals and metatarsus, intermamilar increased distance, hirsutism, hypertrichosis, and low set ears. She also presented with hypopigmented streaks and whorls along the Blaschko's lines on face, trunk, legs, and arms. Chromosomal analysis on lymphocytes and cultured skin fibroblasts revealed a de novo supernumerary marker chromosome in mosaic (47,XX,+mar[38]/46,XX[12]). The karyotype of the parents was normal. Considering this, additional studies were undertaken to enhance the laboratory investigation. The marker chromosome was characterized as an analphoid with C-banding and subsequent study with a high resolution array (Genome-Wide Human SNPArray 6.0 Affymetrix®) was performed. SNP array analysis showed an amplification of 18045 kb in region q26.32q28 of chromosome 3, confirming the origin and breakpoints of the marker chromosome. These results are being validated with fluorescence in situ hybridization (FISH) studies. Hypopigmentation and hyperpigmentation following the Blaschko's lines are relatively common in individuals with chromosomal mosaicism. In cases where there is presence of marker chromosomes, the phenotype depending on the chromosomal region involved, the euchromatic content present and degree of mosaicism. Thus, it is important to characterize this chromosome markers to define the genes involved. Duplication of a specific autosomal segment tends to result in comparable phenotypes, thus the identification of more and more similar cases of analphoid duplication 3q marker will help in establishing a better genotype-phenotype correlation. The combined approach of karyotype and array analysis allowed the correct characterization of the cytogenetics abnormality on this case and also contributed to provide an accurate genetic diagnosis and better counseling to the family.

972T

Clinical features in a 4 year old male with trisomy 8p23.3p11.1. *D.L. Sternen[1], J. Conta[1], S.E. Wallace[1, 2].* 1) Division of Genetic Medicine, Seattle Children's Hospital, Seattle, WA; 2) Division of Genetic Medicine, University of Washington, Seattle, WA.

We report the clinical features of a 4 year old male with trisomy 8p23.3p11.1. There is a limited amount of literature on children with this specific duplication. Oligonucleotide array identified a gain at 8p23.3p11.1 that at minimum is 43.2 Mb (position 313560-43519004 based on hg18). G-banded karyotype showed an unbalanced translocation between chromosomes 8p11.1 and 14p11.1. The deleted 14p region was not covered by the array. A paternal balanced translocation between 8p and 14p was detected. Our patient has remained at the upper end of the growth chart, with current height 75%; weight 90%; head is relatively macrocephalic. He has minimal dysmorphic features including two posterior hair whorls, a short philtrum and wide-spaced teeth. He has mild joint laxity at the elbows and digits, a right transverse proximal palmar crease, and hypoplastic 5th toenails. His hair is coarse and skin shows persistent cutis marmorata. He has severe progressive neuromuscular scoliosis that required VEPTR placement. He has osteopenia, attributed to decreased weightbearing, and suffered two fractures of the right tibia. Frequent infections include chronic otitis media and sinus infections. Quantitative immunoglobulins showed low IgG and IgA; additional work-up for immune deficiency was negative. An echocardiogram, EKG, and renal ultrasound were normal. Head MRI showed absent corpus callosum. Spine MRI was normal. A brainstem auditory evoked response was normal. He has a history of early hypotonia that improved with time. He has gross and fine motor delays with no regression. At 4 years of age he is able to scoot and walks with a gait trainer. He uses approximately 10 signs, 20 words, and a few 2-word combinations. G-tube feeding was initiated due to poor and inconsistent oral intake presumed secondary to severe reflux and oral aversion. We wish to identify additional cases of older children with trisomy 8p23.3p11.1 to expand the phenotype and better characterize the natural history of this disorder.

973T

A long-term survivor with double aneuploidy of trisomy 18 and Klinefelter syndrome (48,XXY,+18): a successful shift from neonatal intensive care to home care. *Y. Ushiroda, M. Doi, H. Motomura, A. Yamashita, A. Yanai, H. Kuniba, H. Moriuchi.* Pediatrics, Nagasaki University Hospital, Nagasaki, Japan.

Introduction Double aneuploidy of trisomy 18 and Klinefelter syndrome is very rare, the natural history of which is hardly known. We herein report a patient with the double aneuploidy whom we have been following for 20 months since his birth until successful home care. Case report The male infant was born at 38 weeks of gestation from a 43-year-old mother. Birth weight was 2082 g. He was hypotonic, cried weakly, and had features characteristic of trisomy 18, such as hypoplastic and low-set ears, micrognathia, overlapping fingers, and rocker-bottom feet. He also had interruption of aortic arch and double outlet right ventricle. Chromosomal analysis was done after obtaining parents' informed consent, revealing a karyotype 48,XXY,+18. The patient's parents desired that his cardiac defects be repaired surgically; however, his underlying condition did not allow him to undergo a major operation. He has been treated with prostaglandins, initially by continuous intravenous infusion and later perorally. His other clinical problems included apnea attack, gastroesophageal reflux, and deafness. Respiratory condition has been well managed with oxygen administration and noninvasive positive pressure ventilation (NPPV), and appropriate nutrition has been maintained by enteral feeding through a duodenal tube. He was discharged home after 222-day stay at the neonatal intensive care unit. The aforementioned supportive care and medical treatment have been maintained with the family's dedicated involvement, enabling him to have a substantial time with his family. He became 20 months old, weighing 3500 g as of June 2011. Discussion Only less than 10 cases of double aneuploidy of trisomy 18 and Kleinfelter syndrome have been reported in the literature, and a 15-month-old infant lived the longest life. In most cases as well as the present one, the main manifestations were those of trisomy 18, including a number of malformations, cardiovascular defects, and respiratory distress. In this case, it was fortunate that his respiratory and circulatory conditions were relatively stable, so that he can survive any of those previously reported and live at home. Conclusion Double aneuploidy of trisomy 18 and Klinefelter syndrome is a rare chromosomal aberration with poor prognosis. However, coping appropriately with each clinical problem may allow patients longer survival and better management in a home care setting.

974T

Challenges in the clinical interpretation of *de novo* single gene deletions detected by high resolution genomic microarray screening. *N. Van der Aa[1,2], G. vandeweyer[2], F. Kooy[2].* 1) University Hospital Antwerp, Antwerp, Antwerp, Belgium; 2) University of Antwerp, Antwerp, Belgium.

The introduction of high resolution arrays allows the detection of very small genomic abnormalities. We screen our patients with intellectual disability routinely on an Illumina iScan system using the HumanCytoSNP-12 BeadChip for the possible presence of chromosomal abnormalities. The data are analyzed using our integrated platform CNV Webstore (BMC Bioinformatics, 2011, 12:4). This allows the detection of abnormalities of 10 consecutive probes at the routine level and even higher for cases of special interest. As a consequence, we have detected a relatively high number of deletions at the single candidate gene level. Examples of de novo single gene deletions in our patient cohort include NLGN4, CLIP2, CMIP and NETO1. The NLGN4 deletion was detected in a male patient with severe autism, and can therefore be considered causative. The deletion in CLIP2 was detected in a patient with autism that also had a 16p11.2 duplication. The phenotype of the index patient was due to the latter duplication, but the deletion in CLIP2, one of the 3 key genes that has been postulated to play a role in the typical cognitive profile observed in the Williams-Beuren syndrome, was present in the apparently unaffected mother and uncle of the patient and the effect of this mutation is under study. The de novo deletion of CMIP (deleted along with GAN that has no clinical consequences in this patient), was identified in a patient with delayed speech development and an autism spectrum disorder. CMIP was recently implicated in the etiology of specific language impairment by genome wide association analysis, suggesting a causative relationship between the CMIP haploinsufficiency and the clinical manifestation of the patient. A de novo deletion of NETO1 was identified in a patient with severe rolandic epilepsy. NETO1 was recently identified as an NMDA-receptor interacting protein required for synaptic plasticity and learning. The detection of these often unique abnormalities poses specific challenges for clinical counselling. We have obtained detailed clinical information for the patients described above, and were therefore able to make the diagnoses. At the same time we learned more on the role of individual genes in human disease. These cases stress the importance of the Decipher database, as more cases with the same abnormalities are needed for optimal interpretation of the data.

975T

Choreoathetosis, congenital hypothyroidism and neonatal respiratory distress syndrome caused by 14q13.3 deletion not encompassing *NKX2-1*: First reported case. *C.P. Barnett[1], S.M Kirwin[2], K.M.B Vinette[2], W. Waters[3], J. Mencel[1].* 1) SA Clinical Genetics, Women's and Children's Hospital/SA Pathology, North Adelaide, South Australia, Australia; 2) Nemours/Alfred I. duPont Hospital for Children, Wilmington, DE; 3) Cytogenetics, Women's and Children's Hospital/SA Pathology, North Adelaide, South Australia, Australia.

Background: Mutations in the NK2 homeobox 1 gene (*NKX2-1*) cause the rare but well defined syndrome known as choreoathetosis, congenital hypothyroidism and neonatal respiratory distress syndrome (OMIM 610978). Here we present the first reported patient with this condition caused by a 14q13.3 deletion which is adjacent to but does not interrupt *NKX2-1*, and review the literature on this condition. Case report: A 23 month old infant presented with a history of developmental delay, hyperkinesia, recurrent respiratory infections and hypothyroidism. Past history included unexplained neonatal respiratory distress requiring oxygen for 24 hours. Choreiform movements and delayed motor milestones were first noted at 6-8 months of age and extensive investigation for known causes of choreoathetosis were normal. At 23 months, examination revealed choreoathetosis, hypotonia and mildly dysmorphic facial features. TSH levels had been consistently elevated (2-4 x normal) from 8 months of age. Brain MRI revealed a hypoplastic pituitary gland but was otherwise normal. The clinical presentation was suggestive of choreoathetosis, congenital hypothyroidism and neonatal respiratory distress syndrome. Sequencing of all exons and splice site junctions of *NKX2-1* was performed but was normal. Array CGH was then performed and a 3.29 Mb interstitial deletion at 14q13.1-q13.3 was detected. The distal region of loss of the deletion disrupted the surfactant associated 3 gene (*SFTA3*) and was adjacent to, but did disrupt, *NKX2-1*. A multiplex PCR assay using fluorescently labelled primers amplifying a region of all exons of *NKX2-1* indicated the *NKX2-1* copy number was normal, ruling out the possibility of small deletions or insertions involving *NKX2-1*. Discussion: *NKX2-1*, located at 14q13.3, encodes important transcriptional factors involved in the developmental pathways for thyroid, lung and brain. The 14q13 deletion in our patient, adjacent to but not involving *NKX2-1*, emphasizes the role that the promoter region of *NKX2-1* or other genes in the region may play in the causation of this condition, including other known neurodevelopmental pathway genes (*RALGAPA1 and NPAS3*) and the surfactant pathway gene *SFTA3*. Conclusion: Deletions at 14q13.3 adjacent to but not involving *NKX2-1* can cause choreoathetosis, congenital hypothyroidism and neonatal respiratory distress syndrome. Array CGH should be done when *NKX2-1* mutations are not identified by sequencing or copy number analysis.

Reproductive fitness in adults with 22q11.2 deletion syndrome. *G. Costain[1,2], E.W.C. Chow[1,3], C.K. Silversides[4,5], A.S. Bassett[1,2,3,5].* 1) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 4) Toronto Congenital Cardiac Centre for Adults, Toronto General Hospital, University Health Network, Toronto, Ontario, Canada; 5) Division of Cardiology, Department of Medicine, University Health Network, Toronto, Ontario, Canada.

22q11.2 deletion syndrome (22q11.2DS) is the most common microdeletion syndrome in humans. Intellectual disability, schizophrenia (SZ), and serious congenital heart disease (CHD) are frequently associated features. These conditions can negatively affect reproductive fitness. As for other genomic disorders, fitness in individuals with 22q11.2DS is unknown.

The proportion with at least one child (PC) and the overall rate of liveborn offspring (LB) in 142 carefully phenotyped Canadian adults (>17 years) with 22q11.2DS [47.9% male; mean (SD) age 34.2 (11.6) years] were compared with those of their 207 unaffected siblings [48.3% male; mean age 36.0 (12.1) years]. Similarly, we also compared these fitness parameters in the subsets of adults with 22q11.2DS with SZ (n=54) and with serious CHD (n= 60) to age-, sex-, birth cohort-, and severity-matched disease comparison groups without 22q11.2 deletions. We identified phenotypic features in 22q11.2DS associated with childlessness using a multivariate logistic regression model.

Twenty (14.1%) adults with 22q11.2DS had in total 40 children; half inherited their parent's 22q11.2 deletion. Eighty-three (40.1%) siblings had 168 children (22q11.2DS/sibling relative PC=0.35, p<0.0001; relative LB=0.36, p<0.0001). Three (5.6%) individuals with SZ and 22q11.2DS had in total 10 children, while 13 (24.1%) individuals with SZ without 22q11.2DS had 25 children (22q11.2DS-SZ/SZ-comparison relative PC=0.23, p=0.01; relative LB=0.40, p=0.12). In contrast, there were no significant fitness differences between those individuals with CHD with and without 22q11.2DS. In addition to current age and male sex, mild to severe mental retardation (OR=5.96, p=0.02) and SZ (OR=22.54, p<0.01) were significant predictors of childlessness in 22q11.2DS. Notably, CHD was not a significant predictor of childlessness in 22q11.2DS.

Individuals with 22q11.2DS have significantly reduced reproductive fitness. This appears primarily related to the severity of the neuropsychiatric phenotype. Nevertheless, these data and the high rate of *de novo* mutations predict an increasing number of individuals with 22q11.2DS in the general population.

977T

A 2.42 Mb interstitial deletion at 12p13.1p13.2 in a female infant with neural tube defect and distinct dysmorphic features. *J. Fahrner[1], E. Wohler[2], C. Dinsmore[1], L. Henderson[1], D. Batista[2], T. Wang[1].* 1) Johns Hopkins University School of Medicine, Baltimore, MD; 2) Kennedy Krieger Institute, Baltimore, MD.

Neural tube defects (NTDs) are a group of common congenital malformations with significant morbidity and mortality. NTDs are known to occur sporadically and result from combined gene-environment interactions. Genes involved in folic acid metabolism have long been recognized and extensively studied as contributing risk factors to developing NTDs. However, the genetic landscape and molecular mechanisms that underlie the risks and severity of NTDs remain poorly understood. Here we report a 2 month-old female with spina bifida, myelomeningocele, hydrocephalus, Chiari II malformation, agenesis of the corpus callosum, developmental delay, and distinct facial and skeletal features. One maternal first cousin of the proband was noted to have spina bifida and hydrocephalus. SNP array was performed using the HumanQuad610 Beadchip and the Illumina BeadArray reader, and the data were analyzed using CNV partition v2.4.4.0 (Illumina, Inc., USA). A 2.42 Mb interstitial deletion at 12p13.1p13.2 (12,170,628-14,586,144; NCBI build 36.1) was identified in the proband but was not found in her unaffected mother and in over 2000 controls. This deletion involves 24 known genes, including low density lipoprotein receptor-related protein 6, or LRP6. Consistent with the predicted LRP6 deletion from the SNP array, the transcript levels of LRP6 in lymphoblasts were found to be lower in the proband than in her mother. LRP6 acts as a co-receptor for the canonical WNT signaling pathway, and a mutation in the gene has been associated with an increased risk of coronary artery disease in humans. However, mutations in LRP6 have not been linked with NTDs in humans. Interestingly, the lack of Lrp6 in mice results in neonatal lethality and multiple congenital anomalies, including spina bifida. Two naturally occurring NTD mouse models were found to have either homozygous hypomorphic or hypermorphic mutations in Lrp6, suggesting a gene dosage effect on the severity of the NTD phenotype. Our report provides suggestive evidence that abnormal LRP6 dosage and/or function may be involved in the pathogenesis of NTDs in humans.

Trisomy X and 7p15.2-p21.1 deletion in a patient with cleft lip and hand-foot-genital syndrome. *A.N. Filose, G.E. Tiller.* Department of Genetics, Kaiser Permanente, Los Angeles, CA.

Hand-foot-genital syndrome is a rare autosomal dominant disorder due to mutations or deletions of the HOXA13 gene on chromosome 7p15.2. We report a three year old female with trisomy X and an interstitial deletion of chromosome 7p15.2-p21.1. She was a former 2000gm term infant born to a 41 year old G9P5sAb1elAb2 Sephardic Jewish mother. Pregnancy was complicated by advanced maternal age and gestational diabetes. Amniocentesis revealed 47,XXX karyotype, and fetal anatomic survey revealed left-sided cleft lip; the couple elected to continue the pregnancy. At birth, a left-sided cleft lip and alveolar defect was evident, with simple low-set ears, short thumbs and great toes, and camptodactyly; the placenta was small with multiple infarcts and calcifications. The infant underwent placement of a gastrostomy tube in the first month of life for poor feeding. At three years of age, she has global developmental and growth delay (weight and head circumference 50% for 14 months). Array CGH revealed a 7.7Mb deletion from 7p15.2-p21.1. The deletion includes the entire HOXA gene cluster, but spares the TWIST locus distally. At least five other patients have been reported with deletion of the HOXA gene cluster and hand-foot-genital syndrome, but none have had cleft lip +/- palate. A patient reported by Hoover-Fong et al. (Am J Med Genet 117A:47, 2003) with deletion from 7p15.1-p21.1 had bilateral cleft lip and unilateral cleft palate, as well as other craniofacial anomalies. This suggests that a locus for facial clefting may lie between TWIST (distal) and the HOXA gene cluster (proximal) on chromosome 7p.

Preliminary analyses of de novo CNVs and sequence variation in the DDD project. *M. Hurles, Deciphering Developmental Disorders Project.* Wellcome Trust Sanger Inst, Cambridge, United Kingdom.

The Deciphering Developmental Disorders (DDD) project is a translational research project that is a collaboration between the Wellcome Trust Sanger Institute and the 23 NHS regional genetics services. The primary objective of the project is to investigate the utility of new genomic technologies for providing genetic diagnoses, by profiling ~12,000 families with children with severe undiagnosed developmental disorders using array-CGH, SNP genotyping and exome sequencing. I will outline the design of custom array-CGH, SNP genotyping and exome sequencing reagents to maximise the ability to identify causative variants, and the development of new, improved analytical approaches to discovering variation, determining de novo status, and interpreting genetic causation. I will summarise the application of these approaches to ~1,000 control samples, and estimation of the background rate of de novo CNVs. I will also review the preliminary analyses of 100+ families and identification of de novo CNVs and sequence variants in these families.

980T

The patterns of deletion at chromosome 15q11q13 defined with array comparative genomic hybridization in Korean Prader-Willi/Angelman syndrome patients. *H.W. Kim[1], S.Y. Shin[1,2,3], E.J. Seo[1,2,3], M. Hong[3], G.H Kim[2,3], J.Y Lee[2], H.W. Yoo[2,3,4].* 1) Dept. of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea; 2) Genome Research Center for Birth defects and Genetic disorders, Asan Medical Center, Seoul, Korea; 3) Medical Genetic Center, Asan Medical Center, Seoul, Korea; 4) Dept. of Pediatrics, University of Ulsan College of Medicine and Asan Medical Center, Seoul, Korea.

Introduction : Prader-Willi/Angelman syndromes(PWS/AS) are imprinting disorders caused by deletion or nonfunctioning of imprinted genes at chromosome 15q11q13. Deletion at the critical regions of Prader-Willi/Angelman syndrome accounts for about 70% of both PWA and AS. According to the location and size of the deletion, a number of other loci rather than the crucial deleted regions may be related to present diverse phenotypes. In the present study, we performed chromosomal microarray study to characterize the pattern of deletions in Korean PWS/AS patients. **Materials and methods :** Among 58 PWS and 21 AS patients who were confirmed by methylation-specific PCR, 40 PWS and 17 AS patients with deletion by FISH study were subjected. Array comparative genome hybridization was performed using 60k oligonucleotide microarray (Agilent Technologies, Santa Clara, CA). Commercial pooled male DNA was used for reference (Promega, Madison, WI). Electronic medical records were retrospectively reviewed. **Results :** The size of deletion ranged from 4.0 Mb to 8.7 Mb. We could classify the patients into three groups according to patterns of deletion; type I (BP1 to BP3), type II (BP2 to BP3), and atypical type (BP2 to BP5). Type II deletion was found in 23 (57.5%) of 40 PWS and 9 (52.9%) of 17 AS. Approximately 1.9 Mb loss of known CNV region proximal to BP1 was more frequent in type I than type II deletion; 45.8% vs 21.9%. A distinct large deletion of 8.7 Mb from BP2 to BP5 was observed in a AS patient presenting seizure, which contains CHRNA7 gene reported as a candidate for the seizure phenotype in 15q13.3 microdeletion syndrome. **Conclusions :** Statistically significant differences were not found in the distribution of deletion patterns between PWS and AS. Common breakpoints were observed determining the consistent deletion patterns in majority. The distinct AS case with large deletion encompassing BP2 to BP5 may underline the contribution of the CHRNA7 gene for seizure phenotype.

981T

The smallest region of deletion on 3p25 in a patient with 3p deletion syndrome. *I. Peltekova[1], A. MacDonald[1], C. Armour[2].* 1) Pediatrics, Kingston General Hospital, Kingston, Ontario, Canada; 2) Clinical Genetics, Kingston General Hospital, Kingston, Ontario, Canada.

The rare 3p deletion syndrome presents with a spectrum of anomalies caused by deletions within the distal short arm of chromosome 3. Some of the phenotypic features of this syndrome include facial dysmorphisms, cognitive impairment, growth retardation, congenital heart defects, and renal and intestinal anomalies. The clinical severity of the 3p deletion syndrome is variable because different deletion sizes and locations within the short arm of chromosome 3 have been shown to cause the disorder. Recently, the smallest causative deletion, consisting of 1.6Mb within 3p25.3-p26.1, was identified in a patient with 3p deletion syndrome. Here we describe an even smaller heterozygous interstitial deletion of 643kb in a girl who displayed typical features of the syndrome. We have performed a comparative analysis of the phenotypes and the deleted regions shared between our patient and the one recently described with the 1.6Mb deletion. The two patients have several typical features of the 3p deletion syndrome, such as mental retardation, seizures and congenital heart defects. In addition, they share a 518kb region of overlap that contains 12 candidate genes: *THUMPD3*, *SETD5*, *LHFPL4*, *MTMR14, CPNE9, BRPF1, OGG1, CAMK1, TADA3, ARPC4, TTLL3,* and *RPUSD3*. The putative functions of several genes as reported in the literature are discussed with respect to their involvement in the 3p deletion syndrome phenotype. We focus on *CRELD1* and its relation to congenital heart defects and organogenesis. We evaluate the implication of *CAMK1* and *SRGAP3* in abnormal cognitive development and mental retardation. We also examine the involvement of *TADA3* in the deregulation of physiologic processes that may account for the multiple anomalies seen in the 3p deletion syndrome. In summary, this report further refines the 3p deletion region and reviews some of the candidate genes implicated in this syndrome.

982T

A new case of interstitial 6p22.3 chromosome deletion : confirmation of the minimal critical region. *L. PINSON[1], A. SCHNEIDER[1,2], M. TOURNAIRE[1,2], M. GIRARD[1,2], P. BLANCHET[1], C. COUBES[1], D. GENEVIEVE[1], P. SARDA[1], G. LEFORT[1,2], F. PELLESTOR[1,2], S. TAVIAUX[1,2], E. HAQUET[1], J. PUECHBERTY[1,2].* 1) Medical genetics, Hôpital Arnaud de Villeneuve, CHRU, MONTPELLIER, Languedoc, France; 2) Chromosomal genetics, Hôpital Arnaud de Villeneuve, CHRU, MONTPELLIER, Languedoc, France.

Deletions of the short arm of chromosome 6 are rare events, mostly discovered by standard cytogenetics. Using molecular cytogenetics, two distinct 6p deletion syndromes were described, corresponding to terminal (6p24-pter) and interstitial (6p22-p24) regions. The introduction of array CGH in clinical diagnostics has led to improved detection and characterization of chromosomal microrearrangement syndromes. Seven cases with an interstitial deletion of the short arm of chromosome 6 involving the 6p22.3 region have been described so far in the literature. From these cases, Bremer et al., (2009) defined a 2.2-Mb minimal critical region (MCR) for the 6p22 deletions, containing 12 genes. The main features reported are developmental delay, hypotonia, brain, heart, and kidney defects, craniofacial anomalies (abnormal skull shape, structural eye and ears abnormalities, short neck) and clinodactyly or syndactyly. We report a de novo interstitial 6p22.3 deletion in an 5.5-year-old girl. The patient was referred to our Department of Medical Genetics because of developmental delay of undefined origin. She presented with psychomotor delay, moderate lower limb spasticity and moderate postnatal microcephaly. The patient has always had friendly and amiable behavior. Clinical examination revealed a triangular face, deeply set eyes, hypotelorism, thin upper lip, posteriorly rotated ears, short neck, clinodactyly of the fifth digit and big hallux. Magnetic resonance imaging of the brain was normal. Conventional cytogenetic studies showed a normal female karyotype (46,XX). Microarray analysis (SNP6.0, Affymetrix) showed a 2.25Mb interstitial deletion of the 6p22.3 region encompassing 11 genes. Interestingly, this deletion corresponds to the MCR defined by Bremer et al., except for the most proximal gene which is not deleted in our patient. Also, it is interesting to note that our patient did not present with heart or kidney defects. We compare the phenotype observed in our patient and the patients with overlapping deletions and discuss candidate genes linked to the features described in the patients with 6p22.3 deletion. Further observations of a larger number of patients with 6p22.3 chromosomal deletions may lead to the recognition of a specific phenotype. To achieve this, it seems important that microarray analyses revealing 6p22.3 deletions be accompanised by detailed clinical data as well as the recording of all the cases in international genetic databases.

983T

Phenotypic variability in individuals with chromosome 15q11.2 microdeletion. *J. Ranells, P. Newkirk, T. Ferlita.* Univ South Florida Col Med, Tampa, FL.

Recent reports describe a broad range of developmental, neurologic and behavioral abnormalities in individuals with microdeletion between breakpoints 1 and 2 proximal to the Prader-Willi/Angelman critical region. This _500 kb region contains four highly conserved non-imprinted genes — *NIPA1*, *NIPA2*, *CYFIP1* and *TUBGCP5*, three of which have a role in central nervous system function. The microdeletion is often inherited from a phenotypically normal parent. We present clinical features of 6 individuals (4 probands and 2 parents) with this microdeletion evaluated in a recent 6 month period. SNP microarray analysis was performed at LabCorp on each proband using the Affymetrix v.6.0 platform. Parental follow-up studies were performed by FISH analysis. Patient 1 is an 8 month old female with left auditory neuropathy, mild developmental delay, hypotelorism and a 627 kb deletion. Father, a college graduate, carries the deletion. Family history is negative for behavioral, neurologic and psychiatric difficulties. Patient 2 is a 4 year old girl with mild developmental delay, hypotonia, language regression at 18 months, autistic characteristics and a 638 kb deletion. Parental studies were normal. Family history is significant for: sister with mild learning difficulties, odd behavior and immaturity; mother with mild anxiety; maternal aunt with seizures; paternal aunt with learning disability, schizophrenia and bipolar disorder. Patient 3 is an 8 year old boy with ADHD, mild intellectual disability, autistic characteristics, minimal ptosis, inferior epicanthal folds, prominent fetal finger pads and 581 kb deletion of 15q11.2, 202 kb deletion of 9p23 and 236 kb deletion of 12q23.1. Mother shares the 15q and 12q deletions and father has the 9p deletion. Twin sister is a slow learner and in speech therapy. Mother had speech therapy. Father and his parents are “loners”. Patient 4 is a 9 year old boy with moderate intellectual disability, severe developmental regression at age 15 months, hypertonia, scaphocephaly, high narrow palate and preauricular pit. He is non-verbal, has oral aversion, GERD and is gastrostomy dependent. He has a 2.193 Mb deletion including the BP1-BP2 region and extending proximally. Mother has schizophrenia. Parents are unavailable for testing. These cases illustrate the difficulty in defining the spectrum of clinical features associated with this deletion and the need for further studies to identify factors that contribute to the variable phenotype.

984T

An 81kb deletion detected by aCGH in a patient with Rubinstein-Taybi syndrome. *E.C. Tan[1], A.H.M. Lai[2], E.C.P. Lim[1], J.S.H. Ng[1], M.S. Brett[1].* 1) KK Research Center, KK Women's & Children's Hospital, Singapore; 2) Genetics Service, KK Women's & Children's Hospital, Singapore.

Rubinstein-Taybi syndrome is a multiple congenital anomaly syndrome characterized by mental retardation, postnatal growth deficiency, microcephaly, broad thumbs and halluces, and dysmorphic facial features. The pattern of inheritance is autosomal dominant although most cases are sporadic. The disorder is usually caused by de novo mutations in the gene encoding transcriptional coactivator CREB-binding protein (*CREBBP*) on chromosome 16p13.3 or the 300KD E1A-binding protein (*EP300*) on chromosome 22q13.

We report a patient who is the second offspring of biologically unrelated parents who are phenotypically normal. They have two other healthy children but the mother had a cousin who had absent speech at age 15. The patient was born at full-term with normal birthweight. At the initial assessment at the Genetics Clinic at 2 years of age, her height was within normal range but her head circumference was on the 10th centile and her weight was on the 90-97th centile for age. At 7 years of age, her height was on the 25th centile but her weight was on the 97th centile for age. Clinical diagnosis of Rubinstein-Taybi syndrome was made based on her physical features of downslanting palpebral fissures, a prominent nose with the nasal septum extending below the alae nasi, broad thumbs and big toes and postaxial polydactyly on the right foot. Renal ultrasound scan revealed bilateral hydronephrosis. She had global developmental delay since infancy. Other than persistent constipation since infancy, her general health is good. She does not speak but can communicate with gestures and understands instructions.

Peripheral blood karyotype analysis was reported as normal (46,XX). Results from Agilent 400K Human CGH array showed copy number loss for chromosome 16p13.3. Amplification of the region across the breakpoint and subsequent sequencing results showed the deletion to be approximately 81 kb. It starts from the 5' untranslated region of the deoxyribonuclease I gene (*DNAse I*), includes the whole of the TNF receptor-associated protein 1 gene (*TRAP1*), and extends into the CREB-binding protein gene (*CREBBP*) which has the last three exons deleted. The molecular results confirm the clinical diagnosis of the patient whose phenotypic presentations are almost certainly due to the identified 16p13.3 microdeletion.

985T

A Rubinstein-Taybi syndrome patient with partial deletion of the CREB binding protein (CREBBP) gene. *E. Wohler[1], A. Bytyci[2], L. Henderson[2], E. Germain-Lee[3], J. Hoover-Fong[2,4], DAS. Batista[1,2,5].* 1) Cytogenetics Laboratory, Kennedy Krieger Institute, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 3) Hugo W. Moser Research Institute and Albright Clinic at Kennedy Krieger Institute, Baltimore, MD; 4) Greenberg Center for Skeletal Dysplasias, Johns Hopkins University, Baltimore, MD; 5) Pathology Department, Johns Hopkins University, Baltimore, MD.

Rubinstein-Taybi syndrome (RTS) is a rare autosomal dominant genetic disorder affecting approximately 1 in 125,000 individuals. Most patients with RTS have a de novo defect in the CREB binding protein (CREBBP) gene. Features of RTS include broad thumbs with radial deviation and broad great toes, seizures, moderate to severe intellectual disability, constipation, short stature and characteristic facies with downslanting palpebral fissures, arched brows, bitemporal narrowing and columella lower than alae. Our patient is a 5-month-old former term male with bilateral thumb deformities, crumpled auricles, hypertrichosis of the forehead with confluence of anterior hairline to lateral brows, mild truncal hypotonia, chronic constipation, and slow motor skill acquisition. Birth weight and length were 7 lbs, 14 oz. (25-50th percentile) and 21 inches (90th percentile), respectively. By 5 months he had symmetric growth failure with height and length below the 3rd percentile and head circumference at the 5th percentile, an abnormal growth pattern that is typical for RTS. The clinical diagnosis of RTS syndrome was suspected in this case. A single nucleotide polymorphism (SNP) array (Illumina 610K BeadChip) revealed a 41 kb deletion on chromosome 16 (3,699,394-3,740,546 bp (NCBI Build 36/hg18)) involving 11 consecutive markers overlapping the distal 3' end of CREBBP. Further gene-specific testing was performed in another laboratory using the oligonucleotide aCGHExonArrayDx platform (GeneDx). This established a heterozygous deletion of exons 17-31 of CREBBP. 5-10% of patients with RTS have a defect in one or more exons of CREBBP. Only one case with RTS has been reported with a partial deletion of CREBBP spanning the same exons 17-31 as in our patient. The clinical indication of RTS in this patient was instrumental for the detection of the abnormality by the SNP array since the number of markers involved and the size of the deletion were below our reporting range.

986T

Severe Aortic Stenosis in a Child with Joubert Syndrome and Related Disorders (JSRD) - a Case Report and Review of Congenital Heart Defects Reported in the Human Ciliopathies. *S.C. Bowdin[1], N. Karp[1], L. Grosse-Wortmann[3], S. Blaser[2].* 1) Clinical & Metabolic Gen, Hosp Sick Children, Toronto, ON, Canada; 2) Department of Radiology,Hosp Sick Children, Toronto, ON, Canada; 3) Department of Cardiology, Hosp Sick Children, Toronto, ON, Canada.

We report a 2 year-old boy with classical features of JSRD including oculomotor apraxia, postaxial polydactyly, episodes of rapid breathing and developmental delay. MRI demonstrated the “molar tooth sign”. The child was also diagnosed with severe congenital aortic stenosis. Sequencing of the AHI, TMEM67, CEP 290 and NPHP1 was negative for mutations. We await results for CC2D2A, INPP5E, RPGRIPIL, ARL13B and TMEM216. JSRD is one of a group of conditions known as `ciliopathies', whose multi-organ involvement results from primary cilia dysfunction. There have not been other reported cases of aortic stenosis associated with JSRD. Cardiac screening is not currently recommended in the management guidelines for JSRD. We speculate that while the presence of congenital aortic stenosis in this child could be caused by an unrelated genetic mechanism, it could also represent a phenotypic overlap with another ciliopathy, the Bardet Biedl syndrome, in which aortic stenosis is present in about 38% of cases. Primary cilia coordinate cellular signal transduction pathways during embryonic development, including Hedgehog. In mouse models of early cardiogenesis, cardiomyocyte differentiation is coordinated by the primary cilium. This implies a role for cardiac primary cilia, as well as nodal cilia, in the pathogenesis of cardiac malformations in human ciliopathies.

987T

Characteristics of kidney and liver disease in 38 patients with Joubert syndrome and related disorders (JSRD). *J. De Dios[1], T. Vilboux[1], K. Daryanani[2], I.B. Turkbey[3], P. Choyke[3], D. Doherty[4], I. Glass[4], M. Parisi[5], J. Bryant[1], M. Huizing[1], T. Heller[1], W.A. Gahl[1], M. Gunay-Aygun[1].* 1) NHGRI, NIH, Bethesda, MD, MD; 2) NIH Clinical Center, Bethesda, MD; 3) Molecular Imaging Program, NCI, NIH, Bethesda, MD; 4) University of Washington, Seattle, WA; 5) NICHD, NIH, Bethesda, MD, MD.

Joubert syndrome and related disorders (JSRD) are a genetically and phenotypically heterogeneous group of ciliopathies defined based on the unique combination of midbrain and hindbrain abnormalities resulting in the pathognomonic “molar tooth sign” on axial brain imaging. JSRD patients can have mutations in a variety of genes that are also associated with other ciliopathies. Similar to other ciliopathies, a subset of patients with JSRD develop hepatorenal fibrocystic disease. Under the NIH clinical protocol, “Clinical Investigations into the Kidney and Liver Disease in Autosomal Recessive Polycystic Kidney Disease (ARPKD)/Congenital Hepatic Fibrosis and other Ciliopathies” (ClinicalTrials.gov: NCT00068224), we evaluated 38 JSRD patients. All patients had the typical “molar tooth sign”. Age at NIH evaluation ranged from 0.9 to 36.2 years (8.6 + 7.3). Four patients from 4 families carried the diagnosis of Senior-Loken syndrome (SLS) and 12 from 10 families were classified as COACH syndrome based on presence of liver involvement. There was history of oligohydramnios in 4 and polyhydramnios in 2 patients. In 5 patients, prenatal ultrasound showed enlarged hyperechoic kidneys, indistinguishable from ARPKD. Six individuals including 3 SLS and 3 COACH syndrome patients received kidney transplantation, one after the NIH visit. Age at kidney transplantation ranged from 4 to 13 years (7.5 + 3). High resolution ultrasound (HR-USG) of the kidneys was normal in 20 of the 33 patients with native kidneys (ages 0.9 to 36.2 years, mean 7.0 + 8.1). The most common ultrasound finding was diffusely increased echogenicity with loss of corticomedullary distinction with or without discrete cysts; kidney size was enlarged in 2, small in 1 and normal in others. Two patients had unilateral multicystic dysplastic kidney. Glomerular filtration rate (GFR) was less than 80 ml/min/1.73 m2 in 12 patients, including 2 who had normal ultrasounds and GFRs of 52 and 65 at ages 9 and 3.5 years, respectively. While all COACH patients (11.6 + 8.8 years) had elevated liver enzymes, review of records showed normal liver enzymes in the first years of life. Nine patients including 7 with COACH had splenomegaly suggesting portal hypertension. No patients showed liver cysts. JSRD patients should be monitored for kidney and liver disease. Next generation DNA sequencing is underway. Genotype phenotype correlations might enable prediction of hepatorenal disease.

988T

New syndrome? situs inversus totalis and infantile spasm and generalized hypotonia with severe global developmental delay. *B. Hashemi[1], K. Siriwardena[1], S. Jain[1], M. Moharir[2], O. Bar-yousef[2], A. Ali[3], D. Chitayat[1,4].* 1) Department of Pediatrics, Divisions of CIINICAL and METABOLIC GENETICS, Hospital for sick children, Toronto, Canada; 2) Department of Pediatrics, Divisions of NEUROLOGY,Hospital for sick children, Toronto, Canada; 3) Department of Pediatrics, Divisions of OPHTALMOLOGY,Hospital for sick children, Toronto, Canada; 4) The Prenatal Diagnosis and Medical Genetics Program, Department of Obstetrics and Gynaecology, Mount Sinai Hospital; UoT, Toronto, ON, Canada.

Situs inversus totalis (SIT) is in most cases a rare sporadic and asymptomatic condition but about 3-5% of these patients have heart defect. CNS abnormalities associated with this condition is rare. We report a patient with SIT and idiopathic infantile spasm. Since to our best knowledge this has not been reported previously it may be a new syndrome caused by a gene associated with laterality determination and brain function. This female patient is 18 month old, born to non-consanguineous parents of Indian origin. The pregnancy was uncomplicated and delivery was at term by C/S due to decrease fetal movement and breech presentation. Postnatal investigation showed situs inversus totalis and hypotonia with roving eyes were noted. At 2 months of age she presented with infantile spasm and Hypsarrythmia on EEG with no response to anti-seizure medications. Ophthalmologic exam showed recently bilateral papilledema and hyperpigmented fovea with cortical blindness. On physical examination all of the growth parameters are WNR, her facial features showed mild frontal bossing, curly hair (not familial), high arched palate and small teeth. Brain MRI showed mild generalized decrease in volume and hypomyelination. Detailed metabolic investigations showed no abnormalities and microarray analysis was normal. Muscle biopsy for mitochondrial cytopathy and hair EM were also normal. SIT is known to be associated with ciliary abnormalities but little is known about cilia function in brain morphogenesis and function. In the mouse mutant for the ciliopathy gene Ftm, olfactory bulbs are present in an ectopic location in the telencephalon. Recent publication showed that a mutation in the in KIF7, a gene associated with human primary ciliary function, causes hydrolethalus and acrocallosal syndromes. Further studies are being done to identify the etiology of the ciliopathy causing the SIT and brain dysfunction in our patient.

989T

Confirmation of the Chromosomal Microarray as a first-tier Clinical Diagnostic Test for Individuals with DD/ID and MCA. *A. Battaglia[1,2], A. Novelli[3], L. Bernardini[3], T. Filippi[1], V. Doccini[1], JC. Carey[2].* 1) Dev Neurosciences, Stella Maris nst/Univ Pisa, Pisa, Italy; 2) Division of Medical Genetics, Dept. of Pediatrics, University of Utah Health Sciences Center, SLC, USA; 3) IRCCS Hospital S. Giovanni Rotondo & CSS Mendel Institute, Roma, Italy.

Submicroscopic structural chromosomal rearrangements are the most common identifiable causes of Developmental Delay/Intellectual Disability (DD/ID) associated with multiple congenital anomalies (MCA). Chromosomal microarray (CMA), able to detect rearrangements as small as 3 Mb or less and to identify position, size and presence of known genes, is increasingly utilized for genetic testing of such individuals. In this study, we analyzed 343 karyotyped patients affected by DD/ID/MCA, observed at the Stella Maris Institute between May 2004 and May 2011. There were 219 (63.8%) males and 124 (36.2%) females, aged 5 months to 19 years. Blood samples, collected from patients and their parents, were analyzed, at the Mendel institute, with CMA at a resolution ranging from 1 Mb to 75 Kb. We identified pathogenic CNVs in 22% (75/343) of our sample (53 males vs 22 females). 41.1% were inherited and 41.7% de novo. 48 of the detected CNVs were deletions and 35 duplications. Most CNVs were detected by CMA at 200 Kb resolution. All CNVs were confirmed using qPCR or FISH. Our study provides further evidence of the high diagnostic yield of CMA for genetic testing of individuals with unexplained DD/ID and MCA, confirming its first-tier use in such disorders.

990T

1p36.2 CNVs Cause Setleis Syndrome, A Focal Facial Dermal Dysplasia. *R.J. Desnick[1], A. Yang[1], L. Edelmann[1], L. Liang[1], I. Nazarenko[1], A. Ma'ayan[2], B.E. Blessing[3], V.K. Proud[3], J.E. Ming[7], J.A. Rosenfled[4], C. Cadilla[5], A.R. Norby[6], D.D. Weaver[6].* 1) Dept Gen/Genomic Sci, Box 1498, Mount Sinai Sch Med, New York, NY; 2) Dept Pharmacology and Systems Therapeutics, Mount Sinai Sch Med, New York, NY; 3) Children's Hospital of the King's Daughters', Norfolk, Virginia 23507; 4) Signature Genomic Laboratories, Spokane, Washington 99207; 5) Department of Biochemistry, University of Puerto Rico School of Medicine, San Juan, PR 00936; 6) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, Indiana 46202; 7) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA 19104.

Setleis syndrome is a rare focal facial dermal dysplasia (FFDD; Type III) characterized by bitemporal scar-like lesions similar to forceps marks as well as other facial abnormalities. Recently, we reported that homozygous nonsense mutations in the transcription factor, *TWIST2*, caused the disease in patients from two unrelated consanguineous families, but not in five other unrelated Setleis syndrome patients (Tukel et al., Am J Hum Genet. 88:289-296, 2010). Array CGH studies of unrelated patients with normal *TWIST2* alleles who had facial dysmorphic features, and developmental delay, mental retardation, autism, attention deficit disorder and/or learning disability, revealed overlapping de novo duplications and a triplication within a 1.2 Mb region on 1p36.22 to p36.21, which contains ~26 genes. Compared to the facial phenotype in *TWIST2*-mutant Setleis syndrome patients, the two patients with the duplication had more subtle dysmorphic facial findings, while the patient with the triplication had more typical facial findings seen in the patients with *TWIST2* mutations, evidencing a dosage effect of a gene(s) in the 1p36.2 region. Since the TWIST2 160 amino acid protein is generally an inhibitory transcription factor in mammalian development, it is likely that one or more of the genes in the 1p36.2 smallest region of overlap (SRO) is normally inhibited during facial development by TWIST2. In this model, increased dosage of a gene(s) on 1p36.2, caused by duplications and triplications in the presence of normal *TWIST2* alleles, would mimic the loss of function *TWIST2* mutations and lead to the Setleis syndrome phenotype. Efforts are underway to identify the specific gene(s) that are normally inhibited by TWIST2 in facial development by systems biology approaches and direct sequencing. Thus, TWIST2 loss-of-function mutations and CNVs that increase the expression of TWIST2 regulated genes can cause Setleis syndrome. Similar etiologic CNV alterations may be responsible for the heterogeneity in other transcription factor diseases and may facilitate identification of the specific genes that they regulate.

991T

Phenotypic heterogeneity in a family segregating two different *NRXN1* deletions. *L.B. Henderson[1], C.D. Applegate[1], R.L. McClellan[2], H.T. Bjornsson[1], S.A. Morsey[3], D.A.S. Batista[3,4], S. Naidu[5], A. Hamosh[1].* 1) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD; 2) Division of Metabolism, Kennedy Krieger Institute, Baltimore, MD; 3) Cytogenetics Laboratory, Kennedy Krieger Institute, Baltimore, MD; 4) Department of Pathology, Johns Hopkins University, Baltimore, MD; 5) Department of Neurogenetics, Kennedy Krieger Institute, Baltimore, MD.

Neurexins are presynaptic cell adhesion molecules that function in neurotransmitter release. Exonic deletions in the neurexin 1 (*NRXN1*) gene are associated with a variety of neuropsychiatric phenotypes including autism, developmental delay (DD), intellectual disability, and schizophrenia. Here we report a family segregating two different *NRXN1* deletions and a spectrum of developmental disorders. The proband was referred to genetics at 23 months of age with a history of failure to thrive, hypotonia, Chiari malformation, and global DD with regression of skills. He also had mild aortic root dilatation and a normal brain MRI. Illumina 610k SNP array was performed and two deletions were identified in band 2p16.3: a 267 kb deletion encompassing the first four exons of the *NRXN1*-(isoform and a 138 kb deletion spanning the last two exons of the *NRXN1*-(/) isoforms. Neither deletion was reported in 2,026 healthy controls. To determine whether these deletions were in *cis* or *trans*, parental arrays were performed and revealed that the larger 5' deletion was maternally inherited and the smaller 3' deletion was paternally inherited. The mother had no history of delayed development, but the father had a history of ADD, scoliosis, and was in a special education setting until age 10. Three of their four other children also had neuropsychiatric features, though less severe than in the proband. A 9 year old girl had ADHD, paranoia, texture avoidance, and learning difficulties; an 8 year old boy had DD, behavioral problems, and a diagnosis of autism; a 3 year old girl had DD and anti-social behavior; and a 2 year old boy was neurotypical. SNP array detected the paternal 3' *NRXN1* deletion in all but the neurotypical 2 year old boy. Mild dysmorphic features in the family included epicanthal folds, down-slanting palpebral fissures, 5th finger clinodactyly, 2,3-toe syndactyly, and inverted nipples; however, these features did not segregate with the *NRXN1* deletions. Furthermore, *PTEN* sequencing in the proband revealed a paternally inherited promoter variant of unknown significance. This variant was not present in the neurotypical child. We are aware of only one other case with homozygous disruption of *NRXN1*, in which a girl presented with Pitt-Hopkins-like syndrome. The family described here exemplifies the incomplete penetrance and variable expression of heterozygous *NRXN1* alterations, which may be attributed to modifier genes such as *PTEN*.

992T

Clinical Dilemma in Interpretation of Microaaray Results: Report on Series of Inherited Copy Number Gain and Loss with Variable Expression. *J. Hiemenga, K. Withrow, C. Forgeng, V. Kirkland, M. Jaworski, J. Bodurtha, A. Pandya.* Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA.

CGH chromosomal microarray studies have opened new diagnostic frontiers; they are often the first tier test in evaluation of children with developmental delay, multiple congenital anomalies, and autism spectrum disorder. Although efforts to create national datasets with phenotypic information on the identified del/dup variants are underway, a paucity of reported phenotypes for novel copy number variants (CNV) makes interpretation of results a challenge. In addition, the notion that CNVs are also noted commonly in the general population further complicates the interpretation of an inherited CNV. De novo alterations in a proband are most often considered causative; however, inheritance of a variant from an unaffected parent raises questions and poses challenges in attributing the phenotype to a given result. We report on the parentally inherited micro deletions /duplications diagnosed through CGH microarray evaluation of symptomatic infants and children from 2009 through 2011 at our center. We have identified 18 children with an inherited CNV. Seventy per cent of affected probands are male. Mothers were the transmitting parent in 2/3 of our series. Five of the transmitting parents were noted to have some phenotypic changes; however the offspring of the transmitting parents always demonstrated a more severe phenotype. One phenotypically normal father transmitted the CNV to two of his affected sons, and one woman with short stature and subtle distinctive features was diagnosed with the CNV after the affected stillborn conceptus was positive for a CNV by microarray. The variable phenotypic expression for our transmitting parents and their affected children will be presented. Possible mechanisms for the variable phenotypic presentation in these cases include variable expressivity, effects of a second “hit” to genomic integrity, unmasking of heterozygous recessive conditions and epigenetic or environmental interactions. A careful medical history and physical evaluation of the parent is warranted to assess for subtle phenotypic expression and when possible, a complete microarray study in the parents may be helpful in delineating the differences. Caution needs to be exercised in counseling these families about the potential relevance of a CNV to the phenotype, especially in prenatal cases.

993T

Alström Syndrome in Taiwan: Familial Variable Expression of Metabolic Abnormalities and Revisit of Syndromic Obesity. *J. Hou.* Pediatrics, Cathay General Hospital, Taipei, Taiwan.

Background: Alström syndrome (AS) is a rare autosomal recessive disorder characterized by infancy-onset obesity, retinal degeneration, sensorineural hearing loss, type 2 diabetes mellitus and chronic nephropathy, caused by *ALMS1* mutations.The natural history of the insulin resistance and development of obesity is unknown. **Aims**: Our objectives were to characterize metabolic parameters, to establish *ALMS1* mutations of Taiwanese AS patients, and to determine whether a genotype-phenotype correlation exists. **Design and Patients**: Six Taiwanese patients (M:F=3:3, age at diagnosis: 10-15y) with cardinal features of AS from different 5 families were evaluated both clinically and biochemically. The 23 exons (locus: 2p13) and intron-exon boundaries of ALMS1 were directly sequenced. **Results**: Specific features vary from patient to patient. All of them have eye and hearing problems, and overweight since childhood, early onset of liver dysfunction with hepatic steatosis, acanthosis nigricans, hyperlipidemia, and insulin-resistance. Other features include early onset lung fibrosis(n=3), overt Type 2 DM (n=3), cerebral atrophy(n=3), gynecomastia (n=3), renal insufficiency(n=1), and pancreatitis associated with hypertriglyceridemia (n=1). DNA studies on the candidate gene *ALMS1* showed homozygous 19-bp deletion: nt(del)11116_11135 in 2 patients, homozygote nt(del)11116_11135 in 1 patient, and compound heterozygous nt(del)11116_11135 with a secondary heterozygous 2-bp deletion (AG) at nt c.10831_10832 in 3 patients, all leading to a frameshift mutation at exon 16. Mutations of *ALMS1* are clustered in exon 16 among Taiwanese patients, with a possible founder effect. **Discussion**: The clinical features, time of onset, and severity vary greatly among and within families. No genotype-phenotype correlation exists. Two novel mutations in the *ALMS1* gene causative for AS have been reported here, thereby increasing the number of reported mutations and providing a wider basis for mutational screening among affected individuals.

994T

Array comparative genomic hybridization (aCGH) in diagnosing Mendelian disorders: how far do we go and when do we stop?! *A. Tsai, D. Klepacka, C. Walton.* Sect Clinical Gen & Metabolism, Childrens Hosp, Denver, B300, Denver, CO.

Array comparative genomic hybridization (aCGH) is a powerful tool for the molecular elucidation and diagnosis of disorders resulting from genomic copy-number variation (CNV). Intra-genic deletions or duplications have become available through increasing probes and improving genomic resolution. However, benign CNV can confound clinical interpretation. We reported the aCGH results on 423 patients who were ascertained in a pediatric genetic clinic during 2009-2011 performed by a single referenced lab using 180K oligoarray. 112 patients were initially found to be abnormal; further parental studies showed 42 were confirmed to have a chromosomal anomaly, 28 have presumed anomalies, 5 have iatrogenic deletion involving a AD gene. 37 have one or more inherited/de novo CNVs yet not sufficient to explain the problems. We report two unique cases in this group to highlight the diagnostic dilemma and ethical concerns. Case 1 is a-11 year-old girl with developmental delays and dysmorphic features, a 180K microarray identified a 0.853 Mb-1.736 Mb duplication at 8p22 which is not found on her mother and a 2.462 Mb duplication at 22q11 that is inherited. Her mother has similar learning concerns and required special education. Because of her facial features are suggestive of Rubinstein-Taybi syndrome, analysis for the EP300 gene was done which revealed a novel variation p.H1744R:c.5231A>G, predicted to be disease-causing by Mutation Taster. Mother does not carry the same variation. Paternal studies were not available. Case 2 is a 5 year-old boy with hypotonia, hypospadias, microcephaly, big teeth, autism and dysmorphism. A 180 K aCGH revealed a 50 kb loss at 8q22.2, involving COH1 gene (Cohen syndrome). Sequencing for COH1 gene revelaed a heterozygous Nonsense mutation: W1328X. Subsequent studies confirmed the neutropenia and eye problems. Here we raise a few cpncerns. In a child with a CMA anomaly, how far do we go for testing, and when do we stop?! Most people argue aqainst further testing as the cost is high. Should this be the case, Case 1 would be missed and future prenatal diagnosis would be misled. In Case 2, the aCGH reveals a clue which makes testing COH1 an exploratory instead of confirmatory testing. This case demonstrated the favorable outcome of exploratory testing as a Nonsense mutation were identified; however, should this a missense mutation, interpreting SNP of unknown significance would be challenging.

995T

Using a combination of MLPA kits to detect microdeletion and subtelomeric rearrangement in Iranian patients with mental retardation. *S. Zeinali[1], M.S. Falah[2], T. Pourmostafaei[3], A. Bidmeshki-pour[4], H. Bagherian[2], Z. Sharifi[2], N. Khazaei[2], M. Mohammadi[5], F. Fardanesh[5], F. Mohammadi[6], S. Amini[2], P. Foroghi[2], S. Malvandi[2], M. Masoudifard[2], S. Kianfar[2], A. Sarhaddi[2].* 1) Department of Molecular Medicine, Biotech Research Center, Pasteur Institute of Iran, Tehran, Iran; 2) Zeinali's Medical Genetics Lab (ZMGL), Kawsar Human Genetics Research Center (KHGRC), Tehran, Iran; 3) Student of MSc in Molecular biology, Razi University, Kermanshah, Iran; 4) Asistant Prof of Molecular Genetics, Razi University, Kermanshah, Iran; 5) National Genetic Counselling Center, State Welfare Organization, Tehran, Iran; 6) Genetic Counselling Center, State Welfare Organization, Kermanshah, Iran.

Introduction: Mental retardation (MR) is a major health issue and it has been estimated that 1 to 3% of the population suffer from it. In syndromic-MR, mental retardation is not the only presentation of the disease and other physical and/or behavioral abnormalities is present. Submicroscopic chromosomal del/dup and sub-telomeric rearrangements are one of the most common causes of MR. Such variations are not routinely detected by conventional chromosomal analysis. These cases need to be investigated with technique like MLPA. The aim of this study was to investigate syndromic-MR using of MLPA method. Methods: Thirty unrelated cases with mental retardation were selected. Blood sample were taken from probands and their parents after obtaining consent. Karyotype analysis was carried out for probands. Those cases that remained normal were investigated for microdeletion syndromes and sub-telomeric rearrangement using MLPA technique. Results: 1st step screening revealed trisomy in chromosome 21 in one cases. In further MLPA study in other cases, we found an abnormality in 3 cases. A deletion in 7q11.23 region (Williams's syndrome), a deletion in 17p11.2 region (Smith-Magenis syndrome) and a duplication in 4p16.3 region were detected in 3 unrelated cases. Deletion in 17p11.2 region was confirmed with by another MLPA kit (P374) with more probes in the region. Conclusions: Micro-deletion syndromes and sub-telomeric rearrangements as two main categories of genetic causes of MR could be investigated easily by MLPA method. It is an cost-benefit and easy method that is recommend as first step screening in patients with syndromic MR and normal karyotype.

Predictors of adaptive functioning in adults with 22q11.2 deletion syndrome. *A.S. Bassett[1, 2], N. Butcher[2], A. Ho[2], G. Costain[2], D. Young[2], E.W.C. Chow[1, 2].* 1) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, ON, Canada.

22q11.2 deletion syndrome (22q11.2DS) is a common genomic disorder with congenital and later onset features including congenital heart disease (CHD), intellectual disability and schizophrenia that may affect long term functioning. Data on adaptive functioning, that is, the relative ability of a person to effectively interact with society and care for one's self, in adults with 22q11.2DS are limited. The Vineland Adaptive Behaviour Scale (VABS) was administered to the primary caregivers of 115 well phenotyped Canadian adults (>17 years) with 22q11.2DS. After excluding eight with moderate to severe mental retardation, the sample comprised 52 men and 55 women with mean age 28.7 (SD 10.2) years. There were 39 subjects (36.5%) with serious CHD and 49 (45.8%) with schizophrenia. Mean full scale IQ, assessed using the Wechsler Adult Intelligence Scale (WAIS-III), was 71.6 (SD 9.3). We used a multivariate linear regression model to identify major phenotypic features associated with functioning. A minority had ever had a spouse or equivalent partner (14%). About one in four had a driver's license. The mean overall VABS score for the sample was 64.7 (SD 18.4), significantly lower than the normal mean of 100 (SD 15) for the VABS scale ($p<0.001$). The proportion of subjects with scores in the functional deficit range was significantly different across the three main VABS domains, with Daily Living Skills less affected than Communication or Socialization ($p<0.001$). IQ and a diagnosis of schizophrenia were significant predictors of overall adaptive functioning ($p<0.001$). Results were similar for the three VABS domains examined. Notably, sex, age and a diagnosis of serious CHD or anxiety/depression were not significant predictors of functioning in 22q11.2DS. There is considerable functional impairment in 22q11.2DS in early to mid-adulthood. This appears to be primarily mediated by the severity of the neuropsychiatric phenotype. Relative strengths in domestic and community interaction skills have important implications for vocational and other service planning.

997T

Unique Phenotype Associated with a Novel Partial Chromosome 5p Deletion/Duplication. *L. Brick[1], J.M. Meck[2], S. Aradhya[2], C. Li[1].* 1) Genetics Department, McMaster Children's Hospital, Hamilton, ON, Canada; 2) GeneDx, Gaithersburg, MD.

Both deletions and duplications of the 5p region have been noted in the literature. The finding of a terminal deletion in tandem with a 5p duplication, however, is rarely reported for chromosome 5p. We report on a 3-year old boy with a complex chromosome 5 abnormality, who presented with a high-pitched cat-like cry, unilateral cryptorchidism, bilateral esotropia, dysmorphic features, short stature (height <5th%), macrocephaly (head circumference >98th%) and developmental delay. The patient was born at 36 weeks gestation and initially required intubation. Medical history is also significant for gastroesophageal reflux, constipation, mild unilateral ankle talipes, a small ventricular septal defect and asthma. Initial karyotype analysis revealed an abnormal male karyotype with extra chromosomal material of unknown origin, attached to 5p15.3. Further characterization of the area using whole-genome oligonucleotide array CGH revealed a 6.0 Mb terminal deletion of chromosome bands 5p15.3 to 5p15.33, as well as an adjacent 24Mb duplication of chromosome bands 5p13.3 to 5p15.31. The co-occurrence of these two genomic imbalances suggests a U-type exchange mechanism. Parental karyotype yielded normal results. The terminal deletion in our patient involves a partial deletion of the cri-du-chat syndrome (CdCS) region (5p13-5p15), and encompasses only the specific critical region for the high-pitched cat-like cry (5p15.3). Our patient exhibits none of the other clinical features of CdCS, a condition that manifests with microcephaly, dysmorphic features, hypotonia, severe mental retardation, and the characteristic cat-like cry. Large duplications in the 5p region lead to a variable phenotype. A review of the literature suggests that duplications distal to 5p13.3 result in significantly fewer physical anomalies than duplications proximal to that region. Our case is novel in that the patient has several significant congenital, medical and developmental anomalies, despite having a duplication that is limited to the region distal to 5p13.3. Since our clinical findings cannot be explained solely by the 5p terminal deletion, we propose that the duplication distal to 5p13.3 can lead to a significant clinical phenotype.

998T

Case report: of a newborn with ambiguous genitalia and mosaicism for the SRY locus. *C. Bupp, J.H. Hersch, J.J. Wetherbee-Landis, C.M. Rajakaruna, K.M. Goodin.* University of Louisville, Louisville, KY.

Ambiguous genitalia in a newborn is a medically and psychosocially difficult finding with a broad differential diagnosis. Initial examination and laboratory results guide further investigations in order to find a diagnosis. We present a patient born with ambiguous genitalia including nonvisible vaginal opening, nonpalpable gonads, hypertrophic clitoris versus micropenis, posterior labial scrotal fusion, and patent anus. Initial pelvic ultrasound identified a uterus but could not identify gonads. Karyotype was 46,XX. Congenital adrenal hyperplasia (CAH) is the most common cause of ambiguous genitalia with normal female karyotype but our patient's 17-hydroxyprogesterone level was not markedly elevated. Less common causes of CAH were ruled out by additional laboratory tests and negative ACTH stimulation test. Antimullerian hormone (AMH) was found to be in the male range. Comparative genomic hybridization (CGH) and FISH for SRY found mosaicism of the SRY locus (3.8-26% positive). Diagnostic laparoscopy demonstrated right ovary and fallopian tube, left testicle with epididymis and nonconnecting vas deferens, and unilateral uterine remnant without functional uterus. A multidisciplinary team care conference was held with the family where it was decided to remove the testicle due to concerns about future malignancy. Pathologic evaluation demonstrated an ovotestis with 90% testicular tissue and 10% ovarian tissue. The patient is being raised as a female and monitored by the multidisciplinary team for further complications and management issues associated with disorders of sexual development (DSD).

999T

Mosaic dup/del 6q22.1q22.2 including COL10A1 in a patient with syndromic developmental delay and symptoms of osteogenesis imperfecta. *I. Filges[1], B. Roethlisberger[2], P. Dill[3], P. Weber[3], A.R. Huber[2], F. Wenzel[1], P. Miny[1].* 1) Division of Medical Genetics, University Children's Hospital and Department of Biomedicine, Basel, Switzerland; 2) Division of Medical Genetics, Center of Laboratory Medicine, Cantonal Hospital Aarau, Switzerland; 3) Division of Neuropediatrics and Developmental Medicine, University Children's Hospital, Basel, Switzerland.

Segmental aneuploidy plays a significant role in the origin of syndromic and non-syndromic developmental delay. Complex mosaic structural aberrations, however, are very rare. We report on a unique mosaic interstitial aberration in 6q22.1q22.2 including a duplication in one and a deletion in a second cell line, initially identified by a dosage aberration in array genomic hybridization (AGH) in a patient with dysmorphisms, mild developmental delay (DD) and an osteogenesis imperfecta (OI) phenotype. This 15 year-old patient with global DD shows turricephaly, sparse hair, dysplastic ears, long face, blue sclerae, crowded teeth, kyphosis, joint hyperlaxity, myopia, conductive hearing loss, frequent bone fractures in early childhood and a proximal fibular osteochondroma. High resolution AGH of DNA from blood lymphocates identified an increased copy number state (2.2) of 4.2 Mb in region 6q22.1q22.2 suggesting mosaicism. FISH studies with locus-specific probes revealed an interstitial duplication in about 2/3 of cells examined, and a deletion of the same region in about 1/3 of cells well explaining array dosage results. Parental array and FISH analyses were normal. The aberrant region contains about 25 genes including COL10A1 which is expressed by hypertrophic chondrocytes of the growth plate. Mutations in COL10A1 lead to Schmid type metaphyseal chondrodysplasia (SMCD). Nonsense mediated decay and dominant negative mechanisms have been proposed. Although AGH has shown its potential in the detection of low-level mosaicism, FISH studies are necessary to further elucidate its nature. The rare interstitial duplication-deletion mosaicism in our patient may result from a single postzygotic event by unequal sister chromatid exchange producing three cell lines, the normal one not detected or present in blood lymphocytes. Studies on cultured fibroblasts are ongoing. Genotype-phenotype correlations of the affected region using existing databases and publications reveal a few overlapping deletions including COL10A1 of patients with DD but no symptoms reminiscent of OI, SMCD or connective tissue disease. We could not identify patients with a duplication of the affected region for comparison. The deletion in our patient may explain the DD phenotype.We hypothesize that the cell line with the duplicated region contributes to the OI phenotype possibly by increased dosage effects of COL10A1 and/or impaired gene regulation. Further functional studies are needed.

Renal Tubular Dysgenesis in Two Siblings with Novel ACE Mutations. *A. Alfares[1], N. Braverman[1], C. Antignac[2], K.B. Brosnihan[3], V. Morinière[2], G. Gubler[2], R. Vanneste[1], R. Gosselin[1], C. Bernard[1], M. Bitzan[1].* 1) Medical Genetics, McGill University, Montreal, Quebec, Canada; 2) INSERM U574, Hôpital Necker Enfants-Malades, Paris, France; 3) Wake Forest University, The Hypertension and Vascular Research Center, Winston-Salem, NC, USA.

Renal tubular dysgenesis (RTD, OMIM #267430) is a rare, autosomal recessive developmental nephron abnormality characterized clinically by fetal anuria and oligohydramnios, and severe postnatal hypotension. It is causally linked to homozygous or compound heterozygous mutations in genes encoding components of the renin-angiotensin system (angiotensinogen [AGT], renin [REN], angiotensin-converting enzyme [ACE], and angiotensin II receptor type 1 [AGTR1]). Here, we report two siblings with novel mutations in ACE. Case 1: The first child of healthy, non-consanguineous parents was delivered by C-section at 33 weeks due to IUGR, severe oligohydramnios and decreased fetal movement. Growth parameters were all < 3rd %ile. She had persistent anuria and systemic, treatment-resistant hypotension. She died of necrotizing enterocolitis at age 14 days, with functioning dialysis. Post-mortem histology showed immature, overcrowded glomeruli, slightly distended microcystic cortical tubules and absence of definite proximal tubules, consistent with RTD. The colon demonstrated small calibre in its entire length. Serum ACE activity was undetectable (<3.8 nmol/mL/min; normal 18-55 nmol/mL/min), angiotensin I (Ang I) greatly increased (1765.6 pg/mL; N 40-80 pg/mL). Case 2: Prenatal ultrasound imaging of a subsequent child of the same parents at 12 and 24 weeks gestation was unremarkable, but showed severe oligohydramnios and IUGR at 28 weeks. Pre-term labour and fetal decelerations at 35 wks prompted C-section. There was profound hypoxia related to pulmonary hypoplasia and pulmonary hypertension that failed to respond to intensive treatment. She remained anuric until her death at 14h post partum. Post-mortem histology was similar to the first case. A novel, maternally inherited heterozygous nonsense mutation in the ACE gene (c.793C>T) was detected, predicting a premature stop codon (p.Arg265X). Exon array analysis with multiple oligonucleotide probes within the ACE gene identified a paternally inherited, novel heterozygous deletion of exons 14 & 15. The biochemical findings of immeasurable ACE activity and excessive Ang I concentration point to deleterious ACE gene mutations. The observed microcolon is a novel finding not previously described in patients with RTD. This report further demonstrates the utility of exon array technology for an autosomal recessive disorder where only a heterozygous mutation is identified by conventional sequencing.

Central choroidal areolar dystrophy type 2: genotype-phenotype correlation. *L. Gabriel[1, 2, 3], M. Avila[1, 3].* 1) Ophthalmology, UFG, Goiania, Goias, Brazil; 2) Dcode Laboratory, Goiania, Goias, Brazil; 3) CBCO, Goiania, Goias, Brazil.

Purpose: Herein we present a case of a 35-year-old brazilian patient with type 2 central choroidal areolar dystrophy caused by the previously described p.G208D mutation in exon 2 of the peripherin 2 (*PRPH2*) gene with a never before reported symptom of progressive intermitent diplopia for the last three years, besides refering central scotomas on both eyes. **Methods**: The patient was submitted to the ocular genetics clinics in Goiania and has undergone bidirectional DNA sequencing of all three coding exons and splice sites of *PRPH2* gene. **Summary of results**: The p.G208D mutation causes a missense alteration in a highly conserved region of the PRPH2 gene affecting an important domain (ROM1) of the peripherin 2 protein that, in this particular case, showed a new symptom to the natural history of type 2 central choroidal areolar dystrophy.

1002T

Novel de novo AVPR2 gene mutation causing CNDI in Swedish patient. *S.S. Joshi[1], J.H. Christensen[1, 2], P. Brandstrom[3], J. Knudsen[1], N. Gregersen[4], S. Rittig[1].* 1) Pediatric Research Lab-A, Aarhus University Hospital, Skejby, 8200, Aarhus N, Denmark; 2) Institute of Human Genetics, Aarhus University, Aarhus, Denmark; 3) Children's Clinic, Ryhov County Hospital, Jönköping, Sweden; 4) Research Unit for Molecular Medicine, Aarhus University Hospital, Skejby, Aarhus, Denmark.

Congenital Nephrogenic Diabetes Insipidus (CNDI) is a rare inherited disorder characterized by reduced ability to reabsorb water in response to the antidiuretic effect of vasopressin on renal collecting duct cells. Patients exhibit polyuria, nocturia, hypernatremic dehydration, failure to thrive, irritability, and fever. CNDI is genetically heterogeneous and may be inherited in an X-linked or autosomal recessive manner. The proband (7.5 years Swedish male), was identified to have CNDI at 1 month of age and diagnosed at 6 months of age during an episode of gastroenteritis. There was no family history of diabetes insipidus. We sequenced coding regions of arginine-vasopressin receptor-2 gene - AVPR2 gene in patient and 4 unaffected family members. We identified a novel de novo mutation (80bp duplication) in exon 2 of AVPR2 gene in the patient. Duplication begins from nucleotide 1312 (gDNA sequence) and consists of 80bp that are identical to nucleotide sequence from 1232-1311. This duplication leads to a frame shift and a stop codon- 4 codons downstream (AAWD 294-297>PRLX). There were no mutations in coding regions of AVPR2 gene, in other family members. In this case, clinical data including the water deprivation test and duplication mutation will aid in understanding the pathophysiology of CNDI. Identification of such mutations will facilitate in early diagnosis of CNDI, genetic counseling and early intervention aimed at reducing morbidity with reference to diagnostic testing.

1003T

Wide phenotypic variability of Kabuki syndrome with MLL2 mutations. *K. Kosaki[1], R. Tanaka[2], R. Kosaki[3], K. Uchida[4], C. Torii[2], T. Ishi[2], T. Sato[5], H. Yoshihashi[6].* 1) Center of Clinical Genetics, Keio University School of Medicine, Tokyo Japan; 2) Department of Pediatrics, Keio University School of Medicine, Tokyo Japan; 3) Department of Clinical Genetics and Molecular Medicine, National Children's Medical Center, Tokyo, Japan; 4) Department of Health and Nutrition, Tokyo Kasei Gakuin University & Junior College, Tokyo, Japan; 5) Department of Endocrinology and Metabolism, Kanagawa Children's Medical Center, Yokohama, Japan; 6) Departments of Clinical Genetics, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

Kabuki syndrome is characterized by long palpebral fissures with eversion of the lateral aspect of the lower eyelids and developmental delay. Recently, MLL2 at chromosome 12q12-q14 has been identified as a causative gene of KS. To date, a broad range of complications has been reported in patients with KS. Yet, when “atypical complication” was present, the clinical diagnosis of KS may become less assuring prior to the identification of the causative gene. Here, we demonstrate a wide phenotypic variability among patients with Kabuki syndrome who have MLL2 mutations. The subjects were recruited from a group of patients with KS who were regularly followed at the authors' institutions at the time of study. A diagnosis of KS was made if they had: long palpebral fissures with eversion of the lateral portion of the lower eyelids, large, prominent or cupped ears; and developmental delay. The entire MLL2 coding region was screened for mutations by using the dideoxy sequencing method. Heterozyogous MLL2 mutations were identified in all of the patients: 6 frameshift mutations (4833 del G fs1721X, 6613-6614 insG fs2242X, 6620 del C fsX2263, 12201-12202 insC fs4106X, 12876-112885 del 10bp fs4380X, and 15529-15530 insCACA fs5199X), 3 nonsense mutations (E970X, Q2445X, and 5282X), and 2 missense mutations (G5189R and R5432W). No apparent genotype-phenotype correlations were noted among the 11 patients. All the patients demonstrate variable degrees of developmental delays including a 29 year-old male without speech ability and a 6 year-old boy with arithmetic ability. Two patients (R5432W and R5282X) had staphyloma of the eye with bulged anterior segments and structurally normal posterior segments. Appearance of the complication in two unrelated patients with different mutations in MLL2 suggests that Kabuki syndrome needs to be considered even in the presence of severe developmental defect of the eyes, such as staphyloma. One patient had a combination of rare complications: obstructive jaundice and severe persistent hypoglycemia due to hypopituitarism. In conclusion, we documented wide phenotypic variability among MLL mutation positive cases including staphyloma of the eyes, a previsouly undescribed servere ophthalmic complication. Such variability should be taken into consideration in the clinical evaluation of suspected Kabuki syndrome cases.

1004T

Trichohepatoenteric syndrome - phenotypic variability and molecular characterisation. *U.H. KOTECHA, R.D. PURI, S. MOVVA, I.C. VERMA.* CENTER OF MEDICAL GENETICS, SIR GANGARAM HOSPITAL, , NEW DELHI, INDIA.

We report two patients of Asian Indian origin, born to non consanguineous parents with clinical features of Trichohepatoenteric syndrome (THES). Both patients had onset of intractable diarrhea from 5-6 months of age, recurrent respiratory infections, growth retardation and developmental delay. Dysmorphic features in both cases were broad forehead, prominent cheeks with trichorrhexis nodosa.The first patient also had Café au lait spots distributed along the lower abdomen and thighs. Ventricular septal defect, atrial septal defect and patent foramen ovale as well as multiple hemangiomas in the liver which gradually regressed were present in the second case. Hepatic hemangiomas have not been observed in the earlier reported cases. Liver histology in case 2 showed chronic hepatitis with cirrhosis and copper accumulation. Other causes of chronic diarrhea were excluded in both patients. Duodenal biopsy showed a villous atrophy of the intestinal mucosa in both cases. Though both patients had a history of recurrent infections suggesting immunodeficiency the serum immunoglobulin levels were elevated in the first case and normal in the second as opposed to low concentrations found in all the previously described cases. The TTC37 gene on chromosome 5 is a large gene with 40 coding exons. In the publication where the molecular basis of THES was identified, four patients of South Asian origin (2 Indian and 2 Pakistani) were reported to harbor a homozygous mutation (c.2802G>A) in Exon 28.With this background we first analyzed our patients for this mutation by restriction enzyme analysis and sequencing of Exon 28 and identified the same mutation in both. Trichohepatoenteric syndrome is an autosomal recessive condition characterized by chronic diarrhea, immunodeficiency, facial dysmorphism, trichorrhexis nodosa and variable degrees of hepatic involvement. The two consistent features observed amongst all previously reported cases include chronic diarrhea and immunodeficiency characterized by low serum immunoglobulin levels. Our patients had normal and elevated levels of serum immunoglobulins as well as hepatic hemangiomas further defining the phenotypic heterogeneity in THES. The possibility of a founder mutation in South Asian population was suggested by Hartley et al, and is further reaffirmed by our findings.

Evaluation of three automated mutation detection software programs for clinical diagnostic sequencing. *J. Machado[1], N. Persaud[1], L. Han[1], M. Eliou[1], P. Ray[1,2], T. Stockley[1,3].* 1) Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Department of Laboratory Medicine and Pathobiology, Toronto, Ontario, Canada.

The Molecular Genetics laboratory at The Hospital for Sick Children analyzes more than 2000 specimens per year using genomic DNA sequence analysis. The increasing demand for genetic testing by DNA sequencing requires rapid, accurate detection of mutations. We evaluated three commercially available automated mutation detection software programs for performance in the commonly clinically sequenced cystic fibrosis conductance regulator (*CFTR*) gene.

Fifty specimens were sequenced for all 24 coding exons and intronic flanking regions of the *CFTR* gene. DNA sequence for each specimen was generated using fluorescent cycle sequencing reactions analyzed on an ABI™ 3730xl capillary sequencer. Each of the fifty specimens was analyzed by three mutation detection software programs: SeqScape™ v2.5, Mutation Surveyor™ v3.24 and SeqPilot™ v3.4.2. The sensitivity and specificity of the software programs were compared to 28 samples tested using the Luminex™ xTAG Cystic Fibrosis Assay.

SeqPilot™ allowed for easy sequence assembly, produced easy to read reports with proper nomenclature and was the most user friendly. SeqScape™ allowed the ability to lock the template, relatively easy sequence assembly, but did not provide variant information. Mutation Surveyor™ easily created templates, listed proper nomenclature, but didn't provide variant information and sequence assembly was difficult.

The SeqPilot™ software detected the least amount of false positives and no false negatives across the *CFTR* gene. Results from the Luminex recurrent mutation assay showed that Mutation Surveyor™ and SeqPilot™ correctly identified and excluded all mutations. SeqScape™ specificity was high, but the sensitivity was low.

Each of the three mutation detection software programs exhibited useful tools for the analysis of DNA sequence data. However SeqPilot™ contained the most favorable features for the specific requirements of mutation detection in a clinical laboratory setting, whereas SeqScape™ and Mutation Surveyor™ would be more appropriate for simple sequence detection analyses.

1006T

Cornelia de Lange syndrome: A five year follow-up and renal lithiasis. *M.A. Aceves-Aceves[1], I.M. Salazar-Dávalos[1], D. García-Cruz[2], A. Moreno-Andrade[3], M.G. González-Mercado[2,4], N.O. Dávalos[2], J.A. Cruz-Ramos[2,4], I.P. Dávalos[2,4].* 1) Facultad de Medicina, CUCS, Universidad de Guadalajara; 2) Instituto de Genética Humana, Doctorado en Genética Humana, CUCS, Universidad de Guadalajara; 3) Universidad Autónoma de Guadalajara; 4) División de Genética, CIBO, Instituto Mexicano del Seguro Social, Guadalajara, Jalisco, México.

Introduction: Cornelia de Lange Syndrome (CDLS) is characterized by typical facies, including low anterior hairline, bushy eyebrows, synophrys, long eyelashes, low-set ears, anteverted nares, depressed nasal bridge, long philtrum, thin lips, cleft palate, mental retardation, upper limb anomalies and hypertrichosis. CDLS presents prenatal and postnatal growth retardation and shows clinical variability. CDLS1 can be caused by mutation in the NIPBL gene (608667) on chromosome 5p13.1, CDLS2, X-linked is caused by mutation in the SMC1A gene (300040) on chromosome X11.2-p11.21, CDLS3 syndrome is caused by mutation in the SMC3 gene (606062) on chromosome 10q25. Case report: The propositus, male, aged 5 years 1 month old,was the product of the 2nd pregnancy, from non-consanguineous and healthy parents, with 35 years (he) and 36 years (she) at this time, no relatives were similarly affected. He was obtained by caesarian section at 36 weeks due to pre-eclampsia. At birth his weight was of 2.100 kg (<pct3) and height of 47 cm (<pct3). Physical examination at two months persists with somatometric parameters <pct 3. Clinically: microcephaly, generalized hypertrichosis, synophrys, anteverted nares, single transverse palmar crease, clinodactyly of 5th finger, syndactyly of 2nd-3rd toes and bilateral cryptorchidism. Karyotype 46,XY. At one year old was detected left renal lithiasis and mild ectasia on the right one by renal ultrasound. The lithiasis was resolved spontaneously. A renal function as well as a cardiological evaluation were normal. At 3 years old, weight, height and OFC continue below the 3rd pct and psychomotor delay was evident (non language, non walking). At this time, renal tubular acidosis was excluded and orchidopexy was done, hypotrophy of the right testicle was reported. At 5 years old, weight of 10.6 k (<pct 3), height of 87 cm (<pct 3) and OFC of 43.5 cm (<pct 3). Radiological evaluation showed craniofacial disproportion, prominent occipital fossa, elongated sella turcica, plumbed anterior cranium, ovoid vertebral bodies, mild dorsal kyphosis, lumbar hyperlordosis, decrease interpedicular distance, slightly horizontal acetabular roofs, bilateral coxa valga and slightly closed sciatic notches. Renal ultrasound reported bilateral nephrocalcinosis. Conclusion: The aim of this work is to present the five year follow-up of a CDLS patient, with antecedent of renal lithiasis and nephrocalcinosis diagnosed by renal ultrasound.

1007T

Neu-Laxova syndrome (NLS) and congenital anomalies of the spectrum of this syndrome in a highly inbred family. Could these anomalies represent clinical manifestations in heterozygotes? *D. Cavalcanti[1], M.T. Sakata[1], F. Poletta[2], J. Lopez-Camelo[3,4], C. Rosenberg[5], E.E. Castilla[3].* 1) Medical Genetics, UNICAMP (FCM), Campinas, São Paulo, Brazil; 2) INAGEMP (Instituto Nacional de Genética Médica Populacional), Brazil; 3) ECLAMC (Estudo Colaborativo Latino-Americano de Malformações Congênitas), Lab. Epidemiologia Genética, Centro de Educação Médica e Investigações Clínicas, Buenos Aires, Argentina; 4) ECLAMC (Estudo Colaborativo Latino-Americano de Malformações Congênitas), Instituto Multidisciplinar de Biologia Celular, CEMIC, La Plata, Argentina; 5) Centro de Estudos do Genoma Humano, IB, USP.

The Neu-Laxova syndrome (NLS) is a lethal rare genetic disease described in 66 probands, with an excess of females (23♂ : 37♀). Of the 52 families with at least one affected, 23 referred parental consanguinity and recurrence occurred in 20, strongly suggesting recessive autosomal inheritance. From the clinical point of view this syndrome presents a great heterogeneity and is characterized by IUGR, microcephaly, ocular proptosis or ablepharon, structural anomalies of hands and feet, oedema and ichthyosis. The aim of this report is to present a large and highly inbred family living in a Brazilian rural region with around 2,000 inhabitants that seems a population isolate. In this family we found one proband with an unusual phenotype and several other individuals affected by apparently isolated congenital anomalies from the spectrum of NLS. The proband's parents are once removed cousins with the following obstetric history: GVIIPIVAIII, being GII a male infant that presented, hydrocephalus, congenital heart defect, club feet and neonatal death; GV was the proband; GVI and GVII normal children; GI, GIII e GIV were spontaneous abortions. The proband presented generalized oedema, ichthyosiform skin, craniorrachischisis and anomalies of hands and feet. Karyotype (46,XX) and CGH-a were both normal. In other family individuals we found four hydrocephalus, five spine bifid and six ichthyosis. All, except one case of spine bifid, had consanguineous parents. The only individual alive with spine bifid has also palpebral ptosis and ichthyosis. The full genealogy shows 809 individuals in seven generations with a mean inbreeding coefficient F=0.008. The simple segregation analysis included the AR inheritance model (p=16.9 IC=7.9-25.9). In conclusion, these data suggest the possibility of clinical manifestation in heterozygotes for this syndrome. Future studies could confirm this hypothesis and hopefully will lead to identify the molecular basis of the NLS. (Supported by: INAGEMP - Instituto Nacional de Genética Médica Populacional).

1008T

Genome-wide DNA Methylation Profiling of CpG Islands in Hypospadias. *S. Choudhry[1], K. Beckman[2], L. Qiao[1], H. Bengtsson[3], M. Segal[3], L. Baskin[1].* 1) Dept Urology, Univ California, San Francisco, CA; 2) Biomedical Genomics Center, Univ Minnesota, Minneapolis, MN; 3) Dept Epidemiology and Biostatistics, Univ California, San Francisco, CA.

Purpose: The etiology of hypospadias remains largely unknown despite intensive investigations. Since steroid hormones are involved in regulating fetal genitourinary development, a leading hypothesis has been to explore the role of endocrine disrupting chemicals (EDCs). EDCs found in the environment such as phthalates, bisphenol A, diethylstilbesterol and some pesticides have both estrogenic and anti-androgenic actions and can interfere with male genital development by competing with natural androgens for the ligand-binding domain of the androgen receptor. Recent studies have suggested that molecular mechanisms that underlie the effects of EDCs on the fetus may involve disruption of epigenetic programming of gene expression during development. We hypothesize that alteration in DNA methylation may contribute to development of hypospadias. **Methods:** To test our hypothesis we assessed whether epigenetic modification of DNA methylation is associated with hypospadias in a case-control study of 31 subjects. We performed genome-wide DNA methylation profiling in bisulphite converted genomic DNA obtained from prepuce tissue samples of 13 severe hypospadias and 19 control subjects using Illumina Infinium HumanMethylation27 BeadChip. Illumina methylation BeadChip enables the direct investigation of methylation status of 27,578 individual CpG sites throughout the genome, which are focused on the promoter regions of 14,495 genes. The methylation level at each CpG site was compared between cases and controls using t-test and linear regression after adjusting for potential confounders including age at the time of surgery and race/ethnicity. **Results:** We identified 10 CpG sites that were associated with hypospadias with a p-value <0.001. These CpG sites were either in or near SLC2A11, C3orf32, MPO, ITPKA, CXorf6, THY1, OSBPL5, MAGEB2, ABCD1 and COX11 genes. Notably, the CXorf6 also known as MAMLD1 gene, which is expressed in the testes during the critical period for sex development, has been previously shown to be mutated in patients with isolated hypospadias. Only one CpG site in the SLC2A11 gene remained statistically significant after correction for multiple testing (p = 7.04x10-06, pcorrected = 0.036). **Conclusion:** This is the first study to investigate hypospadias using a unique and novel epigenetic approach. Our findings suggest utility for the DNA methylation patterns in identifying new genes such as SLC2A11 that may be involved in the etiology of hypospadias.

A patient with marked hypoplasia of the thorax, split-feet, polysyndactyly, renal defect and malrotation of intestine. *K. Haraguchi[1,2], M. Doi[1], H. Kuniba[1], M. Sasaki[1], T. Kosaka[3], K. Mochizuki[3], T. Tokunaga[3], M. Obatake[3], A. Yamashita[1], A. Yanai[1], H. Motomura[1], H. Moriuchi[1].* 1) Department of Pediatrics, Nagasaki University Hospital, Nagasaki, Japan; 2) Department of Pediatrics, Sasebo Municipal General Hospital., Nagasaki, Japan; 3) Division of Pediatric Surgery, Department of Surgery, Nagasaki University Hospital, Nagasaki, Japan.

We report on a female infant presenting a previously undescribed combination of marked hypoplasia of the thorax, split-feet, polysyndactyly, renal defect, malrotation of the intestine, and segmentation defects of the lumbar and sacral vertebrae. A unique feature in the proband was severe deformity of the thorax. To the best of our knowledge, the combination of those defects has never been reported. She was born at 35 weeks of gestation by cesarean section, weighing 2128 g. Her mother had histories of syndactyly, bicornuate uterus and duplication of the intestine. Chest computed tomography with 3D reconstruction demonstrated marked thoracic deformity without significant anomalies of the respiratory tract. Intestinal malrotation and renal defects with hypoplasia on the right and ectopia on the left were also found. Her facial appearance was normal. She survived for five months by intensive care such as high frequency ventilation or high frequency oscillation, but died from sudden deterioration of respiratory condition. Differential diagnosis includes spondylothoracic dysostosis (Lavy-Moseley syndrome) (MIM 608681), acrorenal syndrome (MIM 102520), split-foot deformity with mandibulofacial dysostosis (MIM 183700), split-hand with obstructive uropathy, spina bifida and diaphragmatic defects (MIM 183802), spondylocostal dysostosis 5 or costovertebral segmentation anomalies (MIM 122600), acrorenal-mandibular syndrome (MIM 200980) and short-rib polydactyly syndrome 2 (MIM 263520). All of them are differentiated from the present case, based on the constellation of abnormalities. Chromosomal analysis showed normal karyotype: 46,XX. Molecular karyotyping was performed with array CGH of Agilent 1M platform to the proband-parents trio. We found a 24-kb deletion in 9q21.33 containing C9orf153 and a 123-kb duplication in 10q25.3 containing C10orf118, TDRD1 and VWA2 in the proband and the mother, which have not been registered as copy number variations. Combined with the previously undescribed combination of multiple anomalies, those findings indicate a new clinical entity. Interestingly, a de novo 28-kb microdeletion of 17p13.2, encompassing GPR172B, was also suspected using Agilent Genomic Workbench software. Although function of GPR172B (G protein-coupled receptor 172B) has not been well identified in mammals, our finding may suggest its role in thoracic formation.

16p13.11p12.3 Duplication in a Girl with Multiple Congenital Anomalies and Developmental Delay. *E. Leon, S. Lewin.* Medical Genetics, University of Utah, Salt Lake City, UT.

Chromosome 16 is rich in intrachromosomal segmental duplications or low copy repeats (LCRs) that mediate recurrent genomic rearrangements. Recurrent deletions and reciprocal duplications in 16p13.11 have been previously reported. Duplications have been implicated in autism spectrum disorders, intellectual disability, and schizophrenia. However, the phenotypes associated with CNVs of 16p13.11 are not consistent, and both deletions and duplications of the region have been observed in “phenotypically normal” individuals. We describe a 1-year-old girl with a 2.5Mb duplication in the 16p13.11p12.3 region detected by 2.7 Affimetrix SNP array confirmed by FISH. The proposita was born at term, by emergent C-Section due to placenta abruption, to nonconsanguineous Caucasian young parents. Her prenatal history was remarkable for preeclampsia. Family history is unremarkable. Her birth weight and length were in the 50th centile. She had feeding difficulties and GI reflux during infancy, as well as recurrent URIs and episodes of otitis media. At 11 months of age she had a 1st toe tendon release surgery. At her initial evaluation (1 year) her weight was in the 5th centile, length 50th centile, OFC 75th centile, and foot length < 3rd centile. She has left eyelid ptosis, epichantal folds, bulbous nasal tip, low set and posteriorly rotated ears, high arched/narrow palate, tapered fingers with dysplastic fingernails, severe bilateral 5th finger clindodactyly, and short thumbs. She also has wide sandal gaps, medially deviated and short first toes, hypoplastic toenails, right 2/3 toe syndactyly, left 2nd toe clinodactyly with 3/2 overlapping. She has hypotonia, speech and motor delays. Feet X-rays showed shortening of the 2nd and 3rd metatarsals. Echocardiogram and renal ultrasound were normal. FISH for the 16p13.11 duplication was negative on mother's patient. Paternal FISH analysis has not been performed yet. Reported patients with duplication of 16p13.11 have variable presentations including skeletal features with craniosynostosis, polydactyly, and joint hypermobility; cardiac malformations; cognitive impairment; and behavioral abnormalities. As far as we know, the striking hand and feet anomalies of this patient have not been previously reported in the literature. Description of this case will further the genotype-phenotype information available for 16p13.11 duplication.

1011T

Sirenomelia: A Tale of Four South African Mermaids. *S. Moosa[1,2], A. Krause[1,2].* 1) Division of Human Genetics, National Health Laboratory Service, Braamfontein, Johannesburg, Gauteng, South Africa; 2) School of Pathology, University of the Witwatersrand, Johannesburg, South Africa.

Background: Sirenomelia is a rare, serious congenital anomaly characterized by variable degrees of fusion of the lower limbs. The reported incidence is between 1.1 and 4.2 per 100 000 births, with a male to female ratio of 3:1. It is also known as the mermaid syndrome/malformation, derived from the physical similarity to the sirens of Greek and Roman mythology. Sirenomelia rarely occurs as an isolated anomaly and affected individuals exhibit a range of severe associated malformations, mainly involving the lower vertebral, pelvic and genito-urinary systems. Objective: To describe the largest series of African patients with sirenomelia and to highlight rarer associated anomalies. Design/Methods: Four patients with sirenomelia were seen at the Division of Human Genetics, National Health Laboratory Service and the University of the Witwatersrand, since 2005. Data collected from patient files included: maternal histories, antenatal findings, birth histories, clinical examinations, clinical photographs, X-rays and other test results. We present a detailed comparison of these patients based on clinical and X-ray findings and the results of genetic testing and post-mortem investigation, where applicable. Results: 4/4 patients were born to young, Black South African women. None of the mothers reported a history of maternal diabetes or any significant teratogen exposure. None of our patients survived beyond 2 days of age, and all had different associated abnormalities. 4/4 had a single umbilical artery. Of the 3/4 patients who had upper limb involvement, one patient presented with severe left-sided phocomelia, oligodactyly, radial and ulna ray defects and a rudimentary humerus. 4/4 had features of VACTERL association and 3/4 had X-ray features suggestive of the caudal dysgenesis syndrome (CD). Conclusions: No two patients with sirenomelia are alike, highlighting the variability of the condition. Although 4/4 displayed the characteristic lower limb fusion, they displayed different associated malformations of the upper limb, gastro-intestinal and skeletal systems. The phenotypic overlap between sirenomelia, CD and VACTERL, as seen in our patients, supports the hypothesis that these three entities are possibly part of the same pathogenic spectrum.

Natural history study of Arthrogryposis Multiplex Congenita, Amyoplasia type. *T. Nichols[1], S.S. Hashmi[1], P. Mancias[1], M. Raia[1], G. Gogola[2], J.T. Hecht[1].* 1) The University of Texas Health Science Center, Houston, TX; 2) Shriners Hospitals for Children, Houston, TX.

Arthrogryposis or Arthrogryposis Multiplex Congenita (AMC) are terms used to describe the clinical finding of multiple congenital contractures. There are more than 300 distinct disorders associated with arthrogryposis. Amyoplasia is the most common type of arthrogryposis and is often referred to as the “classic” type. There is no known cause of amyoplasia and no risk factors have been identified. Moreover, there is no established diagnostic criterion, which has led to inconsistency and confusion in the medical literature. The purpose of this study was to describe the natural history of amyoplasia, to determine if there are any identifiable risk factors and develop a list of diagnostic criteria. A retrospective chart review of 59 children with multiple contractures, ascertained at the Shriners Hospitals for Children in Houston, Texas, was performed. In addition, information about prenatal, birth and family histories was obtained from a questionnaire completed in the clinic by a parent/guardian. Analysis was performed using STATA v10.0 to generate frequencies, means and medians. Of the 59 children, 44 were found to have amyoplasia by the diagnostic criteria described below; 15 children had multiple congenital contractures (MCC) only and were used as a comparison group. For the amyoplasia group, with the exception of abnormal amniotic fluid levels during pregnancy, there were no significant demographic or prenatal risk factors identified. However, other common features that discriminate amyoplasia from other types of contracture syndromes include: internally rotated shoulders, extended elbows, and flexed wrists without joint pterygium, round face with one or more midline facial hemangiomas, and normal mouth. These features have been incorporated into an amyoplasia checklist that can be used as diagnostic criteria for discriminating amyoplasia from other isolated and multiple contracture conditions.

A novel mutation in GPC3 gene in a Patient with Simpson-Golabi-Behmel Syndrome (SGBS). *E. Nishi[1], S. Mizuno[1], T. Yamamoto[2].* 1) Dept Pediatrics, Central Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Tokyo Women's Medical University Institute for Integrated Medical Sciences, Tokyo, Japan.

Simpson-Golabi-Behmel Syndrome (SGBS MIM;312870) is es syndrome characterized by prenatal and postnatal over growth, distinctive craniofacies, and mental retardation. The craniofacial features are macrocephaly, hypertelorism, macrosomia, macroglossia, and palatal abnormalities. The mental retardation is commonly mild to severe, with or without brain anomalies. The diagnosis of SGBS is based on clinical findings, family history consistent with X-linked inheritance, and molecular biological testing of glypican-3 (GPC3;300037), which maps to chromosome Xq26. We report a novel mutation of the GPC3 gene in a boy who was born as an extremely-low birth weight baby at 26 gestational weeks and showed prenatal and postnatal overgrowth, hypothyroidism, pervasive developmental disorder. He was seven-year-old Japanese boy with nonconsanguineous parents. He was born at 26 weeks and 2 days by emergency Caesarean section because of fetal distress. His birth weight was 976g (>90th centile), length 37cm(75th-90th centile), head circumference 24.5cm(50th centile), and the Apgar scores were 1 and 3 at 1 and 5 min, respectively. He was large for his gestational age and presented a neonatal hypotonia. He needed tracheal intubation for 8 days and phototherapy for 7days. Also He had difficulties of sucking, so he needed tube feeding. He had a global developmental retardation. At the age of 1 year, because of macrosomia and macroglossia, he had been once diagnosed beckwith-wiedermann syndrome clinically. He had hypothyroidism , febrile convulsions, ventricular septal defect , sleep apnea syndrome by enlarged tonsil needed removing, repeated otitis media with effusion , pervasive developmental disorder diagnosed at the age of 4 year and 9 months old. At the age of five, his height was 114cm (>90th centile), his weight was 23kg (>90th centile), and his head ciecumference was 52.5cm(50th-75th centile), SGBS was suspected because of the assosiation of prenatal and postnatal overgrowth, severe mental retardation, the typical dysmorphic features of face. The moleculae analysis of the GPC3 gene detected a non-reported 2-bp insertion (c.91_92ins GC) in exon 1. He was diagnosed SGBS . This mutation is de novo because it was not revealed in the molecular analysis of the mother.

Particular clinical, psychologic and behavioral features identified in Prader Willi syndrome. *C. Rusu[1, 2], E. Braha[1, 2], M. Volosciuc[2], I. Ivanov[3], M. Gramescu[3], V. Gorduza[1, 3], M. Puiu[4], D. Dan[5].* 1) “Gr T Popa” University of Medicine and Pharmacy, Medical Genetics Department, Iasi, Romania; 2) “Sfanta Maria” Children's Hospital, Medical Genetics Center, Iasi, Romania; 3) Immunology and Genetics Laboratory, Specialty Outpatient Unit of “Sfantul Spiridon”Hospital, Iasi, Romania; 4) “Victor Babes” University of Medicine and Pharmacy, Medical Genetics Department, Timisoara, Romania; 5) Romanian Prader Willi Syndrome Association.

Prader-Willi syndrome (PWS) is a relatively common disorder due to abnormalities in the 15q11.2-q13 region. Major manifestations include hypotonia with poor suck and poor weight gain in infancy, early childhood-onset hyperphagia and obesity, characteristic appearance, hypogonadism, growth hormone insufficiency causing short stature, developmental delay and characteristic behavior. We present 8 cases with PWS recorded in the files of Iasi Medical Genetics Center in order to illustrate some special features and to discuss the diagnosis and management strategy. Clinical diagnosis was based on actualized diagnostic criteria and confirmed by genetic tests (karyotype, MLPA, FISH, methylation test). Frequency of characteristic clinical features was analyzed (globally and separately for different types of genetic defects, compared to literature data), as well as particularities recorded. The most common particular features were: multiple and severe allergies, skeletal abnormalities (tall stature, short metacarpals, marked genu var), seizures and brain MRI abnormalities, as well as behavior particularities (no food seeking with relatively normal weight, preference for computer games instead of puzzle etc). Most of the cases have been followed for a long time and the changing of the phenotype in time is presented. In conclusion, we present particular cases of PWS aiming to illustrate special features and to discuss diagnosis and management strategy.

1015T

Unusual multiple congenital anomalies in a newborn boy of complex etiology: Mosaic 45,XY/45,X, duplication Xp22.33 involving *SHOX*, duplication 15q11.2 and 18q22.2-22.3, and history of maternal liver failure due to paracetamol, illicit drugs and alcoholism abuse. *S. Sampath[1], J.J. Gershanik[2], Y. Lacassie[3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Neonatal Medical Group, New Orleans, LA; 3) Department of Pediatrics Louisiana State University Health Sciences Center and Children's Hospital of New Orleans, LA.

We present a NB boy with multiple congenital anomalies (MCA), born to a 37 yo AA father and a 35 yo G4P3 Caucasian mother with history of alcoholism since she was a teenager. The mother had two normal girls from different unions, and a normal 2-year-old boy with the father of the proband. Early in pregnancy mom was admitted to ICU for liver failure secondary to paracetamol abuse. She also reported alcohol and drugs abuse. US detected abnormal spinal cord ending in the lumbar area with only half the coccyx/pelvis being visible, abnormal leg crossing extending in opposite directions and two vessels cord. Amniocentesis showed a mosaic 46,XY[95%]/45,X[5%]. Because of IUGR and breech presentation, the proband was delivered at 38 weeks via C/S. BW was 2,500 g., Apgar score 9-9. Main findings included: very short neck, humeri and femurs, opisthotonic positioning, high-pitched cry, some facial dysmorphism, ASD and VSD, a large ventral abdominal hernia, 11 ribs and hypoplastic defective vertebrae with low spinal tethered cord, sacral agenesis, CALS over right hip, large penis and undescended testes with rugous scrotum, hip flexed and immobile with hip subluxation, and delayed tibial ossification. Brain anomalies included agenesis corpus callosum and wider intrahemispheric sulci with possible leptomeningeal heterotopia, and cerebellar atropy. Very large gallbladder and large renal calyces were also observed. Since MCA were not explained by the sex chromosomal mosaicism, aCGH on chord blood was performed. aCGH revealed duplication at three loci: 1) Xp22.33, spanning 86 kb including the entire SHOX gene, 2) 15q11.2, spanning 1 Mb that includes 9 RefSeq genes, and 3) 18q22.2-22.3, spanning 1.9 Mb containing one hypothetical transcript. As mutations in *SHOX* including copy number changes have been reported in idiopathic short-stature and Léri-Weill Dyschondrosteosis and *SHOX* is a transcription factor involved during early embryonic development to control the formation of many body structures, especially important in the development of the skeleton and particularly in the growth and maturation of bones in arms and legs, we suggest the skeletal anomalies are probably due to the Xp22.33 duplication. It is not clear however the origin of other anomalies, but a role for duplication involving many genes at 15q11.2 and 18q22.2-22.3 or their interaction effect cannot be discounted. Further studies in the proband and both parents are currently in progress.

1016T

“Holoprosencephaly-polydactyly” (pseudotrisomy 13) syndrome: a new case report. *C. Sergi[1], J. Gekas[2], D. Kamnasaran[3].* 1) Department of Laboratory Medicine and Pathology, University of Alberta, Edmonton, Canada; 2) Human Genetics Research Unit, Centre de recherche de l'hôpital Saint-François d'Assise, Québec, Canada; 3) Department of Pediatrics, Laval University, Québec, Canada.

Background: The etiology of disorders during the development of the prosencephalon is still vastly unknown, although five genes have already been identified, including *SHH*, *SIX3*, *TGIF*, *ZIC2* and *GLI3*, with mutations in subjects with holoprosencephaly or polydactyly. Holoprosencephaly has been described in several genetic syndromes and it has been suggested that “Holoprosencephaly-Polydactyly” or pseudotrisomy 13 may represent a particular subset of prosencephalic developmental disorders. In this study, we report a new case of a fetus with holoprosencephaly-polydactyly syndrome. **Methods and Results:** The proband was the fourth child born from non-consanguineous parents. During the pregnancy, the mother smoked, but was otherwise healthy with no infections and sickness or even medication/drugs used. The family histories were unremarkable. Transvaginal ultrasonography was performed at 20.4 gestational weeks, which led to the prenatal diagnosis of an abnormal fetus, and the decision to terminate the pregnancy at 23 gestational weeks. Autopsy confirmed the diagnosis of a female fetus having alobar holoprosencephaly with an absence of midline structures of the brain and a dilated single ventricle, absent olfactory bulbs and hypoplasia of the optic chiasm. The proband also showed classic facial features of hypotelorism, fused palpebral fissures and cebocephaly. No other extra-cranial findings were noted except for unilateral hexapolydactyly of preaxial type (right thumb) and septal agenesis of the left lung. The parent's and proband's karyotypes were normal. Molecular genetic testing were undertaken by sequencing candidate holoprosencephalic genes (*SHH, SIX3, TGIF, ZIC2*), and a candidate for polydactyly (*GLI3*). No apparent mutations were identified. **Conclusion:** We propose that the abnormalities of our fetus support the demarcation of this syndrome as an autonomous phenotype. Specific diagnostic criteria for holoprosencephaly-polydactyly syndrome need to be complemented by the absence of mutations in the major holoprosencephaly genes.

1017T

Inherited subtelomeric 14qdel10pdup and 14qdup10pdel in mentally retarded family members with different phenotypes, revealed reciprocal 14q10p translocation in their fathers. *V. Adir, E. Shahak, J. Levitatz, N. Ekhilevitch, H. Bar-El, Z.U. Borochowitz.* Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, Technion Institute of Technology, Rappaport Faculty of Medicine, Haifa, Israel P.O. Box 4940, Haifa, 31048, Israel.

Subtelomeric aberrations are responsible for 5% to 10% of unexplained cases of mental retardation. Subtelomeric regions are rich in genes and any change from the normal amount of the genes can cause a pathological phenotype. Each chromosomal site that is unbalanced can cause a specific phenotype, and deletion of genes will cause a different phenotype than duplication of the same genes. In most reported cases of subtelomeric imbalances, the exact cause and effect have not been well described. Here we describe a large family with two distinct mental retardation and malformation phenotypes, which correlate with their two genotype groups. These two genotypes were the outcome of the same genetic founder event, translocation of 14qter with 10pter. Screening the effected children in this family for subtelomeric microdeletions with MLPA P070 and P036 sets of probes revealed two groups of genotypes , group A had a deletion in 14qter and duplication in 10pter, while group B had a duplication in 14qter and deletion in 10pter. Testing their parents and healthy siblings with MLPA showed normal results. However FISH testing revealed balanced translocation involved 10pter and 14qter in one of the fathers. The patients in group A have more severe phenotype with distinct features of malformation, while group B have a milder pathology.

1018T

High frequency of Copy Number Variants (CNVs) in the chromosome 11p15.5 region in patients with Beckwith-Wiedemann syndrome. *B. Baskin[1], S. Choufani[2], C. Shuman[2,3], N. Parkinson[4], E. Lemyre[5], P.N. Ray[4], R. Weksberg[2,3].* 1) Clinical Genetics, Uppsala University Hospital, Uppsala, Sweden; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 3) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 4) Division of Molecular Genetics, The Hospital for Sick Children, Toronto, Canada; 5) Medical Genetics Service, Department of Pediatrics, CHU Sainte-Justine, Montreal, Canada.

Beckwith-Wiedemann syndrome (BWS) is an etiologically heterogeneous overgrowth disorder that results from dysregulation of imprinted growth regulatory genes on chromosome 11p15.5. This condition is characterized by macrosomia, exomphalmos, and macroglossia as well as hemihyperplasia and embryonal tumours. The majority of BWS cases (85%) are sporadic and result from loss of methylation at imprinting center 2 (IC2), gain of methylation at imprinting center 1 (IC1) or paternal uniparental disomy (UPD) involving both imprinting centers. Inherited forms of BWS are mainly due to mutations in CDKN1C but there are an increasing number of reports of patients with CNVs in the 11p15.5 region, some presenting with a positive family history. In order to better define the frequency of such CNVs, we analyzed the data for 435 unrelated patients clinically suspected to have BWS and referred to the molecular diagnostic laboratory for clinical testing by MS-MLPA. In total, molecular alterations were detected in 168 (39%) patients of which 60% showed loss of methylation at IC2, 9% showed gain of methylation at IC1, 22% showed paternal UPD and 9% had CNVs of the chromosome 11p15.5 region. Five out of 14 index cases with CNVs were linked to maternally transmitted deletions and?all were found to have affected siblings. Our results demonstrate that CNVs of chromosome 11p15.5 occur at a frequency of 9% in BWS individuals with positive molecular findings and represent an important contribution to the familial recurrence risk associated with this disorder. These data emphasize the importance of performing deletion/duplication testing in addition to methylation analysis for BWS given the potential impact on genetic counseling for these families.

1019T

Analysis of CNVs of the BP1-BP2 region (15q11.2) suggests mild pathogenicity in autism families. *N. Kommu[1], S. Sanders[2], E. Kaminsky[3], P. Stankiewicz[1], C. Martin[3], A. Patel[4], J. Wiszniewska[4], A. Beaudet[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, BCM MS:225, Houston, TX 77030; 2) Department of Genetics, Center for Human Genetics and Genomics and Program on Neurogenetics, Yale University School of Medicine, New Haven, Connecticut 06510, USA; 3) Emory University School of Medicine Department of Human Genetics Whitehead Building Room 315 615 Michael Street Atlanta GA 30322; 4) Medical Genetics Laboratories Baylor College of Medicine One Baylor Plaza, MS NAB 2015 Houston, TX, 77030, U.S.A.

Reports on the involvement of CNVs of the BP1-BP2 region in schizophrenia, bipolar and epilepsy disorders are conflicting. Further, there is no adequate information about its role in autism families.We studied copy number of the BP1-BP2 region in 1184 Simons Simplex Collection (SSC) families, 1911 NIMH controls and 28,473 cases, mostly with developmental delay referred to the Molecular Genetics Laboratories (MGL). These data were compared to CNV data from ~7700 controls recently reported by other groups.Among the SSC families, there were seven deletions of which five were in the transmitted chromosomes, one in the non-transmitted chromosomes and one de novo event. These families also have 15 duplications: one de novo, six in transmitted chromosomes and eight in the non-transmitted chromosomes. Nine deletions and four duplications were found in 1911 NIMH controls. Among the clinical samples referred to MGL, 153 were deletions (1 in 186) and 90 duplications (1 in 309). About half of these cases have neurological symptoms. Among the 7700 previously reported controls, there were 16 deletions (1 in 481) and 25 duplications (1 in 308).No significant differences in the frequencies of CNVs were observed between non-transmitted and transmitted chromosomes of the SSC parents. Nor there are differences among the autism patients, their unaffected siblings and the controls. The frequency of deletions among samples referred for clinical diagnosis is significantly higher than the controls studied here. Taken together, our results suggest that BP1-BP2 deletions may confer risk in developing a group conditions that include developmental delays and different types of neurological disorders but have low penetrance. Funded by SFARI.

1020T

Copy Number Variants in Cerebral Palsy. *G. McMichael[1], A. Moreno-De-Luca[2], A. MacLennan[1], J. Gecz[3], S. Girirajan[4], E. Eichler[4], C. Martin[2].* 1) Obstetrics & Gynaecology, Universtiy of Adelaide, Adelaide, South Australia, Australia; 2) Human Genetics, Emory University School of Medicine, Atlanta, Georgia, USA; 3) Genetics and Molecular Pathology, SA Pathology at the Women's and Children's Hospital, Adelaide, South Australia, Australia; 4) Genome Sciences, University of Washington School of Medicine, Seattle, Washington, USA.

Cerebral palsy (CP) describes a group of permanent disorders of the development of movement and posture that are attributed to non-progressive disturbances occurring in the developing fetal or infant brain. We hypothesise that CP is caused by many diverse and individually rare genetic abnormalities, including copy number variants (CNVs). To explore our hypothesis that CNVs contribute to the aetiology of CP, we initially tested 50 DNA samples from individuals with CP on a custom-designed 180K chromosomal microarray with targeted plus whole genome coverage. The targeted coverage includes known clinically relevant regions such as microdeletion/duplication syndromes, telomeres and centromeres at a resolution of ~20-50 kb plus exon-level coverage of >1200 genes involved in neurodevelopmental disorders. The whole-genome backbone results in a resolution in unique DNA of ~225kb. Three cases were identified with a CNV that included interesting candidate genes for the CP phenotype; *CTNND2* (446 kb duplication including the first exon), *MCPH1* (219 kb duplication including exons 1-8) and *COPS3* (4 kb deletion including exons 6-8). All three CNVs were shown to be inherited from an unaffected parent. These CNVs may show variable expressivity, reduced penetrance, possible imprinting or the presence of a point mutation on the other allele in affected children, not identified by the CNV profiling. Several other CNV regions were identified including 22q11.22, 15q11.2 (BP1-BP2) and 12p12.1p12.2, as well as single-gene CNVs across *CNTNAP3*, *MC2R*, and *FCSB* and intragenic CNVs in *DLGAP2*, *PARK2, NBEA*, *PAK2*, *MACROD2*, *CNTN1*, *MPV17L* and *NF1*. These same samples were also separately assessed on a 135K custom designed array with targeted coverage of ~50kb in all genomic hotspots and backbone coverage of 350kb. Results confirmed CNV regions for *CTNND2*, *FCSB* and 12p12.1-p12.2. CNV regions were also identified involving Histone cluster genes, Olfactory receptors and 7p21 region as well as single-gene CNVs for *PTCHD3*, *NPHP1*and *TARP* and intragenic CNVs in *NCOR2*, *SH3GL3* and *C16orf62*. Parental samples need to be tested to determine if these imbalances are *de novo* or inherited, which will aid in establishing their significance. The pathogenicity of these rare CNVs is not currently resolved but these preliminary studies into the contribution of CNVs to CP justify further evaluation in a larger cohort which is currently underway.

Microdeletion 22q11.2 in a patient with Goldenhar Syndrome. *S.F. Oliveira[1], P.A.C. Santos[1], E.L. Freitras[2], H.P.N. Safatle[2], C. Rosenberg[2], I. Ferrari[1], J.F. Mazzeu[1].* 1) Genetica e Morfologia, Universidade de Brasilia, Brasilia, Brasilia (Distrito Federal, Brazil; 2) Depto de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo.

Goldenhar syndrome, also known as oculo-auriculo-vertebral syndrome, is a congenital defect from anomalous development of first and second branchial arches. It is heterogenous and its etiology includes unkwown genetic factors, different chromosome aberrations and environmental factors, like maternal vasoactive medication, thalidomide and maternal diabetes. We report a patient with clinical signs of Goldenhar syndrome and Di-George syndrome. We identified a 2,493,883 bp deletion at genomic position 17,276,772-19,770,655 (hg18) in the 22q11.21 region by array-CGH. Deletions of 22q11 have been described in patients with Di-George syndrome and Goldenhar syndrome, however the deletion here described is more proximal and do not overlap with the previously reported deletions associated with Goldenhar syndrome. Several genes mapped to this segment are involved in the embryogenesis of the branchial arches, namely TBX1, required for auricular development, and GSC2 that is related to GSC previously suggested as a candidate gene for Goldenhar syndrome. Therefore TBX1 and GSC2 are also candidates for Goldenhar syndrome.

1022T

Suspected gonadal mosaicism as a cause of Gorlin syndrome. *E. Stattin, P. Lundberg, I. Golovleva.* Clinical Genetics, Umeå University Hospital, SE 901 85, Umeå, Sweden.

Background: Autosomal dominant basal cell nevus syndrome (BCNS; Gorlin syndrome, MIM 109400) is caused by mutations in the human homolog of the Drosophila patched gene-1 (PTCH1) at 9q22.3. The mutation spectra are represented by point mutations (missence, nonsense and those affecting splice sites) and interstitial deletions at 9q22.3. At the same time interstitial 9q22.3 deletion is proposed as a newly recognised overgrowth syndrome. Tumors such as medulloblastoma, rhabdomyomas cardiac and ovarian fibromas, lymphoma and meningioma have been associated with GS. The risk of other malignant tumors is not increased. Delayed development is described but not mental retardation. Objectives: We describe siblings diagnosed with Gorlin syndrome (GS) clinically, verified molecularly and further analysed by SNP array using Illumina's 610-Quad BeadChips. The two boys were children of healthy non-consanguineous parents. Both of the boys fulfilled diagnostic criterion for the diagnosis GS with multiple jaw keratocysts and basal cell carcinomas. But both of them also have mental retardation. The phenotype could not only be explained by GS and therefore further analysis was performed. Methods and results: Conventional cytogenetic analysis by GTG banding on peripheral blood lymphocytes revealed normal karyotypes in both patients however deletion of entire PTCH1 gene was demonstrated by MLPA. To establish if the boys have a larger deletion, we performed SNP array which demonstrated presence of interstitial deletion at 9q22.3. The region covered by the deletion was 7.92Mb (CRCh37/hg19 97700731-105685265) and contained 73 genes, including the PTCH1 and TGFBR1 genes. The deletion was verified by specific probes RP11-435O5 (9q22.32) and RP11-75J9, RP11-185E13, RP11-438P9 (9q31.1) by FISH analysis. FISH with the same probes on parent's blood lymphocytes excluded presence of balanced translocation of 9q22.3 locus and array results did not reveal any aberrations at 9q22.3. Conclusions: This is the first report on possible gonadal mosaicism causing Gorlin syndrome in two siblings.

Angelman syndrome case report with hypothyroidism. *C.E. Monterrubio Ledezma[1], L. Bobadilla Morales[1,2], L.J. Rodríguez Casillas[1], H.J. Pimentel Gutiérrez[1], J.R. Corona Rivera[1,2], A. Corona Rivera[1,2].* 1) Biología Molecular y Genómica, Lab. Citogenética Genotoxicidad y Biomonitoreo “Dr. ECR”. CUCS, UdeG., Guadalajara, Jalisco , Mexico; 2) Unidad de citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Hospital Civil “Dr Juan I Menchaca”.

Introduction. Angelman syndrome (AS) is a neurogenetic disorder with UB3A gene alterations in maternal imprinting (15q11-13). It is characterized by mental retardation, epilepsy, language deficit, facial dysmorphism and characteristic behavioral phenotype. It has an estimated frequency of 1:10,000 to 1:40,000. Objective. To report a new AS case associated with hypothyroidism without goiter. Clinical report. Female nine and a half years old, product of the second pregnancy, threatened abortion presented, delivery was uncomplicated. At birth showed hypertonia, natal teeth and gums cysts, psychomotor development and language retardation; febrile seizures and smiles to any stimulus. Congenital hypothyroidism was discarded. Hypothyroidism is diagnosed from 3 years old (T4 1.03 μg/dL, TSH 7.68 mUI/dL) and medicated whiht levothyronine. At physical examination she showed, weight 33 kg (PC 75), height 1.3 m (Pc 50), head circumference 50 cm (Pc 25); brachycephaly, narrow forehead, round face, almoud eyes, epicanthus, anteverted nostrils, thin lips, short neck, scoliosis, clinodactyly, blue and brown spot, ataxic gait and mirror movements. Paraclinical: electroencephalogram with hypervoltage slow waves; computerized axial tomography, cortico-subcortical atrophy; renal sonogram, ectopic and hypoplastic right kidney. Karyotype 46,XX; FISH probe to test Prader-Willi/Angelman LSI was compatible with deletion 15q11->13. Conclusions. Currently it is not stated that hypothyroidism belong to the spectrum of manifestations of AS. However there have been reported 3 patients with AS and hypothyroidism. Based on the findings of the case and the literature review, it is suggested the directed search of endocrinological alterations such as hypothyroidism in patients with AS.

1024T

Health-related quality of life in patients with cardio-facio-cutaneous syndrome. *S. Sottile[1], A. Kwan[2], P. Magoulas[3], K. Rauen[4].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Pediatrics, Division of Medical Genetics, Stanford University, Stanford, CA; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Department of Pediatrics, Division of Medical Genetics, University of California San Francisco, San Francisco, CA.

Cardio-facio-cutaneous (CFC) syndrome is a rare genetic disorder caused by germline mutations in genes in the Ras-induced mitogen activated protein kinase (Ras/MAPK) pathway, a signal transduction pathway with important roles in both human development and oncogenesis. The past ten years have seen incredible advancements for conditions of the Ras/MAPK pathway, most notably the promise of treating CFC and related conditions at the molecular level by utilizing cancer therapeutics that target the pathway. Future clinical trials for CFC will require measurement of certain endpoints, including health-related quality of life (HRQL), in order to determine the effects of treatment on the individual and caregiver's quality of life. We aimed to study HRQL in a large cohort of patients with CFC. This is the first study to assess HRQL in this population and will serve as a guideline for future studies. HRQL is a multidimensional construct representing a patient's subjective perception of the impact of disease. We assessed HRQL using the Pediatric Quality of Life Inventory™ and designed a survey tailored to the features of CFC by using a generic quality of life survey along with disease-specific modules. Due to age and/or intellectual disability a parent-proxy measure was used. Participants were recruited through CFC International, a support organization for families of individuals with CFC. The study was advertised to approximately 227 members of CFC International; 90 families requested surveys, and 56 surveys were returned (62% return rate). Our results indicated that individuals with CFC may have lower physical, psychosocial and total quality of life as compared to their healthy peers. Difficulty with physical functioning, such as ambulating, self-grooming, and participating in chores may greatly impact quality of life in patients with CFC. Additionally, psychosocial HRQL may be lower for older patients with CFC as compared to younger patients. In contrast, parent HRQL and the impact of CFC on a family may be better for older patients with CFC as compared to younger patients. Finally, HRQL is similar among individuals with different molecular causes of CFC. This is the first study to assess the extent to which CFC may impact an individual and/or caregiver's quality of life and our results serve as an important baseline measurement of HRQL. This survey instrument may be appropriate for measuring changes in HRQL in future clinical trials for CFC syndrome.

A new locus for autosomal dominant renal insufficiency associated with anemia and growth retardation. *B. Loeys[1], J. Huyghe[1], G. Van Camp[1], E. Matthys[2], E. Sys[3], M. Renard[4], A. Raes[5], J. Vandewalle[5], C. Van Hemelrijk[5], G. Mortier[1], L. Van Laer[1].* 1) Center for Medical Genetics, Antwerp University Hospital, Antwerp, Belgium; 2) Department of Nephrology, AZ-Sint Jan, Brugge, Belgium; 3) Department of Nephrology, AZ-Sint Lucas, Brugge, Belgium; 4) Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium; 5) Department of Pediatrics, Ghent University Hospital, Ghent, Belgium.

In 2009, Zivna et al. reported a novel clinical syndrome characterized by autosomal dominant early-onset anemia, hyperuricemia and progressive kidney failure. Causal missense mutations in the renin gene lead to chronic endoplasmatic reticulum stress and unfolded protein response with subsequent site-specific attenuation of renin biosynthesis in the juxtaglomerular apparatus. Here we ascertained a three-generation family with autosomal dominant progressive renal insufficiency associated with congenital anemia, intrauterine and postnatal growth retardation. At term, birth weights ranged from 1800 gram to 2400 gram. Ultrasound exams showed small, dysplastic kidneys without cysts. Pertinent laboratory findings included normochromic, normocytic anemia, increased creatinemia, mild hyperuricemia and absence of proteinuria. Kidney biopsy revealed glomerular sclerosis and tubular atrophy and hypertrophy. Based on the similarities to the phenotype caused by renin mutations, we first excluded renin as the culprit gene based on Sanger sequencing of all exons and flanking intronic regions. In addition, whole genome micro-array analysis did not reveal any chromosomal deletions or duplications. Subsequently, we collected DNA from twelve family members, including seven affected subjects, and performed genomewide linkage analysis using the Illumina Human CytoSNP12. A subset of 10,521 Single Nucleotide Polymorphisms with an interval of circa 250kb were analyzed with Merlin. We identified a candidate region with a maximum LOD-score of 2.71 on chromosome 3q. The region was confirmed and finemapped with microsatellite markers. The linked region measures 32 Mb and contains a total of 357 genes. Based on the phenotype, we prioritized AGTR1 and SUCNR-1 as candidate genes. Both genes are involved in renin-related pathways. Sanger sequencing of both genes failed to reveal any causal mutation. We will apply whole exome sequencing to identify the responsible gene. Zivna et al, AJHG, 2009, 85, 204-213.

1026T

MEF2C mutations are a frequent cause of Rett- or Angelman syndrome like neurodevelopmental disorders. *A. Rauch[1], D. Bartholdi[1], C.M. Rueegger[1], M. Zweier[2], C. Zweier[2], E.K. Bijlsma[3], A. van Haeringen[3], W. Reardon[4], M. Zollino[5], A. Baumer[1].* 1) Institute of Medizinische Genetik, University of Zurich, Schwerzenbach-Zurich, Switzerland; 2) Institute of Human Genetics, Erlangen, Germany; 3) Department of Clinical Genetics, Leiden, The Netherlands; 4) Regional Hospital, Dooradoyle, Limerick, Ireland; 5) Institute of Medical Genetics A Gemelli Catholic University of Rome, Rome, Italy.

The transcription factor MEF2C was recently identified as the phenocritical candidate gene for the 5q14.3q15 microdeletion characterized by profound muscular hypotonia, severe intellectual disability (ID) and variable neurological and minor anomalies. Phenotypic overlap with Rett syndrome was explained by transcriptional interaction of MEF2C and MECP2. Point mutations in MEF2C have been shown to represent a relatively frequent autosomal dominant cause of moderate-severe ID accounting for as much as 1.1% of patients. Nevertheless, to date only 5 patients with MEF2C point mutations have been reported. Due to the phenotypic overlap we screened a cohort of 54 patients previously tested negative for Rett and/or Angelman syndrome for MEF2C mutations or deletions and detected two patients with novel MEF2C mutations (one frameshift and one missense mutation within the MADS domain) within this cohort. In addition we identified one further patient with Rett syndrome like phenotype caused by a MEF2C deletion detected by array-CGH screening after negative MECP2 testing. Two further patients with MEF2C mutation and intragenic deletion were identified subsequently due to suspicion of a MEF2C related disorder. Of note, our patient with the novel missense mutation is the first reported to be able to speak several words at the age of 4 years functioning at the mild to moderate intellectual disability level (IQ55). In summary we present 5 novel patients with MEF2C defects increasing the total number of reported cases to 10 and further delineating the phenotype which resembles both Rett and Angelman syndromes. Our results indicate that MEF2C mutations represent a common differential diagnosis to Rett- and Angelman syndrome accounting for approximately 4 % of such cases.

Distal arthrogryposis is a heterogeneous clinical and genetic condition. Mutations in six different genes encoding the skeletal muscle contractile apparatus have been implicated in distal arthrogryposis and are responsible for 20 to 25% of molecular diagnoses. We report on four patients from 4 different countries with syndromic distal arthrogryposis presenting with a de novo 3p13p14.1 microdeletion gathered through the Decipher network. Several case reports of patients diagnosed by classical cytogenetic techniques with 3p13p14.1 deletion all presented with congenital distal multiple contractures anomalies associated with other phenotypic manifestations. The homogeneity of the clinical phenotype associated with the 3p13p14.1 deletion seems to suggest a microdeletional 3p13p14.1 syndrome. Patients presented with distal abnormalities with congenital multiple contractures (4/4 cases), developmental delay/mental retardation (4/4 cases) and feeding difficulties with low food intake (3/4 cases). Facial dysmorphism was constant (4/4 cases) with low-set and backward rotated ears (3/4 cases), hypertelorism (2/4 cases) and microstomy (2/4). Reviewing two previously reported cases with precisely mapped deletions, we limited the critical region for this condition to a 250kb region containing only 1 gene, EIF4E3 and the first two exons of the FOXP1 gene. The EIF4E3 gene was considered as a good candidate gene since it is a member of Eukaryotic initiation factor 4E family (eIF4E) a cap-binding protein, expressed only in brain and muscles. 5' cap-binding is necessary for translation initiation. The EIF complex participates in stabilisation, storage and degradation prevention of mRNAs before adressing to the ribosome for translation. Direct sequencing of the EIF4E3 exons and intron-exon boundaries and locus quantification by dedicated quantitative PCR in a cohort of 13 French patients affected by isolated or syndromic distal arthrogryposis appeared normal. To conclude, we report on a new candidate locus for distal arthrogryposis in 3p13p14.1 containing the EIF4E3 gene and the two first exons of the FOXP1 gene. Investigating this locus in a larger cohort is needed to determine whether the genes in this interval, FOXP1 or EIF4E3, play a role in other forms of distal arthrogryposis.

1028T

An Unusual Case of Developmental Delay with Plantar Lipomatosis. *L. Diefendorf[1], J. Humberson[2].* 1) Department of Internal Medicine and Pediatrics, Brody School of Medicine at East Carolina University, Pitt County Memorial Hospital , Greenville, NC; 2) Medical Geneticist and Clinical Assistant Professor, Department of Pediatrics, Brody School of Medicine of East Carolina University, Greenville NC.

Case Report: A full term 16-month old female with unremarkable prenatal history presented to genetics clinic with severe global developmental delay, onset at 2 months, without regression. She was unable to roll over or sit independently. Mom reported that she says “ma” and “da” but no other words. She was unable to reach for or pick up objects. Mother reports that she does not focus on people's faces or spontaneously smile. She had several physical exam findings including: midfacial hypoplasia, broad philtrum, high arched palate, elongated pinnae, wide tented upper lip with smaller lower “pouting” lip, deep palmar creases with pillowing, and fat pads (plantar lipomatosis) antero-medial to the heels of the feet with a “pillowing” effect on the soles of the feet. Head circumference was fifth percentile and height and weight were twenty-fifth to fiftieth percentile for age. Vision and hearing were normal. The rest of the physical exam was normal including normal tone and full range of motion of joints. Cytogenetic studies revealed a normal karotype 46, XX and significantly increased (8%) homozygosity on array. MRI was unremarkable. There were no reported seizures. **Discussion:** Fat pads antero-medial to the heels are a relatively rare finding. This can be an isolated congenital anomaly. A literature search on OMIM (NCBI, On-line Mendelian Inheritance in Man) revealed four entries including Cowden syndrome, Proteus syndrome, Multiple Lipomatosis, and Pierpont syndrome. The first three conditions are unlikely in this patient, however her presentation is suggestive of Pierpont syndrome. Pierpont described two children with developmental delay, planter lipomatoisis, and unusual facies. The phenotypical appearance included midfacial hypoplasia, large upper lip with small lower lip, broad philtrum, high anterior hair-line, palatal ridge, antero-medial fat pads on bilateral heel, and global developmental delay. One case had seizures. Another case report by Oudesluijs reported a male patient with developmental delay and similar dysmorphic features including the plantar lipomatosis. All the published case reports to date have been male. There are currently no confirmatory genetic tests available as the cause is unknown. There has been debate over the mechanism of inheritance. If this female patient with 8% homozygosity has Pierpont syndrome then it lends evidence to the autosomal recessive theory.

1029T

Deletion of *TWIST1* in a patient with Duane-radial ray syndrome. *S. Jougheh Doust, J. So.* Clinical and Metabolic Genetic, The Hospital for Sick Children, Toronto, On, Canada.

Mutations in the TWIST1 gene, which is located on chromosome 7p21.1, cause Saethre-Chotzen syndrome (SCS; MIM 101400), an autosomal dominant (AD) syndromic form of craniosynostosis. TWIST1 mutations are detectable in 46-80% of individuals with SCS. Clinical manifestations in SCS show inter- and intra-familial variability. Clinical features can include craniosynostosis, low frontal hairline, ptosis, strabismus, facial asymmetry (secondary to unilateral coronal synostosis), small ears, and limb abnormalities such as 2-3 finger syndactyly, radio-ulnar synostosis and hallux deformities. Craniosynostosis is not an obligate feature of SCS syndrome. Most patients have no intellectual disabilities (ID); however, ID has been reported in patients with large deletions of the chromosome 7p21.1 region. Duane-radial ray syndrome (DRRS; MIM 607323) is characterized by uni- or bilateral Duane anomaly and radial ray malformation. DRRS is inherited in an AD manner and SALL4 gene mutations are responsible for 40-50% of DRRS cases. We report a patient with right-sided Duane anomaly, mild developmental delay with more significant speech delay, obsessive-compulsive disorder, dysmorphic features that include bilateral ptosis, small ears, narrow palate, and radial ray anomalies including thenar and hypothenar hypoplasia with proximally inserted thumbs. No craniosynostosis was appreciated in this patient. High-resolution karyotype and metabolic screening, as well as SALL4 mutation analysis, were normal. Further studies with oligo array detected a 4.9 Mb deletion at chromosome region 7p21.2-7p21.1, which included a complete deletion of TWIST1 gene. Our patient carries a microdeletion at 7p21.1 affecting the TWIST1 gene with clinical manifestations suggestive of DRRS but overlapping with SCS. Mutations in the TWIST1 gene associated with severe craniosynostosis and radial ray hypoplasia have been reported by Grip et al (1999) and Seto et al (2001). Duane anomaly has never been reported in association with a TWIST mutation. This is the first report of a TWIST1 gene deletion in an individual presenting with DRRS. The highly variable phenotype of SCS, together with the genetic heterogeneity in DRRS, as demonstrated by the majority of cases not having SALL4 mutations, make the establishment of a clean-cut diagnosis challenging in this case. Given the microdeletion finding in this patient, we suggest that a DRRS-like phenotype might be part of the phenotypic spectrum of SCS.

Familial cosegregation of Coffin-Lowry syndrome inherited from the mother and Waardenburg type IV syndrome due to deletion of *EDNRB* inherited from the father: A diagnostic odyssey. *Y. Lacassie[1], S. Sampath[2].* 1) Dept Ped/Div Clin Gen, LSU Hlth Sci Ctr, New Orleans and Children's Hospital New Orleans, LA; 2) Dept. Gen, LSU Hlth Sci Ctr, New Orleans. Current address Postdoc Fellow, McKusick-Nathans Inst of Genet Med, JHU, Baltimore, MD.

The presence of two or more conditions in a patient has been recognized for a long time as a rare diagnostic problem due to the patient. We report an AA family that was identified after the proposita was referred for diagnostic evaluation at 4½ months with a history of Hirschsprung that was surgically repaired and few dysmorphic features. These included hypertelorism and telecanthus, and a peculiar light blue iris. We evaluated the whole family with a suspected diagnosis of Waardenburg syndrome (WS). The father had similar dysmorphic features supporting the clinical diagnosis of WS; however, examination of the mother revealed characteristic facial and digital features of Coffin-Lowry syndrome (CLS). The clinical evaluation of the five older siblings of the proposita revealed that three were affected with one or the other condition, one with apparently both disorders, and one possibly normal. The youngest sibling born in 2010 however was the most difficult to diagnose clinically. Molecular testing of the mother identified a novel 2 bp deletion (*c.865_866delCA*) in codon 289 of *RPS6KA3* leading to a frameshift and premature termination of translation 5 codons downstream (*NM_004586.2:p.Gln289ValfsX5*). This deletion also was identified in the proposita and her three sisters with a clinical suspicion of CLS, all of whom, as heterozygotes had very subtle manifestations. The molecular confirmation of WS type 4 (Shah-Waardenburg; WS4) was an odyssey. To evaluate WS types I-IV multiple sequential molecular testing was requested, including Sanger sequencing of all exons, and deletion/duplication analysis using MLPA for *PAX3*, *MITF*, *SOX10*, *EDN3* and *EDNRB*. Sequencing did not identify any disease causing variants, but MLPA identified a heterozygous deletion of the entire *EDNRB* in the father. This deletion was also found in the proposita. The oldest brother and a sister (who is also heterozygote for CLS) have characteristic clinical features of WS4; therefore, molecular testing was considered unnecessary. The youngest brother of the proposita was negative for both mutations. Since the heterozygous deletion was the only change identified in *EDNRB*, this family represents one of the few cases with an autosomal dominant inheritance of WS4. This kinship is an example of the coincidence of two conditions cosegregating in one family, with variable phenotypes requiring molecular testing to confirm the clinical diagnoses.

1031T

Genetics of Kabuki Syndrome: MLL2 mutational spectrum in 100 KS patients. *A.D.C. Paulussen[1,3], M.J. Blok[1,3], C.E. van Roozendaal[1,3], D. Tserpelis[1], C. Posma-Velter[1], R. Vijzelaar[4], J. Schrander[2], Y. Detisch[1,3], C.T.R.M. Schrander-Stumpel[1,3], A.P.A. Stegmann[1,3], H.J. Smeets[1,3].* 1) Dept Clinical Genomics, Maastricht Univ Med Ctr, Maastricht, Netherlands; 2) Department of Paediatrics, Maastricht UMC+,Maastricht, the Netherlands; 3) School for Oncology & Developmental Biology (GROW), Maastricht UMC+,Maastricht, the Netherlands; 4) MRC-Holland, Amsterdam, The Netherlands.

Kabuki syndrome (KS, MIM: 147920) is a clinically recognizable syndrome of multiple congenital anomalies and mental retardation affecting approximately 1:30,000 live births. Key features are a characteristic face, growth retardation, developmental delay and additional features such as hypodontia and persistent foetal fingertip pads. Recently, a gene causing KS was identified through exome sequencing, reporting de novo mutations in the histone methyl transferase (HMT) gene MLL2 in 66% of 53 patients with Kabuki syndrome (Ng et al., Nat Genet.42(9):790-3, 2010). We confirmed the pathogenic significance of this gene in KS in our first published series, demonstrating 76% MLL2 mutations in 45 KS cases (Paulussen et al, Hum Mutat. 32(2), 2011). In a larger follow-up study we screened 100 patients for MLL2 mutations and included MLPA analysis to study exonic deletions and duplications in the MLL2 mutation negative patients. Using Long-Range PCR we further examined the complete MLL2 gene, including introns and 5'/3' UTR in two typically clinical KS patients without a mutation in the coding region to search for exon deletions/duplications not covered by the MLPA kit and/or deep-intronic de novo mutations. The effect of predicted splice-site mutations was investigated at the RNA level. Finally, we determined the mutational origin (paternal/maternal) of several mutations with allele specific PCR. Our data yields a more complete picture of the MLL2 mutational spectrum and further insight in the pathogenic mechanisms leading to KS.

1032T

Noonan syndrome and other genetically related syndromes diagnosed by a custom multiplex mutation panel (CGC Mutation Panel). *P. Tavares[1], A. Lopes[2], L. Lameiras[2], L. Dias[1], J. Sá[2,3], P. Rendeiro[2], A. Palmeiro[2].* 1) CGC Genetics, Newark, NJ 07103, NJ. (www.cgcgenetics.com); 2) CGC Genetics, Porto, Portugal (www.cgcgenetics.com); 3) Hospital Pediátrico de Coimbra, Coimbra, Portugal.

Introduction: Noonan syndrome is a congenital genetic disease that affects both males and females equally (1:1.000-2.500 newborns). Great clinical variability has been identified: heart disease, valvular pulmonary stenosis or hypertrophic cardiomyopathy, short stature of postnatal onset, psychomotor development delay. Often this syndrome is not diagnosed, but it is related to many complex problems such as coagulation defects and lymphatic dysplasias. Differential diagnosis includes major diseases in the same metabolic pathway - Costello, Cardiofaciocutaneous and LEOPARD Syndrome. Method: We developed a custom multiplex mutation panel (CGC Mutation Panel - Pat. Pending) that contains a total of 80 point mutations, 52 point mutations in the 4 main genes involved in Noonan (PTPN11, RAF1, SOS1 and KRAS) and 30 point mutations (on HRAS, BRAF, MAP2K1 and MAP2K2) involved on LEOPARD, Costello and Cardiofaciocutaneous syndromes (genetically related) to identify the most frequent and severe forms. With this panel we analysed 6 cases of Noonan syndrome that had been also characterized by sequencing of the PTPN11 gene and 33 samples (10 prenatal and 23 postnatal) with suspicion of Noonan or related syndromes. Results: All the 6 previously known mutations were also detected with the panel. From the 33 samples (10 prenatal and 23 postnatal), in 1 prenatal sample we detected a Thr3Ile change on PTPN11 gene allowing the diagnosis of Noonan and in 2 of the postnatal samples we diagnosed a Met269Thr change on SOS1 gene and a Glu257Arg on BRAF gene allowing the diagnosis of Noonan and Cardiofaciocutaneous syndromes respectively. Conclusion: This approach is a valuable diagnostics tool, since it detects the most common mutations associated with Noonan Syndrome, not only on PTPN11 gene but also in 7 other genes, improving the capacity for diagnosis. The genes and mutations included in this panel allow a broader clinical spectrum and a faster diagnosis, independently of the sample type, allowing an earlier decision-making process in patient management, being particularly relevant in prenatal diagnosis (cases with increased nuchal translucency and normal karyotype). This panel represents a step forward allowing the molecular diagnosis of Noonan syndrome together with the differential diagnosis for LEOPARD, Costello and Cardiofaciocutaneous syndromes.

Clinical and Molecular Analysis of Patients with Neurocardiofaciocutaneous Syndromes From Turkey. *P.O. Şimşek Kiper[1], Y. Alanay[1], B. Gülhan[1], C. Lissewski[2], D. Türkyilmaz[3], D. Alehan[4], M. çetin[5], G.E. Utine[1], M. Zenker[2], K. Boduroğlu[1].* 1) Hacettepe University Faculty of Medicine Department of Pediatrics, Pediatric Genetics Unit, Ankara, Turkey; 2) University Hospital Magdeburg Institute of Human Genetics Magdeburg, Germany; 3) Hacettepe University Faculty of Medicine Department of Ear-Nose-Throat, Audiology Unit, Ankara, Turkey; 4) Hacettepe University Faculty of Medicine Department of Pediatrics, Pediatric Cardiology Unit, Ankara, Turkey; 5) Hacettepe University Faculty of Medicine Department of Pediatrics, Pediatric Hematology Unit, Ankara, Turkey.

ABSTRACT The neuro-cardio-facio-cutaneous (NCFC) syndromes are a group of disorders which share many clinical features and in which the verification of the diagnosis may require molecular analysis. These syndromes result from germline mutations in genes encoding proteins and kinases of RAS-MAPKinase signal transduction pathway. In our study, we have performed molecular analyses in 31 patients with a clinical diagnosis of NCFC syndromes (26 patients with Noonan, 3 patients with Costello and 2 patients with LEOPARD syndromes) to elucidate the underlying genetic etiology and to establish a genotype-phenotype correlation. Mutation screening of several genes including PTPN11, SOS1, KRAS, RAF1, SHOC2, HRAS, BRAF and RAF1 were performed. Twenty patients out of 31 (64.5%) were found to be mutation positive. Mutations in PTPN11, SOS1 and SHOC2 genes were detected in 15 patients (58%) with Noonan syndrome (NS). PTPN11 mutations were found in two patients with LEOPARD syndrome. HRAS mutations were positive in two of three patients with Costello syndrome (CS), one of which was HRAS:p.E63_D69dup. The other CS patient was found to have a BRAF mutation which led to a change in diagnosis as cardio-facio-cutaneous syndrome. Of 15 NS patients with a mutation, seven (26.9%) showed a mutation on PTPN11, five (19.2%) on SOS1, and three (11.5%) on SHOC2. Pulmonary stenosis was the most common (62%) cardiac anomaly observed. Thrombocyte segregation abnormality was detected in three patients each with one of the mutations of SOS1, PTPN11 and SHOC2 and in two other patients without a mutation. Of 26 patients with NS, 17 (65.3%) had a delay in motor development whereas 14 (53.8%) had cognitive delay. Hearing and speech perception thresholds levels were found within normal limits in all patients tested. In conclusion, the common genetic basis underlying NCFC might cause difficulties in the differential diagnosis and renders molecular analysis essential for confirmation of the clinical diagnosis and patient follow-up.

A Novel Point Mutation in the STS Gene in a Family with X-Linked Recessive Ichthyosis. *R. Badilla-Porras, L. Dupuis, R. Mendoza-Londono.* Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada.

Recessive X-linked ichthyosis is a keratinization disorder due to an inborn error of metabolism that affects roughly 1:2000 to 1:6000 males. The clinical manifestations present early in life and involve generalized dryness and scaling of the skin with polygonal, regular dark scales. The trunk, limbs, neck, ears and scalp are often involved while palms and soles are spared. Extracutaneous signs are described involving corneal opacities, testicular cancer, cryptorchidism and a family history of delayed progression of parturition. The disease is caused by partial or complete deletions or inactivating point mutations in the steroid sulfatase (STS) gene located on Xp22.3 and leading to deficient STS activity. Up to 90% of the described mutations of this gene are complete deletions, which is one of the highest percentages of chromosomal deletions among all genetic disorders. We present the clinical characterization of a family with a clear X-linked pattern of inheritance, an identified mutation and clinical findings in three generations. Our index case presented at 2 months of age with dryness and scaling of the scalp and lower limbs, and later he developed generalized skin lesions. He did not have any extracutaneous findings.He had normal development, non dysmorphic features and no other abnormalities.His mother presented with mild dry skin and pregnancy history of delayed progression of delivery in all her children. Her first delivery was particularly difficult and that child developed perinatal asphyxia.The maternal grandfather presented with classical dermatological manifestations during childhood.Initial molecular analysis by Fluorescent in-situ Hybridization (FISH) and Multiple Linked PCR Analysis (MLPA) showed no deletions in the STS gene. Direct sequencing was subsequently performed for the STS gene and revealed a novel mutation In exon 9 (c.1381 G>T, p.R454L). Two other missense mutations p.R454H and p.454C at the same position have been described to cause X-linked ichthyosis.“Polyphen” predicted the consequence of the variant p.R454L for the protein to be “probably damaging” supporting the suspicion of the c.1381G>T mutation being pathogenic. The cases presented herein highlight the clinical variability in the phenotype of patients with X-linked Ichthyosis and allow a better genotype-phenotype correlation. Mutations at p.R454L present with classical phenotype in males. Females present with mild skin dryness and delayed progress of parturition.

1035T

Clinical course of Noonan-like syndrome with loose anagen hair (NS/LAH, MIM 607721) in individuals carrying mutations of *SHOC2*. *D. Bartholdi[1], M. Lang-Muritano[2], E.J. Schoenle[2], A. Schinzel[1], M. Zenker[3], A. Rauch[1].* 1) Institute of Medical Genetics, University of Zürich, Schwerzenbach, Switzerland; 2) Division of Endocrinology and Diabetology, University Children's Hospital, Zürich, Switzerland; 3) Institute of Human Genetics, University Hospital Magdeburg, Otto-von-Guericke University, Magdeburg, Germany.

Noonan syndrome comprises a group of autosomal dominant inherited disorders with high clinical variability and genetic heterogeneity caused by dysregulation of the RAS-MAPK signaling pathway. The main clinical characteristics are postnatal growth retardation, cardiac defects, lymphatic dysplasia, facial dysmorphism, ectodermal abnormalities, cognitive disability of variable degree, and susceptibility to certain malignancies. Recently, it was demonstrated that mutations in *SHOC2*, coding for a leucine-rich repeat-containing protein which positively modulates the RAS-MAPK signal cascade, cause a clinically distinctive condition previously termed Noonan-like syndrome with loose anagen hair (NS/LAH, MIM 607721). All patients with NS/LAH reported so far share the same 4A>G missense change in *SHOC2* that predicts the substitution of Ser2 by Gly. This amino acid change introduces an N-myristoylation site, resulting in constitutive membrane targeting of SHOC2 that leads to increased MAPK activity. Until now only a limited number of patients carrying *SHOC2* mutations have been reported and information about the clinical course and long term perspective is sparse. We report on the phenotypes and course of 4 patients carrying the 4A>G missense mutations, ranging from 3 to 17 years in age. All 4 patients presented with a highly recognizable phenotype characterized by relative macrocephaly at birth, severe feeding difficulties with growth failure, and ectodermal abnormalities (dry and darkly pigmented skin with ichthyosis or eczema). Additional ectodermal features include thin and slowly growing hair which can be easily plucked, and long and twisted eyelashes. One patient displayed proven growth hormone deficiency. Hyperactive behavior was observed in all individuals as was a hypernasal speech. Cognitive development was within the low-normal range in the two older boys (aged 11 and 17 years). Overall, the patients displayed a highly recognizable phenotype which enabled targeted search of the 4A>G missense change in *SHOC2* and rapid diagnosis.

Computer assisted estimation of the prevalence of dysmorphic features in the general population. *L. Basel-Vanagaite[1 2], L. Karlinsky[2], L. Wolf[2 3], M. Shohat[1 2].* 1) Dept Medical Genetics, Rabin Medical Ctr, Petah Tikva, Israel; 2) FDNA Ltd., Herzlyia, Israel; 3) The Blavatnik School of Computer Science, Tel-Aviv University, Tel-Aviv, Israel.

Over the past few years, we have witnessed a significant improvement in the capacity of genomic data generation and the quality of genetic data analysis, driven mainly by development of high throughput technologies, such as comparative array hybridization and whole exome sequencing. However, these technologies alone are insufficient for revealing genetic aetiology of novel human genetic syndromes, due to the large amount of genomic variation among normal individuals. Therefore, clinical evaluation of children with developmental problems and dysmorphic features continues to present a major challenge to clinicians world-wide. With the ever-growing amount of data generated by these recent technologies, computerized approaches for analyzing facial traits are urgently needed to aid the genetic evaluation and diagnostic process. Currently, the scope and availability of 2D and 3D computer-based analysis of facial traits is limited and does not provide a suitable solution to the clinical requirements. Whereas genetic syndromes frequently involve distinct craniofacial malformations, we have explored the automatic recognition of these traits from 2D facial images, using advanced facial recognition techniques. For each trait out of a short list of subjective clinically relevant anatomical facial features, including the philtrum, the periorbital region and several other characteristics of the entire face, we have constructed a computerized model that describes it in mathematical terms and can detect such features in images automatically and reliably. These models were constructed by applying machine learning techniques to a set of hand labeled dysmorphic faces and incorporate relative measurements as well as variations in appearance. By employing these models to a large image dataset of normally developed school children, we have estimated the prevalence of each feature in the general population. For example, we were able to estimate that the prevalence in the general population of long philtrum is 11.6%; Widely spaced eyes 5.3%; Upslanted palpebral fissure 8.9% and downslanted palpebral fissues 1.8%. This enabling technology could also provide computer aided diagnoses, as well as phenotypic comparison of patients with dysmorphic features. This approach, in combination with whole exome sequencing, can aid in identification of novel genes causing genetic syndromes in unrelated dysmorphic patients having the same syndrome.

1037T

A Simpson-Golabi-Behmel patient with severe neonatal liver involvment. *B. DEMEER[1], D. DJEDDI[2], F. LACAILLE[3], G. MORIN[1], G. JEDRASZAK[1], J. MICHELI[4], R. RHAZLANE[5], S. LANTA[6], F. AMRAM[1], MP. MOIZART[7], M. MATHIEU[1].* 1) Genetics department, Amiens university hospital, France; 2) Pediatrical gastroenterology unit, Amiens university hospital, France; 3) Pediatrical gastroenterology department, Necker Enfants Malades hospital, Paris, France; 4) Pediatrical oncology and haematology unit, Amiens university hospital, France; 5) Paediatrics department, Amiens university hospital, France; 6) Gynaecology and Obstetrics department, Amiens University hospital, France; 7) Molecular genetics department, Tours University Hospital, France,.

The patient is the third child of an unrelated couple, with no known remarkable history. Pregnancy was marked from 22 gestation weeks, by hydramnios and fetal macrosomia, and from 27 GW, by bilateral nephromegaly. The patient was delivered by ceasarean section at 36 GW, and birth parameters were : weight : 4kg105 (P97), height 52cm (P97) and OFC 37cm (P97). On examination, he had hypotonia, feeding difficulties and was icteric. He also presented facial dysmorphism with coarse features, hypertelorism, short nose with anteverted nares and macrostomia. Three abdominal supernumerary nipples and a abdominal diastasis recti were noted. Extremities were normal. No neonatal hypoglycemia was noted. Abdominal ultrasounds confirmed the bilateral nephromegaly, and showed at 2 weeks of age, an hepatomegaly. Biology showed a cholestasis and jaundice. The study of the GPC3 gene showed a single base deletion in the exon 7, confirming the diagnosis of Simpson-Golabi-Behmel syndrome (SGBS). At the age of 6 weeks, because of worseness of cholestastis, persistent jaundice and difficulties displaying the biliary ducts on CT scan, a liver biopsy was performed. It showed no biliary atresia, but found a significant proliferation, portal fibrosis and cholestasis. Apart from the visceromegaly, neonatal liver involvment is rarely associated to the SGBS. We will precisely described the hepatic results and compare this case to the literature.

Genetic diagnosis of Duchenne and Becker muscular dystrophy using next-generation sequencing technology: comprehensive mutational search in a single platform. *B. Lim[1], J. Chae[1], K. Kim[1], S. Lee[2,3], J. Kim[2,3,4], J. Seo[2,3,4].* 1) Seoul Natinoal University Hospital, Seoul, Korea; 2) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University; 3) Department of Biomedical Sciences, Seoul National University Graduate School; 4) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine.

Background: Duchenne and Becker muscular dystrophy (DMD/BMD) might be a suitable candidate disease for application of next-generation sequencing (NGS) in the genetic diagnosis because the complex mutational spectrum and large size of the DMD require two or more analytical methods and have a high cost. We tested whether large deletions/duplications or small mutations, such as point mutations or short insertions/deletions of DMD, could be predicted accurately in a single platform using NGS technology. Methods: A custom solution-based target enrichment kit was designed to capture whole genomic regions of DMD and other muscular dystrophy-related genes. A multiplexing strategy was applied in which four differently bar-coded samples were captured and sequenced together in a single lane of the Illumina Genome Analyzer. The study subjects were 25 patients: 16 with deficient dystrophin expression without a large deletion/duplication and nine with a known large deletion/duplication. Results: Nearly 100% of the DMD exonic region was covered by at least eight reads with a mean read depth of 107. Pathogenic small mutations were identified in 15 of the 16 patients without a large deletion/duplication. Using these 16 patients as negative controls, our method accurately predicted the deleted or duplicated exons in the nine patients with known mutations. Inclusion of non-coding regions and paired-end sequence analysis enabled accurate identification by increasing the read depth and providing information about the breakpoint junction. Conclusions: The current method has an advantage in the genetic diagnosis of DMD/BMD in that a comprehensive mutational search may be feasible in a single platform.

Dynamics of genetic polymorphisms linked to Hemophilia A gene (*F8*) in the Brazilian population. *J.D. Massaro[1], C.E.V. Wiezel[1], C.T. Mendes-Junior[2], M.R. Luizon[3], A.L. Simões[1].* 1) Department of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo; 2) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo; 3) Department of Pharmacology, School of Medicine of Ribeirão Preto, University of São Paulo, SP.

Hemophilia A is a bleeding disorder conditioned by a gene located on the X chromosome and caused by partial or total deficiency of the Factor VIII activity, a plasma glycoprotein necessary for normal blood coagulation. Due to difficulties faced on direct recognition of the *F8* gene mutation, carrier diagnosis is done indirectly by linkage analysis with polymorphic markers located within or near to the gene. These markers may determine the haplotype and the mutation co-segregation within the studied family, and thus detect the carrier status and possibly assist in prenatal diagnosis. This study aimed to evaluate the power of some of these markers in population differentiation and determine their degree of informativeness for diagnosis and genetic counseling of affected families, as well as verifying the possible forensic use of such markers. We determined the allele and haplotype frequencies, genetic diversity, population differentiation, linkage disequilibrium and ancestral composition in Brazilian urban (healthy not related individuals from São Paulo, Rio Grande do Sul and Pernambuco), Quilombo remnant (*Mimbó*, *Sítio Velho* and *Gaucinha* in the State of Piauí) and Amerindian (*Tikúna*, *Baníwa* and *Kashináwa*) population samples by the analysis of four intragenic microsatellites (*F8*Int1, *F8*Int13, *F8*Int22, *F8*Int25.3), located in *F8* introns, and one extragenic (IKBKG). When appropriated, the analysis included a group of hemophilic patients. DNA polymorphisms were detected by PCR, PAGE and silver nitrate staining. Statistical analysis was implemented by GENEPOP, Arlequin, Fstat, MVSP, GDA, ADMIX®3 and PHILIP. Diversity parameters showed differences among the populational samples. Such regional differences in allele frequencies must be taken into account when conducting indirect diagnosis of Hemophilia A. Except for IKBKG, all other microsatellites showed high rates of heterozygosity. Using these markers, the diagnosis was possible in 10 of the 11 families analyzed. The microsatellites *F8*Int22, *F8*Int1, *F8*Int13, *F8*Int25.3 and IKBKG were informative in 63.6% (7/11), 54.5% (6/11), 54.5% (6/11), 45.5% (5/11) and 18.2% (2/11) of the cases, respectively, demonstrating the effectiveness of using these microsatellites in prenatal diagnosis and carrier identification in the Brazilian population. Financial support: Capes, FAEPA.

Molecular analysis by an individual diagnosed with autosomal recessive polycystic kidney disease (ARPKD). *M. Nagel, S. Nagorka, M. Brzeska.* Molec Gen, Ctr Nephrology, Weisswasser, Germany.

Autosomal rezessive polycystic kidney disease (ARPKD) is a genetic disease inherited in a recessive manner. It is less common then autosomal dominant polycystic kidney disease . The incidence is 1 in 6000 bis 1 in 55000 in the US population, but the higher incidence was noticed in the population of Finish and African ancestry (1 in 1000 in Finland and 1 in 20000 in Africa). Mutation in the PKHD1 gene, chromosomal locus 6p12.2 causes ARPKD. In this study, we performed direct sequencing of the entire coding region of the PKHD1 gene in 44 unrelated individuals referred to our laboratory with a clinical diagnosis of autosomal rezessive polycystic kidney disease (ARPKD). The fetal DNA was analysed in 12 cases. There were also 13 patients between the age of 1 and 5 months and 6 patients between the ages of 1 and 2 years. The 5 patients of the deceased newborn were tested for carriership. Sixteen novel mutations were identified. We found eight novel missense mutations: W477S, T3626I, R559Q, V1232E, G894V, S2867C, D1944N, A1987P; two novel splice mutations, IVS35+3A>G, IVS21+1G>A; and six deletions/insertions: c.122delT, c.7132delA, c.1393delA, c.10775del, c.6393insC, and c.10447insT. Six novel mutations, W477S,T3626I,R559Q, D1944N, A1987P and c.10775del were also found in the family members. In conclusion, the new mutations found in these patients almost proved a clinical diagnosis of autosomal rezessive polycystic kidney disease and certainly had pathogenic relevance.

1041T

Hemophilia A diagnose with *F8*Int18B*cl*I SNP and DXS 1108 markers in Brazilian population. *F.A. Saiki[1,2], J.D. Massaro[1], A.L. Simões[1].* 1) Department of Genetics, FMRP, University of São Paulo, USP, Ribeirão Preto, SP, Brazil; 2) São Paulo State University, UNESP - FCAV, Jaboticabal, SP, Brazil.

Hemophilia A is an X linked recessive bleeding disorder caused by a deficiency in blood coagulation Factor VIII. High incidence and morbidity stress the importance of genetic counseling. The great number and heterogeneous nature of human mutations in *F8* gene make direct analysis a hard task. Therefore indirect analysis is necessary to determine linkage between polymorphic markers located close or within *F8* gene to map mutations in affected families by inherited forms of Hemophilia A (HA). Although the ideal is the direct detection and analysis, starting with the analysis of the inversions in Introns 1 and 22, PCR is a reliable diagnostic method and high-cost benefit. The *F8*Int18B*cl*I SNP and DXS1108 were used to check viability in genetic counseling and characterize allelic frequencies, Hardy Weinberg Equilibrium, linkage disequilibrium and heterozygosity in health and not related urban population samples of São Paulo state (men and women), and patients with Hemophilia A and his mothers. Genotyping was performed by PCR/RFLP and PCR, non-denaturing 8% and 11% PAGE and silver staining to *F8*Int18B*cl*I and DXS1108, respectively. Half of the alleles found in the present study of DXS1108 marker were cloned and sequenced. The *F8*Int18B*cl*I distribution in men and women were different for Urban population of São Paulo and HA. The presence of allele for B*cl*I restriction were higher in HA (+, 59% for men and 68% for women) than SP (+, men 43%, 48% women). Despite the high presence of allele restriction, it was lesser than found in Japan, North India and Hungary. The only sample that had a higher prevalence of restriction site absence(-) was Asian Indian. The most frequent allele for DXS1108 in women (SP and HA) and HA patients were *DXS1108*23*, followed by *DXS1108*19*. The sample of SP men presented *DXS1108*23* and *DXS1108*24* alleles as the most frequent. The sample in the present study does not share any allele with Spanish sample. The analysis of linkage disequilibrium revealed highly significant *P*-values. Total heterozygosity (0.6-0.61) considering both markers was higher than identified in other populations as Japanese, North Indian, Asian Indian, Spanish and Chinese. The most frequent haplotype in both markers is -/23 in men and women of SP sample and +/23 for HA sample. The results show that these markers are informative in genetic counseling and diagnose. Financial Support: Capes, FMRP/USP,CNPq.

1042T

A comparative study about death anxiety with Familial Amyloidotic Polyneuropathy familiars (caregivers). *P.Isabel. Santos.* Psychology, Universidade Fernando Pessoa, Porto, Porto, Portugal.

Familial Amyloid Polyneuropathy (FAP) is a neurodegenerative disease caused by a mutant gene in chromosome pair 18 in which methionine is substitute for valine at position 30 (TTR-Met30) characterized by a progressive peripheral and autonomic neuropathy with neural and systemic amyloid deposits. It is an incurable and hereditary disease with autosomal dominant transmission; the children of an affected mother/father have 50% of possibility to inherit the mutation. The late onset (about 30 yrs) and a fatal prognosis (14 years after the onset) are expected. Is a very insidious disease that causes great dependence on a caregivers usually direct relatives (wives, husbands and children). Even the family free from the risk of inheriting the disease (or because they already performed the test and was negative, or because they have no inbreeding), live the disease nearby, and live the pain of a dependent mother/father, husband or wife. So we intent to explore if familiars of FAP patients namely the caregivers have different levels of death anxiety comparatively with a control group. We administered Death Anxiety Scale (DAS, Temper, 1970) in a group familiars of FAP patients (FAM) (N = 91) and a control group, (sociodemographic identical sample, but with no bound to FAP disease) (N = 121). FAP patients score significantly higher in DAS (M= 52.18, DP= 8.32 vs 49.56, SD = 9.12) than a control group. We conclude that being a caregiver for FAP is a source of increasing Death Anxiety. Since Death Anxiety correlates with depression, anxiety and psychopathology (Templer, 1976; Templer; Lavoie; Chalgujian & Thomas-Dobson, 1990). Psychological support should be considered to the familiars of FAP patients.

A Comparison of Enrichment Techniques for Clinical Next-Generation Sequencing of Intellectual Disability, Early Infantile Epilepsy and Congenital Brain Malformations. *S. Topper, V. Nelakuditi, M.A. Dempsey, S. Das.* Human Genetics, University of Chicago, Chicago, IL.

The genetic diagnosis of non-syndromic neurological disease presents unique challenges to clinicians and diagnostic labs: recognizable phenotypes are genetically heterogeneous with many dozens of genes causally implicated, mutations in each gene only explain a negligible percentage of patient cases, and a complex and rapidly developing literature requires constant re-evaluation of the diagnostic strategy. We are pursuing a highly multiplexed approach to the diagnosis of non-syndromic intellectual disability, developmental delay and brain malformations and are evaluating three different enrichment approaches: multiplexed target amplification using the Raindance system, targeted capture using Agilent SureSelect biotinylated RNA baits, and Agilent exome capture. Our region of interest includes 1627 exons from 98 genes, spanning 500,000 bases of coding sequence. For each of 12 samples enriched using the Raindance system, we generated ~16 million 76bp paired-end reads on an Illumina GAIIx. On average, 92% of reads aligned to the human genome, with 25-45% deriving from the target region. With an average depth of 150x, more than 94% was covered at 30x leaving 260 exons (out of 1627) with some small regions insufficiently covered. On average, we identified 250 variants per sample within this region that included 25 missense variants (two to five of which were novel), and 0 or 1 small coding deletions per patient. We successfully identified a causative single base deletion in the AGTR2 gene in a patient with intellectual disability and early infantile seizures in whom extensive single-gene testing had previously been performed with no diagnostic success. We have also identified a number of potentially deleterious mutations in the remaining patients, and validation is currently underway. A subset of these same samples have been enriched for our genes of interest using a custom Agilent SureSelect design and by using Agilent Exome Capture, and comparative data analysis will be presented. We propose that reliable integration of next-generation sequencing into the clinical arena requires sufficient data generation to yield 100% coverage of the target region defined as a minimum coverage of 30x at each base to minimize false positive and false negative rates; and that the target region needs to be supplemented by Sanger-sequencing where it fails to meet those requirements.

A c.1372C→T mutation found in TSC2 gene in a TSC-affected family revealed that it is less likely to account for mental retardation. *T. Tsai[1], S. Lin[2], D. Chu[3].* 1) Graduate Institute of Biomedical Science, Ghang Gung University, Tao-Yuan, Taiwan; 2) Department of Pediatrics, Mackay Memorial Hospital, Taipei, Taiwan; 3) Department of Medical Biotechnology and Laboratory Science, Chang Gung University, Tao-Yuan, Taiwan.

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder characterized by hamartomas in multiple organs. Seizures and mental retardation (MR) are important problems in TSC patients. Mutations in TSC1 and TSC2 genes are major causes of this disorder. In order to depict the correlation between TSC gene mutation and mental retardation, genomic DNA from TSC patients were analyzed for mutation screening. In this report, an inherited pathogenic mutation and an inherited single nucleotide polymorphism (SNP) were identified from a TSC family. In this family, the proband is a TSC patient without MR, but her daughter is a TSC patient with mild MR and her son is a TSC patient with severe MR. Using high-resolution melting analysis followed by bidirectional DNA sequencing, TSC1 c.2829C→T (p.A943A) was identified from the proband and her son. On the other hand, TSC2 c.1372C→T (p.R458X) was identified from the proband, her daughter and son by using whole-gene DNA sequencing. TSC2 c.1372C→T is a pathogenic mutation because the nucleotide substitution creates a new stop codon, leading to production of premature or truncated protein in translation. This pathogenic mutation exists in the proband and her children, but the proband does not suffer from MR. The inconsistency between genotype and phenotype suggests that TSC2 c.1372C→T is less likely responsible for mental retardation in this TSC-affected family.

1045T

Ion Torrent as a potential platform for molecular diagnosis. *X. WANG[1], H. WANG[1,2], D. Muzny[2], I. Newsham[2], Y. Wu[2], C. Buhay[2], H. Dinh[2], R. Gibbs[1,2], R. CHEN[1,2].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center,Baylor College of Medicine, Houston, TX.

As a third generation sequencing platform, Ion Torrent machine is cheaper, much smaller in size, and has faster run time compared to the current existing technology. By combing with the capture enrichment technology, it might sever as an ideal platform for molecular diagnosis. To test this idea, we have designed a custom gene capture panel that includes all currently known 167 retinal disease genes (http://www.sph.uth.tmc.edu/Retnet/). As highly heterogeneous diseases with each type of disease accounting for a small fraction of all patients, accurate diagnoses are essential for genetic counseling and matching specific treatments for each disease. To test the performance, we have enriched and sequenced a HapMap sample using Ion Torrent. A total of 3.5 million reads were generated in a model experiment. Of these, 3.2 million reads (92%) mapped to the human genome while 1.4 million reads (39%) mapped to the targeted region. Excellent coverage of the targeted region was achieved, with 93.7% of targeted bases at >10x sequence coverage. SNP genotypes for the same DNA sample were determined using the Affymetrix 6.0 SNP array. There were 1,379 variant positions within the targeted region that were genotyped by the SNP array (1205 homozygous, 174 heterozygous). Excellent genotype concordance was observed: Specifically, 1194 (99.1%) of homozygous bases and 173 (99.4%) of heterozygous bases were shared. Thus, the combination of Ion Torrent platform and disease specific panel has the potential as an ideal tool for clinic diagnosis in the near future. We are currently in the process of applying this approach to several patients with retinal diseases. Further evaluation of this approach will be reported.

Genetic Counseling: An analysis of awareness, opportunities and accessibility in India at the undergraduate level. *A. NEOGI.* BITS PILANI, India.

Introduction:As a profession,Genetic Counseling is quite new in India,with only one individual having a specialised degree in the same. This study aims to determine the prevalence of genetic counseling-in terms of awareness and opportunities,for potential graduate students from India. **Methods**:There are two parts to this study. **Part 1**: A 20 MCQ survey based on Genetic Counseling(GC)was conducted across 2 universities.75 senior students with life science related majors formed the test population.75 seniors with non-science majors formed the control. **Part 2** (request for training)was conducted in three stages.Stage 1:contacting centres which listed GC services on their website,Stage 2:contacting CGCs through the NSGC for advice and guidance and Stage 3:contacting individuals/centres referred to by the CGCs and other sources. **Results**: **Part 1**: 20% of the test population were aware of the existence of GC as a profession.This was higher than the 10% in the control group.Data excludes percentage of students who `guessed' the meaning of GC without prior knowledge. **Part 2**: Stage 1-Only 2 out of 8 listed organisations responded to a training request. Stage 2-a total of 15 CGCs were approached.2 (13.33%) of the contacted individuals replied,with referrals. Stage 3-contact was made with the 3 referrals.There was a positive response from 2 of them. **Conclusion:**On analysis,I found that the centres which provide genetic counseling and related services can be divided into 3 categories. Small or newly established centres(first category)acknowledge the need to raise awareness and are willing to offer GC related internships. Genetic testing facilities such as hospitals(second category)do not offer exact GC experience but provide exposure to cytogenetic labs to introduce techniques like FISH and diagnostic karyotyping. Well-established genetic counseling centres(third category)are very busy and difficult to reach.They are unable to provide training.Also,at the undergraduate level, no relation exists between genetics modules studied and knowledge of GC as a profession.The low level of awareness amongst students in India can be attributed to the lack of educational programs related to GC and limited access to training.These issues can be addressed if the established centres engage more in public outreach programs and include training in their services.

R143Q MUTATION OF THE POU1F1 GENE, UNDERLYING COMBINED PITUTIARY HORMON DEFICIENCY. *A. AYKUT[1], S. OZEN[2], D. GOKSEN[2], H. ONAY[1], O. COGULU[1], S. DARCAN[2], F. OZKINAY[1].* 1) Department of Medical Genetics,Medical Genetics, Ege University Faculty of Medicine , IZMIR, bornova izmir, Turkey; 2) Department of Pediatrics, Ege University Faculty of Medicine,Izmir,Turkey.

Congenital Hypotyroidism is one of the most common endocrinological problems which lead to irreversible neurological findings and growth retardation. Newborn screening is important for early diagnosis and treatment. The congenital onset of hypotyroidism may result from severely impaired or loss of function of the POU1F1 gene. Patients with POU1F1 mutations show a combined pituitary deficiency with low or absent levels of Growth Hormone (GH), prolactin and Thyroid-stimulating hormone (TSH). We present a 7 month year old girl with a combined pituitary hormone deficiency caused by a defect in POU1F1 gene. The patient, the second child of consanguineous parents was born after an unremarkable pregnancy at the 44th week of gestation by cesarean section. Her birth weight was 3200 gr. The patient was found to be positive for congenital hypothyroidism. She showed a dysmorphic appearance, including anteverted nostrils, downturned mouth, macroglossia, protruding tongue. She was hypotonic, had hypertrichosis and cutaneous hemangiomas. In addition to congenital hypothyroidism, GH and prolactin deficiencies were present. A homozygous mutation at codon 143, arginine to glutamine in patient's POU1F1 gene was detected. The parents were heterozygous for the mutation.

1048T

Glucose Transporter Type I Deficiency Syndrome epilepsy phenotypes and alternative therapies: implications for genetic testing, counseling, and treatment from the world's largest cohort. *A.W. Pong[1], K. Engelstad[1], B. Geary[1, 2], A. Natarajan[1], H. Yang[1], D.C. De Vivo[1].* 1) Neurology, Columbia University, New York, NY; 2) University of Notre Dame, Notre Dame, IN.

Background. Glut 1 deficiency syndrome or DeVivo Disease (Glut 1 DS, SLC2A1 gene, chromosome 1p34.2, MIM 606777) is defined by hypoglychorrachia with normoglycemia, acquired microcephaly, episodic movements, and epilepsy refractory to standard anti-epileptic drugs (AEDs). Gold standard treatment is the ketogenic diet (KD), which provides ketones for cerebral metabolism, thereby treating the effects of neuroglycopenia. Aims. (1)To describe epilepsy phenotypes in the world's largest Glut 1 DS cohort, to facilitate diagnosis and earlier institution of KD, thereby preventing disease progression. (2)To describe cases in which non-KD agents achieved seizure freedom (SF), to highlight potential alternative treatments. Methods. Retrospective chart review of 86 consecutive Glut 1 DS research patients (48 males:38 females, aged <1mo to 35yrs, average age of Glut 1 diagnosis at 6yrs) at the Giblin Laboratory, Columbia University, Aug 1989 to Dec 2010. Findings. 78/86 (90.5%) patients had epilepsy, with average onset at 7 months. Seizure types included: absence, simple/complex partial, generalized tonic-clonic, myoclonic, tonic, drop seizures, infantile and epileptic spasms. We describe the first 2 cases of infantile spasms at 6-9 months, and epileptic spasms at 23 months. 68% (53/78) had >1 seizure type, with generalized tonic-clonic (41/77) and absence (39/77) seizures most commonly. Electrophysiological abnormalities were highly variable over time and only 13/75 (17%) had exclusively normal findings. KD was used in 82% (64/78); 67% (41/61) were seizure free, 2/3 resolved within a week (68 %, 28/41) and ¾ within a month 76% (31/41). SF without KD occurred in 7 patients treated with VPA(1), LTG(1), ZNS and LTG(1), TPM(2), and modified KD(1). Conclusions. Glut 1 DS is a genetic metabolic encephalopathy with multiple neurological symptoms. Variable seizure types and EEG findings, including focal or multifocal findings, may be seen. Infants with seizures or paroxysmal events should be tested for Glut 1 DS. Glut 1 DS may manifest with infantile and epileptic spasms, and it is not clear how often the diagnosis may be missed. Evidence is insufficient to recommend specific AEDs as alternatives to KD. Early diagnosis and initiation of KD and prevention of unnecessary, potentially deleterious, AED trials in Glut1 DS are important goals for the medical community treating children with epilepsy. Developing a Next-Generation Sequencing Gene Panel for Molecular Diagnosis of Genetic Epilepsy. *F. Xia, P. Stankiewicz, M. Vatta, C.M. Eng, Y. Yang.* Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Epilepsy is a common condition affecting more than three million Americans, many of whom have an underlying genetic cause. The list of possible genes for epilepsy has grown significantly during past decades, demonstrating extensive locus and phenotypic heterogeneity for the disorder. Testing a large number of genes in a patient by Sanger sequencing is often necessary but cost-prohibitive, labor-intensive and therefore impractical in clinical laboratories. In recent years, next generation sequencing (NGS) has emerged as a possible revolutionary force to change the paradigm of conventional genetic testing by offering high throughput and inexpensive DNA sequencing. Here we report the NGS analyses of a panel of 32 genes mostly associated with genetic epilepsy. The targeted region of 116 kb includes all the coding exons of the 32 genes as well as 15 bp intronic regions upstream and downstream of the coding exons. RainDance mega-droplet multiplex PCR and two-step tailed primer enrichment systems were utilized for target enrichment and addition of sequencing adaptors, bypassing the library construction steps. More than 1600 unique PCR products of 200 bp or shorter were amplified from the enrichment step and sequenced on the Illumina Hiseq 2000 platform. Approximately 13 Gb of sequencing data from a multiplex of seven samples were obtained from a single Hiseq lane. Aligned sequence data showed that about 77% of the reads are on-target and the average coverage across the panel is greater than 5000X with more than 97% of the reads covered 100x or more. Three control samples previously deep sequenced by the 1000 Genome Project were included in the development. By comparing the variant calls from our data with those from 1000 Genome Project, we observed a sensitivity of greater than 99% for our assay. False positives were observed , which are most likely caused by uneven distribution- of the data quality and coverage across the PCR amplicons and are expected to be reduced by using better data analysis algorithm and improved Illumina Sequencing-By-Synthesis chemistry.

In summary, the development of the NGS epilepsy gene panel will be a novel and improved clinical tool for identifying the genetic basis of the condition and contributing to our understanding of the phenotypic range of these disorders for counseling, education, and possibly the development of new treatments.

Parental attitudes toward the disclosure of individual genotype results for children enrolled in a gene discovery protocol. *J.C. Sapp[1], D.A. Dong[1,2], B.B. Biesecker[3], L.G. Biesecker[1].* 1) Genetic Diseases Research Branch, National Human Genome Research Institute, Bethesda, MD; 2) Genzyme Corporation, Cambridge, MA; 3) Social and Behavioral Research Branch, National Human Genome Research Institute, Bethesda, MD.

The number of rare disorders whose molecular etiologies have been determined using whole genome sequencing (WGS) continues to expand. Although significant and largely theoretical debate exists with respect to the return of individual genotype results to participants enrolled in research protocols employing WGS, little is known about participants' own attitudes towards and preferences regarding the return of results. Understanding and characterizing the personal meaning participants ascribe to receiving individual genotype results is a primary aim of our protocol, which seeks to identify the causative genetic variants of rare and ultra-rare phenotypes using massively parallel (primarily exome) sequencing of individuals and/or families and employs a qualified disclosure policy. Because most probands with rare disorders are children, parents of minor children enrolled in our protocol are asked to participate in qualitative, semi-structured interviews designed to ascertain and understand their attitudes toward WGS, the way they approach decision-making about different categories of results, and their preferences regarding which (if any) results they would wish to receive for their children. Preliminary analysis of the first dozen interviews suggest that parents consenting to WGS to determine the genetic cause of their child's condition approach this decision with attitudes ranging from deep ambivalence to hopeful excitement. They understand the complexity and scope of WGS and frame their preferences about learning many kinds of individual variant results in terms of a perceived possible benefit to their children. Although they express reservations about some categories of results, such as those that increase disease predisposition, most view the idea of choosing to not learn any available information researchers are willing to share with them as much less desirable and would prefer to learn any and all results generated. Interviews will be conducted until data saturation and we will describe our ongoing analysis and the potential implications of our results for the evolving debate about disclosure policies for WGS protocols.

Fragile X AGG genotyping reclassifies risk for expansion in intermediate and small premutation carriers: Results of a multicenter study of 469 mother-child transmissions. *S.L. Nolin[1], E. Allen[2], A. Glicksman[1], S.L. Sherman[2], E. Berry-Kravis[3], F. Tassone[4], C. Yrigollen[4], A. Cronister[5], M. Jodah[5], N. Ersalesi[1], W.T. Brown[1], R. Shroff[6], S. Sah[6], G.J. Latham[6], A.G. Hadd[6].* 1) New York State Institute for Basic Research in Developmental Disabilities, Dept of Human Genetics, Staten Island, NY; 2) Emory University, Dept of Human Genetics, Atlanta, GA; 3) Rush University Medical Center, Chicago, IL; 4) UC Davis and MIND Institute, Davis, CA; 5) Esoterix Genetic laboratories LLC, Westborough, MA; 6) Asuragen, Inc., Austin, TX.

Screening pregnant women to determine their fragile X status has become increasingly common in recent years resulting in the identification of intermediate and small premutation alleles whose stability is unknown. Earlier studies have suggested that the presence of AGGs interspersed within the repeat and the length of uninterrupted CGGs at the 3' end of the repeat may influence repeat expansion. Until now however, the presence of the second X chromosome in females has prevented analysis of the AGG pattern in the expanded allele. An elegant new PCR assay has allowed us to examine the effect of the FMR1 CGG repeat structure on repeat instability. Our study investigated whether the AGG patterns and the length of uninterrupted CGGs at the 3' end of the repeat predicts instability in newly identified intermediate and small premutation alleles with 45 to 69 repeats. Using this new PCR technology, the FMR1 repeat structure was determined for 469 mother-child transmissions from 4 centers. We found that the number of AGG interruptions and the length of 3' continuous CGG repeats were correlated with repeat instability on transmission. The shortest unstable 3'-length was 25 uninterrupted CGGs (in a 45 repeat allele); all alleles with 61 or more 3' uninterrupted CGGs expanded. The expansion risks for alleles with 50-54 repeats was 100% for those without AGGs, but only 28% for alleles with 1 AGG, and 11% with 2 AGGs. Moreover, the magnitude of repeat expansion was larger for alleles that lacked an AGG interruption. The smallest number of uninterrupted CGG repeats that expanded to a full mutation in a single transmission was 51 (of 61 total repeats). These results indicate that AGG genotyping will allow risk estimates to be established for repeat instability in newly identified intermediate and small premutation alleles.

Screening for LHON mutations in Brazilian patients. *E.L. Sartorato[1], P.M.A.D. Miranda[1], M.S.A. Fernandes[2], A.T. Maciel-Guerra[3].* 1) CBMEG, UNICAMP, Campinas - SP, Campinas, Brazil; 2) Departamento de Oftalmologia - FCM, UNICAMP, Campinas - SP, Campinas, Brazil; 3) Departamento de Genética Médica - FCM, UNICAMP, Campinas - SP, Campinas, Brazil.

Leber Hereditary Optic Neuropathy (LHON) is a mitochondrial disease characterized by sudden loss of vision in both eyes, due to optic nerve degeneration. Currently, 17 main LHON associated mutations were published, three of which account for 95% of the cases (primary mutations) and fourteen different mutations account for only 5% of the total (secondary mutations). There is no official data about the frequency of LHON mutations in Brazilian patients. Screening of LHON mutations is important for confirmation of clinical diagnosis, provide prognostic information and more appropriate genetic counseling. Therefore, the aim of this study was to define the LHON mutations frequency in Brazilian patients. We evaluated 55 patients with LHON diagnosis or acquired optic neuropathy of unknown origin. Primary mutations (G11778A, T14484C and G3460A) and secondary mutations were screened. Primary mutations were screened by the method of enzyme restriction and secondary mutations by direct sequencing. Primary mutations were found in 19 patients. The frequencies found were 67% for the G11778A mutation (13 cases), 28% for the T14484C mutation (5 cases) and 5% for the G3460A mutation (only 1 case). The G11778A mutation was more frequent, as well as in others parts of the world. However, the frequency of T14484C mutation was higher while the G3460A mutation frequency was lower. No secondary mutation was found. The absence of these mutations can be attributed to the presence of mutations in regions not analyzed in this study. Analyze molecular allowed us to confirm LHON diagnosis in 38% patients studied.

How do young adults with Leber congential amaurosis perceive gene therapy? *M.P. Napier[1], J.E. Sutherland[2], M.A. Day[2], R.Z. Hayeems[3], D. Chitayat[1,4,5,6,7], C. Shuman[1,7], E. Héon[2,8].* 1) Department of Molecular Genetics, The University of Toronto, Toronto, Canada; 2) Department of Ophthalmology and Vision Sciences, The Hospital for Sick Children, Toronto, Canada; 3) Department of Health Policy, Management and Evaluation, The University of Toronto, Toronto, Canada; 4) Department of Paediatrics, The University of Toronto, Toronto, Canada; 5) Department of Obstetrics and Gynecology, The University of Toronto, Toronto, Canada; 6) Department of Laboratory Medicine and Pathobiology, The University of Toronto, Toronto, Canada; 7) Department of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 8) Department of Ophthalmology and Vision Sciences, The University of Toronto, Toronto, Canada.

Introduction: Successful gene replacement therapy for Leber congenital amaurosis (LCA) has been demonstrated in a canine model. The impressive findings in both safety and efficacy from these studies have led to ongoing human clinical trials for a subset of patients with LCA. To effectively integrate such advances into clinical care, it is important to evaluate potential candidates' expectations, decision-making processes and concerns regarding gene therapy. To this end, this study utilized a qualitative exploratory approach to elicit perceptions regarding gene therapy among individuals who might consider this type of therapy.

Methods: Young adults with a clinical diagnosis of LCA were recruited through the Ocular Genetics Programme at the Hospital for Sick Children. Semi-structured telephone interviews were conducted with 10 patients. These interviews were audio-taped and analyzed in accordance with the principles of qualitative description.

Results: Study participants were aware of ongoing gene therapy research trials and actively sought information regarding advances in ophthalmology and vision restoration. However, differences in opinion were expressed regarding the value of enrolling in clinical trials; two patients are currently enrolled in a gene-replacement therapy trial, five indicated that they would participate if given the opportunity, two were ambivalent, and one would not participate if given the opportunity. Participants' expectations regarding visual improvement varied and influenced their willingness to take part in research trials. However, intrinsic factors also influence decision-making including coping strategies and adaptation to vision loss, and personal resilience.

Conclusions: This is the first qualitative study to explore patients' perspectives on gene replacement therapy clinical trials. The results of this study highlight the complex factors that are involved in gene-therapy related decision-making and provide a framework for health care providers to use when counselling individuals considering gene therapy.

Using Next Generation Sequencing as a clinical diagnostic tool for autism. *T. Brandt[1], O. Jabado[1], S. Yoon[2], V. Makarov[2], Z. Peralta[1], R. Kornreich[1], J. Buxbaum[2], L. Edelmann[1].* 1) Gen & Genomic Sci, Mount Sinai, New York, NY; 2) Psychiatry, Mount Sinai, New York, NY.

The underlying genetic causes of autism are diverse and, consequently, many patients undergo a battery of diagnostic tests. Recently, a large set of individual autism genes has been identified and a prevailing theory is that many different rare mutations underlie the genetic etiology of autism. However, sequencing for many of these newly discovered genes is not yet clinically available. Next generation sequencing (NGS) technologies have made the interrogation of a large number of genes in a single experiment possible, and have made comprehensive sequencing of autism genes clinically feasible. A panel of cytogenetic and molecular genetic tests is being established as a clinical algorithm to offer the highest possible diagnostic yield while minimizing findings of uncertain significance. NGS, though widely used for research, is a relatively new technology for clinical laboratories. As such, the focus of this project is the validation of this tool for diagnostic use with special attention to the false negative and false positive rates as well as the cost effectiveness of sample pooling for this larger scale sequencing project. We are using a pooled targeted sequence enrichment strategy followed by multiplexed Illumina sequencing to interrogate the 33 autism genes with the strongest support in the literature (~200 kb). In addition, we are validating NextGENe commercial NGS analysis software (by Softgenetics, State College, PA) for clinical use by multiple approaches: comparison with an in-house analysis pipeline centered on BWA, SAMTools, and GATK, Sanger sequencing of all calls, and comparison with known calls in HapMap samples and samples from The 1,000 Genome Project. Our approach, clinical considerations, and progress will be outlined.

1056T

Novel Mutations in Iranian Rett syndrome patients. *M. Dehghan Manshadi[1], S. Dadgar[1], O. Ariyani[1], P. Karimzadeh[2], SH. Salehpour[2], H. Tonkaboni[2], M. Houshmand[1, 3].* 1) Genetic Department of Special Medical Center, Tehran, Iran; 2) Shahid Beheshti University of Medical Science, Tehran, Iran; 3) National Institute of Genetic Engineering & Biotechnology, Tehran, Iran.

MECP2-related disorders include classic Rett syndrome, variant or atypical Rett syndrome, and mild learning disabilities in females and neonatal encephalopathy and mental retardation syndromes in males. Classic Rett syndrome is a progressive neurologic disorder in girls characterized by normal birth and apparently normal psychomotor development during the first six to 18 months of life. The girls then enter a short period of developmental stagnation followed by rapid regression in language and motor skills. Seizures occur in up to 90% of affected females; generalized tonic-clonic seizures and partial complex seizures are the most common. Females with classic Rett syndrome typically survive into adulthood, but the incidence of sudden, unexplained death is significantly higher than in controls of similar age. Atypical Rett syndrome is increasingly observed as MECP2 mutations have been identified in individuals previously diagnosed with autism, mild learning disability, clinically suspected but molecularly unconfirmed Angelman syndrome, or mental retardation with spasticity or tremor. Rett syndrome is inherited in an X-linked dominant manner. Approximately 99.5% of cases are single occurrences in a family, resulting either from a de novo mutation in the child with Rett syndrome or from inheritance of the disease-causing mutation from one parent who has somatic or germ line mosaicism. PCR amplification and Sequencing of the three axons of MECP2 gene coding region performed in our research.

1057T

Creating community dialogues; Exploring public opinions about genetics research in Newfoundland Labrador. *E. Dicks, H. Etchegary, J. Green, D. Pullman, C. Street, P. Parfrey.* Clinical Epidemiology Unit, Health Sciences Ctr, St John's, NF, Canada.

Background: Continued advances in genetics have prompted calls for greater public debate and involvement in decision-making about genetics research. Newfoundland Labrador, an island province in Canada is well known as a site of genetics research; however, relatively little work has explored public opinion and knowledge about genetics. We undertook community consultations to better understand how the Newfoundland public perceives various aspects of genetic research. Objectives: To explore public knowledge and values in order to foster greater public involvement in decision-making about genetics research and genetics health services To better understand how the public perceives genetics research so that practitioners can improve existing genetics services Methods: Community groups were identified in St. John's and Grand Falls-Windsor and invited to participate in a two-hour community consultation about genetics research in the province. Six sessions were completed between October 2010 and April 2011, with at least two others planned. Community groups included Rotary Clubs, church groups and women's groups, representing a broad cross-section of the general public (N=90). During the sessions, participants heard a presentation highlighting some of the research of the Interdisciplinary Research Team in Human Genetics at Memorial University. The presentation was followed by a facilitated discussion designed to explore some complex issues raised by genetics research (e.g., the privacy of genetic information, funding for genetics research). Participating groups thus far expressed great satisfaction with the sessions and suggested such presentations should be held regularly. Participants engaged with many of the complex issues raised by genetics research, noting the importance of such research for improving health, but also raising concerns about privacy, access and lack of knowledge about what research is happening in the province. Results to date suggest that the richness and diversity of public opinion could be a valuable resource for critical discussion and more accountable policy-making about genetics research in Newfoundland.

1058T

Validation of open-source colorectal cancer risk assessment software compatible with the U.S. Surgeon General's My Family Health Portrait tool. *W.G. Feero[1, 2], F.M. Facio[3], E. Glogowski[4], H. Hampel[5], J. Stopfer[6], A. Linn[3], D. Barton[3], L.G. Biesecker[3].* 1) Maine-Dartmouth Family Medicine Residency, Fairfield, ME; 2) Genomic Healthcare Branch, NHGRI, NIH Bethesda, MD; 3) Genetic Disease Research Branch, NHGRI, NIH, Bethesda, MD; 4) Memorial Sloan-Kettering Cancer Center, New York, NY; 5) Division of Human Genetics, The Ohio State University, Columbus, OH; 6) Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA.

Background -Family history (FH) is an acknowledged means for identifying the heritable component of an individual's cancer risk. The U.S. Surgeon General's My Family Health Portrait (MFHP) tool has been validated for the collection of family history information, but currently does not provide cancer risk assessment. Here we report on a newly developed open-source software tool designed to screen for heritable colorectal cancer (CRC) risk that is compatible with MFHP. Methods- A CRC risk assessment tool was developed using 2009 NCCN and USPSTF CRC risk assessment guidelines. The tool was designed to use patient-entered family history information to dichotomize individuals into not-elevated or elevated CRC risk categories, and provides basic age and risk-appropriate recommendations for CRC screening to all groups. The tool was validated on 150 pedigrees consecutively derived from the ClinSeqTM population. Risk assessments derived from MFHP were compared to two alternative “gold standards” for detecting risk applied to the same pedigrees: the CDC's Family HealthwareTM (FHT) CRC risk algorithm; and evaluation by 3 expert cancer genetic counselors (GC). Results- The MFHP, FHT, and GC evaluations identified 27, 14, and 16 elevated-risk probands, respectively, in the cohort. There was substantial agreement between GC CRC risk evaluations (average weighted kappa = 0.69 ± 0.04); two of three counselors had to agree that risk was elevated for a pedigree to be scored as such. Using different “gold standards” for the identifying CRC risk, sensitivities, specificities, positive predictive values (PPV) and negative predictive values (NPV) were: MFHP versus FHT, 100%, 90%, 52% and 100%; MFHP versus GC, 81%, 90%, 48% and 98%; FHT versus GC, 75%, 98%, 86% and 97%. Conclusions- The newly created software compatible with MFHP provides a tool for screening for heritable CRC risk. The sensitivities and specificities for MFHP derived using GC pedigree review as the “gold standard” for risk detection are not dissimilar from those of other types of screening tools used in primary care. The new tool has a higher sensitivity but lower specificity than FHT when compared to expert GC evaluation of CRC risk. The apparent “false positive” rate of the software is high; further research is needed to determine if this is a result of actual false positives or differences in risk assessment guidelines used by MFHP, FHT and cancer GCs.

1059T

ACTN3 R577X genotype and sport performance in Roma/Gypsies. *D. Gabrikova[1, 2], D. Hronska[2], S. Macekova[1, 2], J. Bernasovska[1, 2], A. Sovicova[1, 2], A. Bozikova[1, 2].* 1) Excellence Centre of Animal and Human Ecology, University of Presov, Presov, Slovakia; 2) Department of Biology, Faculty of Humanities and Natural Sciences, University of Presov, Presov, Slovakia.

In Europeans the XX genotype of ACTN3 gene polymorphism R577X (rs1815739) is less common among sprint/power athletes compared to general population. Previous studies have shown association between ACTN3 genotype and sprint/power or endurance performance, although not consistently. We examined the distribution of ACTN3 R577X genotypes and relationship between this polymorphism and physical performance in the Roma/Gypsy children. We tested 212 children from a community with very low socioeconomic status and with very little to absent sport activity, training and motivation. A sport performance of children aged 7-14 was tested in 4 sprint/power and 3 endurance disciplines. We did not find any association of the ACTN3 R577X genotype with performance in sprint/power disciplines. Out of endurance tests, the association was significant in flexed arm hang test. We found that the frequency of the XX genotype (13,3%) was significantly lower in Roma population than in general European population.

Paschall[2], H.L. Rehm[14], G. Riley[2], C.J. Saunders[10], S.T. Sherry[2], E.D. Trautman[6], V. Zvereff[6], D.M. Margulies[15].* 1) Channing Laboratory, Brigham and Women's Hospital, Boston, MA; 2) National Center for Biotechnology Information, NLM, NIH, Bethesda, MD; 3) GeneDx, Gaithersburg, MD; 4) LIFE Technologies, Carlsbad, CA; 5) Athena Diagnostics, Worcester, MA; 6) LabCorp/CMBP, Raleigh, NC; 7) Mayo Clinic, Rochester, MN; 8) NIH/NHGRI/OCD/Undiagnosed Diseases Program, Bethesda, MD; 9) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 10) Children's Mercy Hospital, Kansas City, MO; 11) Center for Biomedical Informatics, Harvard Medical School, Boston, MA; 12) Geisinger Health System, Danville, PA; 13) University of Utah Pathology Department/ARUP Laboratories, Salt Lake City, UT; 14) Harvard Medical School, Boston, MA; 15) Correlagen Diagnostics, Waltham, MA.

Both cost and technical difficulty of sequencing large regions of the genome are dropping to a level that enables its routine use in patient care. Limiting the adoption of large-scale sequencing in molecular diagnostics is the difficulty of assessing the clinical significance of detected variants. Each testing laboratory typically performs its own interpretation based on local primary data and expertise in addition to publicly available information. This approach prevents laboratories, physicians, and patients from capitalizing on community expertise and experience and may lead to inconsistent interpretations between different laboratories. Data on variants detected in testing laboratories should be made readily available to the community. Furthermore, it would benefit patients and their physicians to have ready access to each laboratory's interpretation for any given variant. Convergence among interpretations from different laboratories would increase confidence in the consensus interpretation, while divergence would indicate uncertainty and offer opportunity to sharpen the scoring algorithms. A group of major commercial and academic laboratories and bioinformatics groups have come together to support NCBI's ClinVar database as a `pre-competitive' repository of DNA sequence variation detected in the course of clinical diagnostics. The group is establishing procedures and technologies for the sharing of variants, defining critical data parameters required to evaluate pathogenicity of these variants, and working with NCBI to ensure these data can be stored and freely exchanged through ClinVar. Also, a code of conduct is being developed to assure priority for matters relating to patient safety. By making all evidence that underlies variant interpretation freely available, participants in this initiative hope that one of the major barriers to widespread adoption of extensive DNA diagnostic sequencing will be reduced.

1061T

Assessment of clinical usefulness of genetic diagnosis in neurology department of hospital. *Y. Ichikawa, H. Ishiura, J. Mitsui, T. Matsukawa, Y. Takahashi, H. Naruse, M. Taira, S. Tsuji, J. Goto.* Dept Neurology, Univ Tokyo, Tokyo, Japan.

Background: Molecular genetics has revealed many disease genes for neurological diseases, and genetic diagnosis contributes largely to clinical practice in neurology. The more disease genes are identified, the more the role of genetic diagnosis expands in neurology. **Objectives:** To assess the usefulness of genetic diagnosis of neurological diseases **Patients and Methods:** A total of 1392 hospitalized patients of the neurological division in the University of Tokyo Hospital during the period 2006 and 2010 were reviewed. After excluded the patients suffering from stroke or spondylosis or infectious disease, and the admissions for clinical trials, totally 942 subjects were analyzed retrospectively. We applied genetic analysis for subjects as follows; patients with positive family history or those with consanguinity, including spinocerebellar ataxias, spastic paraplegia, myopahty, juvenile parkinsonism or early onset dementia (< 60 yr.). The analysis methods included dideoxy-nucleotide sequence analysis, microarray-based resequncing, array CGH, fragment analysis, and SNP homozygosity mapping. **Results:** The total number of subjects who were analyzed by molecular genetic analysis were 165 (17.5%) among the 942 subjects. Eighty four patients, approximately half of the 165 subjects (50.9%), were diagnosed by genetic analysis. The highest number of the 84 genetically diagnosed patients were spinocerebellar ataxia patients (18 patients: 21.4%) which consisted of 17 autosomal dominant cerebella ataxia (ADCA) patients and one Nepalese Friedreich's ataxia patient. The second share of the genetically diagnosed patients was adrenolekodystrophy (9 patients: 10.7%), followed by Huntington disease (HD, 6 patients: 7.1%), spastic paraplegia (SPG) and Parkinson disease 2 (respectively 5 patients: 6%). Rare diseases such as neuroferritinopathy, vanishing white matter disease, Alexander disease and Hutchinson-Gilford progeria were also diagnosed. Among 27 genetically diagnosed autosomal dominant disease patients (ADCA, HD, SPG), 5 patients' family histories were unknown and had been considered to be sporadic (18.5%). **Conclusion:** Genetic analysis was needed to be applied to 17.5 % of the 942 subjects, and diagnosis of the half of them was determined genetically. Among sporadic cases, there were often patients suffering from hereditary diseases. Rare hereditary diseases were also experienced. Contribution of genetic diagnosis to practice of neurology is important.

A nine-year experience with the genetic testing of the rare disease acrodermatitis enteropathica. *S. KURY[1], S. SCHMITT[1], M. GIRAUD[1], C. TESSON[1], F. AIRAUD[1], B. DRENO[2], M. KHARFI[3], S. BEZIEAU[1].* 1) CHU Nantes, Service de Génétique Médicale, Nantes, France; 2) CHU Nantes, Service de Dermatologie, Nantes, France; 3) Charles Nicolle Hospital, Service de Dermatologie, Tunis, Tunisia.

Background: Acrodermatitis enteropathica (AE; MIM #201100) is a rare and severe zinc deficiency disorder, transmitted in an autosomal recessive mode. It is characterized by three pathognomonic symptoms occurring at birth or after weaning: acral and periorificial dermatitis, alopecia and diarrhea. In 2002, we and others identified SLC39A4 as the AE-causing gene, the mutation of which induced a defective intestinal zinc transport. Since then, a free routine testing of SLC39A4 was proposed in our laboratory to patients suspected of having an AE. Purpose: We report here the results of nine years of genetic testing in patients diagnosed worldwide with AE. We present the main difficulties inherent to the management of a rare disease, and the perspectives offered by the increasing knowledge on zinc transport. Method: In the first place, germinal mutations and rearrangements were screened in patients' genomic DNA by Sanger sequencing and QMPSF of the twelve exons and their splicing sites. Then anomalies of the untranslated and intronic regions were examined. Additional analysis of other candidate genes (SLC30A2, SLC39A5, SLC304A4 or BTD) were performed in selected cases. Results: Up today, we have tested 200 DNA samples, including 97 index cases. Twelve analyses are ongoing or suspended because of a lack of signed informed consent. In the 85 remaining patients, a mutation or a very likely deleterious variant was found in 41 patients: 34/85 (40%) patients were found homozygotes or compound heterozygotes, whereas 7/85 (8.2%) patients were found heterozygotes only. In 44/85 (51.8%) patients no mutation was found at all; misdiagnosis could explain a few negative results, and a few other cases are probably acquired acrodermatitis, but for most cases the influence of a genetic factor cannot be definitively ruled out. Conclusions: The genetic basis of AE is not fully elucidated, because the autosomal mode of inheritance can be questioned by segregation analysis in certain families. In addition, the observation of cases very suggestive of AE with no mutation identified in SLC39A4 lends credence to the hypothetical inovolvement of regulating factors and/or other genes in the pathogenic mechanism of AE. A comprehensive exome sequencing strategy is considered on genes participating in zinc metabolism.

Establishment and application of a standard diagnostic procedure for epidermolysis bullosa in China. *Z. Lin, Q. Chen, M. Lee, Y. Tan, Y. Yang.* Dermatology, Peking University First Hospital, Beijing, China.

Background: Epidermolysis bullosa(EB) represents a group of inherited skin disorders with recurrent mechanically-induced skin or mucosa bullae. With the great progress achieved in the molecular genetics during the past 20 years, nearly all the subtypes of EB can be diagnosed through genetic testing. However, in China, where the genetic testing is not widely performed, accurate diagnosis of EB under the molecular level still needs to be established. Object: To set up a standard diagnostic procedure for EB in China and to adopt it in diagnosis of EB under a molecular level. Methods: We set up an electronic database for managing the EB patients' information. Transmission electron microscopy and antigen mapping were performed to determine the level of cleft and potential defective components of dermo-epidermal basement membrane zone. Mutation analysis was followed to confirm the final diagnosis. Results: With this standard procedure, 19 out of 21 patients with EB were diagnosed based on an accurately gene mutation analysis during the past two years, including 4 cases of EB simplex, 7 cases of junctional EB, 6 cases of dystrophic EB and 2 cases of Kindler syndrome. We detected 23 novel mutations involving 7 different causative genes. Conclusions: A standard diagnostic procedure for EB is necessary in China which may notably improve the accurate diagnosis rate under a molecular level.

The Genetic Testing Registry (GTR): Genetic Tests and More. *D. Maglott[1], B.L. Kattman[1], A. Malheiro[1], J. Lee[1], M. Ovetsky[1], V. Hem[1], V. Gorelenkov[1], W. Rubinstein[1,2], C. Fomous[3], J. Ostell[1].* 1) Natl Ctr Biotech Info, NIH/NLM, Bethesda, MD; 2) University of Chicago Medical Center, Chicago IL; 3) Office of the Director, NIH, Bethesda, MD.

Scientific advances—particularly in the last decade—have expanded our understanding of the genomic and genetic factors involved in health and disease. This increased knowledge has been accompanied by a rapid rise in the number and complexity of genetic tests. Laboratory tests for more than 2,000 genetic conditions are now available, but there is no comprehensive public resource that provides detailed information about the scientific basis of these tests. Enhancing access to detailed test information is important to enable informed decision-making by health care providers, patients, caregivers, clinical laboratory professionals, payers, and policymakers; to assist regulators; and to facilitate research. To address the information gap about genetic tests, NIH developed the Genetic Testing Registry (GTR).

The GTR (http://www.ncbi.nlm.nih.gov/gtr) is a public, online resource integrating information from voluntary submissions by testing entities. After consultation with multiple advisory groups and interested stakeholders, we developed a list of the minimal and optional fields necessary to describe each submitted test. The minimal fields include what the test measures, the methods used, and contact information for the submitting laboratory. The GTR user interface combines flexible search functions with links to related medical and molecular resources. Searches may be general, or may focus on conditions (including drug responses), genes, test methods, analytes, or laboratories. Tests retrieved by a search can be compared by condition, measure, or methodology to facilitate identification and selection of a single orderable test. Search functions are integrated with well-known medical genetic resources such as GeneReviews, OMIM®, PubMed, PubMedCentral, ClinicalTrials.gov, as well as more recent sites at NCBI, namely MedGen, and ClinVar. Both MedGen and ClinVar support GTR, the former to organize information about genetic disorders and the latter to represent the clinical significance of rare variations. Submitters to GTR can register their tests using tools that integrate (1) information they may have supplied to GeneTests (http://www.ncbi.nlm.nih.gov/sites/GeneTests) with (2) information about medically relevant variations accessioned in ClinVar (http://www.ncbi.nlm.nih.gov/clinvar) and (3) pertinent practice guidelines. This presentation will demonstrate content and navigability of the GTR.

EuroGentest Clinical Utility Gene Cards - concise guidelines for genetic testing in 300 diseases. *J. Schmidtke, A. Dierking.* Dept Human Gen, Medizinische Hochschule, Hannover 61, Germany.

EuroGentest, an EU-funded project for the harmonization of genetic testing, has started its second funding period (2011-2013). Unit 2, entitled “Genetic testing as part of health care”, holds amongst others the initiative for the establishment of Clinical Utility Gene Cards (CUGCs). CUGCs are disease-specific and expert-authored guidelines dealing with the risks and benefits of the application of genetic tests in the clinical setting. Clinical utility is an important aspect of genetic testing, but it is also difficult to define. Based on the ACCE framework the here presented guidelines give a balanced summary of the analytical and clinical validity, the clinical utility and cost-benefit issues of genetic tests. Hereby it is important that the specific requirements for a test are evaluated in the context of their impact on the clinical setting and that the laboratory genetic test is only one of the components of an overall intervention. The documents contain following information: disease characteristics (name, mutational spectrum and analytical methods), test characteristics (analytical and clinical sensitivity and specificity) and clinical utility (disease management, cost effectiveness and risk assessment). Details about the clinical setting are presented in four sections: differential diagnostics, predictive testing, risk assessment in relatives and prenatal testing. Each CUGC is authored by a multinational expert team. Potential authors are identified based on their practical experience and their publication record. Subsequent to the completion the documents are peer-reviewed and published by the European Journal of Human Genetics (EJHG). EuroGentest commissions the establishment as well as the annual update of the guidelines. Due to the standardised and concise format, CUGCs offer quick guidance to all stakeholders, including clinicians, clinical geneticists, referrers, service providers and payers. To ensure that all published documents include new developments and findings and reflect the state-of-the-art, all published CUGCs are annually revised. Each CUGC is freely available on the websites of EuroGentest, the EJHG, the European Society of Human Genetics and Orphanet. Until now 40 CUGCs have become citable publications, by the end of 2013 at least 300 CUGCs are intended to be published.

1066T

Patients' feelings and experience towards predictive genetic testing for primary open angle glaucoma. *E. Souzeau[1], K. Burdon[1], A. Dubowsky[2], J.E. Craig[1].* 1) Dept of Ophthalmology, Flinders University, Bedford Park, SA, Australia; 2) Institute of Medical & Veterinary Science, Flinders Medical Centre, Bedford Park, SA, Australia.

Rationale: Primary open angle glaucoma (POAG) is a sight threatening condition, affecting 3% of the population over the age of 50 years. Myocilin mutations are identified in 3-4% of POAG cases and are inherited in an autosomal dominant fashion. Unaffected relatives of Myocilin patients face a very high risk of carrying the familial mutation and developing glaucoma blindness. Cascade testing for relatives of individuals with Myocilin mutations has been shown to be feasible and effective in identifying at risk individuals and preventing glaucoma blindness. However, little is known about individuals' experience and impact of predictive testing for a sight threatening, but treatable condition like glaucoma. **Methods**: Index cases were recruited through The Australian and New Zealand Registry of Advanced Glaucoma (ANZRAG). Predictive testing is offered to family members of individuals with a Myocilin mutation identified through ANZRAG. Individuals who had cascade testing and obtained their genetic result were sent a questionnaire, regardless of their result. The questionnaire focused on pre-test perceived glaucoma and genetic result risks, motivations for being tested and negative and positive feelings about being tested. **Results**: The questionnaire was sent to 30 individuals who underwent predictive genetic testing, 15 of whom were found to carry the familial Myocilin mutation. Our results show that, before being tested, the majority of our participants evaluated their risk of developing glaucoma and their risk of carrying the familial mutation as being high. This provides an insight into their decision to be tested. Most participants were motivated by the ability to take actions based on their result and the ability to provide information to their children regarding their glaucoma risk. Participants discussed their decision to be tested and their results with their family as well as their children if they were old enough. Regardless of their result, all the participants found predictive testing for glaucoma to be beneficial and none of them expressed regrets about being tested. **Conclusion**: These findings give health professionals some insight about patients' motivations and feelings for glaucoma predictive testing as well as some guidance for providing adequate support to these individuals in families carrying Myocilin mutations.

1067T

Tracing ancestral depth of families diagnosed with hereditary gastrointestinal polyps and cancers. *T.M. Tuohy[1], M.C. Done[1], N. Sargent[2], D.W. Neklason[1, 2], R.W. Burt[1, 3].* 1) High Risk Cancers Clinic, Huntsman Cancer Inst, Salt Lake City, UT; 2) Department of Oncological Sciences, Huntsman Cancer Inst, Salt Lake City, UT; 3) Department of Medicine, Univerisity of Utah, Salt Lake City, UT.

Heritable diseases are commonly the results of familial mutations, tracking back through several generations of the same family, to the “founder” in whom the mutation first arose. In conditions where the majority of cases derive from inherited rather than new mutations, it is possible to “tag” the allele on which the mutation arose, using linked markers such as STRs or SNPs. The cohort chosen for this study was ascertained over a ten-year period and included individuals enrolled both before and after clinical genetic testing became increasingly routine, as well as those who do not pursue clinical genetic testing. A two-step method of tagging the suspect locus, accompanied by cross-referencing it to a database of similarly tagged, clinically genetically tested alleles may provide a cost-effective way to enrich the cohort of uncharacterized samples for site-specific candidates carrying individual mutations. Research PCR and sequencing of the candidate matches may then be verified by clinical testing for the indicated site-specific mutation. The additional benefit of connecting distant relatives, and by extension previously unknown branches of such families serves simultaneously as a clinical ascertainment tool, for referral for standard of care, and as a resource for continued research with cohorts of patients and participants who share common genetic origins. We characterized 451 samples from clinically and/or genetically diagnosed individuals in 210 kindreds at 4 highly polymorphic STR markers spanning 3 Mb of the APC locus associated with familial adenomatous polyposis coli (FAP). A genetic diagnosis was previously known for 62 kindreds (database), while only a clinical diagnosis of FAP, AFAP, “>6 adenomas”, “diagnosed with colon cancer”, “hyperplastic polyps”, “family hx of colon cancer”, or “undefined polyposis” was available for the remaining 148 kindreds (test cases). Results were analyzed for either 3 or 4 contiguous STR matches, and samples from the unknown kindreds with perfect or close matches to known kindreds were sequenced for the relevant site-specific mutation. Matches between independently ascertained kindreds harboring the same mutations were also sought to verify or rule out common ancestry. Both genetically and genealogically verifiable, and false-positive, matches between database and test cases were obtained, demonstrating both the utility and the limitations of this approach for APC. Results and analysis will be presented.

1068T

Whole genome sequencing in clinical practice: The first year. *D. Dimmock[1,2], R. Veith[3], M. Gutzeit[3], S. Leuthner[1], R. Willoughby[1], T. May[4], M. Tschannen[2], T. Hambuch[5], P. North[6], H. Jacob[2], E. Worthey[1,2], D. Bick[1,2].* 1) Pediatrics, Med College Wisconsin, Milwaukee, WI, United States; 2) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI, United States; 3) Children's Hospital of Wisconsin, Milwaukee, WI, United States; 4) Institute for Health and Society/Bioethics, Medical College of Wisconsin, Milwaukee, WI, United States; 5) Illumina Inc, San Diego, CA, United States; 6) Pathology/Pediatrics, Medical College of Wisconsin, Milwaukee, WI, United States.

We have demonstrated the power of genomic sequencing to identify the molecular basis of disease, thus modifying managment in a number of clincial cases (Worthey et al; Goh et al). The use of whole genome sequencing (WGS) in routine clinical practice was the logical extension of this approach. However, using WGS in routine clinical practice presents significant challenges. In our institution's clinical whole genome sequencing (WGS) program we have defined protocols for data evaluation, informed consent and data return. The steps in case management include: (1) Identification by physicians within a specialty of a case where genome sequencing is clinically warranted and where all other standard clinical assessments have been exhausted or where the aggregate cost of further testing is in favor of WGS(2) Case review by a committee with expertise in the disease area, genetics, informatics, genetic counseling, and ethics to evaluate whether genomic sequencing can advance the clinical decision-making process (3) Funding (4) Genetic counseling and consenting of the family (5) WGS in a CAP/CLIA certified laboratory (6) WGS data analysis and reporting through our institution's CAP/CLIA laboratory (7) Result reporting to families. At the time of abstract submission 43 clinical cases had been evaluated through our institutional WGS program. Although only 14 cases initially meet full criteria and were approved for WGS, the majority of cases will become eligible after further testing or information from referring physicians. To date only 5 cases have been declined for sequencing either because there was insufficient material available or no clear evidence that genomic testing would benefit care. Simular to pilot studies with Exome sequecing, WGS has acheived actionable clinical results in a subset of patients.

THM1-null Mouse Model of Ciliopathy Manifests Renal Cysts, Retinal Defects and Obesity. *P.V. Tran[1], D.R. Beier[2].* 1) Anatomy and Cell Biology and The Kidney Institute, The University of Kansas Medical Center, Kansas City, KS; 2) Genetics Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

Primary cilia are antenna-like structures that extend from the plasma membrane of most vertebrate cells and are proposed to mediate signaling pathways. Defects in cilia physiology are linked to a growing class of human disorders, termed ciliopathies. Though individually rare genetic diseases, ciliopathies manifest clinical features that are common in the general population, such as renal cysts, retinal degeneration and obesity. As such, studying the pathogenesis of ciliopathies may provide critical insights into the molecular mechanisms of common medical burdens. We have identified a novel ciliary protein, THM1 (Tetratricopeptide Repeat Containing Hedgehog Modulator 1, also termed TTC21B or IFT139), which negatively regulates Hedgehog (Hh) signaling. *THM1* pathogenic alleles contribute to more than 5% of patients with ciliopathies, rendering *THM1* the most commonly mutated gene in these disorders (Davis *et al., Nat. Genet.*, 2011). We report that in conditional knock-out mice, genetic deletion of *Thm1* during late embryogenesis results in renal cysts and retinal defects in the adult mouse, while deletion of *Thm1* during adulthood leads to increased body weight and overall growth. Given the role of THM1 as a negative regulator of Hh signaling, we are investigating a possible role of enhanced Hh activity in these postnatal phenotypes. In support of this hypothesis, cyst formation in an embryonic kidney explant assay was prevented by genetic deletion of *Gli2*, the main transcriptional activator of Hh signaling, and by treatment with small molecule Hh inhibitors. To determine whether increased Hh signaling plays a causal role in the postnatal phenotypes of the conditionally deleted mutants, we are currently generating double *Thm1, Gli2* conditional knockout mice. Hh signaling remains largely unexplored in renal cystogenesis, retinal degeneration and obesity, and exploration of this pathway may reveal novel molecular mechanisms and therapeutic targets for these common illnesses.

Expansion of phenotypic characteristics of *NPHP5*-related disease. *A. Vincent[1], D. Chitayat[2, 3], R. Weksberg[2], E. Heon[1].* 1) OPHTHALMOLOGY, HOSPITAL FOR SICK CHILDREN, TORONTO, ONTARIO, Canada; 2) CLINICAL AND METABOLIC GENETICS, HOSPITAL FOR SICK CHILDREN, TORONTO, ONTARIO, CANADA; 3) PRENATAL DIAGNOSIS AND MEDICAL GENETICS PROGRAM, MOUNT SINAI HOSPITAL, TORONTO, ONTARIO, CANADA.

AIM:The nephrocystin 5 gene (*NPHP5*) originally associated with a clinical phenotype of Senior-Loken syndrome has recently been implicated to cause Lebers congenital amaurosis (LCA). We have comprehensively defined the clinical phenotype of a molecularly confirmed case of *NPHP5* who had atypical features that included hemi-hyperplasia. METHODS:Systemic and ophthalmic evaluation was performed on a child being assessed for hemihyperplasia. Karyotyping and microarray were performed. The region of chromosome 11p15 associated with Beckwith-Wiedemann syndrome was tested for methylation deficits, deletions and mutations. The *PTEN* gene associated with Proteus syndrome and 11 known LCA genes were also sequenced. RESULTS:The child, born to consanguineous parents, showed bilateral syndactyly of 2nd and 3rd toes. Hyperplasia of the right side of the body including face, upper limb and lower limb was first noted at 6 weeks of age. No evidence of visceral embryonal tumors has been noted to-date. The child has developmental delay and parents have noted nyctalopia since 1 year of age. Horizontal nystagmus noted at 3 years, has progressively worsened. At 4.5 years, the best corrected visual acuity was 6/60 in either eye (+6.00 D Sph). Contrast sensitivity was decreased to 0.15 log units. Fundus evaluation showed normal posterior pole with an equatorial concentric band of confluent white retinal lesions and deposits. Round atrophic scars were noted anterior to this. The optical coherence tomography revealed deposition of hyper-echoic material on the retinal pigment epithelium in affected regions. Electroretinogram showed non-detectable rod and cone responses. Ultrasonogram revealed cysts in the kidney and spleen and also showed hyperechoic lesion in the liver. Brain MRI and echocardiography were reported normal. Karyotype and microarray were normal. No mutations or methylation abnormalities were noted in chromosome 11p15 region. No mutations were identified in *PTEN* gene. A homozygous nonsense mutation (c. 1363C>T; p.R455X: previously reported) was identified in *NPHP5*. CONCLUSION:This case with molecularly confirmed *NPHP5*-related disease presented with unusual feature of hemi-hyperplasia and an atypical retinal phenotype. Renal and hepatic abnormalities described in this case are usually seen in *NPHP5*-related disease. All the findings including hemihyperplasia are likely *NPHP5*-related, as body curvature abnormalities have previously been recognized in animal models.

1071T

Exome sequencing to identify genetic causes of primary ciliary dyskinesia with outer dynein arms defects. *M.A. Zariwala[1], M.W. Leigh[2], L.E. Ostrowski[3], S.D. Davis[2], J.S. Berg[4], L. Huang[3], W. Yin[3], J.L. Carson[3], M. Hazucha[3], E.H. Turner[5], A. MacKenzie[5], M. Bamshad[5], D.A. Nickerson[5], J. Shendure[5], M.R. Knowles[3], Genetic Disorders of Mucociliary Clearance Consortium (GDMCC).* 1) Department of Pathology & Laboratory Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 2) Department of Pediatrics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) UNC School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 4) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 5) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

We utilize exome sequencing to investigate genetic etiologies of primary ciliary dyskinesia (PCD)/Kartagener syndrome, an autosomal recessive genetically heterogeneous disorder. PCD is caused by defective structure and/or function of cilia and flagella. The phenotype is characterized by neonatal respiratory distress in full term neonates, recurrent otitis media, male infertility and chronic oto-sinu-pulmonary disease including bronchiectasis. ~50% patients have situs inversus and ~6% have situs ambiguus. Currently, mutations in 12 genes explain ~50% of PCD, but genetic basis in other patients is elusive. For most laboratories, the “gold standard” diagnostic test is ciliary ultrastructural analysis, but this test poses technical challenges, and there is heterogeneity of ultrastructure in patients, e.g. the presence/absence of outer dynein arms (ODA), inner dynein arms, radial spokes and/or central pair. To identify additional PCD-causing genes, we did exome sequencing in 7 unrelated, PCD patients with “classic” ODA defects (absent or truncated ODA). Sanger sequencing for biallelic mutations in *DNAH5* and *DNAI1*, genes commonly mutated in patients with ODA defects, had previously been negative for all 7 individuals. Three of the 7 patients harbored a homozygous stop mutation in a rare, but previously known PCD-causing gene, *DNAI2*. These patients were of Jewish ethnicity and haplotype analysis indicated a founder effect. Additionally, we found biallelic loss-of-function mutations in *DNAH5* in a patient who was previously negative by Sanger sequencing. Further analysis revealed lack of amplification of the mutant allele due to the presence of a rare polymorphism within the primer target, thus causing allele drop-out. We also found two rare, missense variants on highly conserved residues in *DNAH5* in another patient. Finally, we identified a homozygous splice mutation in a novel gene in one patient, and confirmation analyses and mutation profiling in an additional 93 patients is ongoing. In conclusion, we have successfully defined the genetic basis for PCD with ODA defects in 6 of 7 “unsolved” patients using exome sequencing, including a mutation missed by Sanger sequencing, a novel founder mutation in *DNAI2* that may be prevalent in subjects of Jewish ethnicity and a novel PCD-causing gene. This abstract was funded by MO1RR00046, UL 1 RR025747, 5 R01HL071798, 5 U54 HL096458-06, 5 R01HL094976-02 and 5UC2HL102923-02.

1072T

Disruption of CBP gene and decreased expression of CREB, NF2Bp65, c-JUN and c-FOS, BCL2 and c-MYC in a case of Rubinstein-Taybi Syndrome. *L.D. Kulikowski[1], L.C. Torres[2], P.L. Ramos[2], S.M.M. Sugayama[2], C.A. Moreira-Filho[2], M. Carneiro-Sampaio[2].* 1) Department of Pathology, HC FMUSP, LIM 03 Universidade de São Paulo, São Paulo, Brazil; 2) Department of Pediatrics, Instituto da Criança HC-FMUSP, LIM 36, Universidade de São Paulo, Brazil.

Rubinstein-Taybi syndrome (RTS) is commonly caused by microdeletions and point mutations in one copy of the gene encoding CREB-binding protein (*CBP*), although chromosomal translocations and inversions have been identified in a few cases. Here we present clinical and molecular studies of a patient with RTS who has a *CBP* gene disruption revealed by CGH-array and FISH. The patient presents a very severe RTS phenotype and immune dysregulation. Further investigation with Western Blot techniques demonstrated decreased expression of CREB, NF2B, c-Jun and c-Fos and also of BCL2 and c-MYC in peripheral blood mononuclear cells. Given that the patient represents a natural model for inactivation of *CBP* gene, we suggested that this gene is essential for normal expression of these transcriptional factors in peripheral blood mononuclear cells. Furthermore, the presence of structural genomic alterations in *CBP*, as well as gene dosage imbalance, may affect not only locus but also gene regulation in RTS patients.

1073T

Exploring the Intrinsic Functional Gene Dose of Recessive Mendelian Mutations with a Computational Visualizing Approach. *L. Li[1,2,4], M. McGuffin[5], W. Foulkes[1,2,3].* 1) Cancer Genetics Program; 2) Department of Oncology; 3) Department of Human Genetics; 4) Systems Biology Training Program, McGill university; 5) Department of Software and IT Engineering, École de technologie, Montreal, Canada.

Recessive Mendelian disorders are caused by the inactivation of both copies of the disease gene and are often diagnosed among young children with broad variation in phenotype severity. Known contributors to phenotype variation include mutation genotypes, genetic modifiers and environmental factors. Mechanistically, the retention of partial gene function resulting in phenotype attenuation has been demonstrated for several genes. For mutations interfering with gene expression, a partial retention of function may be achieved through the expression of the wild type or in-frame transcripts. Mutations of this category span the spectrum of mis-sense, non-sense, splicing and silence mutations, at both exonic and intronic sequences. Identifying mutations with residual gene function attributed to the expression of intact or in-frame transcripts represents a challenge for molecular diagnostics: it requires sensitive, quantitative gene expression analysis, which is not always practical in the laboratory due to the high cost of the assay, the complexity of the gene expression profile, or the scarceness of RNA material. An alternative approach is to identify mutations with residual function in a computational visualizing lab, by integrating phenotype patterns with genotype information. As a proof of principle, we visualized the phenotypic severity in patients carrying biallelic PMS2 mutations. Mutations were set into two groups according to prior knowledge of gene expression profiles: biallelic truncation or biallelic attenuation, the latter expressing lower levels of wild type or in-frame transcripts compared to wild type alleles. Then the phenotype severity of the two groups was computed and visualized. It appeared that the severity pattern precisely classified the two groups of genotypes, illustrating the feasibility of this approach in identifying genotypes with residual function. A larger dataset on Constitutive Mismatch Repair Deficiency Syndrome, Fanconi Anemia and Ataxia Telangiectasia was further tested for optimizing the visualization method. A novel diagnostic model will be formed from this study: a special group of patients, who are potential beneficiaries of restoring gene function by increasing the expression level of functional transcripts, can be identified in a computational lab with an integrated approach of phenotype clustering , visualization and transcript prediction.

Clinical and Molecular Characterization of Mircovillous Inclusion Disease (MVID) in four Arab Families. *B. Meyer[1], D. Monies[1], H. Al Zaidan[2], A. Mehaidib[3], M. Al Edreesi[4], E. Naim[1], O. Khashoggi[1], M. Faqih[5], Z. Rahbeeni[2].* 1) Department of Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 2) Department of Medical Genetics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 3) Department of Pediatrics, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia; 4) Department of Pediatrics, Dhahran Health Center, Dammam, Saudi Arabia; 5) Department of Pathology & Clinical Laboratory Medicine, King Fahd Medical City, Riyadh, Saudi Arabia.

Four Arab families were included in our study. All five patients exhibited typical clinical features for Microvillous Inclusion Disease including an intractable watery diarrhea with onset near birth. The clinical diagnosis was supported by histopathological investigation. MVID is an autosomal recessive disorder resulting from mutations in *MYO5B*. All patients were from consanguineous families and we confirmed homozygosity in the *MYO5B* locus prior to sequencing this large gene (40 exons). Sequencing identified three novel homoallelic mutations (two nonsense and one missense mutation). Nonsense mutations were present in exons 24 and 36 and are consistent with loss of function. The missense mutation was present in exon 12 and was predicted to be pathogenic by the *PolyPhen-2* package. This was further confirmed by the absence of this allele in 500 control chromosomes. In one family with two affected individuals (monozygotic twins) no mutation was found in the entire coding and flanking region of *MYO5B*. Homozygosity screening did not exclude *MYO5B* and disease may be the result of mutation in a non-coding region of this gene or at a novel locus.

NPHS2, NPHS1 and WT1 mutations in Indian children with initial steroid resistant nephrotic syndrome. *S. sharma, A.K. Dinda, A. Bagga, M. Kabra.* Department of Pediatrics, All India Institute of medical sciences, New Delhi, India.

Objectives Mutations in NPHS2, NPHS1 and W11 genes is a frequent cause of steroid resistant nephritic syndrome (SRNS) and occur in 10-28% of children. The frequency and spectrum of mutations in these genes is unknown for the Indian population. We investigated the prevalence of mutations in these three genes among Indian patients with initial SRNS and their association with clinical outcomes. Methods 120 patients showing initial resistance to 4 weeks of treatment with daily prednisolone were included. Eighty patients with steroid sensitive nephrotic syndrome served as controls. Mutation analysis was performed by conformation sensitive gel electrophoresis (CSGE) of all exons of NPHS2, NPHS1 and WT1 genes. If an aberrant band was detected by CSGE, the corresponding sample was sequenced. Results We screened 120 patients (82 boys and 38 girls) belonging to different parts of India. The mean age of onset of disease was 4.36 years. Of 120 patients screened, 16 (13%) showed 10 different mutations in the NPHS2 gene. Homozygous and compound heterozygous mutations were seen in 8 out of 120 (6.6%) patients. Of 8 patients 3 who were compound heterozygous for R229Q showed complete response to CI (TAC) and 5 did not responded to CP/CI. Of 14 patients with onset of NS in infancy, only one showed a homozygous NPHS2 mutation (p.P175fsX178). Single heterozygous variants were found in 8 out of 120 (6.6%) patients. All heterozygous carriers showed complete response to CP/CI. We detected six novel mutations in the NPHS2 gene and none of the novel mutation was found in SSNS controls. Screening of WT1 gene showed three mutations IVS9+4C>T, IVS9+5G>A and R394W in three girls. The first two mutations were present in intron 9 of the WT1 gene and associated with complete sex reversal with 46,XY genotype (Frasier syndrome) and the third mutation was found in a girl with Wilm's tumor and nephrotic syndrome (Denys Drash syndrome). No mutations were found in NPHS1 gene. Conclusion The incidence of NPHS2 mutations in Indian patients with SRNS is considerably lower than that among European childern (10-30%). All WT1 mutations were present in girls with FSGS 3/12 (25%). Therefore screening of WT1 gene in all females with FSGS is necessary. No clear genotype-phenotype correlation was established. Further genetic studies using more sensitive techniques like direct sequencing and screening for other podocyte genes may help in further understanding the pathogenesis SRNS in Indian children.

Exome sequencing and analysis of split-hand/foot malformation and long-bone deficiency families with non-Medelian inheritance. *R. Uppala[1], U. Ratnamala[2], M. Naveed[3], M.T. Al-Ali[3], N. Al-Khaja[3], A. Bashamboo[4], K. McElreavey[4], S.K. Nath[5].* 1) Surgery-Transplant, University of Nebraska Medical Center, Omaha, NE; 2) Department of Pharmcology, Creighton University, Omaha, NE, USA; 3) Center for Arab Genomic Studies (CAGS), Dubai, United Arab Emirates; 4) Human Developmental Genetics, Institut Pasteur, Paris, France; 5) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA.

Split hand/foot malformation with long-bone deficiency (SHFLD) is a rare, severe limb deformity characterized by tibia aplasia with or without split-hand/split-foot deformity with an incidence of ~1 per million live births. Genomic regions with evidence of linkage for SHFLD were identified at three chromosomal regions including our earlier identified loci at 1q31.1, 1q42.3, 4q34.3, 1q42.2-q43, 6q14.1, and 17p13.1 in a large Arab consanguineous family (UR-078) (Am.J.Hum.Genet; 80: 105-11,2007), which most likely contain novel susceptibility genes for SHFLD. In order to identify the genes responsible for these SHFLD loci, we performed exome sequencing using the SOLiDTM system at x200 coverage followed by high-resolution array CGH analysis. We prioritized our mutation search within the linkage region between SNP markers rs1124110/rs535043, and rs623155/rs1547251 respectively. In addition, we have recently ascertained several multigenerational SHFLD families of different geographic region. Genome-wide linkage analysis of three selected large families (UR-079, UR-080 and UR-083) using high-density SNP array excluded previously identified SHFLD1 and SHFLD2 and SHFLD3 loci and yielded novel digenic loci each in two distinct families (UR-080 and UR-083) indicating that SHFLD is highly heterogeneous. Additional clinical details of the affected individuals from newly studied families, the detailed results of our linkage scan with genes of interest in the novel linked chromosomal regions and exome sequencing data of SHFLD1 and SHFLD2 in selected individuals in Arab family will be presented.

Gene regulatory mutations as a cause of human limb malformations. *J.E. VanderMeer[1,2], T. Laurell[3,4,5], A.M. Wenger[6], G. Bejerano[6,7], G. Grigelioniene[4,8], A. Nordenskjold[9,10], M. Arner[3,5], A. Nordgren[4,8], N. Ahituv[1,2].* 1) Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA 94143, USA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco, CA 94143, USA; 3) Department of Clinical Science and Education, Södersjukhuset, Karolinska Institutet, Stockholm, Sweden; 4) Department of Molecular Medicine and Surgery and Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 5) Department of Hand Surgery, Södersjukhuset, Stockholm, Sweden; 6) Department of Computer Science, Stanford University, Stanford, CA 94305, USA; 7) Department of Developmental Biology, Stanford University, Stanford, CA 94305, USA; 8) Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 9) Department of Women and Children Health and Center of Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 10) Department of Paediatric Surgery, Astrid Lindgren Children Hospital, Karolinska University Hospital, Stockholm, Sweden.

Congenital limb malformations are the second most common human malformation. Many of these malformations appear to have genetic causes, however, mutations that cause isolated limb malformations have been difficult to discover. This could be due to the fact that not all limb malformations are caused by gene coding mutations. Another possible cause could be regulatory mutations - sequence or copy number variations that affect only noncoding regulatory regions - which are known to cause at least three types of limb malformations. As our understanding of noncoding regulatory DNA increases, we will see more cases of malformations caused by this type of mutation. In order to identify additional regulatory mutations that cause human limb malformations, we are collecting DNA from patients with isolated limb malformations and have enrolled over 300 patients to date. Using candidate region sequencing and linkage analysis in combination with computational and in vivo assays to detect regulatory sequences that harbor mutations, we are able to identify genetic lesions and understand how they could affect gene expression. As an example of this analysis, we describe a novel type of mutation in the Sonic Hedgehog limb enhancer (ZRS). Single base mutations in the ZRS have previously been shown to cause preaxial polydactyly and large duplications encompassing the entire ZRS region cause human polysyndactyly phenotypes, but no insertion or deletion mutations entirely within the ZRS have been reported. By analyzing a Swedish family with preaxial polydactyly and triphalangeal thumb, we found a 13 base pair insertion within the ZRS. Computational analysis for transcription factor binding sites suggests that this insertion creates sites for several key transcription factors involved in limb development. Using a mouse enhancer assay, we show that this insertion causes the ZRS to misdirect gene expression to an ectopic anterior region of the developing limb. This is the first report of a small insertion within an enhancer that causes a human limb malformation and suggests a potential mechanism that could explain the ectopic expression caused by this mutation. This and future work on regulatory mutations that cause limb malformations will result in increased knowledge about limb development and the pathogenesis of human limb malformations. In addition, this work provides a model for studying the role of regulatory elements in other isolated disease phenotypes.

1078T

Pitx1 Haploinsufficiency Causes Clubfoot in Humans and Mice. *D.M. Alvarado[1], K. McCall[1], H. Aferol[1], M.J. Silva[1], J.R. Garbow[2], W.M. Spees[2], T. Patel[1], M. Siegel[2,3], M.B. Dobbs[1,5], C.A. Gurnett[1,3,4].* 1) Washington University in St. Louis Departments of Orthopaedic Surgery; 2) Radiology; 3) Pediatrics and; 4) Neurology, St Louis, MO; 5) St. Louis Shriners Hospital for Children, St. Louis, MO.

Clubfoot affects 1 in 1000 live births, though little is known about its genetic or developmental basis. We recently identified a missense mutation in the PITX1 bicoid homeodomain transcription factor in a family with a spectrum of lower extremity abnormalities, including clubfoot. Because the E130K mutation reduced PITX1 activity, we hypothesized that PITX1 haploinsufficiency could also cause clubfoot. Using copy number analysis, we identified a 241kb chromosome 5q31 microdeletion involving PITX1 in a patient with isolated familial clubfoot. The PITX1 deletion segregated with autosomal dominant clubfoot across 3 generations. To study the role of PITX1 haploinsufficiency in clubfoot pathogenesis, we began to breed Pitx1 knockout mice. Although Pitx1+/- mice were previously reported to be normal, clubfoot was observed in 20 of 225 Pitx1+/- mice, resulting in an 8.9% penetrance. Clubfoot was unilateral in 16 of the 20 affected Pitx1+/- mice, with the right and left limbs equally affected, in contrast to right-sided predominant hindlimb abnormalities previously noted with complete loss of Pitx1. Peroneal artery hypoplasia occurred in the clubfoot limb and corresponded spatially with small lateral muscle compartments. Tibial bone volumes were also reduced. Skeletal muscle genes expression was significantly reduced in Pitx1-/- E12.5 hindlimb buds compared to wild-type, suggesting that muscle hypoplasia was due to abnormal early muscle development and not disuse atrophy. Our morphological data suggest that PITX1 haploinsufficiency may cause a developmental field defect preferentially affecting the lateral lower leg, a novel theory that accounts for similar findings in human clubfoot.

1079T

Aberrant firing of replication origins explains nonrecurrent rearrangements in the human genome. *A. Ankala[1], A.R. Hegde[2], A. Meka[3], E.L.H. Chin[1], S.H. Askree[1], S. Bhide[1], M.R. Hegde[1].* 1) Human Genetics, Emory University School of Medicine, Atlanta, GA 30322; 2) Biochemitry and Molecular Biology, University of Georgia, Athens, GA 30602; 3) Georgia Institute of Technology, Atlanta, GA 30332.

Nonallelic homologous recombination (NAHR), nonhomologous end joining (NHEJ) and fork stalling and template switching (FoSTeS) have been put forward as mechanisms to explain DNA rearrangements associated with genomic disorders. However, many nonrecurrent rearrangements in humans still remain unexplained. To further explore the mutational mechanisms of these rearrangements and the resultant copy number changes (CNCs), we investigated 62 clinical cases with intragenic deletions either in the human dystrophin gene (DMD, 50 cases) or in other known disease-causing genes (1 PCCB, 1 IVD, 1 DBT, 3 PAH, 1 STK11, 1 HEXB, 3 DBT, 1 HRPT1 and 1 EMD cases). Breakpoint junction sequence analysis of these deletions revealed presence of repetitive elements in 4 individual cases including 3 DMD and 1 HEXB, microhomologies (2-10 bp) at breakpoint junctions in 35, and insertions ranging from 1 to 48 bp in 16 of the total 62 cases. Among these insertions, we observed tandem repetitions (5-20 bp long) of the template region proximal to deletion breakpoint in six individual DMD cases (6 repeats in 1, 4 repeats in 3, 2 repeats in 1 and 1 repeat in 1 case). These tandem repetitions represent series of replisome slippage and re-replication events. Successful replication of the entire DMD gene is known to be completed by the participation of at least five active origins and six termination regions. Replisome slippage events observed in our current study suggests reversal of replication fork direction across termination regions due to failure of certain replication origins to fire. With a deeper insight into the complex process of replication brought about by recent studies, we propose that CNCs involving DNA deletions and duplications are a result of aberrant firing of active and inactive replication origins coupled with incomplete rescue of replication.

Analysis of X chromosome copy number variations in Brazilian men with idiopathic intelectual disability. *N. Fintelman-Rodrigues, M. Campos Jr, J.M. Santos, M.M.G Pimentel, C.B Santos-Rebouças.* Departament of genetics, State University of Rio de Janeiro, Rio de Janeiro, Brazil.

The evolution of molecular technology has uncovered a number of structural variants in the human genome, mainly in the form of copy number variations (CNVs), corresponding to submicroscopic microdeletions and -duplications. In fact, several studies have already correlated CNVs in distinct genes with different degrees of predisposition to disease, which can influence gene expression affecting genes directly or by changing their dosage. Nevertheless, for many CNVs it is unclear whether they are associated with disease or just represent benign variants. X-linked mental retardation (XLMR) or intellectual disability (ID) is a common, clinically complex and genetically heterogeneous disease arising from many mutations along the X chromosome, which affects between 1/600-1/1000 males. In this study, we analyzed CNVs for 16 genes located at X chromosome (*PQBP1*, *TM4SF2*, *ARX*, *IL1RAPL1*, *RPS6KA3*, *OPHN1*, *FACL4*, *DCX*, *PAK3*, *AGTR2*, *ARHGEF6*, *FMR1*, *FMR2*, *GDI1*, *SLC6A8* and *HUWE1*), with the purpose of evaluating if this new genomic mechanism could be related to cognitive function. The screening was conducted in 92 probands with idiopathic ID (82 from families with a possible history of XLID and 10 from ID affected sib pairs). All patients had normal karyotypes and mutations in *FMR1*, *FMR2* and *MECP2* genes were ruled out. DNA was extracted from peripheral blood and the presence of CNVs was evaluated through Multiplex Ligation-dependent Probe Amplification (MLPA), a method capable of detect CNVs in up to 50 different genomic DNA sequences. The MLPA analysis revealed two independent duplications involving probes for the *HUWE1* gene and the *GDI1* gene, confirmed by quantitative Real Time PCR. The clinical phenotypes of the patients bearing the duplications were not remarkable. The segregation analysis of HUWE1 gene shows that, although the duplication was maternally inherited, it not occurred on the ID affected brother of the proband, leading us to classify this CNV as benign. Conversely, the *GDI1* duplication was considered to be pathogenic and was also seen in a heterozygous state in the mother of the patient. Our results suggest that even though MLPA represents a reliable, easy and low cost effective method for evaluating CNVs, pathogenic CNVs do not appear to be a common etiological factor among our group of ID Brazilian patients. The more widespread use of array-CGH with increased resolution will make possible the identification of additional causal CNVs related to XLID.

Molecular Characterization of Autosomal Recessive Hyper IgE Syndrome in Saudi Arabia. *A. Hawwari, Z. Alsum, S. Al-Hisi, E. Borrero, H. Khalak, O. Alsmadi, R. Arnaout, A. Al-ghonaium, S. Al-Muhsen, H. Al-Dhekri, B. Al-Saud, H. Al-Mousa.* Genetics, Research Center, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia.

DOCK8 is a large protein that is highly expressed in the immune system especially in lymphocytes and has been recently associated with autosomal-recessive hyper-IgE syndrome (AR-HIES). Clinical data of 27 patients diagnosed with AR-HIES were collected from the pediatric clinic at KFSH&RC. Twenty two patients screened for STAT3, Tyk2 and Dock8 mutations. Two novel DOCK8 mutations that resulted in stop codons were found in nine patients. In addition, 4 patients from two separate families were found with 2 gross deletions. In one family the deletions spanned the entire Dock8 gene and the surrounding genes. In the other family, the deletion extended from somewhere at the tip of chromosome 9 to the middle of DOCK8 gene. No mutations were found in STAT3 or TYK2 genes in any of the patients screened. These mutations will be described and correlated to their clinical presentations.

De novo copy number variants associated to intellectual disability have a paternal origin and age bias. *J.Y. Hehir-Kwa[1], B. Rodríguez-Santiago[2], L.E. Vissers[1], N. de Leeuw[1], R. Pfundt[1], L.A. Pérez-Jurado[2], J.A. Veltman[1].* 1) Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Unitat de Genètica, Universitat Pompeu Fabra, and Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), Barcelona, Spain.

De novo mutations and structural rearrangements are a common cause of intellectual disability (ID) and other disorders with reduced or null reproductive fitness. Insight into the genomic and environmental factors predisposing to the generation of these de novo events is of significant clinical importance. In this study we used information from SNP microarrays to determine the parent-of-origin of 118 rare de novo CNVs detected in a cohort of 3,443 patients with ID. The large majority of these CNVs (76%, $p=1.14x10^{-8}$) originated on the paternal allele. This paternal bias was independent of CNV length and CNV type. Interestingly, the paternal bias was less pronounced for CNVs flanked by segmental duplications (64%), suggesting that molecular mechanisms involved in the formation of rare de novo CNVs may be dependent on the parent-of-origin. In addition, a significant increased paternal age was only observed for those CNVs which were not flanked by segmental duplications (p=0.009). This indicates that rare de novo CNVs are increasingly being generated with advanced paternal age by replication-based mechanisms during spermatogenesis.

1084T

Mitotic microhomology-mediated replication-based mechanisms underly non-recurrent pathogenic microdeletions of the *FOXL2* gene or its regulatory domain. *H. Verdin[1], B. D'haene[1], Y. Novikova[1], D. Beysen[2], P. Lapunzina[3], J. Nevado[3], C. Carvalho[4], J.R. Lupski[4], B. Menten[1], E. De Baere[1].* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Dept of Pediatrics, Ghent University, Ghent, Belgium; 3) Instituto de Genética Médica Y Molecular (INGEMM), Hospital Universitario La Paz, Universidad Autónoma de Madrid, Madrid, CIBERER, U783-ISCIII, Spain; 4) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Genomic disorders are often caused by recurrent pathogenic copy number variations (CNVs), with meiotic, non-allelic, homologous recombination as underlying mechanism. A recent study by Vissers et al. 2009 suggested that rare pathogenic CNVs spread throughout the genome are microhomology-mediated and stimulated by local genomic architecture. Here, it was our aim to study whether such mitotic mechanisms and local genomic architecture contribute to a series of non-recurrent, pathogenic, locus-specific CNVs. To this end, we fine-mapped 44 rare pathogenic microdeletions encompassing the *FOXL2* gene and neighbouring region (34), or its regulatory domain (10) respectively, both leading to blepharophimosis syndrome (BPES). For the breakpoint mapping we used targeted arrayCGH, qPCR, long-range PCR and sequencing of the junction products. Microhomology, ranging from 1 bp to 34 bp, was found in 86,7% of the breakpoint junctions, being significantly enriched in comparison with a random control population. This suggests that microhomology-mediated repair mechanisms, such as fork stalling and template switching (FoSTeS), microhomology-mediated break-induced replication (MMBIR), or alternative non-homologous end-joining (MMEJ), underly these microdeletions. Moreover, genomic architectural features, like sequence motifs, non-B DNA conformations and repetitive elements, were found in all breakpoint regions. In conclusion, we propose that the majority of these deletions is not caused by meiotic homology-based mechanisms but by microhomology-mediated replication-based mechanisms like FoSTeS or MMBIR, and thus have a mitotic origin instead. Finally the genomic architecture might stimulate the formation of these rare deletions by increasing the susceptibility for DNA breakage or promote fork stalling.

1085T

A *de novo* paradigm for intellectual disability. *L. Vissers, J. de Ligt, B. van Bon, C. Gilissen, M. Willemsen, I. Janssen, J. Schuurs-Hoeijmakers, M. Steehouwer, W. Nillesen, P. de Vries, K. van der Donk, B. van Lier, P. Arts, H. Scheffer, N. Wieskamp, M. del Rosario, A. de Brouwer, A. Hoischen, T. Kleefstra, B. de Vries, H. Brunner, J. Veltman.* Dept Human Genetics 855, Radboud University Nijmegen Medical Centre, Nijmegen Centre for Molecular Life Sciences, Nijmegen, Netherlands.

Recent studies have indicated that humans have an exceptionally high per-generation mutation rate of 7.6×10^{-9} to 2.2×10^{-8}. These spontaneous germ line mutations can have serious phenotypic consequences when affecting functionally relevant bases in the genome. In fact, their occurrence may explain why diseases with a severely reduced fecundity remain frequent in the human population, especially when the mutational target is large and comprised of many genes. This would explain a major paradox in the evolutionary genetic theory of cognitive disorders.

Previously, we have shown a family-based exome sequencing approach to test this *de novo* mutation hypothesis in 10 patients with unexplained intellectual disability. Unique non-synonymous mutations were identified and validated in nine genes. Six of these, identified in different patients, were likely pathogenic based on gene function, evolutionary conservation and mutation impact. These findings provided a strong experimental support for a *de novo* paradigm for intellectual disability.

The clinical relevance and ultimate proof for disease-causality of these novel genes lies in the identification of *de novo* mutations in additional patients of similar phenotype. As such, we are currently screening ~600 patients with unexplained intellectual disability for mutations in *YY1*, representing one of these newly identified genes. Moreover, we are extending our family-based exome sequencing approach to 100 patients to establish the diagnostic yield for *de novo* mutations in patients with unexplained intellectual disability.

A Cell-Based Translocation Assay System for Screening Plant Extracts for Fibroblast Growth Factor Receptor 3 (FGFR3) Modulators: Therapy of FGFR3-Related Skeletal Dysplasias and Cancers. *Y. Lee[1], C. Tai[1], C. Ko[1], R. Wu[2], K. King[2], Y. Chen[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) Development Center for Biotechnology, Taipei County, 221, Taiwan.

Activating germline mutations of fibroblast growth factor receptor 3 (FGFR3) cause various skeletal dysplasias. In somatic tissues, these mutations are associated with human cancers, making FGFR3 an excellent therapeutic target. Natural products have proved to be the most consistently successful source of drug leads. To identify potential therapeutic natural compounds for the treatment of diseases associated with FGFR3 activation, we established a cell-based protein translocation system. The U2OS cell line, which endogenously expresses FGFR-1, -2 and -4, but not 3, was chosen as the cell platform. We established that the GFP-tagged SH2 domain of the SH2-B) protein specifically interacted with and co-internalized with activated FGFR3, and is thus suitable as a probe for FGFR3 activation in U2OS cells. Proof-of-concept data from a pilot screen using PKC412, a tyrosine kinase inhibitor, as a control are presented. Four plant extracts that inhibited FGFR3 activation (hits) were identified. Furthermore, plant extracts from two closely related species of one hit also showed inhibitory activity against activated FGFR3. Our results show that this system offers a practical strategy for more definitive selectivity-evaluation and counter-screening in the early stages of drug discovery, and demonstrates therapeutic potential in the treatment of diseases associated with dysregulation of FGFR3 activation.

1087T

Molecular analysis of 246 patients with oculocutaneous albinism. *B. Arveiler[1,2], E. Lasseaux[2], C. Rooryck-Thambo[1,2], A. Rouault[2], D. Cailley[2], C. Plaisant[2], D. Lacombe[1,2], A. Taieb[3], F. Morice-Picard[1,2].* 1) Rare Diseases: Genetics and Metabolism, Univ Victor Segalen Bordeaux 2, Bordeaux, France; 2) Service de Genetique Medicale, Bordeaux Universitary Hospital, Bordeaux, France; 3) Service de Dermatologie, Bordeaux Universitary Hospital, Bordeaux, France.

Oculocutaneous albinism (OCA) is a rare autosomal recessive disease affecting 1/20000 person in the general population. OCA is caused by mutations in the TYR (OCA1), P (OCA2), TYRP1 (OCA3), and SLC45A2 (OCA4) genes. Mutations of GPR143 are responsible for X-linked ocular albinism (OA1). Due to extensive phenotypic heterogeneity and lack of genotype-phenotype correlations, molecular investigations are necessary to establish the diagnosis and to evaluate the relative frequency of the different forms of albinism. We analysed 246 patients from various origins (mainly Europe). Point mutations were analysed by DHPLC/HRM and sequencing of exons, intron-exon junctions and promoter regions. Gene dosage anomalies were investigated by semi-quantitative PCR (QMF-PCR) and, more recently, by high resolution (100 bp) array-CGH using a custom array covering the OCA1-4 and OA1 genes. The molecular analysis identified 141 point mutations (missense, nonsense, splice site) in TYR, 88 in P, 8 in TYRP1, 25 in SLC45A2 and 11 in OA1. We identified 3 deletions in TYR, 28 deletions and 2 duplications in P, and 2 deletions in SLC45A2. The relative frequencies of OCA1-4 were: 46.4% OCA1, 35% OCA2, 2.4%OCA3, and 16.2% OCA4. Despite the extensive analysis of the OCA1-4 and OA1 genes, a single heterozygous mutation was found in 28 patients (11.4%), and no mutation was found in 40 patients (16.3%). The thorough analysis of the OCA1-4 and OA1 genes in 246 patients allowed us to establish a diagnosis in 178 patients (72.3%).Intragenic microrearrangements accounted for 10.5% of the OCA1-4 alleles. It is worth noting that microrearrangements represented as many as 25.4% of all OCA2 alleles (including the common exon 7 deletion). This shows that microrearrangements should be searched for systematically in a diagnostic set up. Despite the thorough analysis performed, 27.7% of the patients remained undiagnosed. Mutations may therefore hide in unexplored regions of the genes (deep in introns, or in regulatory elements), or in other genes, which are either involved in syndromic forms of albinism or which still have to be discovered.

1088T

The LMNA c. 1968+5G>C transversion leads to progerin generation and Hutchinson-Gilford progeria syndrome. *V. Benoit[1], P. Hilbert[1], I. Maystadt[1], C. Gaspard[1], S. Castedo[2], T. Kay[3].* 1) IPG - Institut de Pathologie et de Génétique, Biologie Moléculaire, Charleroi, Belgium; 2) GDPN - Genética Médica e Diagnóstico Pré-Natal, Porto, Portugal; 3) Hospital Dona Estefania, Department of Clinical Genetics, Lisboa, Portugal.

Hutchinson-Gilford progeria syndrome (HGPS) is a very rare fatal genetic disorder characterized by precocious ageing in children. Children with HGPS appear healthy at birth and distinctive clinical features appear within the first years of life (including growth retardation, alopecia, lipodystrophy, and atherosclerosis). Most of them die from coronary artery disease at an average age of 13 years. Mutations in the Lamin A/C encoding gene (LMNA) are described to be responsible for the disease, most HGPS patients carrying the 1824C>T mutation (G608G) in exon 11. This transversion activates a cryptic donor splice site. Lamin A products in these patients then consist of mature Lamin A and progerin, a 50 amino-acids deleted Lamin A protein that exerts a dominant negative effect. In a 6 year-old patient affected by HGPS, we have identified a 1968+5G>C variation in the intron 11 of the LMNA gene. This mutation was not present in the DNA of the patient's parents, indicating that it arose de novo. This variant has already been evoked in the LOVD database; the question of its implication in HGPS has been raised but let unsolved with unknown pathogenicity. It seems that no further study has been undertaken as the question of a possible modified splicing still remained. We performed RNA studies and clearly showed that our patient's RNA generated different splicing products, including the normal one and at least one shorter form. By sequencing these products, we were able to demonstrate that this shorter form corresponds to a truncated RNA lacking 150 nucleotides and that the sequence perfectly matched the sequence of progerin. Taken together, our data unequivocally demonstrates that the c.1968+5G>C transversion is a causal mutation of HGPS. Moreover this work reinforces the concept of progerin involvement as a crucial actor in HGPS physiopathology.

1089T

Novel EVC and EVC2 mutations in Ellis-van Creveld syndrome and Weyers acrofacial dysostosis. *A. De Luca[1], M.C. D'Asdia[1,2], M. Magliozzi[1], R. Ferese[1,2], F. Consoli[1,2], V. Guida[1,2], L. Bernardini[1], M.C. Digilio[3], B. Marino[4], B. Dallapiccola[3], I. Torrente[1].* 1) Casa Sollievo della Sofferenza Hospital, IRCCS, San Giovanni Rotondo, Italy; 2) Department of Experimental Medicine, “Sapienza” University, Rome, Italy; 3) Bambino Gesù Children Hospital, IRCCS, Rome, Italy; 4) Division of Pediatric Cardiology, Department of Pediatrics, “Sapienza” University, Rome, Italy.

Ellis-van Creveld syndrome (EvC, MIM ID 225500) and Weyers acrofacial dysostosis (MIM ID 193530) are two allelic conditions that differ in the pattern of inheritance and severity of the phenotype. EvC is inherited as an autosomal recessive trait with variable expression, and Weyers acrofacial dysostosis is an autosomal dominant disorder. Two genes, EVC (MIM ID *604831) and EVC2 (MIM ID *607261), are found mutated in EvC patients. In patients with Weyers acrofacial dysostosis, convincing mutations have been identified in the last coding exon of EVC2. Here we present our experience with the direct analysis of the whole EVC and EVC2 coding regions in 26 independent families with clinical diagnosis of EvC and 2 families with clinical diagnosis of Weyers acrofacial dysostosis. We identified mutations in 21/26 (81%) cases with EvC and 2/2 cases with Weyers acrofacial dysostosis. Of the EvC cases, 16/26 (61%) had mutations in EVC and 5/26 (19%) were mutated in EVC2. The 2 cases with diagnosis of Weyers acrofacial dysostosis had a heterozygous mutation at the 3' end of the last exon of EVC2. We have not identified mutations in 5/26 cases who met our clinical criteria of EvC. SNP-array analysis of 3 cases in which we had not identified mutations in either gene revealed no pathogenic alterations in the DNA copy number. In EvC cases, 16 mutations in EVC and 4 mutations in EVC2 were novel. In patients with Weyers acrofacial dysostosis, one out of the 2 mutations was novel. Current findings expand the EvC and Weyers acrofacial dysostosis mutation spectra and provide further evidence that the 3' end of the last exon of EVC2 is a hot spot for Weyers mutations. Thus, it appears that EVC2 exon 22 should be analyzed with priority in patients with a phenotype consistent with Weyers acrofacial dysostosis. Failure to identify EVC and EVC2 mutations in 5 patients with EvC makes further genetic heterogeneity a possibility. A. De Luca and M.C. D'Asdia contributed equally to this work and should be considered co- first authors.

Screening for microdeletion/duplication syndromes and subtelomeric deletion/duplications in patients with unexplained mental retardation using MLPA analysis. *F.B. Essop, C.A. Robinson, A. Krause.* National Health Laboratory Service, Johannesburg, Division of Human Genetics, the National Health Laboratory Service and the University of the Witwatersrand; Johannesburg, Gauteng, South Africa.

BACKGROUND Mental retardation (MR) affects ~2-3% of the population. Subtelomeric rearrangements are reported to be the cause in 5-10% of idiopathic MR cases. Primary screening of such patients is done by karyotyping. When no abnormality is detected by these methods, multiplex ligation probe-dependent amplification (MLPA) analysis has been used. **OBJECTIVES** To evaluate MLPA as a diagnostic tool in patients with an unknown cause of MR. **METHODS** The P036 kit (MRC-Holland) probe mix consists of one probe for each subtelomere. The P245 probe mix simultaneously screens 21 loci associated with a microdeletion syndrome. Patients with known chromosomal abnormalities were used to validate the kits. A second kit, P070 was used to confirm a subtelomeric deletion/duplication found on the P036 kit. A total of 231 patients presenting with unexplained MR, referred over a 13 month period (July 2009 to Oct 2010) were tested. **RESULTS** 11/231 (4.76%) patients were found to have a subtelomeric deletion or duplication. 12/231 (5.19%) patients were found to have a microdeletion/duplication. 19/231 (8.23%) patients were found to have an interesting result in which the pathological significance of the deletion/duplication is unknown. **CONCLUSION** MLPA is a reliable and valuable method. The efficacy of this was demonstrated when 231 patients were tested and 9.96% abnormal cases were detected. Screening for microdeletion/duplication syndromes and for subtelomeric deletions/duplications by MLPA can be offered to all developmentally delayed patients, although clinical preselection increases the percentage of anomalies detected. Follow-up tests such as sequencing, FISH or a second MLPA kit must be done to avoid false positive results.

Detection of inherited mutations for Alport syndrome using Next Generation Sequencing. *P. Hilbert[1], M. Lizon[1], D. Goossens[2], J. Del-Favero[2], K. Dahan[1].* 1) Dept Molec Biol, Inst Pathologie et Génétique, Gosselies, Belgium; 2) Multiplicom NV, Waterfront Research Park, Galileïlaan, B-2845 Niel, Belgium.

Alport Syndrome is a progressive renal disease with cochlear and ocular involvement. The most common form (approximately 80%) is inherited in an X-linked pattern. The autosomal recessive and dominant forms constitute about 15% of the cases. X-linked Alport Syndrome is caused by mutations in the type IV collagen alpha chain 5 (COL4A5) whereas the type IV collagen alpha chain 3 (COL4A3) and 4 (COL4A4) are responsible for recessive and dominant Alport syndrome. Genetic testing for mutations in the respectively 52, 48 and 51 exons of COL4A3, COL4A4 and COL4A5 has become an integral part of clinical practice but the use of conventional Sanger sequencing is time-consuming and expensive. To determine whether amplicon based Next Generation Sequencing (NGS) would enable accurate, thorough, and cost-effective identification of Alport syndrome, we set up a project with Multiplicom (www.multiplicom.com) to design a two step multiplex PCR for the amplification of all the coding regions of the three responsible genes. 149 amplicons ranging from 270 Bp to 510 Bp were amplified in 4 multiplex PCR reactions. Genomic DNA from 24 patients with known inherited mutations or polymorphisms were studied. To differentiate patients within a single run, Multiple Identifiers (MIDs) were introduced during the PCR. The sequences were run on a GS-FLX 454 (Roche) (titanium chemistry) and analyzed with the SeqNext module of Sequence Pilot software (JSI medical). All the variants (21 mutations plus frequent SNPs) were confirmed and there were zero false positive calls. Our data confirm that amplicon based NGS will allow widespread genetic testing and genetic counseling for Alport syndrome.

Spinal Muscular Atrophy (SMA) in Singapore - an eleven-year experience in a diagnostic laboratory. *H.Y. Law, I.S.L. Ng, G.P. Tan, C.S. Yoon, E.S. Tan, S.S. Jamuar, A.H.M. Lai.* Dept Pediatrics, KK Women's & Children's Hosp, Singapore, Singapore.

Purpose: Spinal muscular atrophy (SMA) is one of the most common inherited childhood disease characterized by progressive muscle weakness, paralysis and eventually death. Our lab has been offering DNA analysis to confirm SMA since year 2000. This is to summarize our findings for SMA diagnosis in this major Children's Hospital in Singapore and to estimate the local carrier frequency. **Methods:** Homozygous deletion of *SMN1* gene was detected by restriction enzyme digest of PCR amplified exon 7 and 8 products of both *SMN1* and *SMN2* genes using forward primers modified to introduce *Hinf* I site for *SMN1* in the case of exon 7, and *Dde* I site for *SMN2* in the case of exon 8. Multiple Ligation-dependent Probe Amplication (MLPA) kit (MRC-Holland SALSA P021-SMA) was used to estimate gene copy number to confirm carrier status of parents of affected children with homozygous *SMN1* gene deletion. **Results:** SMA diagnostic test was carried out from year 2000-2010 for 101 children aged 2 days to 16 years and 23 adults 19 - 65 years at external adult neurologists' requests. Homozygous deletion of *SMN1* gene was confirmed in 45 children and 2 adults (19 and 29 year old). Age of onset and diagnosis for children were between 2 days to 6 months for 14 (30% Type I), 6 to 8 months for 7 (15% Type II), 10 months to 6 years for 23, and one child was diagnosed at 15 years old. This shows that 55% of patients had Type III SMA. With the ethnic composition of 74% Chinese, 13% Malay, 9% Indian and 3% other ethnicity in Singapore, our finding shows 29 SMA patients were Chinese (62%), 7 Malay (15%), 5 Indian (11%) and 6 others (13%). Carrier testing done for 14 couples whose children had homozygous deletion of *SMN1* found single copy *SMN1* gene in all individuals tested except for 2 spouses from 2 separate couples, who probably had “2+0” genotype (8%). Prenatal diagnosis was carried for 18 pregnancies of which 3 were diagnosed to have homozygous deletion of *SMN1*. **Conclusion:** Data collected over 11 years show an average of 4.2 SMA cases diagnosed per year. For over 35,000 deliveries each year, we approximate that the carrier frequency in Singapore is at least 1 in 50. Since our lab is only one of the 2 centres offering SMA test, the actual number of SMA diagnosed is likely to be more. Analysis of *SMN1* copy number in parents of SMA patients showed that carrier screening is feasible in this population.

Molecular screening of Ichthyosis Vulgaris in Iranian patients. *S. MATOO, N. HATAMNEJADIAN, A. YASARI MAZANDARANI, A. TAVAKOLI TAMEH, B. SEDAGHATI KHAYAT, M. MAHDAVI, SH. ABADPOUR, A. EBRAHIMI.* Dr.Ahmad Ebrahim Molecular Genetics ,PhD Parseh Medical Genetic Counseling center, Floor 7,NO.75,Royan Alley,Keshavarz Bolv. Tehran,Iran Tel-Fax:+98 21 88966579,88996889 E-mail:ae35m@yahoo.com.

Abstract Hereditary autosomal dominant Ichthyosis Vulgaris (IV), the most common form of ichthyosis, is a genetic disorder that can be caused by mutation in the Filaggrin gene (FLG) on 1q21.3. Although the prevalence of disorder depends on the location but there is a frequency about 1:250 - 1:5,000. Some common mutations were reported such as R501X and c.2282del4 among white individuals of European descent or 3321delA in Southern Chinese and Japanese cases. Methods: Fifty affected patients clinically diagnosed as IV were selected. The blood samples were collected and DNA was extracted. All 3 coding regions of FLG gene were amplified using intronic primers and the PCR products were analyzed by direct sequencing. Result: We found some novel sequence variations but the frequency of common reported mutations is lower than previously studied populations. According to the result, the molecular screening is recommended in order to clinical differential diagnosis. Keywords :Ichthyosis Vulgaris , FLG , PCR.

1094T

Identification of 15 novel mutations in Sotos syndrome. *S. Boulanger[1], M. D'amico[1], A. Destree[1], I. Maystadt[1], D. Lederer[1], H. Van Esch[2], J. Van Den Ende[3], N. Van Der Aa[3], K. Segers[4], P. Hilbert[1].* 1) Human Genetics Center, Institute of Pathology & Genetics, Charleroi, Belgium; 2) Human Genetics Center, K.U.Leuven, Belgium; 3) Department of Medical Genetics, University of Antwerp, Belgium; 4) Department of Human Genetics, CHU University of Liege, Belgium.

Sotos syndrome (MIM 117550) is a genetic disorder characterized by three cardinal features; distinctive facial appearance, overgrowth and learning disability. Moreover, major features can also occur ; behavioral problems, cardiac anomalies, renal anomalies, scoliosis and seizures. This syndrome is inherited in an autosomal dominant manner but more than 95% of patients have a de novo mutation. NSD1 (nuclear receptor SET domain1) is the only gene known to be associated with Sotos syndrome and a mutation in that gene is found in about 80-90% of affected individuals. The gene contains 23 exons encoding a 2696 amino acids protein. Depending on the criteria defined for patient screening, 27-93% (among non-Japanese individuals) of point mutations are found, approximately 5% of partial or total gene deletion and about 10% have a 5q35 microdeletion that encompasses NSD1 gene. The experience in our Human Genetics Center is based on a total of 86 patients presenting at least the 3 cardinal features but referred by different physicians working anywhere in Belgium. The entire coding region of NSD1 gene was sequenced and large rearrangements were investigated by MLPA (Multiple Ligation dependent Probe Amplification from MRC-Holland). We here describe the clinical features for 18 patients (~21%) for whom an intragenic mutation has been found. Among the mutations detected (6 nonsense, 7 missense and 5 frameshifts), 15 are novel . Up to now, no large rearrangements have been found in our population.

1095T

Detection of a mutation in Lenz microphthalmia family by exome sequencing. *T. Kaname[1], K. Yanagi[1], Y. Muramatsu[2], T. Tohma[3], H. Hanafusa[1], K. Morita[4], S. Ikematsu[4], Y. Itagaki[5], K. Kurosawa[6], S. Mizuno[2], K. Yoshiura[7], K. Naritomi[1].* 1) Dept Med Gen, Univ Ryukyus, Nishihara, Japan; 2) Dept Pediatr, Centl Hosp, Aichi Hum Serv Centr, Aichi, Japan; 3) Wanpaku Clinic, Okinawa, Japan; 4) Dept Biores Engr, ONCT, Okinawa, Japan; 5) Suita Municipl Hosp, Osaka, Japan; 6) Divn Med Genet, Clin Res Inst, Kanagawa Child Med Centr, Kanagawa, Japan; 7) Dept Hum Genet, Nagasaki Univ Grad Schl Biomed Sci, Nagasaki, Japan.

We present a large family with microphthalmia in Okinawa. In all male patients, bilateral microphthalmos, cardiovascular malformations, renal abnormalities, and mental retardation were observed. The pedigree showed X-linked recessive inheritance. Patients were diagnosed as having Lenz microphthalmia according to their clinical findings and the form of inheritance. Lenz microphthalmia syndrome was first described as a type of X-linked microphthalmia in 1955. It is known to exhibit genetic heterogeneity at this time, and two loci, Xq27-q28 and Xp11.4, have been mapped to be associated with the syndrome. In order to identify a mutation in the family, we performed exome sequencing by using a next generation sequencer and TruSeq Exome Enrichment system (illumina). To increase the sensitivity of detecting the mutation, pooled DNA with four affected males in the family was used for one exome sequencing. Of 552 called SNPs or indels on chromosome X, 51 were novel (not registered in SNP131). Then, four hemizygous (not detected as heterozygous) changes were found in exons. After comparison of exome data between affected and unaffected males, one substitution was identified and was confirmed by conventional direct sequencing in all the patients. The exome sequencing using pooled DNA of patients is effective and sufficient for mutation screening in families with X-linked recessive disorders.

1096T

Homozygous and heterozygous *IGFALS* mutations are detected in a significant fraction of patients with primary IGF-I deficiency and postnatal growth deficit. *A. Campos-Barros[1], S. de Frutos[1], E. Barroso[1], A. Gómez[1], R. Gracia-Bouthelier[2], J. Sánchez del Pozo[3], E. Gallego[3], K.E. Heath[1].* 1) Institute of Medical & Molecular Genetics (INGEMM), Hospital Univ. La Paz, UAM, IdiPaz, CIBERER, U753, Madrid, Madrid, SPAIN; 2) Pediatric Endocrinology, Hospital Universitario La Paz, Madrid, SPAIN; 3) Pediatric Endocrinology, Hospital Universitario 12 de Octubre, Madrid, SPAIN.

Introduction: Approximately 25% of proportionate short stature patients present with IGF-I deficiency in the face of normal or supranormal GH response tests, a condition defined as primary or idiopathic IGF-I deficiency. Dysfunctional *GH1* variants, mutations in the GHR coding gene, *GHR*, or in *STAT5b*, implicated in the post-receptor signalling pathway, explain a very low fraction of cases with primary IGF-I deficiency. On the other hand, recent reports have shown that mutations in *IGFALS* (16p13.3), encoding the acid-labile subunit (ALS) of the IGF-I/IGFBP-3/ALS ternary complex, may play a role in the etiology of primary IGF-I deficiency and short stature, indicating that ALS plays an important role regulating IGF-I bioavailability during postnatal growth. *Aim*: To investigate the frequency of *IGFALS* mutations in children with primary IGF-I deficiency and short stature without a known molecular defect. *Subjects*: 92 children with postnatal growth deficit (height <-2.0 SDS); decreased IGF-I (<-1.5 SDS) and normal or supranormal GH response tests. *Methods:* Mutation screening of coding sequences, intron/exon boundaries and known regulatory regions of *IGFALS*, *GHR*, *IGFBP3* and *IGF1* by HRM, DNA sequencing and MLPA. *Results*: We identified a total of 12 families with *IGFALS* mutations presenting 9 different mutations, 6 of which have not been previously described (p.S274F, p.R63G, p.L15dup p.R493H, p.T66K and p.L124P). Five unrelated families, sharing a common haplotype in the mutated allele, presented with the same mutation, N276S, previously described (Heath et al., 2008). Eight out of 9 mutations affect conserved residues, all located in leucine-rich repeat motifs of the mature ALS protein, whereas p.L15dup alters the hydrophobic signal peptide domain sequence of the precursor protein. None of the mutations were detected in 384 chromosomes from healthy controls. Two patients presented with a heterozygous *GHR* mutation, p.R229H, previously described (Goddard et al. 1995). ***Conclusions***: *IGFALS* mutations represent the most frequent molecular defect (13.0%) in the studied cohort of primary IGF-I-deficient patients with postnatal growth deficit. The detection of heterozygous *IGFALS* mutations in patients with decreased IGF-I, IGFBP-3 and ALS levels and postnatal growth deficit supports the hypothesis that ALS haploinsufficiency may be a factor involved in the etiology of moderate postnatal growth deficit associated with partial IGF-I deficiency.

We have analysed 215 cases with congenital hypothyroidism (CH) born to consanguineous families using microsatellite and sequencing analyses and found twelve mutations (seven novel) in TSHR and a mutational hotspot in exon 10 of the gene. Although the rate of mutation detection was low, our results revealed the TSHR as the major known-causative gene for the development of thyroid dysgenesis (CHNG) in consanguineous families. In silico analyses of the predicted structural effects of TSHR mutations indicated a good degree of correlation between the genotype and the disease phenotype. In addition we investigated the existence of the mutations we detected in fifty sporadic cases with CHNG, and found that these did not exist in non-familial cases. This study provides a clear evidence that TSHR is the primary known-locus for CHNG in consanguineous community, and that other Mendelian loci responsible for the development of the disease in the majority of cases remain unknown. Genome-wide autozygosity mapping studies we currently conduct in our cohort might help to identify novel genes causing congenital hypothyroidism.

Ghrelin, a ligand of the growth hormone (GH) secretagogue receptor (GHSR), is mainly known as the sole orexigenic hormone and as a strong stimulator of GH secretion. Surprisingly, murine models in which the ghrelin axis - i.e. ghrelin or its receptor - is disrupted do not show a pronounced lean and short phenotype, but mainly display subtle changes in glucose and lipid metabolism. So far, very few *GHSR* mutations have been implicated in short stature with or without altered GH secretion tests.

The objective if this study is (i) to further test the contribution of GHSR to isolated GH deficit (IGHD) and idiopathic short stature (ISS) and (ii) to provide a most complete description of the phenotype associated with each *GHSR* variation.

We screened the *GHSR* in 290 independent children with ISS or IGHD. We assessed the phenotype (height, weight, somatotrope investigation) of subjects carrying a *GHSR* variation. Constitutive activity, ghrelin response and cell surface expression of the new variants were assessed through appropriate in vitro assays.

Nine molecular defects were identified: in addition to three previously described mutations (A204E, W2X and R237W), we found six novel variations in the heterozygous state in six probands presenting with ISS (n=1) or IGHD (n=5). According to the functional studies that are underway, those *GHSR* mutations should account for 3 to 5% of the short stature phenotype in the study group. Except for W2X and R237W, short stature was transmitted in a dominant manner with incomplete penetrance. Variable expressivity of the disease phenotype was noticed. Several of the new variants so far studied showed an impaired constitutive activity associated or not with decreased cell surface expression.

This study, which strengthens the importance of GHSR constitutive activity in human growth, shows that GHSR mutations are responsible for at most 5% of short stature in humans.

1099T

Nonclassic Thyrotropin Resistance: *TSHR* Mutation Carriers with Discrepantly High Thyroidal Iodine Uptake. *S. Narumi[1], K. Nagasaki[2], T. Ishii[1], K. Muroya[3], Y. Asakura[3], M. Adachi[3], T. Hasegawa[1].* 1) Dept of Pediatrics, Keio Univ School of Med, Tokyo, Japan; 2) Dept of Pediatrics, Niigata Univ Medical and Dental Hospital, Niigata, Japan; 3) Dept of Endocrinology and Metabolism, Kanagawa Children's Medical Center, Yokohama, Japan.

Biallelic inactivating mutations in the thyrotropin (TSH) receptor gene (*TSHR*) are the chief molecular mechanism underlying end-organ insensitivity to TSH (*i.e.,* TSH resistance). Most patients with TSH resistance have low to normal thyroidal radioiodine uptake, which is consistent with the physiological knowledge that TSH stimulates iodine uptake via the Gs/cAMP pathway. To date, only one *TSHR* mutation-carrying family with discrepantly high thyroidal ^{123}I uptake has been reported[1].

In this study, we aimed to test whether *TSHR* mutation carriers with high ^{123}I uptake are observed in a cohort of Japanese patients with congenital hypothyroidism. We enrolled 24 Japanese patients having congenital hypothyroidism and high ^{123}I uptake, and sequenced *TSHR*. As a result, we identified two patients with biallelic *TSHR* mutations: p.[T145I]+[R450H] in one and p.[R450H]+[I661fs] in the other. The two subjects had slightly high ^{123}I uptake (41.8 and 43.0%, reference 8-40) but had a normal-sized thyroid. To verify the pathogenicity of the three mutations, we evaluated the capacities of mutant TSHRs to activate Gs- and Gq-coupled signaling pathways *in vitro*. Expression experiments revealed that T145I-TSHR retained partial ability to transduce both Gs- and Gq-coupled pathways, whereas I661fs-TSHR could transduce neither of them. R450H-TSHR had partial ability to transduce Gs-coupled signaling but had abrogated ability to transduce Gq-coupled signaling, indicating that coupling to Gq was dominantly affected.

In summary, we showed that 8% of Japanese congenitally hypothyroid patients with high ^{123}I uptake has inactivating *TSHR* mutations. Expression of this apparently discrepant phenotype, which we propose to term nonclassic TSH resistance, is presumably associated with the characteristic signaling property of the mutant TSHR, namely the Gq-dominant coupling defect.

Whole exome sequencing in *SCN1A*-negative Dravet syndrome reveals novel candidate genes and suggests genetic heterogeneity. *G.L. Carvill[1], S.C. Yendle[2], J. McMahon[2], J. Cook[1], S.F. Berkovic[2], I.E. Scheffer[2], H.C. Mefford[1].* 1) Division of Genetic Medicine, Department of Pediatrics, University of Washington, Seattle, WA; 2) Epilepsy Research Center and Department of Medicine, University of Melbourne, Australia.

Dravet syndrome is an early-onset epileptic encephalopathy characterized by a distinct seizure pattern and progression, as well as patient decline and ultimately severe disability. The molecular etiology of _75% of Dravet syndrome patients can be attributed to *SCN1A* heterozygous mutations, with 90% of mutations arising *de novo*. In addition, *PCDH19* mutations have been identified in a Dravet-like syndrome; single cases have been described with dominant *GABRG2* and recessive *SCN1B* alterations. Consequently, a quarter of Dravet syndrome patients lack a definitive molecular diagnosis. In order to identify novel candidate genes for Dravet syndrome, we performed exome sequencing in six *SCN1A* mutation-negative patients, including two parent-proband trios and four unrelated probands. A *de novo* disease model revealed an unexpected, previously unidentified *SCN1A* acceptor splice-site mutation in the proband of the first trio, thus validating this approach for disease-gene identification. The patient of the second trio carries a *de novo*, rare, missense mutation in *GABRA1*, a GABA receptor subunit, which was not present in 1200 control exomes. Given the established inhibitory neurotransmitter properties of GABA and associated receptors, along with previous reports of *GABRA1* variants in two unrelated cases of milder, generalized epilepsy, this gene is an excellent candidate for Dravet syndrome. Mutation screening in additional patients with Dravet syndrome is ongoing. Analysis of the four probands revealed no putative mutations in *SCN1A*, *GABRA1*, nor any other known Dravet gene. Moreover, there was no gene in which each of the remaining four probands carried a rare variant. These results suggest that non-*SCN1A* Dravet syndrome may be marked by diverse genetic heterogeneity. Two candidate genes have been identified based on the presence of rare (but distinct) variants in two of the four probands; familial segregation studies of these variants are underway. We are investigating additional rare, highly conserved (GERP>3.5) variants in a strategic manner based on the likelihood of the variant's deleterious effect. Genes harboring *de novo* variants will be assessed in additional patients. In conclusion, whole exome sequencing to detect *de novo* disease-causing mutations in a severe epilepsy syndrome is an effective approach and has identified at least one candidate gene for follow up in Dravet syndrome.

1101T

Refinement of the benign familial infantile seizures (BFIS) chromosome 16 epilepsy locus in a large Utah family. *N. Singh[1], R. Mao[1,4], E. Lyon[1,4], S. Shetty[1,4], M. Dixon[2], M. Leppert[2], F. Filloux[3].* 1) Pathology, Univ Utah, Salt Lake City, UT; 2) Human Genetics, Univ Utah, Salt Lake City, UT; 3) Pediatrics, Univ Utah, Salt Lake City, UT; 4) ARUP Laboratories, Salt Lake City, UT.

Current estimates suggest that up to 40% of childhood epilepsies are caused by inherited genetic defects. Information about the precise defect that causes such epilepsies reduces the need for invasive procedures to determine the cause of seizures and can provide a precise target for tailored therapies, both of which greatly reduce the burden to children and their family members. One such childhood epilepsy is the early-onset benign familial infantile seizures (BFIS). In these patients, seizures typically begin around 3-8 months, and are characterized by psychomotor arrest, cyanosis, head and eye deviation to one side, diffuse tonic contraction and bilateral clonic jerks. Seizures in BFIS often occur in clusters but are short-lived and disappear within a few days, weeks or months in all patients. The later development of children with BFIS is generally normal. However, other complications are known to occur in some families with BFIS, and these include debilitating migraine headaches and an involuntary movement disorder known as paroxysmal dyskinesia (PD). We phenotypically characterized and collected DNA samples from a large four-generation Utah family with BFIS. Of the 41 family members collected, 14 exhibited at least one seizure beginning as early as 2 months with the majority of individuals experiencing multiple seizures. Extensive follow up on affected individuals demonstrated that no individuals had seizures past early childhood, and adult patients did not experience migraines or paroxysmal dyskinesia. A genome-wide linkage analysis using an autosomal dominant inheritance model with 70% penetrance gave a maximum LOD score of 4.99 for the D16S746 marker on chromosome 16p11.1. Adjacent polymorphic markers localized a 0.67cM region of no recombination at 16p11.2-q12.1. Four obligate carriers and six non-penetrant individuals were also identified. A larger overlapping region on chromosome 16 has been previously shown in multiple studies to harbor a gene for both BFIS and BFIS with PD. While the genetic region identified in our study appears small, the physical region is approximately 16Mb and contains 54 UCSC genes. An 11Mb human genome sequence gap that flanks the chromosome 16 centromere contributes to the paucity of known genes in this large physical region. Further examination of this critical linkage region in affected individuals will include an Affy 6.0 SNP analysis and next generation sequencing.

Exclusion of known lymphedema genes in two families with severe congenital lymphedema. *M. Amyere[1], S. Greenberger[2], D. Chitayat[3], E. Pras[4], K. Chong[3], T. Uster[3], H. Reznik-Wolf[4], D. Marek-Yagel[4], L. Boon[5], M. Vikkula[1].* 1) Human Molecular Genetics, de Duve Institute, Brussels, Belgium; 2) Vascular Biology Program and Department of Surgery, Children's Hospital Boston and Harvard Medical School, Boston, MA 02115, USA; 3) Prenatal Diagnosis and Medical Genetics Program, Mount Sinai Hospital; University of Toronto, Toronto, Ontario, Canada; 4) Danek Gartner Institute of Human Genetics, Sheba Medical Center, Ramat-Gan, Israel; 5) Centre for Vascular Anomalies, Division of Plastic Surgery, Cliniques Universitaires Saint-Luc, Brussels, Belgium.

Lymphedema is a soft tissue swelling resulting from abnormal accumulation of interstitial fluid containing high molecular weight proteins due to abnormal drainage of lymph by the lymphatic vasculature. Primary lymphedema is due to an abnormal lymphangiogenesis which usually starts in utero. Some of the cases are inherited and in most cases have autosomal dominant or recessive mode of inheritance. Some of the autosomal dominant cases have incomplete penetrance and variable expression. Both syndromic and non-syndromic cases have been caused by mutations in genes with major role in lymphangiogenesis including FOXC2, VEGFR3, SOX18, CCBE1, PTPN14 and GCJ2. We report two consanguineous families with recurrence of an autosomal recessive form of congenital lymphedema. One of the families is of Iranian-Jewish and Israeli descent and the other of Iraqi descent. Direct sequencing of the known lymphedema genes including coding sequences and intron-exon boundaries, did not identify any mutation. Whole genome scan using Affymetrix SNP-Chip 250K was thus performed in both families and no copy number change was identified in the affected members. Autozygosity mapping and parametric linkage analysis also excluded the candidate lymphedema-genes. Three overlapping autozygous regions were identified in the two families and were confirmed by linkage analysis. Our findings provides evidence for the existence of new causative gene or genes associated with the autosomal recessive form of congenital lymphedema. (E-mail: Miikka.vikkula@uclouvain.be).

Genetic Linkage Analysis to Identify Susceptibility Loci for Primary Biliary Cirrhosis (PBC) in British Columbia's First Nations Peoples. *S. Asuri[1,2], S. McIntosh[1], L. Fields[1], L. Arbour[1,2].* 1) Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Division of Medical Sciences, University of Victoria, BC, Canada.

Introduction: While rare in most populations, PBC is highly prevalent in the First Nations (FN) population in British Columbia reflecting a referral rate for liver transplantation eight times higher than non-FN. PBC is a chronic autoimmune liver disease progressing from destruction of interlobular bile ducts to cirrhosis, often necessitating liver transplantation. It mainly affects women, in their 40-60s. Other autoimmune diseases frequently co-exist with PBC. Both genetic and environmental factors are considered to likely influence the pathogenesis. Genetic factors that predispose to PBC are continuously being elucidated and indicate population specificity. Our goal was to identify susceptibility loci that may contain genes predisposing to PBC in this population using genome wide family based linkage analysis. **Methods:** To date 130 FN participants from 31 families had enrolled in the study (45 affected and 85 without PBC) Two of three diagnostic criteria (positive AMA, increased liver enzymes, liver biopsy with defining features) were necessary for inclusion as a case. After review of medical records, anyone with inconclusive diagnosis, lack of DNA sample were excluded. The final whole-genome linkage which included 32 “affected” and 35 informative “unaffected family controls” from 26 families was performed using one array of the Affymetrix 5.0 set. *Merlin* was used to perform multipoint parametric and nonparametric linkage. Linkage disequilibrium was controlled for to prevent inflation of LOD scores. **Results:** The maximum LOD score of 2.3 was seen at chromosome 19p13 and LOD scores >2.0 were seen at 1q23, 6q21, 9q21, 17p13. Genes residing in these loci were identified as plausible candidates, including *ICAM-1, Netrin-1* (previous association with PBC), *RUNX-2*, *CDKAL1*, *STX-8*, *DNMT-1*, *TYK2* (association with other autoimmune disease), *Netrin-1*, *TrkB*, *TJP2*, *laminin(4*, *GAS7*, *Pin-1* (involved in apoptosis regulation), *PBX-1*, *CD2AP*, *WASF-1*, *Fyn* (regulation of immune signaling pathways such as *TGF-*) , *NF*2) , *IFN* pathway). **Conclusion:** As with other recent genome-wide analysis multiple loci were recognized to possibly contribute to genetic susceptibility for PBC. Although some loci contain genes previously implicated in PBC and other autoimmune diseases such as SLE, arthritis and psoriasis, unique loci harboring genes that may play a role in PBC pathogenesis were also identified. Further evaluation of this association is underway.

Linkage and homozygosity mapping identifies a 14 bp deletion in *CHX10* in families with microphthalmia and brain atrophy. *K.K. Selmer[1], G.D. Gilfillan[1], P. Strømme[2], O.J. Kanavin[2], T. Hughes[1,3], K. Brandal[1], R. Lyle[1], D.E. Undlien[1,3].* 1) Dept. of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Dept. of Pediatrics, Oslo University Hospital, Oslo, Norway; 3) Institute of Medical Genetics, University of Oslo, Oslo, Norway.

Anophthalmia and microphthalmia (AM) are common causes of blindness, and birth prevalence is approximately 30 per 100 000 individuals. More than half of the patients have a syndromic form with other clinical symptoms in addition to the eye anomalies.

The purpose of this study was to find the genetic cause of an autosomal recessive form of microphthalmia in three Pakistani families with one affected child each. All three patients were also severely affected by progressive and widespread brain atrophy. The families all originated from a small Pakistani village founded by eight brothers in the 1820's. Consanguineous marriages were common in this community and the parents in one of the three families were cousins. Linkage analysis in combination with homozygosity mapping was performed by genotyping SNPs genome-wide. The longest homozygous stretch shared by the patients was 2.4 Mb and reached the maximum possible LOD score for these families. This region was a strong candidate region, as it contained one of the genes known to be responsible for non-syndromic AM; the *CHX10* gene. This gene was sequenced and a 14 bp deletion in exon 3 was identified in all three patients. The deletion interrupted the reading frame and created a premature stop codon downstream from the deletion. As severe forms of brain atrophy have not been described in other patients with homozygous *CHX10* null mutations, we hypothesized that another linked gene was also homozygously mutated. Targeted DNA capture of the candidate region was performed and the DNA sequenced with the use of high throughput sequencing techniques. The sequencing of this region did not reveal any likely disease mutations.

We have identified a 14 bp deletion in three Pakistani families with microphthalmia and brain atrophy. Learning difficulties and autism have previously been described in patients homozygous for *CHX10* null mutations, so it is possible that our patients represent a severe form of this clinically heterogeneous disease. However, the severe brain involvement which led to death in all three patients, could also suggest that an additional, unknown disease locus is involved.

1105T

Role of Fragile X Related Proteins in mammalian circadian behaviors and glucose homeostasis. *J. Lumaban, D. Nelson.* Molec & Human Gen, Baylor College Med, Houston, TX.

Fragile X syndrome, the most common form of inherited developmental disability, results from the absence of the *fragile X mental retardation 1* (*FMR1*) gene product FMRP. *FMR1* has two paralogs in vertebrates: *fragile X related gene 1* and *2* (*FXR1* and *FXR2*). One of the behavioral symptoms observed in fragile X patients is the increased occurrence of sleep disorders. *Fmr1* or *Fxr2* knockout (KO) mice display a shorter free-running period of locomotor activity in total darkness (DD) compared to wild-type mice, while mice lacking both *Fmr1* and *Fxr2* (double knockout) exhibit complete loss of rhythmic activity in both the light:dark cycle (LD) and DD. DKO mice also display significant alterations in the cyclical patterns of abundance of core clock component messenger RNAs in the liver, but not in the suprachiasmatic nucleus. These findings suggest that Fmrp and Fxr2p are acting downstream of the central clock to control rhythm in mice, but it is unclear how the FXRs affect the peripheral outputs, such as in the liver.

Locomotor assays with restricted feeding demonstrate that the *Fmr1/Fxr2* DKO mice were able to adjust their rhythm to food availability. Remarkably, these mice also had a significantly higher mortality rate (~60%) in the first three days of restricted feeding, which suggests a difference in their physiological response to food restriction. Circadian cycling in the liver is known to contribute to glucose homeostasis, and we are testing for the specific involvement of FXRs in this system. In mice of similar body weight, body fat is significantly lower in the *Fmr1/Fxr2* DKO mice compared to WT. They had consistently low levels of glucose, cholesterol, and leptin over a 24hr cycle, while the cycling of the other metabolic markers in the blood- adiponectin, glycerol, free fatty acids, and triglycerides, but not insulin- is out of phase. The DKO mice also exhibited exaggerated clearance of a bolus of glucose, and hypersensitivity to insulin, even as both insulin production and gluconeogenesis appear normal. The close association of food input to the circadian system and the timing of sleep and wakefulness, together with the typical disturbances of circadian behavior and sleep in Fragile X syndrome, open up a new perspective for the investigation and treatment of patients suffering from this disorder.

Evaluation of a PCR-based assay using Sizing PCR in combination with CGG Repeat Primed (RP) PCR for FMR1 screening in a clinical setting. *K. Storm, N. Peeters, W. Wuyts, F. Kooy.* Department of Medical Genetics, University & University Hospital of Antwerp, Edegem, Antwerp, Belgium.

Abnormal expansion of the CGG repeat (> 200 CGGs) in the 5' untranslated region of the FMR1 gene (Xq27.3) causes Fragile X syndrome, a common cause of inherited mental retardation. This CGG expansion causes hypermethylation of the FMR1 promotor region resulting in FMR1 gene silencing. Smaller unmethylated CGG expansions have been associated with premature ovarian insufficiency (POI) and Fragile X tremor/ataxia syndrome (FXTAS). The CGG repeat lengths can be divided in four diagnostic categories: 1) normal alleles with ≤ 49 CGG repeats 2) gray zone alleles (50-58 CGGs) 3) premutation alleles (59-200 CGGs) and 4) full mutation alleles with more than 200 methylated CGG repeats. In our lab's routine Fragile X testing, the length of the CGG repeat is first sized by PCR with primers flanking the CGG repeat. If no normal allele is amplified in males or no heterozygosity for normal alleles is observed in females, further investigation by Southern blot (SB) analysis is required to detect/exclude larger CGG repeats and to examine the methylation status of the FMR1 gene. Although regarded as the golden standard, SB analysis is laborious, time consuming and requires large amounts of high quality DNA. We now evaluated a commercially available assay, Asuragen's CE-marked AmplideX FMR1 PCR Kit, by analyzing a heterogeneous set of DNA samples (from different matrices) including a whole range of FMR1 expansion types (normal, gray zone, premutation, full mutation and mosaic samples of both genders) that were previously characterized by PCR and SB in our lab. We were able to detect retrospectively all known expansions, including mosaic patterns. Homozygous, heterozygous (resolution of 1 repeat) and expanded allele carrier status could reliably be determined in females. Exact sizing was possible for a spectrum of premutation alleles. The assay is also sensitive to size mosaicism and AGG interruptions. In conclusion, this PCR-based assay provides a final conclusion for the large majority of referred cases and reduces the need for SB testing. For a minority of samples, a methylation-sensitive test is still required to unequivocally distinguish (large) premutation alleles from (small) full mutation alleles where correct interpretation still depends on methylation status.

1107T

Functional Characterization of novel variants in Noonan Syndrome. *J.J. Lee[1], B.H. Lee[1,2], J.M. Kim[1], G.H. Kim[1], J.H. Choi[2], H.W. Yoo[1,2].* 1) Medical Genetics Center, Asan Medical Center, Seoul, Korea; 2) Dept. pediatrics, Asan Medical Cetner Children's hospitol, Seoul, Korea.

Noonan syndrome (NS) exhibits functional alterations of the Ras-mitogen-activated protein kinase (MAPK) pathway. Mutations in *PTPN11* (39.0%), *SOS1* (20.3%), *RAF1* (6.8%), *KRAS* (5.1%), and *BRAF* (1.7%), encoding the members of the Ras-MAPK pathway, were identified in 59 Korean patients with NS. Among these, p.P261T and p.S259T of *RAF1* and p.K170E of *SOS1* were not previously reported. All these mutations are located on highly conserved sites. In silico analyses also predicted these variants as mutations. p.P261T and p.S259T are located in conserved region 2 (CR2) domain of RAF1. The phosphorylated status of p.S259 in the CR2 domain suppresses RAF1 activation in the resting state; when GTP-Ras binds RAF, this residue becomes dephosphorylated, leading to a partial disinhibition or activation of RAF1. In particular, the mutations in two variants, p.S259T and p.P261T, were located at or near the p.S259 residue. Accordingly, their in vitro activities were higher than those of wild-type RAF1 in the presence of growth factor. On the other hand, p.K170E in *SOS1* is located in the HF domain, where NS mutations have rarely been reported. The HF domain is predicted to interact with the pleckstrin-homology (PH)-RAS-exchange motif (Rem) domain linker or helical linker. The ionic interactions between p.R552 or p.S548 in the PH-Rem linker and p.D140 and p.D169 in the HF domain are critical for stabilizing this autoinhibitory conformation of SOS1. p.K170E is located near these ion-pair connections and expected to affect this pairing, partially disrupting the autoinhibitory conformation to expose the Ras-binding site, even in the resting state. Consistent with this inference, endogenous expression of the Ras-GTP complex was higher in the COS-7 cells expressing p.K170E than in those expressing wild-type SOS1. In conclusion, our study helps to understand molecular pathogenic mechanisms underlying NS.

Congenital diarrheal disorders: translating whole exome sequencing to the clinic. *M. Yourshaw, D. Liu, S.F. Nelson, M. Martín.* University of California Los Angeles, Los Angeles, CA.

Selective and generalized nutrient malabsorption causes chronic diarrhea and may require life-long total parenteral nutrition (TPN). Although several mutations have been identified that cause generalized malabsorptive diarrhea (GMD), many cases have an unknown genetic etiology. Metabolic profiles and histology may be insufficient to indicate appropriate genetic testing and to diagnose and prescribe treatment for such cases. We selected a number of patients for unbiased whole exome sequencing. Sequencing libraries were prepared from sheared DNA that had been extracted from saliva samples. The libraries were enriched for protein-coding regions of the genome by in-solution capture with RNA probes. Libraries were sequenced on either the SOLiD or Illumina platforms. The short sequencing reads were aligned to the reference human genome. Mean oversampling of bases was ~40X and ~25% of the ~45Mb targeted exome was read at least 10X. Variants were identified and filtered on sequencing and mapping quality. We filtered for alleles that would adversely affect protein coding or splicing, and that were not found in dbSNP or control exomes. Using custom software, under a recessive model, we searched for potentially harmful variants that were homozygous or compound heterozygous. In instances where DNA from affected siblings was available, we required that both siblings have the same alleles. In addition to identifying a number of alleles that require further functional validation, we identified a single plausible variant genome-wide in one patient: a novel nonsense mutation in proprotein convertase subtilisin/kexin type 1 (PCSK1), a calcium activated serine endoprotease, A deficiency in PCSK1 can lead to a diverse combination of symptoms including severe enteropathic diarrhea and diabetes insipidus. This information was instrumental in diagnosing previously unsuspected diabetes in this patient and led to appropriate treatment.

Demonstration of the interactions of genes and environment in determining the phenotype of a genetic disease using a mouse model of a fatty acid oxidation disorder. *W. Wang[1], A.-W. Mohsen[2], J. Palmfeldt[3], M. Barmada[1], Y. Wang[2], N. Gregersen[3], J. Vockley[1,2].* 1) Department of Human Genetics , Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA, USA; 2) Department of Pediatrics,School of Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 3) Research Unit for Molecular Medicine, Institute of Clinical Medicine, Aarhus University Hospital and Faculty of Health Sciences, University of Aarhus, Aarhus, Denmark.

Objective:Gene-environment interactions are typically measured in epidemiological studies. Ascertaining reproducible cellular change in genetically susceptible individuals to environmental exposure remains a challenge. Restricting the search for interactions to gene products that interact in relevant biological pathways is promising. Very long chain acyl-CoA dehydrogenase (VLCAD) deficiency identified through newborn screening is a clinically heterogeneous fatty acid) -oxidation disorder without clear genotype-phenotype correlations. Acute symptoms are often induced by stress. We studied fasting effects using a genetic mouse model to explore changes in gene-environment interaction and identify gene-gene interactions in associated pathways. Methods:The mitochondrial proteome of VLCAD deficient mice was quantitatively compared to wild type mice in fed and fasted states. iTRAQ labeling with nano-LC/LTQ-Orbitrap mass spectrometry was employed to identify the changes in both deficient and wild type groups and the differences in response to fasting. The affected pathways were evaluated using Ingenuity Pathway Analysis and a regression model was applied to assess the changes associated with ACADVL gene and fasting. Results: We identified numerous proteomic changes associated with gene deficiency and fasting as well as gene-gene interactions within relevant pathways. Most of changes induced by fasting were different and few changes were shared in the mutant and wild type mice. The pattern of changes in chaperone proteins including HSPD1 and HSPE1 upon fasting was different in them. Two consensus proteins NUDT7 and NLTP were altered in deficient mice regardless of feeding status. Fasting reversed the compensatory increase in oxidative phosphorylation in fed deficient mice. Secondary changes in fasted deficient mice were involved in cardiac dysfunction. Conclusion: Fasting induced different proteomic changes in deficient mice indicate differences in the interactions of genes and gene-environment, and important roles of these interactions in the pathogenesis of VLCAD deficiency. Particularly, fasting in mutants reversed the protective response in specific pathways induced by genetic deficiency alone. Our system presents an approach to explore gene-environment interaction and their contribution to gene-gene interactions. Future characterization of functional interactive genes and association studies in humans will provide further insight into disease mechanism.

1110T

Identification of a Novel Gene for Autosomal Dominant High-grade Myopia Using Whole Exome Sequencing. *T. Young[1,2,3], A. Powell[2], T. Klemm[3], S. Rozen[3], V. Soler[2], T. Yanovitch[1], E. Nading[1], F. Hawthorne[2], L. Goh[3], K-N. Tran Viet[2].* 1) Pediatric Ophthalmology, Duke Univ Eye Ctr, Durham, NC; 2) Duke Center for Human Genetics, Duke University Medical Center, Durham NC; 3) Duke- National University of Singapore, Singapore.

Purpose: To identify a gene for autosomal dominant high-grade myopia in a large Caucasian pedigree using deep sequencing technology. Methods: A 15-member family with high-grade myopia (8 affected, mean affected dioptric spherical equivalent of -12.00) was ascertained. Next-generation sequencing at 50X using the Illumina Hi Seq technology and whole exome capture processing was performed. Sequence reads were aligned, and processed for single nucleotide variant and insertion/deletion calls. In-house pipeline filtering analyses along with comparisons using the 1000 Genomes and dbSNP databases were performed. Expression studies using RT-PCR of extracted mRNA converted to cDNA of systemic and ocular tissues were performed using exon-specific primers. GAPDH primers were designed for housekeeping expression studies. Results: A novel premature stop codon mutation Q53X was discovered for the gene SCO2 which maps to chromosome 22q13.33. This followed segregation in all affected family members, and was not found in 800 control DNA samples. Expression of SCO2 was determined in the retina, retinal pigment epithelium, and sclera of 24 week fetal and adult eye tissues. Conclusions: An SCO2 gene mutation was found to segregate with high-grade myopia in a large autosomal dominant pedigree. The gene product is implicated in cellular copper homeostasis. Copper deficiency has historically been associated with myopic refractive error development. A biologic mechanism for this gene may involve poor collagen and elastin cross-linking of the scleral wall, and/or subtle retinal photoreceptor alteration. This is the first identification of a novel causative gene for autosomal dominant high-grade myopia.

Interferon gamma impact on Epidermolysis Bullosa Simplex in patients with keratin 14 mutations. *T. Farez[1], M. Bchetnia[1], M. Tremblay[1], G. Leclerc[2], A. Dupérée[2], J. Powell[3], C. McCuaig[3], C. Morin[2], V. Legendre-Guillemin[1], C. Laprise[1].* 1) Dept Sciences fondamentales, universite du Quèbec à Chicoutimi, Saguenay, Canada; 2) Centre de santé et de services sociaux de Chicoutimi, Saguenay, Canada; 3) Hôpital Sainte-Justine, Montréal, Canada. Hôpital Sainte-Justine, Montréal, Canada. Hôpital Sainte-Justine, Montréal, Canada.

Scientific context: Epidermolysis bullosa simplex (EBS) is a rare genetic disease characterized by basal keratinocytes cytolysis, intraepidermal blister formation and skin fragility. EBS is classified into different phenotypes according to the severity: EBS-localized (EBS-loc), EBS-generalized (EBS-gen) and EBS-Dowling-Meara (EBS-DM). It is generally inherited in an autosomal dominant manner and caused by mutations in keratin 5 (KRT5) or keratin 14 (KRT14) genes. In normal cells, both keratin types are associated to form an intermediate filaments network that allows maintaining skin integrity. In EBS, mutations lead to disruption of intermediate filaments assembly. In addition to type I keratin 5 (K5) and type II keratin 14 (K14), the epidermis basal layer produces keratin 15 (K15), that also belongs to type II keratin. Radoja and al. (2004) have suggested that stimulating K15 production could remedy to cytoskeleton defects in EBS harboring K14 mutations by forming heterodimers with K5. More therapeutic molecules need to be tested in order to reduce the symptoms or cure this disease and modulation of K15 could be a promising avenue. Objectives: Based on literature data, our interest focused on the effect of interferon gamma (IFN-.) on cultured keratinocytes from EBS KTR14 mutants by analyzing K15 production level. Methods: Samples consisted of 3 immortalized keratinocyte cell lines isolated from patients (1 EBS-DM and 2 EBS-loc) and 3 isolated from controls. A dose-response with IFN-. was performed for 48 hours. The amount of K15 was measured by Western blot. KRT15 gene expression level was measured by qRT-PCR. Results: The amount of K15 is decreased with increasing amount of IFN-. . This decrease is more important in patient's cell lines than in control ones. The qRT-PCR data validates these results. Indeed, KRT15 RNA expression is decreased in presence of IFN-. but tendency did not reach significance. Conclusion: These results suggest that IFN-. reduces K15 production in EBS.

1112T

Potential therapeutic target of 185delAG, 5382insC, as two types of mutations in BRCA1, in breast cancer. *H. Fiuji[1], A. Avan[2, 3], M. Maftouh[3], R. Mirhafez[4], A. Avan[5].* 1) Department of Biochemistry, Payam Nour University, Mashhad, Iran; 2) 3. Department of Clinical Genetics, Section Oncogenetics, Medical Faculty, VU Medical Center Amsterdam, Amsterdam, The Netherlands; 3) Department of Medical Oncology, VU Medical Cancer Center Amsterdam, VUmc, PO Box 7057, 1007 MB, Amsterdam, The Netherlands; 4) 4. Department of Modern Sciences and Technologies, Faculty of Medicine, Mashhad University of Medical Science, Mashhad, Iran; 5) Clinic of Wilson's disease, Imam Reza Hospital, Tabriz University of Medical Sciences, Tabriz, Iran.

BRCA1 is one of the most important genes that is interfering with other genes particularly BRCA2, p53, which can be crucial for breast and ovarian cancer. In this abstract we have shown two significant mutations and its role on protein encoding. Investigation of these prevalence mutations in BRCA1, 185delAG, 5382insC, can give a clue for curing breast and ovarian cancers.massive activity of BRCA1 and taking part in cell as maintaining genome by engaging in DNA repair, cell cycle check point control and also mitotic or cell division steps show the significant role of this gene. 185delAG, 5382insC which have located on exon2 and exon 20, respectively, bring about to produce of deficient protein (BRAt). These are prevalence mutations among major population in the world, however, these mutations has found essentially in the Jewish- Ashkenazi with high frequency in the family breast and ovarian cancers, resulting in interbreeding among the group. This group has ancestors from Eastern and central Europe and 1% of this population are carriers of the most common founder mutation, the BRCA1 185delAG and 5382insC truncation. These are frame shift mutation that results in a premature stop signal at codon 39, 1829Ter, for 185delAG and 5382insC, respectively in the BRCA1 protein. This mutation is also carried by significant numbers of non-Jewish Spanish, Spanish Gypsy, and women of mid-eastern decent. Women carrying these mutations have an approximate 65% lifetime risk for developing breast cancer and 15%-54% lifetime risk for developing ovarian cancer.taken together, 185delAG and 5382insC have critical points for BRCA1 gene structure and produce of truncations protein causing to influence on breast and ovarian cancers. These mutations are founded among the other different country populations and it shows global prevalence of them. Furthermore, our results also suggest the presence of these two mutations in some of the Iranian patients and also, highlight its potential as a therapeutic target for treatment of breast and ovarian cancers.

1113T

Deletion of Porcn in mice confirms that defective WNT signaling causes the features of human Goltz syndrome (Focal Dermal Hypoplasia). *W. Liu[1], T. Shave[2,4], X. Wang[1], A. Balasa[3], S. Wen[1], H. Nguyen[2,4], I. Van den Veyver[1,5,6].* 1) Dept OB/GYN, Baylor Col Med, Houston, TX; 2) Dept MCB, Baylor Col Med, Houston, TX; 3) Dept Pediatrics, Baylor Col Med, Houston, TX; 4) Stem Cells and Regenerative Medicine Center, Baylor Col Med, Houston, TX; 5) Dept MHG, Baylor Col Med, Houston, TX; 6) The Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston TX.

Focal Dermal Hypoplasia (FDH) is caused by dominant loss-of-function mutations in X-linked PORCN. PORCN orthologues in Drosophila and mice encode endoplasmic reticulum proteins required for secretion of Wnt proteins. Hence, the pleiotropic features of FDH likely result from defective WNT signaling, but molecular proof and animal models have been lacking. We generated conditional Porcn mutant mice by introducing intronic loxP sites and a neomycin gene in the mouse Porcn locus for conditional inactivation. Porcn-ex3-7flox mice have no apparent developmental defects, but chimeric mice retaining the neomycin gene (Porcn-ex3-7Neo-flox) have limb, skin and urogenital abnormalities. Conditional Porcn inactivation by EIIa-driven Cre-recombinase results in increased embryonic lethality. Prx-Cre driven inactivation produces FDH-like limb defects, while Krt14-Cre driven inactivation produces alopecia and abnormal dentition. Cell-based assays confirm that human PORCN mutations can reduce WNT3A secretion. Combined with findings on the Porcn animal model, this demonstrates that human FDH indeed results from defective WNT-signaling.

1114T

Increased oxidative stress in Nijmegen Breakage Syndrome results from PARP hyperactivation after DNA damage. *M. Digweed, H. Krenzlin, I. Demuth, B. Salewsky.* Institute of Medical and Human Genetics, Charité - Universitätsmedizin Berlin, Berlin, Germany.

The NBN gene codes for the protein nibrin, an integral member of the MRE11/RAD50/NBN (MRN) complex essential for the processing of both physiological DNA double strand breaks and those resulting from exposure to ionizing radiation. Hypomorphic mutation of the NBN gene underlies Nijmegen Breakage Syndrome (NBS), an autosomal recessive genetic disease. The cardinal features of NBS can be attributed to a failure in DSB repair/processing: immunodeficiency, radiosensitivity, meiotic failure and an extremely high incidence of malignancies. The occurrence of cancer is particularly high in NBS compared to other genetic instability syndromes and is even increased amongst heterozygous relatives. In order to understand this tumor predisposition we have been examining effects of NBN mutation beyond the DSB repair defect itself. Such studies in conditional NBN null mutant mice have indicated disturbances in redox homeostasis. Clearly this could contribute to DNA damage, an increased mutation rate and cancer. Indeed, several hours after exposure of mouse cells to a mutagen, the complete absence of nibrin results in high levels of reactive oxygen species. The same is true, if not so pronounced, for NBS patient cells. This increased oxidative stress is caused by depletion of NAD+ due to hyperactivation of the strand-break sensor, Poly(ADP-ribose) polymerase. Indeed, specific inhibition of PARP reverses the oxidative stress phenotype of both null mutant nibrin mouse cells and NBS patient cells. We conclude that the increased mutation rate in NBS patient cells and the extremely high incidence of malignancy amongst patients is due to the combination of a primary DSB repair deficiency with secondary oxidative DNA damage.

1115T

Dominant mutations in RP1L1 are responsible for occult macular dystrophy (Miyake's Disease). *T. Iwata[1], M. Akahori[1], K. Tsunoda[1], Y. Miyake[1, 2], Y. Fukuda[3], H. Ishiura[3], S. Tsuji[3], T. Usui[4], T. Hatase[4], M. Nakamura[5], H. Ohde[6].* 1) National Institute of Sensory Organs, Tokyo, Japan; 2) Aichi Medical University, Aichi, Japan; 3) University of Tokyo, Tokyo, Japan; 4) Niigata University, Niigata, Japan; 5) Nakamura Eye Clinic, Nagoya, Japan; 6) Keio University, Tokyo, Japan.

Occult macular dystrophy (OMD, Miyake's Disease) is an inherited macular dystrophy characterized by progressive loss of macular function but normal ophthalmoscopic appearance. Typical OMD is characterized by a central cone dysfunction leading to a loss of vision despite normal ophthalmoscopic appearance, normal fluorescein angiography, and normal full-field electroretinogram (ERGs), but the amplitudes of the focal macular ERGs and multifocal ERGs are significantly reduced at the central retina. Linkage analysis of two OMD families was performed by Affymetrix SNP 6.0 array and the SNP High Throughput Linkage analysis system (SNP HiTLink). Coding exons of four protein coding genes in the candidate region were analyzed for sequence variations by direct DNA sequencing. Immuno-staining for RP1L1 was carried out on frozen sections of normal cynomolgus and paraffin section of normal marmoset. Genome wide linkage analysis localized the disease locus to chromosome 8p22-p23. Among the 128 genes in the associated region, 22 genes were expressed in the retina, and four candidate genes were selected. No mutations were found in the first three candidate genes, methionine sulfoxide reductase A (MSRA), GATA binding 4 (GATA4), and pericentriolar material 1 (PCM1), however, amino acid substitution of p.Arg45Trp in retinitis pigmentosa 1-like 1 (RP1L1) was found in three OMD families and p.Trp960Arg in a remaining OMD family. These two mutations were detected in all affected individuals but none in 876 controls. Immunohistochemistry of RP1L1 in the retina section of cynomolgus and marmoset monkey revealed expression in the inner segment of rod and cone photoreceptor, supporting a role of RP1L1 in the photoreceptors that, when disrupted by mutation, leads to OMD. Identification of RP1L1 mutations as causative for OMD has potentially broader implications for understanding the differential cone photoreceptor functions in the fovea and the peripheral retina. The function of RP1L1 is being investigated.

DOOR syndrome is a rare disorder characterised by sensorineural hearing loss, hypoplastic or absent nails on hands and feet and intellectual disability. Additional clinical features include seizures from infancy, optic atrophy, polyneuropathy, and, sometimes, dental, cardiac and renal abnormalities. Autosomal recessive inheritance has been suggested, although de novo dominant mutations cannot be excluded as causal. We have sequenced exomes of three unrelated patients with DOOR syndrome. Agilent SureSelect Exome capture followed by 90bp pair-end sequencing on Illumina HiSeq platform was used to sequence the exomes to >40x average read depth. The reads were aligned using Novoalign software, and single nucleotide variants and indels were identified and annotated using a combination of Samtools, Dindel, Annovar software and in-house scripts. Since DOOR syndrome is a very rare condition with just over 30 patients having been described in the literature so far, we used strict filtering to reduce the number of potential candidate causal variants. Filtering included removing variants described in dbSNP build 130, 1000 Genomes Project, 46 controls genomes released by Complete Genomics and an in-house database of 224 sequenced exomes, as well as removing genes in which loss-of-function variants are frequent. To identify candidate causal variants, we then investigated both autosomal recessive and de novo dominant mutation models. We used homozygosity mapping in a patient from a family with known consanguinity to identify 11 identical-by-descent candidate genes harbouring non-synonymous coding variants. None of the other two unrelated patients had rare homozygous or compound heterozygous variants in these genes. No other gene had homozygous or compound heterozygous rare variants in all three patients. To investigate a de novo dominant mutation model, we looked for the genes that had rare loss-of-function, non-synonymous or essential splice-site variants. No genes had such changes in all three patients, and 37 genes had such changes in two patients. Further evaluation in family members and unrelated patients is underway.

1117T

Mapping of a lethal disorder with pulmonary hypertension and limb deficiency. *D.C. Lynch[1], K.M. Boycott[2], D.E. Bulman[3], J.S. Parboosingh[1], A.M. Innes[1].* 1) Medical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada; 2) Children's Hospital of Eastern Ontario, Ottawa, Ontario; 3) Ottawa Hospital Research Institute, Ottawa, Ontario, Canada.

The Hutterite population of North America is a genetic isolate and provides a powerful opportunity for mapping genetic diseases. Several Mendelian disorders are present in the population, some of which are unique to or overrepresented in the Hutterites. Alveolar capillary dysplasia (ACD) is a rare and invariably lethal form of persistent pulmonary hypertension of the newborn. A distinct form of ACD has been reported in the literature associated with bilateral tibial agenesis and missing digits, which we have termed alveolar capillary dysplasia with limb deficiency (ACD-LD). The objective of this study is to map a locus and identify a mutation for ACD-LD, which is presumed to follow an autosomal recessive pattern of inheritance. We studied one Hutterite family which includes two children with a disorder resembling ACD-LD and two unaffected siblings. Due to the endogamous nature of the population, a homozygosity mapping approach was used. A 27 Mb region of shared homozygosity in the patients was identified on chromosome 10 using an Affymetrix Genome-Wide Human SNP Array 6.0 and genotyping with microsatellite markers. Two genes within the region, NRP1 and BAMBI, were prioritized for sequencing due to their potential involvement in lung vascular and/or limb development, but no mutations were identified. Within our lab, whole exome sequencing in as little as one Hutterite patient has been shown to be an efficient method of disease gene identification when paired with homozygosity mapping. Whole exome sequencing using the Agilent SureSelect platform is underway; analysis of the genes within the linkage interval is expected to reveal a putative mutation.

1118T

Whole exome sequencing in a consanguineous pedigree reveals 2 novel RYR1 mutations in patients with complete external ophthalmoplegia. *S. Shaaban[1,2,3], C. Andrews[1,2,3,4], J. Demer[5], E. Engle[1,2,3,4,6,7,8].* 1) Neurology, Children's hospital Boston, Boston, MA; 2) FB Kirby Neurobiology Center, Boston, MA; 3) Harvard Medical School, Boston, MA; 4) Howard Hughes Medical Institute, Chevy Chase, Maryland; 5) Ophthalmology, Neurology, Bioengineering and Neuroscience Interdepartmental Programs, Jules Stein Eye Institute, University of California, Los Angeles, California; 6) Medicine (Genetics), Children's hospital Boston, Boston, MA; 7) Ophthalmology,Children's hospital Boston, Boston, MA; 8) Manton Center for Orphan Disease Research,Children's hospital Boston, Boston, MA.

Three affected children (2 sibs and a first cousin once removed) of a consanguineous pedigree of Mexican ethnicity presented to ophthalmology with complete ophthalmoplegia, ptosis and facial diplegia and were also noted to have developmental delay and hypotonia. The presentation was consistent with atypical Moebius syndrome, while MRI revealed normal cranial nerves in the subarachnoid space and hypoplastic extraocular muscles (Dumars et al.J AAPOS. 2008 Aug;12(4):381-9). Array-based linkage and homozygosity analysis highlighted a 7.8 Mb region of shared homozygosity on chromosome 19 between the three affected children. Whole exome sequencing of one of the sibs and the cousin revealed 2 novel missense mutations at RYR1 gene which fell within the region of homozygosity. The 2 mutations segregated with the affection status in the pedigree, altered evolutionary conserved residues, and were predicted to be damaging by Polyphen 2 and Pmut. RYR1 encodes a ryanodine receptor found in skeletal muscle and RYR1 mutations have been previously reported in malignant hyperthermia susceptibility, central core disease, and minicore myopathy with external ophthalmoplegia; the latter seems to be the diagnosis in our patients. Utilizing linkage, homozygosity analysis and the new technology of next generation sequencing helped redefine the phenotype and delineated the genetic etiology underlying the phenotype in our pedigree.

1119T

PKD1 and PKD2 gene variation in Italian patients affected by Autosomal Dominant Polycystic Kidney Disease (ADPKD). *P. Carrera[1, 2], F. Rigo[1], S. Calzavara[2], C. Montrasio[2], P. Messa[5], A. Edefonti[5], R. Magistroni[6], F. Scolari[7], P. Manunta[4], A. Boletta[3], M. Ferrari[1, 2, 4].* 1) San Raffaele Scientific Institute, Center for Translational Genomics and Bioinformatics, Milano, Italy; 2) Diagnostica e Ricerca San Raffaele, Milano, Italy; 3) San Raffaele Scientific Institute, Division of Genetics and Cell Biology, Milano, Italy; 4) University Vita-Salute San Raffaele, Milano, Italy; 5) IRCCS Policlinico, Milan, Italy; 6) University of Modena, Italy; 7) Spedali Civili di Montichiari, University of Brescia, Italy.

ADPKD is the most common genetic nephro-pathology in humans, affecting about 1/1000 individuals. Aim of the present work was to identify variants of PKD1 and PKD2 genes in Italian patients affected by ADPKD. Analysis of PKD1 and PKD2 variation would allow: to confirm the diagnosis in clinically uncertain/atypical cases; to offer genetic counseling in at risk families; to exclude the presence of a mutation in related donors for kidney transplantation; to define the molecular spectrum of PKD1 and PKD2 in Italian patients. A semi-automated Sanger direct sequencing protocol has been developed for detection of variants in PKD1 and PKD2. Specific amplification of PKD1 was achieved either following previously published protocols or by using newly designed PCR/sequencing primers. By this protocol we analyzed a total of 278 subjects as follows: 190 unrelated patients belonging to families, 66 relatives and 22 patients with no reported familiarity. In the majority of patients (191/212, 90%) variants were present. In 94% (178/190) of familial cases variants were found in PKD1 and/or PKD2. In sporadic cases, 59% (13/22) were positive. In 20 patients, variants were present in both genes and 83 had more than one variant in PKD1. In addition, a high level of genetic variability (55 SNPs) in these genes was observed with an average of about 12 SNPs/patient in PKD1 and 2 SNPs/patient in PKD2. This is further attested by the evidence that 84.5% of the identified variants have never been described before. By combining results for truncating and known variants we identified pathogenic mutations in 61% (117/191) of patients with gene variants, 100 (85,5%) with a mutation in PKD1, 17 (14,5%) mutated in PKD2. For variants not yet determined with respect to their pathogenicity, a prediction was attempted according to PKDB criteria (Rossetti et al., 2010). Concordance of the results obtained with SIFT, AGVGD and PolyPhen2 allowed the calling of 18 likely-neutral and 12 highly-likely-pathogenic variants. In many cases there's no concordance between the softwares and the interpretation of additional information becomes relevant. Segregation in members of the family increases the score for pathogenicity/neutrality of a variant; otherwise the concurrent presence of a known mutation could lean to consider the indeterminate change more likely as neutral. Combining our previous data with these results, allowed us to identify pathogenic mutations in 67% (129/191) of patients.

1120T

A novel nucleotide change in the intron 12 of the SPAST gene might produce an aberrant protein transcript. *A. Magariello[1], M. Liguori[1], A. Patitucci[1], L. Citrigno[1], R. Mazzei[1], FL. Conforti[1], C. Ungaro[1], W. Sproviero[1,2], D. Bosco[3], M. Plastino[3], A. Gambardella[1,2], M. Muglia[1].* 1) Institute of Neurological Sciences, CNR, Mangone (CS), Italy; 2) Institute of Neurology, University `Magna Graecia', Catanzaro, Italy; 3) U.O. of Neurology “S. Giovanni di Dio” Crotone, Italy.

Hereditary spastic paraplegia (HSP), also known as Strümpell-Lorrain syndrome, is a large group of inherited and heterogeneous neurologic disorders caused by degeneration of the corticospinal axons. All modes of inheritance (autosomal dominant, autosomal recessive and X linked) have been reported; however autosomal dominant (AD) inheritance is the main mode, accounting for about 70%-80% of all HSPs. Mutations in the SPAST gene are the most common causes of ADHSP since it has been described for up to 40% of cases. To date, more than 300 SPAST mutations have been reported; they are mostly single nucleotide changes or small deletions/insertions, but large deletions and duplications have also been identified. No significant genotype-phenotype correlation were found. We report about a 58 -year-old man who complained for a progressive ambulation impairement started at 50 years. At the time of the neurological examination he showed a moderate spastic paraparesis with hyperreflexia in the lower limbs, spontaneous clonus in his legs and a modest hypoesthesia at the lower extremities; he also complained for urinary incontinence. Electrophisiological examination and RMI scans of brain and spinal cord resulted within the normal range. In the evaluation of his family tree, one brother and 2 second-degree cousins were only reported affected by autism-like behavioural symptoms. Genomic DNA was extracted after receiving informed consent from the patient. All 17 coding exons of the SPAST gene were amplified by standard conditions of polymerase chain reaction and analysed by direct sequencing of the amplicons utilizing the ABI 3130 genetic analyzer (Applied Biosystems). A heterozygous nucleotide change c.1493+18 g>t in the intron 12 of the SPAST gene was identified. The identified nucleotide change c.1493+18 g>t was not reported in the SNPs databases. The silico analysis predicted that the transition g>t at position +18 from the exon 12 generates a novel cryptic donor splice site. Therefore, the reported change might produce an alternative splicing corresponding to an aberrant transcript. To date different nucleotide changes in intronic sequences not directly involving but near the splice site of the SPAST gene were already reported as aberrant. The c.1493+18 g>t is probably the first pathological chance lying far from the splice site. However a mRNA expression study is in progress in order to verify the real functional effect of this nucleotide change.

Assay design for detection of the SMN1 “2+0” genotype in carriers of Spinal Muscular Atrophy (SMA). *G. Pont-Kingdon[1], A. Wilson[1], E. Lyon[1,2].* 1) Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT.

Spinal Muscular Atrophy is a severe neuromuscular degenerative disease due to the absence of the survival motor neuron protein encoded by the SMN genes. The disease is autosomal recessive and necessitates mutation in both alleles of the SMN1 gene. In 95% of cases, the disease is due to homozygous deletion of the SMN1 gene. A second gene SMN2 is partially active and influences the severity of the disease from extremely fatal to mild. When combining all SMAs with different degrees of severity, the disease has an incidence of 1/10 000 live births and a carrier frequency (number of individual with a chromosome with no copies of the SMN1 gene) around 1/40. The large majority of carriers (95%) have one chromosome with one SMN1 gene and the other chromosome with zero (“1+0” genotype) while non carriers have two copies of the SMN1 gene (one on each chromosome, “1+1” genotype). Four to five percent of the normal population has three copies of the SMN1 gene indicating the existence of chromosomes with two SMN1 genes in cis (on the same chromosome). Carrier screening methods establish the number of SMN1 gene in a genome. If an individual carries one chromosome with two copies of SMN1 and one chromosome with no SMN1 genes (“2+0” genotype), the result would be two SMN1 copies, erroneously classifying this individual as a non carrier. These carriers are missed by any technology used currently. Several quantitative assays have been designed for determination of the SMN1 gene copy number. We are adapting and testing previously developed quantitative real time PCR assays that distinguishes carriers “1+0“ and non carriers “1+1” to also distinguish the ”2+0” carrier genotype. Mathematical modeling and estimation of error rate due to sampling and experimental errors allowed us to predict that both genotypes ”1+1” and “2+0” will provide a different distribution of data if samples are tested in multiple replicates. This method could identify carriers independent of the gene copy per chromosome.

Molecular analysis of *ZEB2* responsible for the Mowat-Wilson syndrome. *Y. Yamada[1], K. Yamada[1], S. Mizuno[2], E. Nishi[2], N. Ishihara[3], N. Akimura[4], K. Matsuda[4], N. Okamoto[4], Y. Hiraki[5], N. Wakamatsu[1].* 1) Dept Gen, Inst Dev Res, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 2) Ctrl Hosp, Aichi Human Service Ctr, Kasugai, Aichi, Japan; 3) Nagoya Univ Sch Med, Nagoya, Japan; 4) Res Inst, Osaka Med Ctr Maternal Child Health, Osaka, Japan; 5) Hiroshima City Children's Ctr Health Dev, Hiroshima, Japan.

The mutations of *ZEB2* (*ZFHX1B*) cause an autosomal dominant disorder of Mowat-Wilson syndrome associated with profound mental retardation, delayed motor development and specific facial features such as hypertelorism, often with microcephaly, epilepsy, congenital heart disease, and Hirschsprung disease. We performed molecular analysis of *ZEB2* to confirm diagnosis of Mowat-Wilson syndrome. To screen for mutation, DNA fragments including each exon of *ZEB2* from patients and normal controls were amplified by PCR and subjected to direct sequencing analysis. In this study, we report 4 novel frame-shift mutations were found in the typical patients with Mowat-Wilson syndrome, three mutations deleted one base (164delC, 55fs74X; 647delG, 216fs223X; 1493delC, 498fs515X), and a 4-bp duplication (639insCCTG, 213fs238X). Further, the nonsense mutations of R695X and R921X reported previously were found from new patients, respectively. In other 5 typical cases, we observed deletion of whole or partial *ZEB2*. We have identified 50 mutations in *ZEB2* up to the present. The nonsense mutation R695X, which is considered a hot spot mutation of *ZEB2*, was identified in 9 independent cases. In 48 typical cases, 20 nonsense mutations and 28 frame-shift mutations were detected. These mutations generated truncated protein without the zinc finger domain located in the C-terminal region. The other two cases with milder mutation (one amino acid deletion and splicing error mutant with small amounts of normal mRNA) result in atypical clinical features including moderate mental retardation. On the other hand, we observed chromosomal deletions including *ZEB2* in 20 cases with typical or more severe features.

1123T

Genetic Profile for Patients with Familial Hemophagocytic Lymphohistiocytosis Type 5. *K. Zhang[1], JA. Johnson[1], D. Kissel[1], U. Zur Stadt[3], AH. Filipovich[2].* 1) Div Human Gen, Cinncinnati Children's Hosp, Cincinnati, OH; 2) Division of Bone Marrow Transplant and Immune Deficiency, Cincinnati Children's Hospital Medical Center USA; 3) , Research Institute, Children's Cancer Center, Hamburg Germany and Department Hematology and Oncology, University Medical Center Hamburg Eppendorf, Hamburg, Germany.

Familial hemophagocytic lymphohistiocytosis (Familial HLH or FHL) is an autosomal recessive disorder of immune regulation, characterized by defects in cell-mediated cytotoxicity that results in fever, hepatosplenomegaly and cytopenias. It typically occurs in early childhood, but many adult cases have also been reported. It is often rapidly fatal unless treated with chemotherapy, immune suppression and follow by bone marrow transplantation.Several genes are specifically associated with FHL including PRF1 (FHL2), UNC13D (FHL3), STX11 (FHL4) and STXPB2 (FHL5). The purpose of this study is to characterize STXBP2 mutations in North American patients with FHL5. PCR based sequencing of the entire coding regions and exon/intron boundaries of the STXBP2 gene were undertaken in a total of 329 unrelated patients with the clinical diagnosis of HLH. The significance of missense variants were evaluated with a lab developed algorithm including database reviews (HGMD, NCBI etc.) as well as in silico analyses (PolyPhen, SIFT, Grantham Scale, etc.). This study was performed with the approval of Cincinnati Children's Hospital Medical Center IRB. Bi-allelic STXBP2 mutations were found in 32 unrelated families. Heterozygous mutation and sequence variants were also identified in 22 additional symptomatic patients; the significance of these variants in the development of HLH in the heterozygous state is currently unknown. Fourteen novel mutations and 9 sequence variants were found in this cohort of patients. There are a few common mutations were observed. P477L is a mutation found frequently in patients with Arabic descent. 1247-1G>C and G541S are the two common mutations in Caucasian patients. G541S can be observed by itself or cosegregated with the 795-4C>T variant. While L130S and T345M are almost always observed together, T345M by itself also presented in about 2% of the local control population, and is likely a benign polymorphism. Thirty-five other sequence variants are also found in this cohort of patient and do not appear to result in aberrant protein. Bi-allelic STXBP2 mutations are identified in approximately 10% of North American patients with FHL and sequencing analysis of STXBP2 gene should be included as part of the standard genetic evaluation of these patients. Further studies are necessary to characterize the role in the disease development of the novel missense and splicing site variants observed in this study.

1124T

Comprehensive analysis of novel disease-causing copy number variants in syndromic obesity. *C.S. D'Angelo, C.P. Koiffmann.* Dept Genetics, Univ Sao Paulo, Sao Paulo, Brazil.

There are numerous reports of dysmorphic syndromes including obesity and developmental delay as presenting clinical features. Many have an overlapping phenotype that represents a diagnostic challenge. The most prevalent of these conditions is Prader-Willi syndrome (PWS), which is due to lack of paternal expression of imprinted genes within chromosome 15q11q13. Other syndromes with obesity have been associated with deletions of chromosomes 1p36, 2q37, 6q14.1q15, 6q16, 9q34, 11p14.1, 17p11.2. In addition, several rare copy number variants (CNVs) have been detected in obese patients with no known genetic diagnosis but demonstrating complex “obesity-plus” phenotypes. After microarray analysis in a series of patients with dysmorphic syndromes that include obesity and developmental delay, we identified several cryptic chromosomal imbalances representing new aetiologies of syndromic obesity and, hence, novel obesity loci for targeted follow-up. We developed a set of custom-designed MLPA probes to rapid screen for regions of copy number gains and losses that might be overrepresented in a cohort selected for syndromic obesity. Most obese patients had normal methylation test for PWS or had other common causes of syndromic obesity, such as 1p36 and 17p11.2 deletions, ruled out. To date, we have found six of over 150 patients carrying chromosomal deletions at 15q11.2 (three), 2q37 (two), and 9q34 (one). The latter were further characterized by a customized oligonucleotide-based DNA microarray (SurePrint G3 Human 8x60K from Agilent). Haploinsufficiency of HDAC4 and EHMT1, located at the critical region for 2q37 and 9q deletion syndromes, have been suggested as being involved in the regulation of body weight and critical for brain function. The two del (2)(q37.3) patients have a similar sized terminal deletion of ~6 Mb encompassing HDAC4, whereas the 9q deletion is only 600 kb in size extending from the telomere into EHMT1. We detected a single-copy of the SNORD116 snoRNAs to patients with a PWS or PWS-like phenotype. Deletion of only these genes is sufficient to cause PWS. As of now, we have not confirmed any of the newly discovered obesity loci to be recurrent. Overall, these data suggest that despite extensive overlap of phenotypes, very few obese patients share identical aetiologies. It warrants screening them for novel genomic regions involved in the cause of obesity syndromes as the same genes are likely to be implicated in common obesity. CEPID-FAPESP, CNPq.

1125T

New gene variants in Idiopathic Scoliosis. *K.F Fendri[1, 3], S.A.P Patten[1, 3], P.E Edery[2], F.M Moldovan[1, 3].* 1) Orthopaedic Molecular Biology Laboratory, Sainte-Justine Hospital Research Centre, 3175 Cote-Sainte-Catherine Rm 4731, Montreal, H3T 1C5 (Quebec), Canada; 2) Cytogenetics service, Civil Hospice of Lyon, East Hospital Bloc, CBPE 6th floor, 59 Boulevard Pinel, Bron Cedex 69677, France; 3) Faculty of Dentistry, University of Montreal, PO Box 6128 Stn CV, Montreal, H3C 3J7 (Quebec), Canada.

Adolescent Idiopathic Scoliosis (AIS) is the most common form of spinal deformity. It occurs primarily in girls and progresses during pre-pubertal and pubertal growth. The aetiology and molecular mechanisms of AIS are not clear; currently the consensus is that AIS has a multifactor aetiology, with multiple genetic factors. Many loci for AIS have been mapped to different chromosome regions but no genes have yet been clearly identified as responsible for AIS, and most importantly, the resulting protein defects remain to be demonstrated. Recently, a collaboration study using genetic linkage analysis to the mapping of a dominant disease-causing gene to two critical genomic intervals 3q12.1 and 5q13.3 in a large multiplex French family. We aim to identify the gene(s) that could be involved in AIS and to validate their involvement by both genetic and functional analyses. A large multiplex AIS French family was chosen for this study based on clinical and radiological data. Two strategies were carried out to discover mutations causing the AIS disease, whole-exome sequencing using high-throughput technology and candidate regions genes' sequencing using sanger technology. Sequence data were analyzed through a customized computational pipeline to identify variants in 4 family patients. Biological activity of mutant proteins is under evaluation by in vivo functional studies in zebra fish. The sequencing of the candidate genes' coding sequences was conducted on all family members. Sequence analysis revealed 2 rare SNPs located on the coding regions of a gene suggesting its possible association to AIS disease in this family. These 2 SNPs are located on the C-terminal region of the protein and affect its structure and probably its cellular activity leading to the disease. This region interacts with the mRNA of a gene which defects cause scoliosis as a secondary phenotype. Whole-exome sequencing of family patients identified new genetic variants that could be responsible for the AIS disease in this family. The pathogenic nature of all these variants is currently under investigation in the zebra fish model. Identifying susceptibility genes for AIS will facilitate the understanding of underlying biochemical pathways (functional studies) and ultimately the development of specific therapies (pharmacological studies). This is likely to have important implications, given that AIS aetiology is unknown. Supported by the Fondation Yves Cotrel, Institut de France.

1126T

Identification of novel genes for frontotemporal lobar degeneration using whole genome sequencing. *I. Gijselinck[1,2], S. Philtjens[1,2], T. Van Langenhove[1,2], S. Engelborghs[2,3], J. van der Zee[1,2], R. Van Den Berghe[4], P. Santens[5], G. Maes[1,2], K. Peeters[1,2], M. Mattheijssens[1,2], P.P. De Deyn[2,3], C. Van Broeckhoven[1,2], M. Cruts[1,2].* 1) Neurodegenerative Brain Diseases Group, Department of Molecular Genetics, VIB, Antwerpen, Belgium; 2) Institute Born-Bunge, University of Antwerp, Antwerpen, Belgium; 3) Department of Neurology and Memory Clinic, Hospital Network Antwerp Middelheim and Hoge Beuken, Antwerpen, Belgium; 4) Department of Neurology, University Hospitals Leuven and University of Leuven, Leuven, Belgium; 5) Department of Neurology, University Hospital Ghent and University of Ghent, Gent, Belgium.

In genetically complex adult-onset diseases, sampling sufficient individuals of a Mendelian multiplex family informative for genetic linkage studies is often complicated due to e.g. the late-onset of disease and the variable disease onset and penetrance. Frontotemporal lobar degeneration (FTLD) is a complex neurodegenerative brain disease with a positive family history in up to 50% of patients of which today we can explain only 30 to 40% by a causal mutation in one of four of the known genes. The emerging technology of whole genome sequencing (WGS) might be an alternative solution allowing for direct identification of disease-causing genetic variants in selected patients and nuclear families. We are using this approach to identify novel FTLD genes that might identify new disease pathways and biological insight in the disease process. We obtained the whole genome sequence of 15 unrelated, mainly early-onset, familial FTLD patients and of an affected sib of four of the selected patients. Analysis of the genome sequences resulted in about 4 million variants per genome. We obtained an average coverage of 70-fold genome sequence and captured on average 96% of both alleles. All DNA variants were annotated and prioritized using multiple variant filtering procedures including sequence quality, genomic location, allele frequency, zygosity, predicted functional consequences and presence in the sequenced patients. In this way, the number of variants was reduced to a manageable number of possible candidate variants, with approximately 250 missense or splice variants segregating in each sib pair. We are genetically validating the selected variants and determining their frequency in control individuals and extended patients cohorts. Identification of a shared variant in multiple patients might indicate a founder mutation, while a gene with different deleterious variants in multiple patients might indicate a major FTLD gene. In-depth analysis will show whether the WGS approach is successful in indentifying coding or non-coding, rare high-penetrant disease mutations in complex diseases. The identification of novel FTLD genes will provide valuable insights into the pathogenesis of the disease and will eventually lead to the development of disease models, therapeutic targets and more efficient molecular diagnostics.

1127T

Whole-genome sequencing to identify disease causing mutations in hereditary sensory and autonomic neuropathy. *C. Gonzaga-Jauregui[1], W. Wiszniewski[1], J. Reid[1,2], I. Kurth[3], R.A. Gibbs[1,2], J.R. Lupski[1,4,5].* 1) Molec & Human Gen, Baylor College Med, Houston, TX, USA; 2) Human Genome Sequencing Center, Baylor College Med, Houston, TX, USA; 3) Institute of Human Genetics, University Hospital Jena, Jena, Germany; 4) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 5) Texas Children's Hospital, Houston, Texas, USA.

Next-generation sequencing technologies and targeted capture have enabled high-throughput sequencing of exomes to discover pathogenic variants and identify new genes involved in mendelian diseases. However, exome sequencing is based in capture and enrichment of only the ~2% coding fraction of the genome to identify simple nucleotide variants (SNVs). Whole-genome sequencing allows the unbiased detection of all different types of variation in a given individual, from SNVs to copy-number variants (CNVs) that may be responsible or contribute to a disease phenotype. Hereditary and sensory autonomic neuropathies (HSAN) affect primarily the peripheral nerves and are characterized by progressive loss of sensitivity in the extremities; the different subtypes vary in the degree of autonomic involvement. Several genes have been identified to cause the different subtypes of HSAN but the genetic cause of the disease in some individuals remains unknown. We have used massively parallel sequencing by oligo ligation/detection technology, SOLiD, to perform whole-genome sequencing at ~30x average depth of coverage of a female patient affected by hereditary sensory and autonomic neuropathy (HSAN) who tested negative for mutations in known HSAN genes and other neuropathy associated genes. Comparison of the genomic sequence obtained to the human genome reference assembly identified 3.2 million single nucleotide polymorphisms (SNPs); 19,151 of these occur in coding regions of which 9,814 cause non-synonymous substitutions. Filtering of these variants for high quality calls and common variants present in dbSNP and observed by the 1000 Genomes Project, in order to look for novel variants, reduced the list of potential candidate variants to 232 nonsynonymous changes. Considering that the patient is the daughter of a first cousin marriage, we undertook a recessive model of inheritance for her disease, focusing on homozygous variants, narrowing our list of candidate genes to nine. Whole-genome sequencing can be applied to identify the genes and mutations responsible for mendelian phenotypes for which the molecular basis remains unknown, even if they are genetically heterogeneous. This technology will soon be performed routinely to achieve accurate genetic diagnosis and aid in clinical practice.

1128T

High-Throughput Sequencing for Causal Gene Discovery in Mendelian Diseases. *S.N. Jhangiani[1], M.N. Bainbridge[1], D.R. Murdock[1], F.J. Probst[2], J.L. Jeffries[3], I.F. Newsham[1], Y.Q. Wu[1], M. Wang[1], D.M. Muzny[1], R.A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas, USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas, USA; 3) Department of Pediatrics (Cardiology), Baylor College of Medicine and Texas Children's Hospital, Houston, Texas, USA.

Discovering the causative alleles of the approximately 3,000 Mendelian diseases that as yet have no associated genes will elucidate key pathways, facilitate diagnostics and help guide therapy. The HGSC Mendelian Diseases Project, in collaboration with investigators in the Texas Medical Center, has generated more than 1Tb of high quality sequencing data from more than 150 subject samples representing greater than 35 disorders with autosomal recessive, autosomal dominant, *de novo* and X-linked inheritance patterns. These disorders affect a wide range of systems and processes including: heart, immune, mitochondrial, neuronal, skeletal, tumor formation, development and others.

We used a high-throughput, multiplexed capture sequencing pipeline capable of generating 1,500 capture libraries per month, and a fully automated bioinformatics pipeline that integrates multiple functional, gene model and allele frequency databases for variant analysis. This pipeline combined with high-throughput sequencing (HTS) has proven useful and cost effective in associating genes with diseases. We have implicated novel genes in eight Mendelian disorders, including a single family with Multiple Lipomatosis. Novel mutations have also been discovered in known causative genes in four disorders including: three novel mutations implicated in *MYH7* to cause Left Ventricular Non-compaction, a congenital heart disorder with over 18 associated genes. *MYH7* is not commonly sequenced in LVNC thus highlighting the value of whole exome sequencing for diagnostics in genetically heterogeneous diseases. This work demonstrates that the future of high-throughput sequencing will play in integral role in clinical management with diagnostics and treatment.

Exome Sequencing of Four Dyschromatosis Universalis Hereditaria Patients and One Unaffected Person from a Chinese Pedigree. *Y. Li[1], H. Liu[2], H. Liany[1], F. Zhang[2], J. Liu[1].* 1) Human Genetics, Genome Inst Singapore, 60 Biopolis Street, #02-01, Genome, Singapore, Republic of Singapore; 2) Shandong Provincial Institute of Dermatology and Venereology, Shandong Academy of Medical Science, P R China.

Dyschromatosis universalis hereditaria (DUH) and dyschromatosis symmetrica hereditaria (DSH) are pigmentary dermatoses that are most commonly seen in Japanese and Chinese. They may show autosomal dominant or recessive inheritance modes, and recent evidence indicated that DSH and DUH were genetically distinct disorders. DSH has been mapped to chromosome 1q21.3 [Zhang et al 2003, Miyamura et al 2003, He et al 2004] with autosomal dominant inheritance in Asian families. Chromosome 6q24.2-q25.2 with autosomal dominant inheritance in two Chinese families [Xing et al 2003] and chromosome 12q21-q23 with autosomal recessive inheritance in an Arabian consanguineous family [Stuhrmann et al 2008] were reported to be implicated in DUH. We investigated the genetic architecture of DUH by target sequencing 50 Mb of exomes for each of the four DUH patients and one unaffected person from a Chinese pedigree with 31 members using Illumina GAII platform. The mean coverage depth is 45.4, and on average, 93.7% of targeted bases were covered by >=5x, 86.7% of targeted bases were covered by >=10x. 68276 high quality SNPs and 19666 short indels were discovered among the 5 persons. Analyses assuming autosomal dominant and recessive inheritance modes were carried out. Several implicated genes and further validation strategies will be discussed.

Whole Exome Sequencing in a single nuclear family finds novel compound heterozygous changes in KCTD7 causing late infancy-childhood neurodegeneration. *T.C. Markello[1,2], D.A. Adams[1,2], L. Wolfe[2], M. Sincan[2], K. Fuentes Fajardo[2], MP. Jones[3], U. Harper[3], S. Chandrasekharappa[3], C.J. Tifft[2], C. Boerkoels[2], W.A. Gahl[1,2], Nisc Comparative Sequencing Program.* 1) Med Gen Branch, NIH/NHGRI, Bethesda, MD; 2) Undiagnosed Diseases Program, NIH/NHGRI, Bethesda, MD; 3) NHGRI/IR/CGB/CGS, Bethesda, MD.

Two of four siblings who were normal at birth developed late infantile ataxia with slowly progressive myoclonus and severe degenerative neurological dysfunction. Four grandparents, both parents and all four siblings underwent traditional linkage analysis with a maximum LOD score of 0.82 at 17% of the genome, which corresponded to the same regions located by Boolean logic SNP chip linkage. The parents and four siblings underwent whole exome sequencing with Agilent Sure select 38MB exon capture and sequencing on an Illumina GIIx platform with an average 150x coverage. For the proband 79% of the UCSC coding bases were covered with high quality, most probable genotype MPG score ⁄ 10. A combined 112,936 variants were identified in the 6 genotypes. Using standard frequency, linkage, Mendelian consistency and deleterious prediction filters biallelic mutations in a single gene *KCTD7* were detected. This gene has been linked to the similar but non-identical phenotype myoclonic epilepsy in two previous families by homozygosity mapping. Our family extends the phenotype of recessive loss of function in *KCTD7*. It also demonstrates that SNP based linkage from simple Boolean logic can produce the same chromosome linkage map as traditional linkage programs run with microsatellite markers.

1131T

Mutations in the Amiloride-Sensitive Epithelial Sodium Channel in African patients with cystic fibrosis-like disease. *L. Mutesa[1, 2], C. Verhaeghe[2], J.F. Vanbellinghen[2], V. Dhennin[3], V. Bours[2, 3].* 1) Medical Genetics, National University of Rwanda, Kigali, Rwanda; 2) Center for Human Genetics, University of Liege, Liege, Belgium; 3) GIGA-Genomics Facility, University of Liege, Liege, Belgium.

BACKGROUND The defect in chloride and sodium transport in cystic fibrosis (CF) patients is a consequence of CFTR loss of function and/or an abnormal interaction between cystic fibrosis transmembrane conductance regulator (CFTR) and amiloride sensitive epithelial sodium channel (ENaC). Apart from the defective chloride secretion, loss of functional CFTR results in increased sodium absorption through the ENaC channel in CF patients. A few patients were described with CF-like symptoms with a single CFTR mutation and/or an ENaC mutation. OBJECTIVE To study African patients with CF-like symptoms and to relate the disease to gene mutations of ENaC genes. METHOD We investigated whether mutations in the genes that code for the different subunits of ENaC gene (SCNN1A, SCNN1B and SCNN1G) might result in cystic fibrosis (CF)-like disease in patients in whom only one CFTR gene is mutated, or that carry no mutations at all in the CFTR coding region and its exon/intron junctions. We extensively performed ENaC genes sequencing in these CF-like patients and established the frequency of identified ENaC mutations in a cohort control. RESULTS In total, 66 sequence variants in ENaC genes were found in 60 CF-like patients. Several novel ENaC gene mutations were identified and some of them were located in highly conserved domains and consistent with a pathophysiological role. Only three novel mutations including p.V348M and p.W423R in SCNN1B subunit and p.R180W in SCNN1G were observed once in our patients, but not in controls. The preliminary functional studies performed using expression in Xenopus laevi oocytes showed that the p.V348M is a gain of function mutation with a high amounts (2-30%) functional ENaC activity. CONCLUSION Our data suggest that CF-like syndrome in Africa could be associated with ENaC mutations. The combination of ENaC and CFTR mutations may play a hitherto unrecognized role in lung diseases.

Identification of genes for nonsyndromic hearing impairment using haplotype sharing and exome sequencing. *M. Schraders[1], K. Neveling[2], J. Oostrik[1], C.F.H.A. Gilissen[2], R.J.C. Admiraal[1], J.A. Veltman[2], H.P.M. Kunst[1], E.H. Hoefsloot[2], R.J.E. Pennings[1], H. Kremer[1,2].* 1) Department of Otorhinolaryngology, Head and Neck Surgery, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 2) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands.

Linkage analysis and homozygosity mapping are valuable tools for the discovery of genes mutated in autosomal recessive nonsyndromic hearing impairment (arNSHI), which have been successfully used for the identification of the majority of the currently known arNSHI genes. Insight in the causes of arNSHI in western Europe and the US, however, remained limited. In our group, we demonstrated that homozygosity mapping can be successfully employed in mixed populations such as that of the Netherlands. Additionally, we recently identified a 5th gene by this approach. However, in about 70% of the families with arNSHI no significant shared homozygous regions could be found. Therefore, we initiated whole exome sequencing in the proband of 20 families using the SureSelect human exome kit (Agilent) and the SOLiD sequencing technology (Life Technologies). On average 25,018 genetic variants were identified per patient. After exclusion of known variants using dbSNP130 and variants detected in a in-house database on average 2,124 variants remained per patient, 557 of which were located in the coding regions or the canonical dinucleotides of splice sites. For each patient we selected the variants with at least 5 variant reads and which were consistent with the recessive inheritance pattern of the disease. Moreover, haplotype sharing by affected individuals of the same family as derived from the SNP genotyping was taken into account. This procedure resulted in 2-8 candidate genes per family. Subsequently, segregation analysis was performed in families for which DNAs of parents or unaffected family members were available. So far we have selected two novel promising candidate genes for further analysis. Also, in three families hearing impairment could be attributed to novel compound heterozygous mutations in the known deafness genes *LOXHD1*, *TMC1*, and *MYO15A*.

Identification of a frameshift mutation in HMGB3 (MIM 300193) in a family with Lenz microphthalmia (MCOPS1; MIM 302300). *A.F. Scott[1], D.W. Mohr[1], L.M. Kasch[1], J.A. Barton[1], B. Craig[1], B.A. Marosy[1], K.F. Doheny[1], W.C. Bromley[2], T. Roderick[2], E.W. Jabs[3].* 1) McKusick-Nathans Institute for Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD 21287; 2) Ctr for Human Genetics, P.O. Box 770 Bar Harbor, ME 04609; 3) Dept of Genetics and Genomic Sciences, Mount Sinai Sch Med, NYC, NY 10029.

Goldberg and McKusick (1971) reported a kindred from Maine with X-linked kyphoscoliosis, microphthalmos, mental retardation, and microcephaly similar to that first described by Lenz (1955). Forrester et al (2001) mapped the gene, MCOPS1 (MIM 309800) to Xq27-28. We obtained an affected proband and his mother from the Maine pedigree. The proband was subject to whole genome sequencing using Complete Genomics, Inc. and to Illumina paired-end sequencing following X-exome capture (Agilent). Both methods confirmed a frameshift mutation in the fourth coding exon of the evolutionarily conserved high mobility group protein HMGB3 (MIM 300193; Phastcons score of 1) resulting in a readthrough that produces VADYISRKESLMVQRVLLKLPGKRWKRKMKKRRRKKRRRRRRRRMN-KETVYLSPCEYLES* in place of VADYKSKGKFDGAKGPAKVARKK-VEEEDEEEEEEEEEEEEEDE*. Subsequently, Sanger sequencing on the mother confirmed her carrier status. Morpholino knock down of the Xenopus ortholog, Xhmgb3, was reported to have a significant role in retinal progenitor proliferation during eye development and to produce reduced eye and brain sizes in developing embryos (Terada et al, 2006). Confirmation in additional pedigrees will validate the first association of a human disorder with HMGB3 mutations.

Replication evidence that constituents of the apical plasma membrane contribute to Meconium ileus in Cystic Fibrosis. *X. Li[1], H. Corvol[2,3], W. Li[4,1], T. Chiang[1], F. Lin[5], P-Y. Boelle[3,6], M. Drumm[7], G. Cutting[8], M. Knowles[9], P. Durie[10], J. Rommens[5,11], L. Sun[4,12], L. Strug[1,4].* 1) Program in Child Health Evaluative Sciences, Hospital for Sick Children, Toronto, ON, Canada; 2) AP-HP, Hôpital Trousseau, Pediatric Pulmonary Department; Inserm U938, Paris, France; 3) Université Pierre et Marie Curie-Paris 6, Paris, France; 4) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 5) Program in Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON, Canada; 6) AP-HP, Hôpital St Antoine, Biostatistics Department; Inserm UMR-S707, Paris, France; 7) Case Western Reserve University Departments of Pediatrics and Genetics, Cleveland, Ohio, USA; 8) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 9) Cystic Fibrosis-Pulmonary Research and Treatment Center, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 10) Program in Physiology and Experimental Medicine, Hospital for Sick Children, Toronto, ON, Canada; 11) Department of Molecular Genetics, University of Toronto, ON, Canada; 12) Department of Statistics, University of Toronto, Toronto, ON, Canada.

Cystic Fibrosis (CF) is a life-shortening recessive disease caused by mutations in the CFTR gene. Lung disease and the occurrence of common comorbidities such as intestinal obstructions vary in CF patients, even across individuals with the same CFTR mutations. This suggests the involvement of genes other than CFTR, which we aim to identify. The intestinal complication, Meconium Ileus (MI), which occurs in ~16% of newborn CF patients, is >88% heritable. A genome-wide association study (GWAS) by the North American (NA) Consortium for CF Modifiers (n=3763) identified two genes (SLC6A14, p=9.88E-09 and SLC26A9, p=1.28E-12) associated with MI accounting for ~5% of the MI phenotypic variation. To increase power and identify more phenotypic variance, we performed a hypothesis driven GWAS (GWAS-HD) (Strug et al., 2010), which incorporates knowledge of CF to prioritize GWAS results. We hypothesized that variation in other gene products that reside in the apical membrane of epithelial tissue where CFTR resides may influence residual or adapted epithelial functions, and could modify CF disease phenotypes. GWAS-HD provided evidence that multiple constituents of the apical plasma membrane were associated with MI (permutation p=0.0002, testing 157 apical genes jointly). SLC9A3 and ATP2B2, now also reached genome-wide significance after prioritization by the hypothesis (q-value < 0.05). SNPs in SLC6A14 and SLC26A9 were replicated (p=0.001 and p=0.0001, respectively) in a combined sample of an independent NA collection (n=1,140 genotyped at 14 SNPs) and a French population-based cohort with genome-wide data (n=1,232). The French cohort also provided replication of SLC9A3 in a gene-based analysis (p= 0.017) and replication of the apical hypothesis (p=0.022, testing the 157 apical genes jointly), which required genome-wide data. The replicated association evidence for the apical membrane candidates in MI indicated that (1) GWAS-HD uncovered additional association evidence for genes with MI that would not otherwise have been shown to reach statistical significance with the available patient group; (2) current therapeutic paradigms aimed at improving delivery of the mutated CFTR gene product could be complemented by modulation of epithelial function as determined by apical solute transporter activities; and (3) GWAS-HD can be applied to studies of other Mendelian disorders or complex traits when additional information is available.

Looking for regulators of dystrophin Dp71 gene expression in hepatic cells. *C. Becerril[1], E. Blancas-Sánchez[2], P. Zapata-Benavides[1], J. Dávila-Velderrain[1], B. Cisneros[3], M. Bermúdez de León[2].* 1) Facultad de Ciencias Biológicas, Universidad Autónoma de Nuevo León, San Nicolás de los Garza, Nuevo León, México; 2) Laboratorio de Biología Molecular, Centro de Investigación Biomédica del Noreste, Instituto Mexicano del Seguro Social, Monterrey, Nuevo León, México; 3) Departamento de Genética, Centro de Investigación y de Estudios Avanzados del I.P.N., México, D.F., México.

Mutations on DMD gene lead to Duchenne muscular dystrophy, the most common and severe dystrophy in children (1/3,500 live born males). DMD gene has at least 7 different promoters, which give products with independent regulation tissue- and time-specific. Dystrophin Dp71, the smallest product, is transcribed from intron 62 and expressed in all non-muscular tissues. However, Dp71 function still remains unclear. To evaluate the molecular mechanism that underlined the Dp71 expression, different cell models have been employed, including muscle and neuronal cells. In muscular cells, Dp71 expression is down-regulated during myogenesis by the lack of activating factors Sp1 and Sp3; otherwise, the induction of Dp71 expression in neuronal differentiation is caused by activation of Sp1 and the relief of repression by AP2-alpha. Previously, we reported that beta-naphthoflavone, a polyaromatic xenobiotic, down-regulate the Dp71 mRNA and protein expression in hepatic cells. Hence liver is the key organ involved in xenobiotic metabolism, we considered that the knowledge of the regulation of Dp71 in liver cells could contribute to identify and understand its function in this organ. To elucidate the transcriptional mechanism of Dp71 in hepatic cells by beta-naphthoflavone, we analyzed the Dp71 expression and identified transcriptional factors and elements involved in its regulation. Dp71 mRNA half-life was determined in hepatic cells by quantitative RT-PCR, and no changes were observed in beta-naphthoflavone-treated cells with respect to control cells (9.11 ±2.9h versus 9.22± 1.6h, respectively). Dp71 promoter sequence analysis, using TRANSFAC database, showed that -224 to +65 region contains several Sp1/Sp3 and YY1 binding sites. Probes spanning basal promoter region were designed and used to analyze specific transcriptional complexes by Electrophoretic Mobility Shift Assays (EMSA). EMSAs revealed the interaction of Sp-family transcriptional and YY1 factors to their respective DNA elements. These results were confirmed by supershift assays with specific anti-Sp1 and anti-YY1 antibodies. Functional analyses to demonstrate Sp1/Sp3 and YY1 factors on Dp71 gene expression in hepatic cells are in progress.

1136T

Studying familial hypercholesterolemia by means of real-time pcr expression. *T.Yu. Komarova, A.S. Golovina.* Genetics, Institute of Experimental Medicine, St.-Petersburg, Russian Federation.

Aims. Familial hypercholesterolemia (FH) is a common (1:500) monogenic disease caused by low density lipoporotein (LDL) catabolism lowering due to dysfunction of the specific LDL receptor (LDLR). We aimed to investigate if the LDLR mRNA level in freshly isolated peripheral venous blood leukocytes was inversely correlated with plasma level cholesterol in patients with heterozygous FH. **Methods.** Fresh leukocytes were prepared from peripheral venous blood by means of centrifugation at 1500g with the Lymphosep cushion. Leukocytes from the interphase were collected and washed three times with RPMI medium. Viability of leukocytes was tested by Trypan blue dye exclusion. Total RNA was prepared from 1-2 millions of viable white blood cells by means of AquaPure RNA Isolation Kit (Bio-Rad Laboratories, USA) and 1-2 mkg of total RNA was used for first strand cDNA synthesis with iScriptTM cDNA Synthesis Kit (Bio-Rad Laboratories). Approximately 100 ng of cDNA was used in real-time PCR mRNA quantitation test. TaqMan technology was used with R6G labeled TaqMan probe to quantitate the reference gene - UBIC (ubiquitine C) mRNA and fluorescein labeled TaqMan probe was used to amplify LDLR mRNA exon 4 fragment in the same tube using CFX96 device (Bio-Rad Laboratories). Normalized relative expression of the LDLR gene in FH samples was compared to expression of the LDLR gene in healthy individual and plotted versus blood plasma total cholesterol figures.

Results. We found LDLR mRNA level to be highly variable in FH blood leukocytes ranging from 0.2 to 1.8 times content of LDLR mRNA in the control individual. We found that most possible mechanism of LDLR gene dysfunction in common deltaG197 (also known as G218del or FH-Lithuania mutation) variant heterozygous leukocytes is due to mRNA level lowering and not to defects in the intracellular protein maturation and transport. Patients taking up high dose of statins usually demonstrate the elevated level of LDLR mRNA.

Conclusions. We found no inverse correlation between LDLR mRNA level in peripheral blood FH leukocytes and plasma cholesterol level. So far, quantitation of LDLR mRNA in leukocytes cannot be used for prediction of disease severity and efficacy of hypocholestorolemic drug treatment in heterozygous FH.

1137T

Genotype- phenotype correlation in beta thalassaemia. *Z. Abdul Latiff[1], M. Sivalingam[2], ML. Looi[2], ND. Husin[2], FZ. Mohd Radin[2], R. Mohd Isa[2], SZ. Syed Zakaria[1], NH. Hussin[3], H. Alias[1], H. Ibrahim[4], R. Jamal[2].* 1) Department of Paediatrics, UKM Medical Centre, Kuala Lumpur, Malaysia; 2) UKM Medical Molecular Biology Institute, UKM Medical Centre, Kuala Lumpur, Malaysia; 3) Department of Pathology, UKM Medical Centre, Kuala Lumpur, Malaysia; 4) Institute of Paediatrics, Hospital Kuala Lumpur, Malaysia.

Thalassaemia is the commonest single gene disorder in Malaysia with an estimated 5% carrier rate for) -thalassaemia. The clinical manifestation of) -thalassaemia disease depends on the type of) gene mutations, (-gene interaction and the Xmn1 polymorphism. This study was aimed at identifying the) -gene mutations in local thalassaemia patients and the complementary effect of co-inheritance of (-gene mutations and Xmn1 polymorphism in) -thalassaemia patients. A total of 264 samples was studied, consisting of thalassaemia major (n = 104), thalassaemia intermedia (n= 29), HbE) thalassaemia (n=130), and HbE (n=1). Detection of (and) gene mutations and characterization of the secondary modifier Xmn1 polymorphism in .-globin gene were performed by Multiplex PCR ((SEA, (20.5, (FIL, (3.7, (4.2, (MED), ARMS, sequencing and RFLP PCR respectively. A total of 19) mutations were characterized and 91% of alleles were identified. Alleles of 12 patients failed to be identified. CD26 and CD41/42 were the most common) -gene mutations found in Malay and Chinese population respectively. Patients were then genotypically classified into thalassaemia major () °/) °), n=55; thalassaemia intermedia () °/) $^{+}$ or) $^{+}$/) $^{+}$), n=68; HbE) thalassaemia (CD26/) ° or CD26/) $^{+}$), n=95; HbE homozygous (CD26/CD26), n= 11 and) thalassaemia heterozygous with one affected allele () °/) or) $^{+}$/)), n=23. The sensitivity of clinical diagnosis of thalassaemia major, intermedia and HbE) thalassaemia was 97.8%, 18.5% and 88.5% respectively. HbE homozygous patients exhibited high HbA2 value (median value 70%). Thalassaemia major and intermedia patients required more frequent transfusion compared to other genotypically classified groups (χ2=37.012, p=0.0001). Xmn1 polymorphism in heterozygous [+/-] state was most common in HbE) thalassaemia patients. Of 37 HbE) thalassaemia patients, those with Xmn1 polymorphism [+/-] were observed to have high HbA2 value; required less frequent transfusion compared to those without the Xmn1 polymorphism. Six) thalassaemia patients were found to co-inherit (thalassaemia, namely (SEA and (3.7. Co-inheritance of (- thalassaemia did not significantly alleviate the severity of HbE) thalassaemia. In conclusion, molecular analysis should be used for accurate diagnosis and to help personalize the management of thalassaemia. Analysis of Xmn1 polymorphism may help in the management as heterozygous state of Xmn1 polymorphism alleviate the severity of thalassaemia.

1138T

Increased rate of nontruncating mutations in the *NF1* gene among individuals with *NF1* related disorders and pulmonic stenosis: A novel genotype-phenotype correlation and insight. *S. Ben-Shachar[1,2], S. Constantini[2], E. Sach[3], D.G. Evans[3], S.M. Huson[3].* 1) Genetic Institute, Tel Aviv Sourasky Medical Center, Tel-Aviv, Israel; 2) The Gilbert Israeli Neurofibromatosis center, Tel Aviv Sourasky Medical Center, Tel-Aviv, Israel; 3) Genetic Medicine Research Group, Manchester Biomedical Research Centre, Manchester Academic Health Sciences Centre, University of Manchester and Central Manchester Foundation Trust, St Mary's Hospital Manchester, United Kingdom.

Background: Neurofibromotosis type 1 (NF1) is caused by heterozygous mutations in the *NF1* gene. Pulmonic stenosis (PS) appears in NF1 more often than expected, Particularly in patients with the Neurofibromatosis-Noonan (NFNS) and Watson syndrome (WS) phenotypes. **Objective:** To test whether specific types of mutations in the gene are associated with PS in WS and NFNS. **Methods:** We have tested PS rates and genotype-phenotype correlation among individuals with NFNS/WS and PS, based on previously published cases as well as a new cohort of patients. **Results and conclusions:** Comparing to NF1, NFNS patients (regardless of gene mutation) had higher rates of PS (32% vs. 1.1%). When stratifying patients with NFNS according to the mutation type the increased PS rates appear to be driven by the NFNS group with non-truncating mutations: 66.7% PS in NFNS with non-truncating *NF1* mutation vs. 1.1% in NF1, p<0.001, LR= 55; while NFNS patients with truncating mutations were not different from NF1 patients. Moreover, of 5 individuals with WS phenotype and well characterized mutations, only one had a truncating mutations, while three had non-truncating mutation and one had a large intragenic deletion. We conclude that PS in *NF1* related disorders is clearly associated with non-truncating mutations in the NF1 gene providing a new insight of genotype-phenotype correlation associated with NF1 gene. Hence, we recommend cardiac evaluation for any individual diagnosed with NF1 related disorders having a non-truncating mutations.

1139T

TRIM50 forms a complex with HDAC6 and p62/SQSTM1 that localizes to aggresomes. *C. Fusco[1], L. Micale[1], M. Egorov[2], M. Monti[3], E.V. D'Addetta[1], B. Augello[1], G. Cotugno[1], F. Cozzolino[3], A. Calcagni[1], M.N. Loviglio[1], R. S. Polishchuk[2], P. Pucci[3].* 1) Medical Genetics, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Foggia, Italy; 2) Telethon 3 CEINGE Advanced Biotechnology and Department of Organic Chemistry and Biochemistry, Federico II University, 80131 Naples, Italy; 3) CEINGE Advanced Biotechnology and Department of Organic Chemistry and Biochemistry, Federico II University, 80131 Naples, Italy.

TRIM50 is hemizygous in patients affected by Williams Beuren syndrome, a microdeletion neurodevelopmental genomic disorder. TRIM50 encodes a cytoplasmic E3-ubiquitin ligase that catalyzes the binding of specific substrates to the ubiquitin leading them to the degradation by activating processes as Proteasome and/or autophagy. Here we showed that TRIM50 forms highly motile, labile and dynamic cytoplasmic bodies that are precursors of the aggresome. In fact we showed that upon proteasome inhibition, TRIM50 localizes to the aggresome in a microtubule dependent manner. In addition, we identified HDAC6 as a new binding partner of TRIM50, an association that is strengthen under conditions of proteasome impairment. Using HDAC6-deficient mouse fibroblasts we demonstrated that HDAC6 is required for the proper localization of TRIM50 within the aggresome. Moreover, among a number of putative TRIM50-interacting proteins identified by nano LC-MS/MS, we found that TRIM50 interacts with p62/SQSTM1, a multifunctional adaptor protein implicated in various cellular processes including autophagic clearance of aggregation-prone polyubiquitinated proteins. Of note TRIM50 modulates the protein level of HDAC6 and p62, mainly increasing their insoluble aggresome fractions. Our work showed that TRIM50 bodies, by its E3-ubiquitin ligase are aggresome precursors. When TRIM50 fails, by its E3-ubiquitin ligase, to drive its proteins target to proteasomal degradation, an alternative route is taken to ensure their sequestration transporting them to the aggresome via the association with HDAC6 and possibly their subsequent removal by p62-mediated autophagy. Since aggresomes are cytoprotective by sequestering and eliminating deleterious aggregated proteins, we can suggest that haploinsufficiency of TRIM50 might play a role in the determination of Williams Beuren syndrome phenotypes resulting in the accumulation of ubiquitinated and aggregated proteins sensitizing cells to proteotoxic stressors.

Molecular Analysis of NPHS2 gene in a Brazilian cohort with childhood Nephrotic Syndrome. *M.S. Guaragna[1], A.C.G.B. Lutaif[2], S.Z.P. Rigazzo[2,4], V.M.S. Belangero[2,4], G. Guerra-Júnior[3,4], M.P. de Mello[1].* 1) Centro de Biologia Molecular e Engenharia Genética, CBMEG, Universidade de Campinas, UNICAMP, São Paulo, Brazil; 2) Centro Integrado de Nefrologia, CIN, Universidade de Campinas , UNICAMP, São Paulo, Brazil; 3) Grupo Interdisciplinar de Estudos da Determinação e Diferenciação do Sexo, GIEDDS, Universidade de Campinas, UNICAMP, São Paulo, Brazil; 4) Departamento de Pediatria, Faculdade de Ciências Médicas, FCM, Universidade de Campinas, UNICAMP, São Paulo, Brazil.

Nephrotic Syndrome (NS) is defined by edema, massive proteinuria, hypoalbuminemia and hyperlipidemia. Clinically, NS has been divided into two categories based on the response to steroid therapy: steroid-sensitive (SSNS) and steroid-resistant (SRNS). Among the SRNS, the renal histology typically shows focal segmental glomerulosclerosis (FSGS) with a high rate of development of end stage renal disease (ESRD). Inherited impairments of the glomerular filtration barrier (GFB) have been identified as important causes of NS. The GFB is composed of a fenestrated endothelium, the glomerular basement membrane and podocyte foot processes. The *NPHS2* gene encodes a protein called podocin, which has an important role in GFB. Mutations in *NPHS2* are frequently the cause of early onset autosomal recessive form of the disease (AR SRNS). In this study we report the molecular evaluation of *NPHS2* gene of 40 Brazilian patients (n=80 alleles) with infantile NS. The 8 exons, promoter region and intron/exon boundaries of *NPHS2* were direct sequenced. A total of seven already described missense mutations (7/80, 8.75%) have been identified in 6 heterozygous patients: p.P20L, in 2 patients (2.5%); p.A242V, in 1 patient (1.25%); p.E264Q, in 1 patient (1.25%); p.R229Q variant, in 2 patients (2,50%), one of them also carry the p.A284V mutation (1.25%). It has been shown that the p.R229Q is a polymorphism that in compound heterozygousis with another *NPHS2* mutation contributes to AR-FSGS. The significance of familial or sporadic heterozygous cases with only one mutation is still unclear. The *NPHS2* mutation may interact with other genes producing an additive effect in the frame of a multigenic inheritance. Or, there could be a sort of susceptibility to develop proteinuria conferred by the genetic background where other factors may represent the breaking event. These results are presented for the first time in a Brazilian cohort and emphasize the relevance of the molecular analysis of NS in childhood to define its etiology. SRNS is a clinically heterogeneous disease and the genotypic information may guide further treatment for these patients. Additionally, since SRNS patients with homozygous or compound heterozygous mutations in NPHS2 have reduced risks for recurrence of FSGS in a renal transplant compared with children without mutations, living related donor transplantation might be considered more promptly.

1141T

A novel mutation in the AMELX gene and multiple crown resorptions. *J.W. Kim[1,2], S.K. Lee[1], K.E. Lee[1], S.E. Jung[1], S.J. Song[1], S.H. Cho[1].* 1) Pediatric Dentistry, Seoul National University School of Dentistry, Seoul, Korea; 2) Molecular Genetics, Seoul National University School of Dentistry, Seoul, Korea.

Amelogenesis imperfecta (AI) is a heterogeneous group of genetic disorders with regard to genetic etiology and clinical phenotype and affects tooth enamel with no other non-oral syndromic conditions. X-linked AI is caused by mutations in the AMELX gene the only AI candidate gene located on the X chromosome. To date, 15 mutations in the AMELX gene have been found to cause AI. We identified a proband associated with generalized hypoplastic enamel with unusual multiple crown resorption in premolars and molars. Pedigree analysis suggested an X-linked hereditary pattern. We performed mutational analysis for the AMELX gene based on the candidate gene approach. Sequencing analysis revealed a novel mutation in exon 6 (g.4090delC, c.517delC, p.Pro173LeufsX16). This frameshift mutation produces a premature stop codon within exon 6 and is predicted to replace 33 amino acids at the C-terminus with 15 novel amino acids if the mutant mRNA escapes the nonsense-mediated decay system. Although crown resorption in AI patients occurs frequently in hypoplastic type, an association with the AMELX mutation has not been previously reported. We believe that these findings will broaden our understanding of the clinical phenotype and pathogenesis of X-linked AI. This work was supported by a Science Research Center grant to the Bone Metabolism Research Center (20110001025) and a grant (20100020542) from the National Research Foundation of Korea (NRF), both funded by the Ministry of Education, Science, and Technology (MEST) of the Republic of Korea.

Molecular characterization of thalassemia: Effect of Alpha gene Number on phenotype. *R. Kumar, S. Agarwal.* Department of Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India.

Introduction: Co-inheritance of (thalassemia reduces (/) chain imbalance and the amount of redundant alpha globin, with an ameliorating effect, while the presence of extra (globin genes will have an adverse effect. Aim: To find to frequency of alpha gene deltion in triplication and their effect on phenotype on beta thalassemia Material and Methods: 241 thalassemia cases who visited OPD, Department of Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow during the period of 2007-2010 were studied. Beta thalassemia mutations were detected by ARMS-PCR whereas GAP-PCR technology was used to detect alpha gene nubmer Results: The overall prevalence of alpha gene deletion was found 12.5% and that of alpha triplication was 5.8%.The frequency of alpha gene deletion in homozygous thalassemia intermedia group was found significantly higher than homozygous beta thalassemia major group (p value=0.029). Similarly the alpha gene triplication was found higher in heterozygous thalassemia intermedia group than thalassemia trait group (p value=0.000). The phenotypes of 5 cases out of 12 homozygous thalassemia intermedia cases were explained on the basis of coinheritance of alpha thalassemia. 13 cases of thalassemia trait were co inherited with alpha triplication and out of these 13, 9 cases were presented as thalassemia intermedia. Conclusion: alpha gene number plays an important role in modulating the phenotype of thalassemia and thus alpha gene number should also be analysed along with beta thalassemia mutations during prenatal daignosis of thalassemia.

Analysis of the polymorphism -930 A/G (rs9932581) in the CYBA gene in pediatric patients with sickle cell anemia. *M.B. Melo[1], G.P. Gil[1], G. Ananina[1], M.B. Oliveira[1], M.J. Silva[1], D. Stancato[1], F. Menaa[1], M.N.N. Santos[2], A.S. Araujo[3], M.A. Bezerra[3], F.F. Costa[4].* 1) CBMEG, Univ Campinas, Campinas SP, Brazil; 2) Department of Clinical Pathology, Univ Campinas, Campinas, SP, Brazil; 3) Hemope, Recife, PE, Brazil; 4) Hemocentro - Department of Clinical Medicine, Univ Campinas, Campinas, SP, Brazil.

Sickle cell anemia (SCA), although resulting from the homozygosity of a single mutation at position 6 of the) -globin locus, displays heterogeneous phenotypes. The severity of this threatening-life disease can be estimated using an online calculator (e.g. Sebastiani et al., 2007 with scores ranging from 0 to 1) or based on clinical evaluation (e.g. Xandra et al., 2010 with scores ranging from 0 to 285), but this severity estimation is not sufficient to explain the molecular mechanisms associated to the observed phenotypes. Indeed, one mechanism that may help to explain the heterogeneity of the disease might be the oxidative stress, resulting from vaso-occlusive ischemia-reperfusion as well as hemolysis. The NADPH is an important source of superoxide anion (O2.-) in vascular cells. One of its subunits p22phox is encoded by the CYBA gene (16q24), which has several allelic variants, such as -930 A/G (rs9932581). Studies suggest an association between the allele G frequency of this variant and (i) hypertension, (ii) increased expression of the CYBA gene. However, the allele A frequency is less encountered in hypertensive patients and is associated with lower expression of the gene. These data indicate the dominance of the allele G compared to the allele A. Here, we hypothesized the association of the alleles with the severity of SCA pediatric patients using Mann-Whitney test. From 92 SCA pediatric patients with age ranging from 2 to 17 years old, direct sequencing of the fragment containing the variant -930A/G was performed. The Hardy-Weinberg equilibrium was tested by Chi-square test and the severity scores were calculated using both P. Sebastiani's online calculator and Xandra's clinical evaluation method. We observed that the genotype distribution is in Hardy-Weinberg equilibrium. From the severity scores using Xandra's method (mean ± SD: 53 ± 36 - range: 0 to 120), the genotype group AA was significantly ($p<0.05$) associated with low severity. However, this finding was not confirmed with Sebastiani's method (mean scores ± SD: 0.46 ± 0.39 - range: 0.028 to 0.997). Due to the complexity of the disease and also to the age of the patients, the methods used to evaluate severity scores may reveal different results and consequently genotype-phenotype associations are difficult to establish. In this work, the method by Xandra and colleagues was able to detect association between the AA genotype and low severity of the disease in SCA pediatric patients.

1144T

Functional Consequences and Structural Interpretation of Mutations of Human Choline Acetyltransferase. *X. Shen[1], T. Crawford[2], J. Brengman[1], G. Acsadi[3], S. Iannaconne[4], E. Karaca[5], C. Khoury[6], J. Mah[7], S. Edvardson[8], Z. Bajzer[9], D. Rodgers[10], A. Engel[1].* 1) Dept. of Neurology, Mayo Clinic, Rochester, MN, USA; 2) Dept. of Neurology and Pediatrics, John Hopkins Hospital, Baltimore, MD, USA; 3) Children's Hospital of Michigan, Detroit, MI, USA; 4) Dept. of Neurology, University of Texas Southwestern Medical Center, Dallas, TX, USA; 5) Dept. of Medical Genetics, Ege University, Izmir, Turkey; 6) Dept. of Neurology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; 7) Dept. of Pediatrics, University of Calgary, Calgary, Alberta, Canada; 8) Dept. of Pediatric Neurology, Hadassah University Hospital, Jerusalem, Israel; 9) Dept. of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA; 10) Dept. of Molecular and Cellular Biochemistry and Center for Structural Biology, University of Kentucky, Lexington, KY, USA.

Choline acetyltransferase (CHAT; EC 2.3.1.6) catalyzes synthesis of acetylcholine from acetyl-CoA and choline in cholinergic neurons. *CHAT* mutations cause potentially lethal congenital myasthenic syndromes associated with episodic apnea (CHAT-CMS) (MIM ID 254210). Here we analyze the functional consequences of 12 missense and 1 nonsense mutations of CHAT in 11 patients. Nine of the mutations are novel. We examine expression of the recombinant missense mutants in Bosc 23 cells, determine their kinetic properties and thermal stability, and interpret the functional effects of 11 mutations in the context of the atomic structural model of human CHAT. With amino acid changes based on the 83 kDa M type CHAT (NP_065574), 5 mutations (p.Trp421Ser, p.Ser498Pro, p.Thr553Asn, p.Ala557Thr, p.Ser572Trp) reduce enzyme expression to <50% of wild-type. Mutations with severe kinetic effects are located in the active-site tunnel (p.Met202Arg, p.Thr553Asn and p.Ala557Thr) or adjacent to the substrate binding site (p.Ser572Trp), or exert their effect allosterically (p.Trp421Ser and p.Ile689Ser). Two mutations with milder kinetic effects (p.Val136Met, p.Ala235Thr) are also predicted to act allosterically. One mutation (p.Thr608Asn) below the nucleotide binding site of CoA enhances dissociation of AcCoA from the enzyme-substrate complex. Two mutations introducing a proline residues into an (-helix (p.Ser498Pro and p.Ser704Pro) impair the thermal stability of CHAT.

1145T

Heme oxygenase-1 gene promoter polymorphism is associated with reduced incidence of acute chest syndrome in children with sickle cell anemia. *C. Bean[1], S. Boulet[1], D. Ellingsen[1], M. Pyle[1], E. Barron-Casella[2], J. Casella[2], S. Ofori-Acquah[3], W.C. Hooper[1], M. DeBaun[4].* 1) Division of Blood Disorders, Centers for Disease Control, Atlanta, GA; 2) Division of Pediatric Hematology, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Division of Hematology/Oncology/BMT, Emory University, Atlanta, GA; 4) Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, TN.

Sickle cell anemia (SCA) is a common hemolytic disorder with a broad range of complications, including anemia, vaso-occlusive episodes, acute chest syndrome (ACS), pain and stroke. Despite the clinical importance of the role of vaso-occlusive episodes in pain and ACS, there remains limited insight into their underlying etiology. Sickle erythrocytes have a high rate of lysis, releasing large amounts of hemoglobin into the plasma. Free heme released from hemoglobin induces vascular inflammation and is a major source of oxidative stress in patients with SCA.

Heme oxygenase-1 (*HMOX1*) is the inducible, rate limiting enzyme in the catabolism of heme and may attenuate the severity of outcomes from vaso-occlusive and hemolytic crises. A $(GT)_n$ dinucleotide repeat located in the promoter region of the *HMOX1* gene is highly polymorphic, with long repeat lengths linked to decreased activity and inducibility. We examined this polymorphism to test the hypothesis that short alleles are associated with decreased risk of adverse outcomes (pain requiring hospitalization and ACS) in a cohort of 949 children with SCA.

Allele lengths varied from 13 to 45 $(GT)_n$ repeats and showed a trimodal distribution, with peaks at 23, 30 and 39 repeats. Compared with children with longer allele lengths, children with two shorter alleles (4%; ≤25 repeats) had lower rates of hospitalization for ACS (IRR 0.28, 95% CI: 0.10-0.81), after adjusting for gender, age, asthma, and percent fetal hemoglobin. No relationship was identified between allele lengths and pain rate. To our knowledge, this is the first study to examine the role of genetic variation in *HMOX1* in a population of patients affected with a congenital hemolytic disorder and, we demonstrate that genetic variation in the inducible form of heme oxygenase is associated with ACS. Specifically, patients homozygous for short $(GT)_n$ repeat alleles have a significantly lower rate of hospitalization per patient year for ACS, a leading cause of death in patients with SCA. Greater understanding of the role of the heme oxygenase response in these patients may be a key to improved prediction and treatment strategies.

1146T

Homozygous c.369_370delAG and c.374_376delCGC Mutation in STX11 Gene in a Patient with Familial Hemophagocytic Lymphohistiocytosis. *H. Onay[1], D. Yilmaz Karapinar[2], A. Aykut[1], S. Gokce[2], B. Karapinar[2], F. Ozkinay[1,2].* 1) Department of Medical Genetics , Ege University Faculty of Medicine, Izmir, Turkey; 2) Department of Pediatrics, Ege University Faculty of Medicine, Izmir, Turkey.

Familial hemophagocytic lymphohistiocytosis (FHL) is a rare autosomal recessive lethal condition characterized by fever, cytopenia, hepatosplenomegaly, and hemophagocytosis. Upto date three genes that cause FHL have been identified. Perforin gene (PRF1) mutations have been identified in %20-50 of the patients with FHL. Mutations in MUNC13-4 and Syntaxin 11(STX11) genes also cause FHL. A 2-year old boy was referred to Pediatric Intensive Care Unit for hepatic failure, hypotension, hematochezia, and coma. Glasgow coma score was 12. He had splenomegaly, fever (unresponsive to antibiotheraphy), pancytopenia, bleeding diathesis, and low fibrinogen levels. Bone marrow biopsy was performed. Bone marrow was hypocellular, major cell type was histiocytes, and contained hemophagocytic macrophages. Due to consanguinity between parents and child age being under two years, the diagnosis was considered as familial (primary) hemophagocytic lymphohistiocytosis (FHL). The patient was referred to Medical Genetic Department for mutation analysis. Sequencing of the STX11 gene revealed a homozygous c.369_370delAG and c.374_376delCGC mutation. This rare mutation was solely described in a Turkish family. The age of onset of our patient was similar to the patients in this previous report. Although HLH 2004 treatment regimen was applied, the patient deceased due to cardiac arrest at the end of 4 days. Herein we present a case with FHL with a very rare 5 bp deletion mutation in STX11 gene.

Klein[1,10].* 1) National Center for Biotechnology Information, National Institutes of Health, DHHS, Bethesda, MD, USA; 2) Department of Pediatric Hematology/Oncology, Hannover Medical School, Hannover, Germany; 3) Department of Experimental Hematology, Hannover Medical School, Hannover, Germany; 4) Institute of Pathology, Hannover Medical School, Hannover, Germany; 5) Department of Hematology/Oncology, Core Facility II Genomics, Freiburg University Medical Center, Freiburg, Germany; 6) Department of Immunology and Molecular Pathology, Royal Free Hospital & University College London, London, UK; 7) Research Center for Immunodeficiencies, Pediatrics Center of Excellence, Children's Medical Center, Tehran University of Medical Sciences, Tehran, Iran; 8) Department of Pediatric Cardiology, Hannover Medical School, Hannover, Germany; 9) Department of Infectious Diseases, Isfahan University of Medical Sciences, Isfahan, Iran; 10) University Children's Hospital Munich, Dr. von Haunersches Kinderspital, Munich, Germany.

We describe an unusual clinical phenotype associating intermittent neutropenia, progressive T- and B-cell lymphopenia, and atrial septal defects in three members of a consanguineous kindred. Homozygosity mapping and candidate gene sequencing revealed a mutation in the gene STK4 (formerly MST1). STK4 is the human ortholog of Drosophila Hippo, the central constituent of a highly conserved pathway controlling cell growth and apoptosis. STK4-deficient lymphocytes and neutrophils exhibit enhanced loss of mitochondrial membrane potential and increased susceptibility to apoptosis.

Schermer[3,12].* 1) Center for Human Genetics, Bioscientia, Ingelheim, Germany; 2) Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany; 3) Renal Division, Department of Medicine and Centre for Molecular Medicine, University of Cologne, Cologne, Germany; 4) Department of Pediatrics, University of Cologne, Germany; 5) Medical Genetics Center, Cairo, Egypt; 6) Children's Hospital, Ain Shams University, Cairo, Egypt; 7) Institute of Human Genetics, University Hospital of Schleswig-Holstein, Campus Lübeck, Germany; 8) Department of Paediatric Neurology, University Children's Hospital of Zurich, Zurich, Switzerland; 9) Klinikum Oldenburg, Zentrum für Kinder- und Jugendmedizin, Elisabeth Kinderkrankenhaus, Neuropädiatrie, Oldenburg, Germany; 10) Department of Pediatrics II, Innsbruck Medical University, Innsbruck, Austria; 11) Cologne Center for Genomics and Centre for Molecular Medicine, University of Cologne, Cologne, Germany; 12) Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases, University of Cologne, Cologne, Germany; 13) Department of Tumor Virology, German Cancer Research Center Heidelberg, Germany; 14) Department of Radiology, University of Cologne, Cologne, Germany; 15) Department of Anatomy, University Hospital of Cologne, Cologne, Germany.

Joubert syndrome (JBTS) is characterized by a specific brain malformation, the molar tooth sign, and various additional pathologies. It results from mutations in any one of at least 10 different genes. JBTS has been linked to dysfunction of primary cilia, since the gene products known to be associated with the disorder localize to this evolutionarily ancient organelle. Here we report the identification of a novel locus for Joubert syndrome, *JBTS12*, on chromosome 15q25.3-q26.3, with mutations in the *KIF7* gene in a consanguineous JBTS family and subsequently in other patients with JBTS of different severity. One patient carried a heterozygous *KIF7* mutation together with two hypomorphic *TMEM67* mutations, suggesting that disease in this patient may be oligogenic, resulting from the mutational load with three mutant alleles in two JBTS genes. KIF7, an ortholog of the *Drosophila* kinesin *Costal2*, is a known regulator of Hedgehog signaling and a putative ciliary motor protein. We found that KIF7 co-precipitated with nephrocystin-1 (NPHP1), another protein mutated in JBTS and related ciliopathies. Knockdown of *KIF7* expression in cell lines caused defects in cilia formation and induced abnormal centrosomal duplication and fragmentation of the Golgi network. The Golgi phenotype affected all three compartments of the Golgi apparatus, and could be rescued by over-expression of full-length KIF7. In contrast, over-expression of a KIF7 truncation lacking the predicted motor domain led to the same Golgi phenotype as the knockdown of *KIF7*. We observed an increase of tubulin acetylation and changes in the cell shape. Consistently, KIF7 was found to interact with the histone deacetylase HDAC6 and the polarity complex protein PAR3. In conclusion, loss of KIF7 function affects microtubule stability and growth direction which may impact cilia, centrosomes and Golgi and represent a disease mechanism for JBTS. *KIF7* represents a prime candidate for mono- and oligogenic forms of other ciliopathies related to JBTS, namely Meckel-Gruber-, Senior Loken- and Bardet-Biedl syndrome, Leber congenital amaurosis and nephronophthisis.

FORGE Canada: A nation-wide effort to identify genes causing Mendelian disorders. *K.M. Boycott[1], C.L. Beaulieu[1], J. Marcadier[1], J. Michaud[2], J. Friedman[3], M. Samuels[2], B. Knoppers[4], B. Fernandez[5], F. Bernier[6], S. Scherer[7], M. Brudno[8] FORGE Canada Consortium.* 1) Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON, Canada; 2) Centre de Recherche de l'Hôpital Ste-Justine, Montréal, QC, Canada; 3) University of British Columbia, Vancouver, BC, Canada; 4) Centre of Genomics and Policy, McGill University, Montreal, QC, Canada; 5) Discipline of Genetics, Memorial University, St. John's, NFLD, Canada; 6) Department of Medical Genetics, University of Calgary, Calgary, AB, Canada; 7) The Center for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 8) Department of Computer Science and Donnelly Centre, University of Toronto, Toronto, ON, Canada.

Single-gene disorders, while individually rare, have, in aggregate, an enormous impact on the well-being of families. The majority of the estimated 10,000 genes that cause these conditions remain unknown and with the introduction of massively parallel next-generation sequencing techniques a unique opportunity exists to identify the remaining genes causing Mendelian disease. It is estimated that 500,000 Canadian children are affected with a rare genetic disorder. The objective of the FORGE Canada Consortium - Finding of Rare Disease Genes in Canada - initiative is to rapidly identify disease genes for over 100 childhood monogenic disorders, in an 18 month time-frame with established funding through Genome Canada and the Canadian Institutes of Health Research. To this end we have developed a collaborative national consortium of clinicians and scientists - with over 150 members and including clinical site-leads from all 21 Clinical Genetics Centres in Canada. Our clinical coordination has enabled identification of sufficient patient resources for the study of many disorders which individually would not have been possible through purely local ascertainment. We have established a pipeline for discovery that includes resources for over 175 disorders; each disorder has an identified team lead to guide the research for that particular project. We are using whole-exome, and in some cases whole-genome, re-sequencing at the three Science and Technology Innovation Centres in Canada. We have established a National Data Coordination Centre to facilitate data analysis, data sharing and development of improved analysis tools. Once potential causative variants are identified through this pipeline, team leads are responsible for validation and further study of these genes in their research laboratories. Guidelines for the application of these new technologies for the investigation of childhood disease are being created through an integrated GE^{3}LS research component, including knowledge translation to clinical practice. Examples of gene identification successes will be highlighted including Hadju-Cheney syndrome and other disorders currently in progress. The wealth of knowledge this effort will generate will immediately translate to improved patient care and will provide pathways for further study and potential therapeutic investigation. Through the FORGE Consortium, Canada is emerging as an international leader focused on the study of rare genetic disease.

1150T

Whole-exome sequencing in a single proband reveals causative mutation in autosomal recessive peeling skin syndrome. *R.M. Cabral[1], M. Kurban[1], M. Wajid[1], Y. Shimomura[1, 2], A.M. Christiano[1, 3].* 1) Dermatology, Columbia University, New York, NY; 2) Epidemiology, Columbia University, New York, NY; 3) Genetics & Development, Columbia University, New York, NY.

We ascertained a large consanguineous family segregating peeling skin syndrome noninflammatory type A (OMIM 270300) as a recessive trait. Autozygosity mapping using the Affymetrix 10K genotyping chip revealed a 15Mb region with strong evidence for allele sharing among affected individuals, with a LOD score of 10.9. We then performed whole-exome sequencing using the SOLiD 4 platform on a single affected family member. We identified a total of 1,093 variants that were not present in any public databases or our internal database of exome variants derived from ethnically-matched unrelated samples. Only one homozygous variant was present in the autozygous region, 229C>T, located within the gene CHST8. We validated this finding with Sanger sequencing in all members of the pedigree and demonstrated co-segregation with the trait. The CHST8 gene encodes a Golgi membrane carbohydrate sulfotransferase, N-acetylgalactosamine-4-O-sulfotransferase 1 (GalNAc4-ST1), known to be highly expressed in pituitary, cerebellum and brain. Immunohistochemistry on frozen normal skin sections with a polyclonal antibody raised against GalNAc4-ST1 showed that this enzyme is also expressed throughout the epidermis, predominantly in the granular and cornified layers. To investigate the effect of the 229C>T mutation (R77W) on the function of GalNAc4-ST1, we performed a colorimetric assay for sulfated glycosaminoglycan (GAGs) quantification, and compared total amounts of sulfated GAGs between human keratinocytes (CCD1106 KERTr cell line) transfected with wild type and mutant CHST8 cDNA constructs. We observed decreased levels of total sulfated GAGs in cells transfected with the mutant CHST8 construct compared to wild type, suggesting loss of function of mutant GalNAc4-ST1. Both wild type and mutant GalNAc4-ST1 co-localized with the Golgi membrane marker GM130, as assessed by immunofluorescence staining of CCD1106 cells. However, Western blot analysis revealed lower expression levels of the full length GalNAc4-ST1 protein, as well as an additional lower molecular weight immunoreactive band in cells transfected with the mutant CHST8 construct compared to wild type CHST8. These results demonstrate that the R77W mutation leads to decreased expression levels of GalNAc4-ST1, possibly by leading to decreased protein stability and increased degradation, which results in loss of function.

Deficiency of adaptor protein complex 4 causes autosomal recessive intellectual disability with absent speech, shy character, progressive spastic paraplegia and short stature. *L. Colleaux[1], O. Philippe[1], A. Raas-Rothschild[2], S. Eck[3], E. Graf[3], R. Buchert[4], G. Borck[1], A. Ekici[4], F.F. Brockschmidt[5,6], M.M. Nöthen[5,6], A. Munnich[1], T.M. Strom[3,7], A. Reis[4], R. Abou Jamra[4].* 1) INSERM U781,Fondation IMAGINE, Département de Génétique, Hôpital Necker-Enfants Malades, PARIS, France; 2) Department of Human Genetics and Metabolic Diseases, Hadassah Hebrew University Medical Center, Jerusalem, Israel; 3) Institute of Human Genetics, Helmholtz Center Munich, German Research Center for Environmental Health, Neuherberg, Germany; 4) Institute of Human Genetics, University of Erlangen, Erlangen, Germany; 5) Department of Genomics, Life & Brain Center, University of Bonn, Bonn, Germany; 6) Institute of Human Genetics, University of Bonn, Bonn, Germany; 7) Institute of Human Genetics, Klinikum rechts der Isar, Technische Universität München, München, Germany.

Intellectual disability of autosomal recessive inheritance represents an important fraction of severe cognitive dysfunction disorders. Yet, the extreme heterogeneity of these conditions markedly hampers gene identification. Here, we report on eight affected individuals from three consanguineous families that all presented with severe intellectual disability with absent speech, shy character, stereotypic laughter, muscular hypotonia that progressed to spastic paraplegia, microcephaly, feet deformity and decreased muscle mass of the lower limbs, inability to walk, and growth retardation. Using a combination of autozygosity mapping and either Sanger sequencing of candidate genes or next generation exome sequencing, we identified one mutation in each of three genes encoding adaptor protein complex 4 (AP4) subunits: a nonsense mutation in *AP4S1* (NM_007077.3:c.124C>T,p.Arg42*), a frameshift mutation in *AP4B1* (NM_006594.2: c.487_488insTAT,p.Glu163_Ser739delinsVal), and a splice mutation in *AP4E1* (NM_007347.3, c.542+1_542+4delGTAA,r.421_542del,-p.Glu181Glyfs*20). Adaptor protein complexes (AP1-4) are ubiquitously expressed evolutionarily conserved heterotetrameric complexes that mediate different types of vesicle formation and the selection of cargo molecules for inclusion into these vesicles. Interestingly, two mutations affecting *AP4M1* and *AP4E1* have recently been found to cause cerebral palsy associated with severe intellectual disability. Our findings illustrate the power of combining systematic autozygosity mapping with large-scale sequencing for unraveling the molecular bases of autosomal recessive ID. More importantly, combined to previous observations, these results support the hypothesis of a crucial role of AP4- mediated trafficking in brain development and functioning and demonstrate the existence of a clinically recognizable AP4 deficiency syndrome.

Mutation in *STXBP5L* in a novel neurodegenerative disorder with severe axonal peripheral neuropathy, neurogenic muscular atrophy and optic atrophy. *M. Corbett[1], R. Sharma[1], K. Smith[2], A. Hoischen[3], J. Veltman[3], M. Bahlo[2,4], E. Haan[5,6], J. Gecz[1,5,7].* 1) Genetics and Molecular Pathology, SA Pathology, North Adelaide, Australia; 2) The Walter and Eliza Hall Research Institute of Medical Research, Parkville, Australia; 3) Department of Human Genetics, Radboud University Nijmegen Medical Centre, Nijmegen, The Netherlands; 4) Department of Mathematics and Statistics, University of Melbourne, Parkville, Australia; 5) School of Paediatrics and Reproductive Health, The University of Adelaide, Adelaide, Australia; 6) South Australian Clinical Genetics Service, SA Pathology, Adelaide, Australia; 7) School of Molecular and Biomedical Sciences, The University of Adelaide, Adelaide, Australia.

We describe a consanguineous pedigree with two siblings affected by a novel neurodegenerative disorder associated with severe axonal peripheral neuropathy, neurogenic muscular atrophy, hypotonia, muscle weakness, optic atrophy and developmental delay. Homozygousity mapping identified an identical by descent (IBD) region on chromosome 3, 110459136 bp-123879723 bp (hg18 March 2006 build) between the single nucleotide polymorphisms (SNPs) rs2673391 and rs1355563, with a LOD score of 2.31. All coding exons, microRNA and conserved sequences (based on elements with LOD > 50 from the 28 way Vertebrate Multiz alignment track from the UCSC genome browser) totaling approximately 1 Mbp of the IBD interval were enriched from genomic DNA of the proband using array based sequence enrichment (*Roche*). The enriched DNA was sequenced using *Roche GS FLX* pyrosequencing and resulting data mapped to the human genome. 1171 homozygous sequence variants were identified in the IBD interval and those localized to coding sequences were filtered against dbSNP130 to reveal a single, unique, missense variant in syntaxin binding protein 5 like (*STXBP5L*). The product of *STXBP5L* is an as yet uncharacterized protein expressed in the central and peripheral nervous system. The closely related STXBP5 (or tomosyn) protein is known to inhibit neurotransmitter release through inhibition of the formation of the SNARE complexes between synaptic vesicles and the plasma membrane. This suggests a potential role of STXBP5L in neurotransmitter transport or release. On aggregate, our clinical, genetic and molecular data suggest that mutation in *STXBP5L* provides a plausible explanation for this novel, progressive neurodegenerative disorder.

BLOC-1 mutation screening in Hermansky-Pudlak Syndrome reveals a new HPS subtype, HPS-9, associated with mutations in PLDN (pallidin) and a novel BLOS3 (HPS-8) mutation. *A.R. Cullinane[1], J.A. Curry[1], C. Carmona-Rivera[1], G. Golas[2], C.G. Summers[3], C. Ciccone[1], N.D. Cardillo[1], H. Dorward[1], R.A. Hess[1], J.G. White[4], D. Adams[1,2], M. Huizing[1], W.A. Gahl[1,2].* 1) Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda MD 20892, USA; 2) Intramural Office of Rare Diseases Research, Office of the Director, National Institutes of Health, Bethesda MD 20892 USA; 3) 3. Departments of Ophthalmology and Pediatrics, University of Minnesota, Minneapolis, MN 55455 USA; 4) 4. Department of Laboratory Medicine, University of Minnesota, Minneapolis, MN 55455 USA.

Hermansky-Pudlak Syndrome (HPS) is an autosomal recessive condition characterized by oculocutaneous albinism and a bleeding diathesis due to absent platelet delta granules. HPS, a genetically heterogeneous disorder of intracellular vesicle biogenesis, and has 8 known subtypes, 7 of which are associated with genes encoding different Biogenesis of Lysosome-related Organelles Complex (BLOC) proteins. We screened patients with HPS-like symptoms for mutations in HPS1-6 and found no functional mutations in 38 individuals. We then examined these individuals for all 8 genes encoding the BLOC-1 proteins. We identified homozygous nonsense mutations in PLDN, encoding the BLOC-1 subunit, pallidin, in a single individual with characteristic features of HPS. No PLDN mutations have previously been described in humans, although Pldn is mutated in the HPS mouse model pallid. The pallidin protein interacts with the early endosomal t-SNARE syntaxin-13. We could not detect any full-length pallidin protein in our HPS-9 patient's fibroblasts or melanocytes despite normal mRNA expression of the mutant transcript. An alternative transcript was detected in the patient that would skip the exon that harbors the mutation; however, we demonstrate that, if this transcript were translated into protein, it would not interact with syntaxin-13 although it correctly localizes to early endosomes. We also identified only the second mutation to date in BLOS3, causing HPS-8. In this infant's melanocytes, BLOS3 mRNA expression was significantly reduced compared to control, suggesting nonsense-mediated decay was occurring for this mutation. Absence of either PLDN or BLOS3 causes instability of the BLOC-1 protein complex, and in both HPS-9 and HPS-8 melanocytes, the melanogenic protein TYRP1 showed aberrant localization, increased plasma-membrane trafficking, and failure to reach melanosomes. These results help explain the patients' severe albinism and establish a common cellular defect within patients having BLOC-1 gene mutations.

Mutations in *MEGF11* cause juvenile open angle glaucoma. *B.J. Fan[1], D.Y. Wang[1], X. Chen[1], K. Linkroum[1], E.A. DelBono[1], J.L. Haines[2], J.L. Wiggs[1].* 1) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 2) Center for Human Genetic Research, Vanderbilt University School of Medicine, Nashville, TN.

Juvenile open-angle glaucoma (JOAG) is a rare disorder that is typically inherited as an autosomal dominant trait. Family linkage studies have suggested 5 genetic loci harboring genes responsible for JOAG, including *GLC1A* (1q24.3-q25.2), *GLC1J* (9q22), *GLC1K* (20p12), *GLC1M* (5q22.1-q32) and *GLC1N* (15q22-q24). *Myocilin* (*MYOC*) was identified as the causative gene at *GLC1A*, whereas the responsible genes at the other loci remain to be identified. Our fine mapping study identified 6 adjacent SNPs at *GLC1N* associated with JOAG in a Chinese case-control sample. In the present study, we further refined the association using an independent sample of Caucasian populations and identified *multiple EGF-like-domains 11* (*MEGF11*) as a potential causative gene for JOAG. A total of 579 unrelated patients with glaucoma, including 40 patients with JOAG and 539 patients with adult-onset primary open angle glaucoma (POAG), and 365 control subjects were genotyped for the 6 SNPs at *GLC1N* by ABI TaqMan assays. The SNP rs441949 in *MEGF11* showed a significant association with JOAG in the Caucasian sample ($p = 0.0027$, Bonferroni-corrected $p = 0.016$; OR = 2.47, 95%CI: 1.40-4.33). The other 5 SNPs were not associated with JOAG ($p > 0.07$). None of these SNPs were associated with POAG ($p > 0.25$). All exons and splicing junctions of *MEGF11* were screened for sequence alterations in the JOAG patients and a subset of controls. Twenty-two sequence alterations were identified in *MEGF11* in the JOAG patients, ten of which were novel including 2 nonsynonymous changes (G238D and D899N) which were absent in the control group (n = 65). Both G238D and D899N are evolutionarily conserved and predicted to have pathological effects using PolyPhen-2. Overall our results support *MEGF11* at the *GLC1N* locus as a novel disease-causing gene for JOAG. **Grant support:** NEI Grants R01EY015872 and P30EY014104, Research to Prevent Blindness and The Massachusetts Lions Eye Research Fund.

Genetic heterogeneity in the Brittle Cornea Syndrome (BCS) - New evidence that *ZNF469* and *PRDM5* regulate extracellular matrix development and maintenance within the same pathway. *C. Giunta[1], F. Manson[2], E.M.M. Burkitt Wright[2], H.L. Spencer[2], N. Zoppi[3], A.R. Janecke[4], C. Bürer-Chambaz[1], H. Al-Hussain[5], M. Wilson[6], M. Bakshi[6], D. Sillence[6], M. Colombi[3], B. Steinmann[1], M. Rohrbach[1], G.C.M. Black[2].* 1) Division of Metabolism, University Children's Hospital and Children's Research Center, Zurich, Switzerland; 2) 2Genetic Medicine Research Group, Manchester Biomedical Research Centre, Manchester Academic Health Sciences Centre, University of Manchester and Central Manchester Foundation Trust, St Mary's Hospital Manchester, UK; 3) Division of Biology and Genetics, Department of Biomedical Sciences and Biotechnology, Medical Faculty, University of Brescia, Brescia, Italy; 4) Division of Clinical Genetics, Innsbruck Medical University, Innsbruck; 5) King Khaled Eye Specialist Hospital, Riyadh, Saudi Arabia; 6) Department of Clinical Genetics, Children's Hospital at Westmead, Sydney, Australia.

The Brittle Cornea Syndrome (BCS; MIM 229200) is an autosomal recessive connective tissue disorder caused by mutations in *ZNF469* (Abu et al., 2008) and is characterized by extreme thinning and fragility of the cornea that may rupture even in the absence of adequate trauma and can lead to blindness. Keratoconus or keratoglobus, high myopia, blue sclerae, hyperelasticity of the skin without excessive fragility, and hypermobility of the small joints are additional features of BCS. In a cohort of thirteen BCS affected families (Al-Hussain et al., 2004), genome-wide SNP-homozygosity mapping and sequencing identified *ZNF469* mutations in only nine families, thus suggesting genetic heterogeneity in BCS. Thereafter, autozygosity mapping in two newly identified large BCS families of Pakistani origin allowed us to identify the transcription factor PRDM5 as the second gene mutated in BCS, thus confirming genetic heterogeneity (Burkitt Wright et al., 2011). Screening of further patients identified homozygous mutations in *PRDM5* in five additional BCS families, including three from Al-Hussain et al. 2004, who had tested negative for *ZNF469* mutations, as well as heterozygous *PRDM5* mutations in individuals homozygous for *ZNF469* mutations. The phenotypic spectrum of BCS appears similar, if not identical, in patients with mutations in either *ZNF469* or *PRDM5.* Heterozygous carries for a *PRDM5* mutation present with a clear intermediate phenotype. It remains to be investigated if the presence of *ZNF469* together with P*RDM5* mutations in the same individual is associated with a more severe phenotype. In our patient cohort consisting meanwhile of 20 families, we have identified distinctive syndromic features of BCS, including hypercompliant tympanic membranes, hip dysplasia, and severe hypermobility also of the large joints, thus being reminiscent of the hypermobility type of Ehlers-Danlos syndrome (MIM 130020). PRDM5 is a widely expressed transcription factor that modulates many aspects of tissue development and maintenance, such as cell fate and cell adhesion, via mechanisms that include Wnt signaling. Our study indicates that regulation of expression of extracellular matrix components, particularly fibrillar collagens, by PRDM5 and ZNF469 is a key molecular mechanism that controls normal corneal and other connective tissue development and maintenance and, if disturbed, underlies the generalized connective tissue disorder in BCS including the devastating corneal fragility.

Comparative study of mutation spectra in North-West Russia familial hypercholesterolemia: St. Petersburg versus Petrozavodsk. *A.S. Golovina[1,2], T.Y. Komarova[2].* 1) Biochemistry, SPbSU, Saint-Petersburg, Russian Federation; 2) Institute of Experimental Medicine of the NorthWest Branch of the Russian Academy of Medical Sciences (IEM NWB RAMS).

Introduction Familial hypercholesterolemia (FH) is a common monogenic disease leading to premature coronary and cerebral atherosclerosis. FH is caused by mutations in the low density lipoprotein receptor (LDLR) gene or in the APOB gene coding for the LDLR major ligand -apolipoprotein B-100. Aim of the present study was to compare spectra of mutations leading to FH development in patients from two major cities in North-West Russia: St. Petersburg and Petrozavodsk.

Methods

We used venous blood of 60 Petrozavodsk FH patients to extract DNA and different methods of molecular biology including PCR, SSCP-analysis, molecular cloning in Escherichia coli, and DNA sequencing. Data were compared with mutation spectra in 100 St.Petersburg FH patients.

Results

1. R3500Q APOB mutation that is frequent variant in European populations does not occur in FH patients from both cities. 2. None of FH patients from Petrozavodsk carried mutation FH-North Karelia in the LDLR gene, that is typical for the residents of eastern Finland but found only once in St. Petersburg. 3. C139G and G197del LDLR gene mutations that are recurrent in St. Petersburg FH do not occur in Petrozavodsk sample. 4. We have identified new mutation c.192del10/ins8 in two unrelated patients from Petrozavodsk. This mutation represents a complex rearrangement in the 5 `part of the LDLR gene third exon.

Conclusion

New mutation c.192del10/ins8 results in shift of the reading frame and creates a premature stop codon in the LDLR gene fourth exon. Therefore, this mutation is a likely cause of FH in both heterozygous patients.

Adams-Oliver syndrome, identification of a putative causal gene using exome sequencing. *S.J. Hassed[1], G.B. Wiley[2], S. Wang[2], J.Y. Lee[1], S. LI[1], Y. Xu[1], Z.J. Zhao[3], J.J. Mulvihill[1], J. Robertson[2], P.M. Gaffney[2].* 1) Dept Pediatrics/Gen, Univ Oklahoma Med Ctr, Oklahoma City, OK; 2) Oklahoma Medical Research Foundation, Oklahoma City, OK; 3) Dept. Pathology, Univ Oklahoma Med Ctr ,Oklahoma City, OK.

Adams-Oliver syndrome (AOS) is a rare genetic disorder characterized by vertex scalp defects resembling cutis aplasia and terminal limb malformations. Other features include congenital heart defects, agenesis of corpus callosum, capillary hemangioma, club foot, cryptorchidism, syndactyly, and cutis marmorata. All features are congenital, show a high degree of variability, and do not progress with age. The mode of inheritance is likely autosomal dominant. Pathogenesis remains unknown, but may involve abnormal vasculogenesis followed by vascular disruption that impairs tissue formation distally: the critical site appears to be the small vessels. Array comparative genomic hybridization was performed using the Roche/NimbleGen chip with normal results in 6/7 patients, suggesting that AOS is not the result of a microdeletion or microduplication. In an attempt to identify a susceptibility gene, the exomes of multiple members from two unrelated families with AOS were enriched and sequenced. Polymorphisms identified in each exome sequence were then screened to isolate functional mutations. Screening criteria include non-synonymous amino acid changes, absence from both dbSNP build 130 and the 1000 Genome Project pilot data, removal of mutations within segmental duplication regions, and the requirement that remaining variations be within regions annotated as Most Conserved Elements among vertebrates. Comparison of the sequence data both within and between the two families identified a single putatively causal gene harboring two mutations concordant with the disorder and with each mutation being unique to one family. Both mutations occur in the same highly conserved functional site despite being located in separate exons. Protein studies were undertaken to confirm the functional role of these mutations in the etiology of AOS.

Novel X-linked Disorder Identifies the Phenotype of a Germline Mutation in PIGA: The Gene Somatically Mutated in Paroxysmal Nocturnal Hemoglobinuria. *J.J. Johnston[1], A.L. Gropman[2], J. Martin[2], J.C. Sapp[1], J.K. Teer[1], R.A. Brodsky[3], L.G. Biesecker[1,4], NIH Intramural Sequencing Center.* 1) Genetic Disease Research Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 2) Division of Neurology, Children's National Medical Center, Washington, DC, USA; 3) Division of Hematology, Department of Internal Medicine, Johns Hopkins University, Baltimore, MD, USA; 4) NIH Intramural Sequencing Center, National Human Genome Research Institute, Rockville, MD, USA.

Phosphatidylinositol glycan class A (PIGA, MIM 311770) is involved in the first step of glycosylphosphatidylinositol (GPI) biosynthesis. Many proteins are anchored to the cell by GPI and in the absence of GPI anchors, these proteins are degraded intracellularly. The loss of CD55 and CD59 on erythrocytes causes complement-mediated lysis in paroxysmal nocturnal hemoglobinuria (PNH), a disease that manifests after clonal expansion of hematopoietic cells with somatic PIGA mutations. While somatic PIGA mutations have been identified in many PNH patients, it has been proposed that germline mutations are lethal. We report a family with an X-linked lethal disorder with cleft palate, neonatal seizures, contractures, CNS structural malformations, and other anomalies. The family presented with three deceased male children and two obligate carrier females. Samples were unavailable for two of the three children. X chromosome inactivation studies in carrier females showed 100% skewing supporting X-linkage. A single sample from an obligate carrier female was included in an X exome next generation sequencing screen to identify the causative alteration for this phenotype. The sequencing yielded 18,509,569 reads. 52.1% of the reads could be uniquely aligned to the X exome target with an overall coverage of 107X. We found 1,271 substitutions and 89 insertions/deletions. We filtered variants for nonsynonymous, splice, frame-shift, and stop alleles as the mutation caused a lethal phenotype. Variants were also filtered for heterozygosity because the test subject was an unaffected carrier female. Variants present in eight control samples sequenced with the same methodology, dbSNP or the ClinSeq™ cohort (401 control individuals) were excluded. This left six variants, including a single nonsense mutation, c.1234C>T in PIGA, which predicts p.Arg412X. This variant segregated with affection/carrier status in the family. Frameshift, nonsense, or splice mutations in PIGA were not identified in over 400 controls. This mutation is very similar to mutations known to cause dysfunction of PIGA in PNH. The genetic data show that the c.1234C>T p.Arg412X variant is a severe change in the gene, is rare in the population, is present in an affected child, and is linked to the affected chromosome in this family. We conclude that this variant in PIGA caused the phenotype in this family, and this family presents the long-sought phenotype for PIGA germline mutations.

Insulin-like growth factor-1 polymorphism and cancer risk: a systematic review and meta-analysis. *M.S. Haerian[1], B.S. Haerian[2].* 1) Research Center for Gastroenterology and Liver Disease, Shaheed Beheshti University, M.C., Tehran, Iran; 2) Department Pharmacology, Faculty of Medicine, University of Malaya, Kuala Lumpur, Malaysia.

Objective: Insulin receptor substrate-1 (IRS-1) protein plays an important role in the IGF-1 signaling pathway. It is involved in development and progression of various cancers. In this study, we assessed the relationship between of the IRS-1 G972A gene polymorphism with the risk of breast, colorectal, and prostate cancers. Materials and Methods: We meta-analyzed the related studies that evaluated the role of G972A polymorphisms with cancer risk under alternative genetic models. Results: Meta-analysis of the pooled data showed no allelic and genotypic association of the G972A polymorphism with cancer risk. Sub-analysis by cancer type supported this result in each type of cancer. Conclusion: Our data suggested that the IRS-1 G972A polymorphism is not a risk factor for breast, colorectal, and prostate cancers.

Detection of High Levels of Urinary Apoptotic Nucleic Acids and Promoter Hyper-methylation of Multiple Tumour Suppressor Genes in Prostate Cancer. *A. Haj-Ahmad, M. Abdalla, Y. Haj-Ahmad.* Norgen Biotek Corp, Thorold, Ontario, Canada.

Prostate cancer is the most frequently occurring cancer and is the second highest cause of cancer mortality in males. Serum prostate specific antigen (PSA) is currently used as an indicator for the diagnosis and management of prostate cancer. Patients with a serum PSA level between 2.5 ng/mL and 10 ng/mL will often undergo prostate biopsies to confirm prostate cancer. However, <30% of these men will biopsy positive for cancer; meaning that the majority of men underwent an invasive biopsy with little benefit. A non-invasive biomarker, which can detect prostate cancer at an early stage, is therefore urgently needed. Urinary Apoptotic Nucleic Acids (uaNAs) were isolated from urine obtained from 3 groups of individuals (Prostate Cancer patients, Benign Prostatic Hyperplasia patients and healthy control individuals). By analyzing the levels of the uaNAs among the three groups we found that the uaNAs levels were significantly higher in the Prostate Cancer group when compared to the uaNAs levels observed in the BPH and control groups. Based on the aforementioned results, we decided to investigate the potential of using elevated levels of uaNAs for the early diagnosis of PCa. Toward this, we investigated whether the appearance of epigenetic changes that contribute to the development of cancer correlated positively with uaNA levels. This association was explored based on the following reasoning: during carcinogenesis, as the number of aberrant epigenetic mutations rises, cellular proliferation also rises which also means higher rates of apoptosis as cells compete for minimal resources; this shows up as elevated levels of apoptotic bodies in circulation and hence in urine. Therefore, the epigenetic silencing of known tumor suppressor genes was investigated with the purpose of correlating these aberrant events with the observed increase in uaNA levels in prostate cancer patients. Based on this hypothesis, we have established a correlation between the number of hyper-methylated tumour suppressor genes and the levels of uaNAs that together could be used for the early detection of PCa.

Genetic study of Tunisian familial hematological malignancies. *w.s. HAMADOU[1], R. ELABED[1], Y. BEN YOUSEF[3], A. KHELIF[3], H. SOBOL[2], Z. SOUA[1].* 1) U.R :biology of leukemias and lymphomas (03/UR/08-19) laboratory of Biochemistry, Faculty of Medicine, Sousse, Tunisia; 2) Department of Oncology Genetics, Prevention and Screening, IPC, Marseille, France; 3) Clinical Hematology Department, CHU F. Hached, Sousse, Tunisia.

Several genes associated with hematological malignancies have been described in the literature, but the genetic basis of familial aggregations remain poorly known. Among the genes that predispose to hematologic malignancies, there are ARTLS (regulation and expression of apoptotic proteins), PRF1 (lytic function and T lymphocytes immunosuveillance), CASP8 (apoptosis), CEBPA (control of cell proliferation and differentiation), FAS (cell necrosis and apoptosis). To determine the involvement of these genes, we conducted this preliminary study in searching of recurrent germline mutations in 8 Tunisian patients related in pairs by direct sequencing of the coding regions of five candidate genes: ARTLS1, PRF1, CASP8, CEBPA and FAS. Patients were dignosed for different types of hematologic malignancies: Hodgkin's disease (HD), non-Hodgkin lymphoma (NHL), myelodysplastic syndrome (MS), acute lymphoblastic leukemia (ALL) and chronic myelogenous leukemia (CML). This strategy has identified 4 mutations in the gene FAS including 3 silent mutations and missense mutation (c.365C> T p.Thr122Ile). For ARTLS1 gene, an heterozygous silent mutation (c.570C> T p.Arg190Arg) is found in 2 related patients and an homozygous, heterozygous missense mutation (c.442T> C p.Cys148Arg) in 5 patients. The CEBPA gene revealed a single silent mutation (c.690G> T p.Thr230Thr). For the gene PRF1 two silent mutations were identified. For the CASP8 gene a silent homozygous mutation was detected (c.1011G> A p.Lys337Lys) in 2 related patients and a homozygous missense mutation (c.904 C> G p.Asp302Glu) was detected in one patient. This study will be continued on other familial cases, while including other candidate genes for better understanding familial aggregations of hematologic malignancies and consists of reliable diagnostic tools to improve medical care.

Extending the Benign and Malignant Phenotypes Associated with Germline *DICER1* Mutations. *N. Hamel[1,2], M. Tischkowitz[1,3], A. Bahubeshi[1,3], B. Pasini[4], S. Asioli[5], G. Baynam[6], A. Overkov[7], R.P. Frieder[8], M. Dishop[9], N. Graf[10], M. Ekim[11], D. Bouron-Dal Soglio[12], J. Arseneau[13], R.H. Young[14], N. Sabbaghian[1,3], A. Srivastava[1,3], J.R. Priest[15], W.D. Foulkes[1,2,3].* 1) Program in Cancer Genetics, Departments of Oncology and Human Genetics, McGill University, Montreal, Canada; 2) The Research Institute, McGill University Health Center, Montreal, Canada; 3) Lady Davis Institute, Segal Cancer Center, Jewish General Hospital, Montreal, Canada; 4) Department of Genetics, Biology and Biochemistry, University of Turin, Italy; 5) Department of Biomedical Sciences and Human Oncology, University of Turin, Italy; 6) Genetic Services of Western Australia; 7) School of Paediatrics and Child Health, University of Western Australia, Australia; 8) Cancer Risk Assessment and Prevention, Santa Monica & Department of Obstetrics and Gynecology, David Geffen School of Medicine at UCLA, USA; 9) Department of Pathology, The Children's Hospital, Aurora, USA; 10) Department of Pathology, The Children's Hospital at Westmead, Sydney, Australia; 11) Department of Pediatric Nephrology, School of Medicine, Ankara University, Ankara, Turkey; 12) Department of Pathology, CHU Sainte Justine, Montreal, Canada; 13) Department of Pathology, McGill University, Montreal, Canada; 14) Department of Pathology, Massachusetts General Hospital, Harvard University, Boston, USA; 15) The International Pleuropulmonary Blastoma Registry, Children's Hospitals and Clinics of Minnesota, Minneapolis, USA.

DICER1 is crucial for embryogenesis and early development. Thus far, 40 different germ-line *DICER1* mutations have been reported in 42 probands world-wide. Although the range of attributable phenotypes continues to be described, germ-line mutations are definitely associated with pleuropulmonary blastoma, cystic nephroma, ovarian sex cord stromal tumors (especially Sertoli-Leydig cell tumor) and multi-nodular goiter. We report here *DICER1* mutations predicted to be deleterious in seven additional families who, in addition to the above phenotypes, also manifested uterine cervix embryonal rhabdomyosarcoma (cERMS, four cases), Wilms tumor (WT, three cases), cervical primitive neuroectodermal tumor (cPNET, one case), pulmonary sequestration (one case) and hamartomatous intestinal polyp (one case). Taken together, these findings show that cERMS, WT and likely PS, cPNET and hamartomatous intestinal polyps fall within the spectrum of *DICER1*-related diseases. Undifferentiated pleomorphic sarcomas may also rarely occur in mutation carriers. Moreover, *DICER1* appears to be the first gene implicated in the etiology of both cERMS and cPNET.

1163T

Direct Detection and Enumeration of Circulating Tumor Cells (CTC) by castPCR Analysis of Digitally Enriched Samples. *T. Hartshorne, D. Deng, S. Sproul, Y. Bao, Y. Fawn, D. Merrill, P. Brzoska, C. Chen.* Life Technologies, 850 Lincoln Centre Dr. Foster City, CA94404, USA.

The molecular characterization and enumeration and of circulating tumor cells (CTCs) promises to be valuable for cancer diagnosis, survival prognosis, and therapeutic guidance. However, current CTC analysis methods first require extensive enrichment of rare CTCs in human blood. We report here a new approach for direct detection of CTCs in whole blood samples using digital sample enrichment and highly sensitive competitive allele-specific TaqMan PCR (castPCR) to detect rare amounts of somatic mutations and quantitative reverse transcription PCR (qRT-PCR) to detect cell type-specific gene expression. Whole blood samples from lung cancer patients, or samples from normal individuals mixed with characterized lung cancer cell line cells, were partitioned in aliquots of 2.5-50 µL in 96- or 384-well plates, such that each well contained either one or no cancer cells in the presence of 2x104-4x105 normal white blood cells and 1x107-2x108 red blood cells. The sample partition process resulted in a 20-400x digital enrichment of the relative ratio of CTC to normal cells in CTC-positive wells. castPCR clearly identified somatic mutations and CK19 tumor cell biomarker expression in whole blood samples containing small numbers of spiked-in cancer cells, but not in normal whole blood samples. Furthermore, the CK19 marker and KRAS mutation were identified together in the same sample wells, indicating that the identified mutation was specifically derived from the cancer cells. In blood samples from two lung cancer patients, all CK19-positive CTC-containing wells were also positive for the EGFR p.L858R mutation. Approximately 1/3 of the circulating lung tumor cells in a patient with the EGFR p.L858R mutation also were positive for the EGFR p.T790M mutation, which is an inducible drug-resistant CTC marker. All sample wells that were negative for EGFR mutations were shown to contain corresponding wild type allele sequences. In conclusion, our data suggest that the combination of digital sample enrichment and castPCR plus RT-qPCR technologies could be used to directly detect cancer mutations and enumerate CTCs in whole blood without prior biophysical sample enrichment. This new approach may pave the way for noninvasive CTC monitoring and individualized therapy.

Investigating the function of microseminoprotein-beta in prostate cancer. *J.E. Hayes[1,2], X. Xu[1,3], H. Lilja[4,5], R.J. Klein[1].* 1) Cancer Biology and Genetics , Memorial Sloan-Kettering Cancer Center, New York, NY 10065 USA; 2) BCMB Program, Weill Cornell Graduate School of Medical Sciences, New York, NY 10065, USA; 3) Immunology & Microbial Pathogenesis Program, Weill Cornell Graduate School of Medical Sciences, New York, NY 10065, USA; 4) Department of Clinical Laboratories, Surgery (Urology) and Medicine (GU-Oncology), Memorial Sloan-Kettering Cancer Center, New York, NY 10065, USA; 5) Department of Laboratory Medicine, Lund University, Skåne University Hospital, 205 02 Malmö, Sweden.

Background: Multiple genome-wide association studies on prostate cancer (PrCa) have identified a single nucleotide polymorphism, rs10993994, that is associated with inherited PrCa risk. This SNP is of particular interest as it lies in the proximal promoter region of microseminoprotein-beta (*MSMB*), a gene that encodes for a major secreted protein of the prostate () -MSP) which was previously suggested to have an anti-proliferative effect on PrCa cells. Previous work from our lab suggests that rs10993994 may be a functional SNP and play a role in determining physiological levels of) -MSP in the serum and semen of healthy, young men. As of yet, the physiological function of) -MSP remains unknown.

Objective: We hypothesize that) -MSP acts to hinder the growth of PrCa cells, acting as a putative tumor suppressor. Therefore, it is our objective to elucidate the function of) -MSP and to determine the mechanism by which it acts.

Results: We have performed a series of *in vitro* and cell-based experiments to determine the physiological function *MSMB*. Adding exogenous) -MSP to PrCa cell lines reproducibly decreased cell viability over time course studies. Though a previous study visually observed apoptosis upon the addition of exogenous) -MSP, we did not observe any caspase 3/7 activity in our assays. We then followed up to determine if exogenous) -MSP acted to inhibit cellular proliferation and/or alter the cell-cycle. Finally, initial studies provide evidence that the function of) -MSP is conserved between mouse and humans, despite being evolutionarily divergent.

Conclusions: Our initial results further support the anti-proliferative effects that) -MSP has on PrCa cells, though the exact mechanism remains elusive.

1165T

Whole-exome sequencing of a rare case of familial childhood acute lymphoblastic leukemia. *J. Healy[1], V. Saillour[1], M. Bourgey[1], A. Alter[1], M. Larivière[1], J.F. Spinella[1], C. Richer[1], S. Busche[2,3], B. Ge[3], A. Montpetit[3], P. Awadalla[1,4], T. Pastinen[2,3], D. Sinnett[1,4].* 1) Sainte-Justine UHC Research Center, University of Montreal, Montreal, Qc, Canada; 2) Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Qc, Canada; 4) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Qc, Canada.

Acute lymphoblastic leukemia (ALL) is the most common cancer in children, accounting for approximately 25% of all pediatric cancer cases. However familial childhood ALL is extremely rare. Few families with multiple non-twinned siblings diagnosed with childhood ALL have been reported, and to date no highly penetrant leukemia susceptibility gene(s) has been identified to explain this uncommon occurrence. We postulated that pure (nonsyndromic) familial childhood ALL could result from the accumulation of disadvantaging rare DNA variants in predisposing genes or biological pathways. To address this hypothesis, we used next-generation sequencing technologies to capture and re-sequence the whole-exomes of a family comprising the mother, father and two male non-twinned affected siblings (sibling A and sibling B). Both brothers were diagnosed with the identical ALL subtype, pre-B hyperdiploid childhood ALL, three years apart. The similar clinical and molecular characteristics of the siblings suggest shared etiologic factors. Using the Agilent SureSelect All Human Exon Kit and the SOLiD 3 Plus system, we captured and sequenced a total of 20.7 Gb of exonic sequence for the entire family, with a mean coverage of 47X. For each individual, approximately 96% or 36.4 Mb of the targeted bases were covered⁄ 1X and 68%; of the targeted bases or 25.7 Mb passed our thresholds for variant calling. We identified 48,688 positions at which the called allele(s) differed from the reference genome in at least one of the four family members. In total, we identified 20,260 germline variants in sibling A and 30,752 in sibling B, of which 347 (1.7%) and 477 (1.6%), respectively, were rare (MAF<5%) in dbSNP. We investigated non-synonymous homozygous variant and compound heterozygous positions shared between the siblings. Based on several criteria (PolyPhen annotation, known allele frequency, etc.), we identified variants that are strong functional candidates to explain this case of pure familial childhood ALL. In parallel, high-density genotyping was also performed (Illumina Omni 2.5M) for quality control and structural variant detection. We identified shared copy number variants among the brothers that could also be involved in leukemogenesis. Although these genetic and structural variants require independent validation and functional assessment, this is the first study to identify genetic factors involved in pure familial childhood ALL.

Lobular endocervical glandular hyperplasia found in a Peutz-Jeghers syndrome patient positive for STK11 mutation. *A. HIRASAWA[1,2], T. AKAHANE[1], T. TSURUTA[1], K. BANNO[1], N. SUSUMU[1], K. SUGANO[2], D. AOKI[1].* 1) Dept Gyne/Obst, Sch Med, Keio Univ, Tokyo, Japan; 2) Genetic Clin, Keio Univ Hosp, Tokyo, Japan.

Peutz-Jeghers syndrome (PJS) has been frequently associated with adenoma malignum, a subtype of cervical adenocarcinoma. Lobular endocervical glandular hyperplasia (LEGH) has recently been proposed to be a possible precursor of adenoma malignum. It has been reported that many cases previously diagnosed as adenoma malignum now would be diagnosed as LEGH. However, only a few reports have focused on a possible link between LEGH and glandular tumor of the uterine cervix associated with PJS. Herein, we report a case of LEGH found in a PJS patient positive for STK11 mutation. The patient was a 42-year-old woman with a diagnosis of PJS during childhood. She noticed her 7-year-old son to have similar pigmentation of the lips, the oral cavity, and the fingers to hers, raising her concern that the son might have PJS like her. She brought him to our outpatient genetic counseling clinic. She had ever undergone a total of 6 laparotomies for repeated intussusception due to small-intestinal polyps since her childhood, but had never consulted detailed genetic counseling or examination. After obtaining her informed consent, mutation analysis of STK11 gene was performed in the present mother, and deletion was identified in the exon. We gave explanation during genetic counseling that the mother should be screened for cervical lesions for surveillance purposes, and thus, she visited our gynecological department. At her first visit, gynecological examination revealed excessive watery vaginal discharge and polycystic mass of the uterine cervix. Then, the patient received diagnostic laser conization of the cervix, and LEGH was pathologically diagnosed. However, considering that the presence of adenocarcinoma could not be ruled out and that she did not require fertility preservation, the patient underwent modified radical hysterectomy and bilateral salpingo-oophorectomy. Pathological examination of the surgical specimen revealed the presence of LEGH, but there was no evidence of adenoma malignum. In women with PJS, not only periodic observation of the intestinal tract but also surveillance of the uterine cervix are essential, keeping in mind the presence of cervical LEGH and adenoma malignum.

Differential methylation in pancreatic cancer and the associated effects on gene expression. *J. Hoskins[1], J. Jinping[1], H. Parikh[1], I. Collins[1], S. Hussain[2], L. Amundadottir[1].* 1) Laboratory of Translational Genomics, National Cancer Institute, Gaithersburg, MD; 2) Laboratory of Human Carcinogenesis , Center for Cancer Research, National Cancer Institute, Bethesda, MD.

Pancreatic cancer ranks among the most deadly cancers, with a mortality rate nearly equal to its rate of incidence. Previous works have reported significantly different DNA methylation profiles between tumor and normal pancreatic samples across the genome, suggesting epigenetic effects on gene expression. However, only one other group thus far has compared methylation changes with transcriptome-wide changes in gene expression. In this study we have attempted to expand on this work by using a customized NimbleGen 720K CpG Island Plus RefSeq Promoter Array in methyl-DNA immunoprecipitation (MeDIP) analysis of 10 pancreatic cell lines (1 normal and 9 tumor) and 10 normal/tumor paired tissue samples. By using a Bonferroni-corrected "Probe Sliding Window" ANOVA analysis, we found over 9000 peaks of significant ($p<0.01$) differential methylation between tumor and normal pancreatic samples, of which 7114 were associated with nearly as many genes. Previous studies have reported less than 2000 differentially methylated genes in pancreatic tumor samples. Of these gene regions, 3503 were hypermethylated, and 3611 were hypomethylated in tumor samples. In order to associate these methylation differences to changes in gene expression, we performed RNA sequencing on 7 of the pancreatic cell lines (1 normal and 6 tumor). There was good correlation between hypermethylation and down-regulation of gene expression. However, hypomethylation was a much poorer predictor of increased transcription. Several hypermethylated and down-regulated genes from this analysis are in agreement with another recent study, but many associations identified are novel. Further analysis and validation of this data should yield plenty of new information on DNA methylation changes in pancreatic cancer, and the effects of these changes on gene expression.

CNVs AND CN-LOH IN MDS AND AML: A STUDY OF 140 CASES. *X. Hu[1], A. Iqbal[2], A. Ahmd[2], G. Raca[3], X. Xu[3], D. WolFF[4], R. Burack[2], B. Kipphut[2], D. Mulford[2], M. Li[1].* 1) Cancer Genetics Lab, Baylor College of Medicien, Houston, TX; 2) Dept of Pathology and Laboratory Medicine, Univ of Rochester Med Ctr, Rochester, NY; 3) Univ of Wisconsin-Madison, WI; 4) Dept Pathology and Laboratory Medicine, Med Univ of South Carolina, Charleston, SC.

Myelodysplastic syndromes (MDS) are a group of heterogeneous myeloid neoplasms with high risk of progression to acute myeloid leukemia (AML). The molecular pathogenic mechanisms that underlie the transformation of MDS to AML are largely unknown. About 50% of MDS patients show no cytogenetic abnormalities, making monitoring disease progress in these patients difficult. We hypothesize that some cryptic genomic copy number variations (CNVs) and regions with copy number neutral loss of heterozygosity (CN-LOH) may be or harbor genetic events responsible for the disease transformation. We studied 140 patients with newly diagnosed MDS (n=80) or AML (n=60) to evaluate genomic alterations using a custom designed cancer specific CGH microarray that targets over 500 cancer genes and more than 100 cancer-associated genomic regions. Thirty six MDS cases were studied for CN-LOH using a SNP array or a combined CGH/SNP array platform that detects both CNVs and CN-LOH. CNVs were identified in all patients including 66 patients with normal cytogenetic results. The CNVs were enriched in genomic regions containing cancer genes TP73, CSF1R, NOTCH1, AKT1, BLM, and BUB1B in both MDS and AML. However, heterozygous deletion of MSH2 and CDKN1B were more commonly seen in patients with MDS; and heterozygous deletion of CNBP, ABL1, and PTEN were more prominent in patients with AML. Twenty-five of the 36 MDS cases showed CN-LOH of⁄ 10Mb in 63 genomic regions. Although CN-LOH was distributed throughout the whole genome, 1p and 14q were more frequently involved. These results demonstrate the utility of arrays that detect both CNVs and CN-LOH in cancer analysis. Our study revealed many previously unrecognized CNVs and CN-LOH in patients with MDS and AML, which may play important roles in the transformation of MDS to AML and be or contain biomarkers for cancer diagnosis and/or appropriate targeted therapies.

Combined Analysis with Copy Number Variation Identifies Hotspot-located Risk Loci in Lung Cancer. *L. Hu, X. Chen, X. Li, Y. Liu, Z. Zhang, P. Wang, X. Yi, J. Zhang, Y. Zhu, Z. Wei, F. Yuan, X. Kong.* Molecular genetics, Institute of Health Sciences, Shanghai, Shanghai, China.

Lung cancer is the most important cause of world-wide cancer death, and its occurrence is susceptible to inheritance and environment. However, the mechanisms mediating genetic factors and environment are far from fully understood. Copy number variations (CNVs) are prevailing genetic variations in the genome, and current studies have proved that CNVs will be a promising target affected by tumor and cancer. To further test this hypothesis, we systematically analyzed the CNV-association in two datasets of lung cancer, which were about 2000 cases (and 2000 controls) from Environment And Genetics in Lung cancer Etiology (EAGLE) and 850 cases (and 850 controls) from the Prostate, Lung, Colon and Ovary Study Cancer Screening Trial(PLCO). We firstly used a prefound association method to test the datasets separately, and then tested the association-accordance through CNV-type distribution comparison between the both datasets. Finally, we identified seven CNV-loci associated with lung cancer. Three of these loci could be validated through previous physiological studies or association publications about cancer. Interestingly, our further analysis showed that shared associated CNVs are linked with recombination hot-spot while significant CNVs in separate testing are far from hot-spots, which implicated that some hot-spots are harmful to lung cancer in different populations. We searched the physiological function of the separate significant CNVs, and found EGFR-signaling related genes (and other genes) around these CNVs were reported with cancer or lung cancer, which proved that critical genes might be targeted in lung cancer by rare CNV-mutations. In a word, our analysis provided more new cues in cancer studies, especially prompted the affected mode of CNV with different origins.

Genetic variants in sex hormone metabolic pathway genes and risk of esophageal squamous cell carcinoma. *P.L. Hyland[1,2], N. Hu[1], W. Wheeler[3], K. Yu[4], T. Ding[5], J-H. Fan[6], S.M. Dawsey[7], C.C. Abnet[7], A.M. Goldstein[1], Z-Z. Tang[5], Y-L. Qiao[5], N.D. Freedman[7], P.R. Taylor[1].* 1) GEB, DCEG, NCI, NIH, Rockville, MD; 2) CPFP, CCT, NCI, NIH, Rockville, MD; 3) IMS, Inc., Silver Spring, MD; 4) BB, DCEG, NCI, NIH, Rockville, MD; 5) Shanxi Cancer Hospital,Taiyuan, People's Republic (PR) China; 6) Dept of Epidemiology, Cancer Institute (Hospital), Chinese Academy of Medical Sciences, Beijing, PR China; 7) NEB, DCEG, NCI, NIH, Rockville, MD.

Esophageal cancer (EC) is the sixth leading cause of cancer-related deaths worldwide and exhibits a dramatic geographic distribution in incidence and histological subtype. In China, EC is the fourth leading cause of cancer death, where essentially all cases are histologically esophageal squamous cell carcinoma (ESCC) as opposed to adenocarcinoma which is more common in the Western world. Recently, it has been suggested that sex hormones may be associated with the risk of ESCC. Therefore, we examined the association between genetic variants in sex hormone metabolic genes and ESCC risk in a high risk population from north central China. We also investigated jointly the association between risk of ESCC and multiple genetic variants within an overall sex hormone metabolic pathway (and/or subpathways) defined according to current biological knowledge. A total of 1026 ESCC cases and 1452 controls were genotyped for 1250 tagged single nucleotide polymorphisms (SNPs) in 51 sex hormone metabolizing and sex hormone-related genes such as transporters and signaling receptors (collectively referred to here as sex hormone metabolic genes). Pathway-, subpathway-, gene- and SNP-based associations with ESCC risk were evaluated using the adaptive rank-truncated product (ARTP) method and the additive model within unconditional logistic regression adjusted for age and sex. We also conducted stratified analyses by gender. Statistical significance was determined through use of permutation. No associations were observed for genes involved in the overall sex hormone metabolic pathway (P=0.14) or in the subpathways (androgen synthesis: P=0.30; estrogen synthesis: P=0.15; and estrogen removal: P=0.19) with risk of ESCC. However, six genes (including *SULT2B1*, *CYP1B1*, *CYP3A5*, *CYP3A7*, *SHBG* and *CYP11A1*) were significantly associated with ESCC risk (P<0.05). Our comprehensive examination of 51 genes in the sex hormone metabolic pathway is consistent with a potential association with risk of ESCC, and the identified six genes in particular merit confirmation in future studies.

Introduction: Leukemia is a heterogeneous disease involving many fusion oncogenes(1), which are resulted due to genetic abnormalities like translocations, deletions, are helpful in differential diagnosis and prognostic stratification and are directly involved in Leukemogenesis(2).As environmental factors coupled with natural genetic variations drive the genetic abnormalities and hence the fusion oncogenes, frequencies of fusion oncogenes and their splice variants can vary in different geographical regions. Methods: Bone marrow samples were collected from 501 Leukemia patients. RNA was extracted by TriZol method(3).RT-PCR was used to study the different leukemic fusion oncogenes(3). Interphase-FISH was employed to confirm the results of RT-PCR(4). Frequencies of fusion oncogenes and their splice variants were compared to western populations using SPSS version 17. Results: Significant differences between Pakistani and western populations with respect to frequencies of BCR-ABL splice variants b2a2 & b3a3 in CML, SIL-TAL1(del 1),TEL-AML1 (t 12;21) oncogenes in adult ALL and BCR-ABL (t 22;9),E2A-PBX1 (t 1;19), TEL-AML1 (t 12;21), MLL-AF4 (t 4;11) in paediatric ALL (p=0.01). This shows that cumulative frequencies of fusion oncogenes related with poor prognosis (BCR-ABL (t 22;9),SIL-TAL1 (del 1), E2A-PBX1(t 1;19), MLL-AF4 (t 4;11) are higher in Pakistani pediatric ALL patients than western counterparts(74.2% vs 27%, p=0.01) while reverse is the case of TEL-AML (16.5% vs 25%, p=0.01) associated with good prognosis(Table 1). Conclusions/Discussion: Significant difference between Pakistani and western populations in terms of splice variants of different fusion oncogene frequencies indicate ethnic differences in genetics of leukemia, in accordance with previous reports (5,6). These results explain the molecular genetic basis of poor prognosis and survival of paediatric ALL and adult AML patients in Pakistan(7). Our studies have implications in clinical management of Leukemia at healthcare policy-making bodies and clinical centers.References:1:Pallisgaard et al. Blood 1998;92(2):574-88.2:Vardiman,et al. Introduction NQO1 participates in cellular defense against oxidative stress and regulates apoptosis via p53- and NF-kappaB-mediated pathways. We have previously found that homozygous missense variant NQO1*2(rs1800566) predicts poor survival among breast cancer patients, particularly after anthracycline-based adjuvant chemotherapy. Here we investigated NQO1 and NF2B protein expression and global gene expression profiles in breast tumors with correlation to tumor characteristics and survival after adjuvant chemotherapy. **Methods** We used immunohistochemical analysis of tissue microarrays to study NQO1 and NF2B expression in two series of tumors: 1000 breast tumors unselected for treatment and 113 from a clinical trial comparing chemothepapy regimens after anthracycline treatment in advanced breast cancer. We used gene expression arrays to define genes co-expressed with NQO1 and NF2B. **Results** NQO1 and nuclear NF2B were expressed in 83% and 11% of breast tumors, and correlated inversely (p=0.012). NQO1 protein expression was associated with estrogen receptor (ER) expression (p=0.011) whereas 34.5% of NF2B-nuclear/activated tumors were ER negative (p=0.001). NQO1 protein expression and NF2B activation showed only trends, but no statistical significance for patient survival or outcome after anthracycline treatment. Gene expression analysis highlighted 193 genes that significantly correlated with both NQO1 and NF2B in opposite directions, consistent with the expression patterns of the two proteins. Inverse correlation was found with genes related to oxidation/reduction, lipid biosynthesis and steroid metabolism, immune response, lymphocyte activation, Jak-STAT signaling and apoptosis. **Conclusion** The inverse relationship between NQO1 protein expression and NF2B activation, underlined also by inverse patterns of association with ER and gene expression profiles of tumors, suggests that NQO1 - NF2B interaction in breast cancer is different from several other tissue types, possibly due to estrogen receptor signaling in breast cancer. Neither NQO1 nor NF2B protein expression appear as significant prognostic or predictive markers in breast cancer.

1173T

Comprehensive characterization of BRCA1/2 mutational spectrum in breast/ovarian cancer patients from Lithuania. *R. Janavicius[1, 2], V. Rudaitis[3], L. Griskevicius[1].* 1) Hematology and oncology center, Vilnius University Hospital Santariskiu clinics, Vilnius, Lithuania; 2) State Research institute Innovative Medicine Center; 3) Dept. of Gynecology, Vilnius University Hospital Santariskiu clinics, Vilnius, Lithuania.

BACKGROUND. The germline mutations in BRCA1/2 genes are the most significant and well characterized genetic risk factors for breast and/or ovarian cancer. Detection of mutations in these genes is an effective method of cancer prevention and early detection. Different ethnic and geographical regions may have different BRCA1 and BRCA2 mutation spectrum and prevalence due to founder effect. The population of Lithuania has over several centuries undergone limited mixing with surrounding populations and is mostly of indigenous Baltic origin. The aim of our study was to asses full BRCA1/2 mutational spectrum in Lithuanian population. METHODS. We performed comprehensive mutation analysis of BRCA1/2 genes in 380 unrelated breast and/or ovarian cancer patients (with/without family history) and predictive unaffected patients (with family history) using high resolution melting (HRM) screening (on Light Cycler 480/Light Scanner 384) followed by direct sequencing (ABI 3500) and MLPA for large genomic rearrangements (LGR). RESULTS. Overall, we have identified 19 different mutations (12 in BRCA1 and 7 in BRCA2 genes). 5 frequent pathogenious mutations in BRCA1 gene (c. 4035delA, c. 5266dupC, c.181T>G, c.1687C>T and c. 5258G>C) comprised 48%, 28%, 6%, 3% and 3% respectively of all BRCA1 gene mutations; a single BRCA2 mutation (c.658delGT) comprised 43% of all mutations in this gene. Two novel BRCA1 (c.4516delG, c.2481delA) and 3 novel BRCA2 genes mutations (c.6999insT, c.5697_5710del14, c.6410delA) were identified; no LGRs were found. The most common c.4035delA appears to be true Lithuanian (Baltic) founder mutation and haplotype genotyping was initiated. CONCLUSIONS. Characterization of BRCA1/2 mutational spectrum in Lithuania enabled to develop screening protocol for 6 common BRCA1/2 mutations, which are prevalent in 88% of all mutations. This knowledge will provide more efficient approach for the individualization of genetic testing affordable for all breast/ovarian patients and their relatives, which will be of utmost importance in the era of targeted therapy.

1174T

Linkage study suggests common genetic determinants for chronic lymphocytic leukemia and monoclonal B-cell lymphocytosis. *T.M. Jarvinen[1], S. Liyanarachchi[1,2], I. Comeras[1,3], L. Senter[1,3], G. Lozanski[4], E. Hertlein[5], J.C. Byrd[5], A. de la Chapelle[1,2].* 1) Human Cancer Genetics Program, Ohio State University, Columbus, OH, USA; 2) Department of Molecular Virology, Immunology and Medical Genetics, School of Biomedical Science, Ohio State University, Columbus, OH, USA; 3) Department of Internal Medicine, Ohio State University Comprehensive Cancer Center, Columbus, OH, USA; 4) Department of Pathology, Ohio State University Medical Center, Columbus, OH, USA; 5) Department of Internal Medicine, Division of Hematology, Ohio State University Comprehensive Cancer Center, Columbus, OH, USA.

Chronic lymphocytic leukemia (CLL) characterized by an accumulation of mature B-cells is the most common adult leukemia in the Western world. Monoclonal B-cell lymphocytosis (MBL), a suggested precursor lesion of CLL, is an indolent hematologic condition with low levels of circulating B-cell clones (<5000/mm^3). Advancing age and male sex are known risk factors, but genetic determinants are unknown. Previous linkage studies conducted in CLL have identified multiple putative disease loci, but no predisposing gene has been identified to date. We conducted a genome-wide linkage scan in a multi-generational family. Altogether 17 individuals were genotyped: 3 with CLL, 6 with MBL and 8 unaffected. Greater than 250000 SNPs were typed using the Illumina Human CytoSNP-12 platform. The number of SNPs analyzed was reduced to 5000 by selecting the most highly heterozygous marker in every 500 kb segment. The overall genotyping success rate was 97% and Mendelian inheritance errors were negligible (0.03%). Linkage analysis was performed with Merlin software by applying both nonparametric and parametric approaches, using either a dominant or recessive model. Considering the 3 CLL cases as affected and 6 MBL cases as unaffected, a region in chromosome 15q gave a peak with nonparametric linkage (NPL) score of 0.48 (the maximum predicted attainable score being 0.58). Considering the 6 MBL cases as affected and the 3 CLL cases as unknown, the same region in chromosome 15q gave a peak NPL score of 0.54 (maximum predicted 0.85). Considering the CLL and MBL cases as affected, the genome-wide maximum NPL score of 0.86 (maximum predicted 1.36) was obtained in the same region in chromosome 15q. The other strongest peaks when considering CLL as affected were observed in chromosomes 3q and 20pq. To our knowledge, this is the first linkage study to address genetic determinants for MBL. However, the study was confined to a single pedigree. None of the observed linkage peaks in CLL or MBL coincided with previously identified candidate loci nor did they reach statistical significance in terms of standard thresholds. To date, a single association study has directly assessed the inherited genetic susceptibility to MBL showing that genetic predisposition is at least partly shared between CLL and MBL. In line with this, our results suggest that CLL and MBL share genomic regions conferring susceptibility to both phenotypes. Predisposing genes in these regions remain to be identified.

Genome-wide association analysis of lymphoma. *V. Joseph[1], T. Kirchhoff[1], J. Brown[2], D.B. Yehuda[3], A. Dutra-Clarke[1], N. Hansen[1], J. Przybylo[1], V. Devlin[1], A. Viale[1], R. Klein[1], A. Zelenetz[1], K. Offit[1].* 1) Dept. Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 2) Dana Farber Cancer Center, Boston, MA,; 3) Hadasaah University, Jerusalem, Israel.

Background: The incidence of lymphoma has doubled over the past two decades in the U.S., the etiology of the most common types of the disease remains unknown. There is increasing evidence that genetic predisposition has a significant impact on the development of lymphomas. Genome-wide association analysis (GWAS), have proven to be useful tool for the identification of inherited susceptibility loci for human cancers. Objective: Discovery of novel germ line variants predisposing to lymphoma and lymphoma subtypes using GWAS. Methods: We have carried out a genome wide association study to discover genetic loci conferring risk for development of lymphomas using Affymetrix 6.0 SNP arrays on 959 kindreds of lymphoma. These consisted of 204 Hodgkins disease and 752 Non-Hodgkins disease cases. Amongst the NHL subtypes, we had 37% follicular, 36% diffuse large B-cell, 9% CLL/SLL, 9% mantle and 3% marginal zone lymphomas. As controls, we have used publically available data acquired from dbGAP initiative on 4059 individuals genotyped by Affymetrix 6.0 as part of schizophrenia and diabetes studies. To reduce population heterogeneity, both cases and controls chosen were only of European (EU) ancestry. Results: We performed logistic regression of each lymphoma subtype using factors such as age and four principal components of the population variation of samples on 5018 sample. After QC and QA test, 597831 SNPs were passed for analysis. In the pan-lymphoma analysis, we have discovered a SNP with in a gene that was recently reported as member of DNA repair pathway(p=5.48E-08). In the follicular subtype, we have confirmed the HLA 6q region that harbor the HLA-DQ1 locus (p=1.0E-08; rs2621416) as an important lymphoma susceptibility locus. Genomic inflation 3 was 1.05. We also discovered novel loci on chr11 upstream of ZBTB16, a zinc finger transcription factor implicated previously in leukemia. Our data also suggests the first evidence for the role of transcription factor KLF12 in Hodgkins lymphoma. We are currently performing a replication stage on 1250 lymphoma cases and 1900 controls, all of EU ancestry to confirm these early findings. Conclusion: There is preliminary evidence of germline variants in humans increasing risk for lymphocytic malignancies. Our findings provide new insights into the molecular pathogenesis of lymphoma.Acknowledgement:Lymphoma Foundation and Barbara Lipman Research Fund.

Elevated Levels of Oxdatively Damaged DNA in Patients with Selenoprotein Deficiency. *M. Karbaschi[1], E. Schoenmakers[2], M.D. Evans[1], K. Chatterjee[2], M.S. Cooke[1].* 1) University of Leicester, Leicester, United Kingdom; 2) Institute of Metabolic Science, Cambridge, United Kingdom.

Selenium (Se) is a vital dietary element for eukaryote and prokaryotic cells. In humans, its biological role is mediated principally by incorporation of selenocysteine, into selenium containing proteins. About 30 different selenoproteins have so far been observed in human cells and tissues, performing a variety of different functions including removal of cellular reactive oxygen species, reduction of oxidised methionines in proteins, metabolism of thyroid hormones, transport and delivery of selenium to peripheral tissues, protein folding and ER stress, plus proteins whose precise function is unknown [1].One of the best-known functions of selenoproteins is displayed by the family of selenium-dependent glutathione peroxidases which reduces hydrogen peroxide, and damaging lipid and phospholipid hydroperoxides to harmless products such as water and alcohols [2]. This function helps to reduce the risk of induction of further oxdatively generated damage to biomolecules and accordingly reduces risk of a variety of damage-related pathological conditions. In this study, we examined the baseline levels of oxdatively damaged DNA in two individuals, one adult and one child with compound heterozygous defects in the selenocysteine insertion sequence-binding protein 2 (SECISBP2) gene. As part of a complex phenotype, using hOGG1-modified comet assay, we noted a significant (P<0.0001) increased baseline levels of 8-oxoguanine and alkali labile sites in dermal fibroblasts, vs. age/gender match controls in the presence and absence of exogenous H2O2 (50 μM, 30 min). Using the same assay, we demonstrated that whilst DNA repair processes were unaffected, antioxidant defences were impaired, the likely source of the elevated baseline levels. Similar results were noted following exposure to 10 J/cm2 UVA (P<0.0001), accounting for the pronounced photosensitivity seen in these subjects. These results demonstrate the central role of selenoprotein in cellular antioxidant defence.

Genes in the inflammatory and innate immunity pathway and prostate cancer. *R. Kazma[1], J.A. Mefford[1], I. Cheng[2], S.J. Plummer[3], B.A. Rybicki[4], G. Casey[3], J.S. Witte[1].* 1) Department of Epidemiology and Biostatistics and Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 2) Epidemiology Program, Cancer Research Center of Hawai'i, University of Hawai'i, Honolulu, HI; 3) Department of Preventive Medicine, Noris Comprehensive Cancer Center Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Department of Biostatistics and Research Epidemiology, Henry Ford Hospital, Detroit, MI.

Prostate cancer is the leading cancer in terms of incidence and second leading cancer in terms of mortality among men in developed countries. Several observations support the hypothesis that the inflammatory and innate immunity responses might play a role in prostate cancer initiation and progression. To determine whether genes coding for proteins involved with inflammatory and innate immune responses are associated to an increase in risk or to a higher rate of progression of prostate cancer, we undertook a comprehensive analysis of 318 single nucleotide polymorphisms (SNPs) in 46 candidate genes controlling inflammation and innate immunity. Our sample comprised 878 aggressive prostate cancer cases and 536 controls recruited from the major health care providers in Cleveland Ohio and the Henry Ford Health System in Detroit. First, we investigated the potential associations with single marker tests, gene-gene and gene-environment interaction tests. Non-genetic factors considered in gene-environment interaction tests included smoking, family history of prostate cancer, body mass index, non-steroidal anti-inflamatory drugs, omega-3 fatty acids, trans-fatty acids, red meat, and a high glycemic index diet. Second, we used a kernel-based logistic regression to study sets of SNPs within each gene and across pathways. The kernel-based logistic regression corrects for linkage disequilibrium patterns and can account for SNP-SNP interactions within each SNP set. Finally, we evaluated association with prostate cancer progression using a Cox proportional hazards model for cases only. All analyses were adjusted for age, ethnicity, genetic ancestry, institution, and initial PSA level.

COX-2 gene polymorphisms (rs20417 and rs5277) and risk of Colorectal cancer. *F. Khorshidi, M. Mohebbi, M. Montazer Haghighi, M. Yaghoob Taleghani, B. Damavand, M. Vahedi, M.R. Zali.* Shahid beheshti University, The research center of gastroenterology and liver, Tehran, Tehran, Iran.

Background: The incidence of colorectal cancer (CRC) is lower in Iran than in Western countries, being the fifth and third most common cancer in men and women. However, its incidence in Iran has increased recently. Evidence derived from several lines of investigation suggest that prostaglandins, metabolites of arachidonic acid, play an important role in colon cancer development.Cyclooxygenase-2 (PTGS2) overexpression has been implicated in various cancers. Aim: To determine the possible modulating effect of the COX-2 polymorphisms, rs20417 and rs5277, on the risk of colorectal cancer (CRC) in a Iranian population. Methods: This case-control study includes 100 patients with CRC and 100 control subjects with no polyps who underwent total colonoscopy. Genotypes of the COX-2 polymorphisms (rs20417 and rs5277) were determined by polymerase chain reaction-based restriction fragment length polymorphism. COX-2 genotypes were analyzed and odds ratios with 95% confidence intervals were estimated by logistic regression. Result: A significant difference was observed in the distribution of the COX-2 polymorphism -765G→C (rs20417) between cases and controls (P=0.014). The -765GC genotype was more prevalent in this study in both groups. Furthermore, the distribution of the COX-2 polymorphism, rs5277, was not significantly different between CRC cases and controls (P= 0.983). Conclusion: Our results suggest that -765G→C polymorphism in COX2 could be a good prognostic indicator for patients with CRC. Genotyping this polymorphism may be useful for predicting the clinical outcome of sporadic CRC. Keywords: Colorectal cancer; Cyclooxygenase-2; Genetic polymorphism.

Sorting Nexin 3 Overexpression Disrupts EGFR and MET Endosomal Trafficking Promoting Cell Proliferation and Tumorigenicity in Pediatric Glioblastoma. *D. Khuong Quang[1], H. Al-Halabi[2], T. Haque[2], D. Faury[3], B. Meehan[3], J. Rak[3], S. Albrecht[4], N. Jabado[1,2,3].* 1) Department of Human Genetics, McGill University, Montreal, Canada; 2) Department of Experimental Medicine, McGill University, Montreal, Canada; 3) Department of Pediatrics, Montreal Children's Hospital, Montreal, Canada; 4) Department of Pathology, Montreal Children's Hospital, Montreal, Canada.

Introduction: Amplification/mutation of receptors-tyrosine-kinases (RTK) plays a major role in gliomagenesis. Using microarray data we generated, we identified overexpression of Sorting Nexin 3 (SNX3), a protein involved in the endosomal trafficking of RTK including EGFR. Our hypothesis is that dysregulated expression of SNX3 may delay RTK degradation and promote sustained intracellular activation through these receptors, mimicking RTK amplification seen in adult-GBM events in a subset of pediatric-GBM (pGBM). In addition, we assessed the effect of SNX3 overexpression on oncosome production. Microvesicles and exosomes allow the sharing of oncogenic and transforming signals between neighbouring cells and have an important role in adult gliomagenesis. *Methods:* We stably overexpressed cMyc-tagged-SNX3 in pGBM (SF188 and SJG2) and aGBM (U87) cell lines. Parallel SNX3 knock-down experiments were performed in cell lines. Effects of overexpression/silencing of SNX3 were investigated on EGFR and MET activation, cell signaling and cell proliferation in vitro and in vivo (xenograft model NOD/SCID mice). We quantified the level of microvesicles and exosomes produced in SNX3 overexpressing cells in comparison to empty vector controls. *Results:* SNX3 overexpression delayed EGFR and MET degradation following RTK engagement. This increased and sustained activation of Ras and JNK pathways and cell proliferation in vitro. Importantly, it promoted tumour formation in NOD-SCID mice. Experiments done on SNX3-knocked down cell lines led to a decreased intracellular signalling. In vitro, SNX3 overexpression was associated with increased production of microvesicles and exosomes compared to controls. *Conclusion:* Our results indicate that SNX3-overexpression disrupts physiological trafficking of multiple membrane receptors including EGFR and MET leading to sustained activation of signalling pathways that promote cellular proliferation and tumorigenicity. We also show increased oncosome formation in association with SNX3 overexpression, highlighting this as a potentially novel mechanism of enhancing tumorigenesis in pGBM.

Hoffmann-La Roche Ltd., Basel, Switzerland; 8) Current address: Estonian Genome Centre, University of Tartu, Estonia; 9) For the Nordic Society of Pediatric Hematology and Oncology.

Acute lymphoblastic leukemia (ALL) is the most common pediatric cancer in the developed countries. With modern treatment protocols children with ALL have a good prognosis, but for unknown reasons, approximately 20% of patients do not respond to treatment. Thus, there is a need for improved stratification of ALL patients into groups for alternative treatment protocols. We have performed a survey of allele-specific gene expression (ASE) of over 8,000 genes in RNA samples from 197 ALL patients whose in vitro response to ten anti-cancer drugs is known (Milani *et al*, Genome Res. 2009, 19(1):1-11). Our hypothesis was that ASE could be used as a guide to identify genes with cis-acting regulatory genetic variants that could explain the differences in treatment response between ALL patients and serve as biomarkers for stratification of the patients for treatment. We used ASE to select 56 genes that displayed ASE in a large number of the patients for detection of regulatory genetic variants by second generation sequencing. A target region of 3.1 megabases in size, including all exons, introns, UTRs and 5 kb of flanking sequences of the 56 gene regions, was enriched from genomic DNA of 63 ALL samples using hybrid-capture methods and sequenced on an Illumina Genome Analyzer. In this region, we called 8,384 SNPs that were present in at least two samples. From these we selected 768 putative regulatory SNPs for genotyping in a set of 1,000 samples from Nordic ALL patients and in controls matched for country of origin. The genotype data was subjected to association tests between different patient groups and between ALL patients and controls to detect putative functional regulatory genetic variants.

Multiplex sequencing of targeted genes for GWAS fine mapping. *D. Klevebring[1,2], M. Neiman[1,2], J. Lindberg[1,2], S. Sundling[1], F. Wiklund[1], H. Grönberg[1], K. Czene[1], P. Hall[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Science for Life Laborarory, Karolinska Institutet, Stockholm, Sweden.

Aim To identify potential causative genetic variants in genomic regions that have been associated with cancer risk through genome wide association studies (GWAS). To investigate whether these potential causative variants have larger effect sizes than the tag SNPs identified by GWAS. **Background** GWAS has been successfully used to identify loci associated with risk in several diseases, including breast and prostate cancer. However, SNPs identified are commonly regarded as tag-SNP, not themselves mediating the functional effect. In order to identify putative functional germline variants, large-scale sequencing of selected loci will be a valuable tool. This study aims to identify potential causative genetic variants in linkage regions around three tag-SNPs identified through GWAS using an in-house developed highly multiplexed sequencing approach. This approach allows for sequencing genomic regions of up to 500 kilobases in hundreds of cases and controls. For each sample, the full genomic sequence of the captured regions will be acquired. **Methods** We have developed a strategy for highly multiplexed sequencing of a limited genomic region (<500 kb) based on a two-tagging approach. From a sample set of breast cancer cases and controls, where mammographic density is available, we have performed sequencing of three genomic loci associated with breast cancer risk, where one of them is also associated with mammographic density. A custom sequence capture kit is used to perform multiplexed capture of the targeted regions, after which sequencing is carried out. **Preliminary results**We have developed a sequence capture-based low-cost sample preparation for highly multiplexed barcoding of hundreds of samples in order to sequence a specified genomic region smaller than 500 kilobases. Sequencing of a 96-sample multiplexed library been successfully carried out and for the majority of samples coverage is sufficient (>10x) to identify germline varation.

Identification of lung adenocarcinoma driver mutations by pooled exome sequencing and network reconstruction. *X. Kong, S. Yin, B. Lin, L. Hu.* Institute of Health Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences.

Recent advances in high-throughput sequencing technologies provide opportunities to examine the cancer genome in a comprehensive and unbiased manner. However, such studies are typically limited to few individuals and pinpointing the driver mutations that contribute to tumorigenesis is rarely straightforward. Here we report pooled whole-exome sequencing and a network construction approach for rapid and cost-effective detection of pathogenic mutations in lung adenocarcinoma (ADC). We created eight pools of DNA from a cohort of 39 ADC tumor samples and 66 normal controls for exome sequencing and after data filtering and function arguments, we identified 1551 rare mutations in 1278 genes that were predicted to affect protein function in ADC. We then applied a unified network reconstruction to identify functionally related modules that are highly targeted by ADC rare mutations. These ADC mutations were further stratified according to their interaction with previous known cancer genes and background mutations identified in normal subjects. We subsequently resequenced and confirmed 662 high likely driver mutations which we suggest act in concert to carry out specific functions that are causally linked to tumorigenesis. We find evidence for important driving roles of immune genes, kinases and miRNAs. Our study illustrates how mutation network reconstruction can be used to identify causal mutations in individual cases even in the presence of incomplete sequencing coverage.

Cancer specific promoter methylation in tubulocystic and papillary renal cell carcinomas. *M. Korabecna[1,2], P. Steiner[1], T. Vanecek[1], E. Pazourkova[2], Z. Musil[2], M. Hora[3], O. Hes[1].* 1) Sikl's Institute of Pathology, Faculty of Medicine in Pilsen, Charles University in Prague; 2) Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University in Prague; 3) Department of Urology, Faculty of Medicine in Pilsen, Charles University in Prague.

BACKGROUND: Tubulocystic renal cell carcinoma (TC RCC) belongs to the rare recently described renal tumors. Pathologic and cytogenetic findings support the evidence for the close relatedness of TC RCC to papillary renal cell carcinoma (PRCC) but the data concerning the methylation status of tumor related genes in TCRC are missing. We performed this pilot study to obtain the methylation profiles for comparison between TC RCC and PRCC. METHODS: 16 cases of TCRCC and 480 cases of PRCC were retrieved from cohort of 16.000 primary kidney tumors from Pilsen Tumor Registry. We selected suitable frozen samples of tumors (2 TCRC and 4PRCC) and their adjacent morphologically normal tissues for DNA isolation. The extent of promotor methylation of a 48 genes panel (tumor suppressors and genes involved in epithelial to mesenchymal transition) was examined using the Methyl Profiler DNA Methylation PCR Array Systems (SABiosciences, Qiagen). Cluster analysis (SABiosciences, Qiagen) was used for data evaluation. RESULTS: We provide the evidence that the methylation profiles of TC RCC contain the same hypermethylated genes (e.g. PDLIM4, RASF1, RUNX3, SOCS1) as PRCC. The VHL gene, which is often hypermethylated in clear cell renal carcinomas and whose status seems to be important with regard to response to sunitinib therapy, was unmethylated in all samples examined by us. CONCLUSION: The character of methylation profiles provides the new helpful tool for evaluation of biological relatedness of rare renal tumors with the high potential to bring new insights in their complex pathogenesis and therapy response. Loss of FADS2 function at 11q13 cancer hot spot region causes synthesis of unusual butylene-interrupted fatty acids. *K.S.D. Kothapalli, W.J. Park, P. Lawrence, J.T. Brenna.* Division of Nutritional Sciences, Cornell University, Ithaca, NY.

Several human cytogenetic and fine mapping studies have pin-pointed HSA 11q13 region as a major hotspot for a number of human cancers. Many mechanisms including 11q13 deletions, loss of heterozygosity, translocations and allelic amplification have been reported. The fatty acid desaturase cluster, encoded by genes FADS1, FADS2, and FADS3, localize within a 100 kb region on human chromosome 11q12-13.1. FADS2 and FADS1 encode for critical enzymes for long chain polyunsaturated fatty acid (LCPUFA) biosynthesis, introducing double bonds between specific carbon atoms. Omega-3 (=3 or n-3) and omega-6 (=6 or n-6) PUFA are key nutrients linked to most of the diseases of humans, specifically cardiovascular (CVD), cancer, diabetes and metabolic syndrome, and are key structural components of neural tissue. The LCPUFA DGLA (20:3n-6), ARA (20:4n-6), EPA (20:5n-3) and DHA (22:6n-3) are precursors for cell signaling eicosanoids and docosanoids that are very valuable drug targets. In several cancer cells the critical rate limiting step catalyzed by delta 6-desaturase (FADS2) enzyme is non-functional. The reason for this defect has been suggested to be due to extensive chromosomal deletions, but no molecular evidence is available. The Δ8-desaturation substrates 20:2n-6 and 20:3n-3 are often detected in these cancer cells, thus suggesting that the elongation step is functional. Recently, as an alternative LCPUFA synthetic route we demonstrated delta-8 desaturation pathway catalyzed by a FADS2 product. Here we present using MCF7 breast cancer cells a) evidence of metabolic restoration of delta 6-desaturase and delta 8-desaturase activities by heterologous expression of FADS2, b) in the substantial absence of FADS2 activity, FADS1 compensates by producing unusual butylene-interrupted 5,11,14-20:3 and 5,11,14,17-20:4 fatty acids and c) competition between FADS1 and FADS2 for the same substrates. Cyclooxygenase (COX) normally acts on the double bonds at positions 8 and 11, thus the absence of the double bond at position 8 renders them inactive as substrates for prostaglandin biosynthesis. The loss of FADS2-encoded activities in cancer cells completely shuts down the classical and alternative LCPUFA pathways, eliminating eicosanoid and docosanoid precursor biosynthesis and thus further limiting cell-cell signaling. Our present results provide an impetus to better understanding the role of fatty acid desaturases, especially FADS2 as a tumor suppressor in neoplastic disorders.

Genomic characterization of familial lung cancer patients. *Y. Kukita[1], K. Taniguchi[1], J. Okami[2], M. Higashiyama[2], Y. Suzuki[3], S. Sugano[3], R. Matoba[4], J. Kato[5], N. Kato[5], I. Nakamae[5], T. Kawabata[6], K. Kodama[2,7], K. Kato[1].* 1) Research Institute, Osaka Medical Center for Cancer and Cardiovascular Diseases, Japan; 2) Department of Thoracic Surgery, Osaka Medical Center for Cancer and Cardiovascular Diseases, Japan; 3) Graduate School of Frontier Sciences, the University of Tokyo, Japan; 4) DNA Chip Research Inc., Japan; 5) Graduate School of Biological Sciences, Nara Institute of Science and Technology, Japan; 6) Institute for Protein Research, Osaka University, Japan; 7) Yao Municipal Hospital, Japan.

Massively parallel sequencing enables identification of causative mutations of genetic diseases by analyzing small family members. In our hospital, several familial cancer cases have been collected, and we analyzed genomes from an affected sib pair with familial lung cancer using SNP array and exome-sequencing. Although these subjects had no unusual large insertions/deletions, we detected many large homozygous regions (more than 200 Mb of the genome per person), and they were thought to be the products of consanguineous union. By exome-sequencing, we identified more than 500 novel non-synonymous variants per person after subtracting known polymorphic variants. Combining results from both assays leaded identification of a homozygous CHEK2 mutation that caused unstable structure of the gene-product. Because CHEK2 is known as a multi-organ cancer susceptibility gene, additional causative mutations may involve for the phenotype of our subjects. We are investigating association of remaining novel variants with lung cancer.

1186T

C-Kit and Bcl-2 Expression in Testicular Cancer. *S. Lai[1,2], LK. Green[1,2].* 1) Pathology, Baylor College of Medicine, Houston, TX; 2) Pathology, Michael E. DeBakey VA Medical Center, Houston, TX.

Recent developments in understanding the molecular biology of testicular cancer implicated a number of key players including p53, pRb, pINK protein, c-kit and bcl-2 protein. Expression and gain of function mutation of the c-kit gene that encodes a receptor tyrosine kinase (KIT) have been reported in gastrointestinal stromal tumor and seminoma. It is suggested that activated mutation of c-kit occurs early in germ cell development and that gonocytes with an activated c-kit receptor are restricted in their differentiation, escaping normal cellular development. Genes in apoptosis pathway such as Bcl-2 play an important role in tumorigenesis of cancers. We studied c-kit and Bcl-2 expressions by immunohistochemistry in 18 testicular cancers including 8 pure seminomas, 7 mixed germ cell tumors, 1 metastatic adenocarcinoma, 1 leiomyosarcoma and 1 large cell lymphoma. We found that c-kit was diffusely and strongly expressed in pure seminomas and metastatic adenocarcinoma, while only focal and weak c-kit positivity was shown in seminoma and nonseminomatous components of mixed germ cell tumor. Bcl-2 expression was seen in metastatic adenocarcinoma and lymphoma, but not in seminoma, mixed germ cell tumor or leiomyosarcoma. We analyzed the prognostic or predictive significance of expression of both markers.

1187T

PTGER4 is regulated by ETV6, a transcription factor implicated in childhood leukemia. *J. Larose[1], C. Malouf[1,2], S. Langlois[1], D. Sinnett[1,3].* 1) Division of Hemato-Oncology, Research Center Sainte-Justine University Health center, Montreal, Canada; 2) Department of Biochemystry, Faculty of Medecine, University of Montreal, Montreal, Canada; 3) Department of Pediatrics, Faculty of Medecine, University of Montreal, Montreal, Canada.

Pre-B acute lymphoblastic leukemia (pre-B ALL) is the most prevalent pediatric cancer in Western countries. The translocation t(12;21), which produces an ETV6-AML1 chimera, is observed in ~25% of pre-B ALL cases and is one of the most frequent genetic alterations found in childhood ALL. However, this chromosomal rearrangement is insufficient to initiate leukemogenesis alone. At diagnosis, the second copy of ETV6 is deleted in most pre-B ALL patients carrying the t(12;21), thereby leading to its inactivation. ETV6, a transcriptional repressor of the Ets family, is essential for haemopoiesis. We postulated that ETV6 plays a role in childhood leukemogenesis through the deregulated expression of its transcriptional targets. Using a combination of expression microarray analysis and qRT-PCR experiments in patients with leukemia we identified several putative transcriptional targets of ETV6. One of these targets, PTGER4, encodes a G-protein-coupled receptor for prostaglandin E2 (PGE2). To determine whether PTGER4 is a direct target of ETV6, we performed gene reporter assays and chromatin immunoprecipitation in three human cell lines, including a lymphocytic cell line. We showed that ETV6 regulates the transcription of PTGER4 by targeting a region close to the basal promoter. The observed repression is mediated by both ETV6 functional domains: the pointed domain involved in oligomerization and protein interactions and the ETS DNA-binding domain. Although ETV6 was significant enriched on PTGER4 promoter, ETV6-mediated transcriptional regulation did not depend on consensus Ets-binding sites. To further dissect the impact of altered regulation of PTGER4 in leukemogenesis, we conducted functional studies. Using different constructs to regulate the expression of ETV6, we showed that PTGER4 deregulation influences cell cycle, proliferation and apoptosis. Our work highlights that PTGER4 is a transcriptional target of ETV6 and that its ETV6-mediated transcriptional regulation requires molecular mechanisms that are different from the other Ets transcription factors.

Does germline variation in the number of Glutathione S-transferase gene copies affect the risk of metachronous colorectal neoplasia? *C. Laukaitis[1, 2], C. Fuentes-Mauss[2].* 1) Department of Medicine, University of Arizona College of Medicine, Tucson, AZ; 2) Arizona Cancer Center, University of Arizona, Tucson, AZ.

Twin studies assign 1/3 of variation in colorectal cancer (CRC) risk to inherited genetic factors, but the hereditary cancer syndromes account for just 5% of CRC. Having a first-degree relative with CRC increases a person's CRC risk by 2-3 fold, but most often that risk is not inherited in a Mendelian fashion. We seek to uncover gene variations that can improve cancer risk-assessment protocols.Both single nucleotide polymorphisms (SNPs) and variation in gene copy number (CNV) can influence CRC risk, either by causing a high-penetrance hereditary cancer syndrome or through more complex mechanism. This project addresses the contribution to familial cancer risk of inherited SNPs and CNVs in Glutathione S-transferase (GST) genes. These genes vary in sequence and copy number, their gene products are important in detoxification of potential carcinogens, and variation in their copy number has shown variable association to colorectal cancer risk. Equivocal results from studies attempting to correlate CNV in the GSTM1 and GSTT1 genes could have technical or biological reasons: 1) early studies could not differentiate between individuals with one versus two GST gene copies because they relied on PCR for genotyping; 2) data have been collected in many populations with wide variation in both environmental exposures and the frequency of GST gene deletions; 3) the advanced CRC phenotype assayed may have confounded association; and/or 4) lack of a biological effect. It is worth re-visiting the hypothesis that GST gene copy number influences CRC risk using new technology that can accurately assess gene copy number, examining a large but ethnically homogenous population, and choosing an outcome early in the neoplastic process with less confounding by variables. We assessed three GST genes for SNP and CNV variation in individuals from two negative interventional trials to ask whether variants in these genes predict adenoma recurrence. SNP genotypes for the GSTM1, GSTT1, and GSTP1 genes were determined using microarray analysis and we have extrapolated gene copy number genotype from these data. We have confirmed the genotype in a subset of samples using MLPA (CNV) and TaqMan (SNP) technology. Finally, we are testing whether a specific CNV and/or SNP genotype influences risk of metachronous adenoma development.

1189T

MicroRNAs contribute to the chemoresistance of cisplatin and paclitaxel in patients with head and neck squamous cell carcinoma. *AC. Laus[1], T. Macedo[1], AC. Carvalho[2], C. Scapulatempo Neto[1], AL. Carvalho[1], EI. Palmero[1], MMC. Marques[1].* 1) Molecular Oncology Research Ct, Barretos Cancer Hospital, Barretos, Brazil; 2) Biological Science Department, Sao Paulo Federal University.

Head and neck squamous cell carcinoma (HNSCC) is a devastating disease. Despite advances in diagnosis and treatment, mortality rates have not improved significantly over the past three decades. MicroRNAs (miRNAs) are small non-coding RNAs that function as negative regulators of gene expression. They are strongly implicated in human cancers, including HNOC and the evidences for the involvement of miRNAs as important regulators of chemosensitivity and chemoresistance in HNSCC poorly understood. High mobility group A2 (HMGA2) expression has been shown to be associated with enhanced selective chemosensitivity to cisplatin, in cancer cells. Since HMGA2 expression in HNSCC is regulated in part by miRNA-98 (miR-98) and let-7i, our aim in this study was to compare the differential expression of both microRNAs and to investigate their relationship with the chemoresistance against cisplatin and paclitaxel. Forty six patients from Barretos Cancer Hospital were diagnosed with HNSCC and were treated with neoadjuvant chemotherapy using cisplatin and paclitaxel in combination. The progression free survival rate to this therapy was assessed applying RECIST criteria. After the neoadjuvant therapy, the patients were evaluated and separated into two groups: those with good response to therapy (complete or partial response) and those non-responders (progression or stable disease). Total RNA was extracted from FFPE tumor biopsies using RecoverAll Total Nucleic Acid Isolation Kit (Ambion), and quantified with NanoDrop 2000 spectrophotometer. The quality of miRNAs was assessed using Bioanalyzer Small RNA chip (Agilent). The expression levels of miR-98 and let-7i were measured by miRNA Quantitative Real Time PCR, using 7900HT Fast Real-Time PCR System (Applied Biosystems). Our results showed that both miR-98 and let-7i were down-regulated in 66% and 50% of the patients with good response to therapy, respectively. The relationship of HMGA2 protein expression with the chemosensitivity to cisplatin in HNSCC and considering that this protein is a target of miR-98 and let-7i, our results suggest that the down-regulation of both miRNAs can be related with the good response to neoadjuvant therapy.

1190T

Novel regions of suggestive linkage in African American hereditary prostate cancer families. *E.M. Ledet[1], J.E. Bailey-Wilson[2], D.M. Mandal[1].* 1) Department of Genetics, Louisiana State Univ HSC, New Orleans, LA; 2) National Human Genome Research Institute, National Institutes of Health, Baltimore, MD 21224.

Prostate cancer is a complex multi-allelic disease and the most common malignancy in men throughout the world. In the United States, incidence of prostate cancer in African American men is more than twice than that of any other race. Also, a lifetime risk of mortality from prostate cancer is 3% for white men and 4% for African-American men. Thus far, numerous disease susceptibility loci have been identified for this cancer but definite locus-specific information is not yet established due to the tremendous amount of genetic and disease heterogeneity. Additionally, despite high prevalence of prostate cancer amongst African American men, this population has been under represented in genetic studies of prostate cancer. In order to identify the susceptible locus (loci) for prostate cancer in African Americans, we have performed linkage analyses on members of 15 large high-risk families. Specifically, these families were recruited from Louisiana and represent a uniquely admixed African American population exclusive to Southern Louisiana. In addition to geographical constraints, these families were clinically homogeneous creating a well characterized collection of large pedigrees. The families were genotyped with Illumina Infinium II SNP HumanLinkage-12 panel and extensive demographic and clinical information was documented from the hospital pathological reports and family interviews. Both non-parametric and parametric allele-sharing linkage analyses were performed using Merlin, version 1.1.2. Under the dominant model, we identified two novel regions, 12q24 (HLOD=2.21) and 2p16 (HLOD=1.97), with suggestive evidence of linkage. This is the first time that chromosome 12q24 and 2p16 has been shown to be associated with prostate cancer in high-risk African American families. The results illustrate the significance of utilizing large unique, but homogenous pedigrees.

Evidence for population-based screening of BRCA1 and BRCA2. *E. Levy-Lahad[1,2], E. Gabai-Kapara[1,2], B. Kaufman[3], C. Catane[3], S. Regev[4], P. Renbaum[1], U. Beller[5], M-C. King[6], A. Lahad[7].* 1) Medical Genetics Institute, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Hebrew University Medical School, Jerusalem, Israel; 3) Division of Oncology, The Chaim Sheba Medical Center, Tel Hashomer, Israel; 4) The Institute for Medical Screening, Chaim Sheba Medical Center, Tel Hashomer, Israel; 5) Department of Obstetrics & Gynecology, Shaare Zedek Medical Center, Jerusalem, Israel; 6) Department of Medicine (Medical Genetics) and Department of Genome Sciences, University of Washington, Seattle, WA; 7) Department of Family Medicine, Hebrew University Medical School, Jerusalem, Israel.

Background: Inherited BRCA1 and BRCA2 mutations are associated with high risks of breast and ovarian cancer, and acceptable prevention measures (e.g. risk reducing salpingo-oophorectomy) significantly reduce morbidity and mortality. In Ashkenazi Jews (AJ), three variants account for ~95% of deleterious mutations, with a combined population carrier rate of 2.5%. Testing for common mutations in AJ is inexpensive and highly specific, and could fulfill WHO screening criteria if carriers ascertained from the general population were shown to be at high cancer risk. Current risk estimates are based on female carriers ascertained through personal or family history and thus may be subject to selection bias. ***Aim:*** To determine cancer risk in women with BRCA1/BRCA2 mutations by identifying carrier families through healthy males in the general AJ population. ***Methods:*** AJ males with no personal cancer history were tested for BRCA1/BRCA2 mutations. Relatives of carriers were tested and cancer risk in females was assessed based on genotype and family history. ***Results:*** Among 8196 males, 175 were heterozygous for one or more BRCA1/BRCA2 founder mutations (2.2%). Among their female relatives with mutations, risks of breast and ovarian cancer were comparable to current risk estimates: ~80% by age 75 for breast and ovarian cancer combined. Indeed, of female carriers in these families, 45% had been previously diagnosed with breast or ovarian cancer. As expected, family history of breast or ovarian cancer was more common in carriers vs. non carriers ($p<0.001$), especially in BRCA1 carriers ($p=0.02$). However, 63% of families with BRCA1/BRCA2 mutations had minimal or no family history of breast or ovarian cancer. Lack of family history was related to low incidence as a result of paternal inheritance, small family size, male preponderance and few females inheriting the familial mutation. Women carriers in these families would be missed using current referral criteria. ***Conclusions:*** Risk of breast and ovarian cancer to women with BRCA1/BRCA2 mutations is high in the general population. By WHO criteria, population-based screening is justified. This is currently feasible and cost-effective in any population with common founder mutations and could be universally applicable given genomics-based advances in genetic testing. General genetic screening for a dominant adult-onset disease is a novel proposition, and its practical and psychosocial aspects should be further explored.

Glioblastoma Multiforme: genomic estimates of tumor purity and revised classification. *B. Li[1], Y. Senbabaoglu[1], W. Peng[2], J. Li[1,2].* 1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Human Genetics, University of Michigan, Ann Arbor, MI.

Glioblastoma Multiforme (GBM) is an aggressive brain tumor with poor prognosis. Accurate definition of GBM subclasses is important for understanding its biological heterogeneity, and provides the knowledge base for better diagnosis and informed treatment. Recently, the Cancer Genome Atlas (TCGA) project characterized > 200 GBM samples, of which 128 were analyzed by both DNA genotyping and expression profiling, presenting an opportunity for integrated analyses. As primary tumors often contain both aneuploid cells and euploid cells, we used allele-specific copy number alteration (CNA) data from Illumina genotyping arrays to estimate the fraction of aneuploid cells, termed Aberrant Genome Proportion (AGP), and incorporated this measure of tumor purity in class discovery. Our genomic estimates of tumor purity correlate poorly with histopathologic report of tumor content, yet unlike the latter, are strongly correlated with principal components of total copy number data and gene expression data. Similar relationship between intratumoral heterogeneity and apparent between-tumor diversity is also seen in the ovarian cancer dataset from TCGA, suggesting that AGP is an important covariate in tumor classification. Combined analysis of expression and CNA data lead to a revised scheme of GBM classification, with two main subtypes: Typical and Atypical. Atypical GBMs are of high purity, are previously assigned to the Proneural group, carry signatures of secondary GBM such as IDH1 and TP53 mutations, are hypermethylated, and came from younger patients with better outcome. Typical GBMs span a continuum of expression profiles that parallels the purity gradient, carrying characteristic PTEN mutations, EGFR focal amplifications, gains of chr7 and losses of chr10. Importantly, proneural samples within the Typical group have significantly worse outcome than the rest of Typical samples. Using inferred AGP we extrapolated the expression profiles for pure tumor cells and found that Classical and Mesenchymal subtypes are recognizable among Typical GBMs, yet previously described Typical-Proneural and Neural subtypes are in fact not separable. We propose a step-wise diagnostic protocol for GBM that Incorporates these findings. Acknowledgement: We thank members of TCGA Research Network for sharing data and for helpful discussions.

Testing for BRCA1/2 mutations in hereditary breast cancer in Rio de Janeiro, Brazil. *M.A.F.D. Lima, K.R.L. Souza, A.C.E. Santos, C.H. Costa, A. Moreira, M. Moreira, F.R. Vargas.* Instituto Nacional do Câncer, Rio de Janeiro, Rio de Janeiro, Brazil.

Breast cancer (BC) is the second most frequent cancer among women in the world, and it is the most common neoplasia among women in Brazil (INCA, 2010). It is estimated that approximately 10% of BC and ovarian cancer (OC) cases are related to hereditary cancer syndromes (Lynch et al., 2008). We present our experience with testing for BRCA1/2 mutations in 141 BC and OC patients referred to our cancer genetic counseling unit. All patients included in this cross-sectional study fulfilled ASCO 1997 or NCCN 2008 criteria, and pre-test evaluation included medical geneticist and psychologist consultations. Probability models (Penn II, Myriad II and BRCAPro) were used to assess likelihood of BRCA1 or BRCA2 germ-cell mutations. Of a total of 141 families (138 female and 3 male probands) bilateral BC was observed in 14.1% patients; unilateral BC in 76.5%; bilateral OC in 3.5% and unilateral OC in 1.4%. BC was associated to other tumors (not OC) in 2 patients (kidney and gastrointestinal stromal tumor). Mean age for diagnosis of BC and OC was 42.1 years (range 20-74 years). Germ-cell BRCA1/2 disease-causing mutations were identified in 12 probands. There was no difference in groups with and without mutation regarding age of first tumor. Sensitivity and specificity of Penn II, Myriad II and BRCApro models were calculated. Penn II seems to be the most sensitive and BRCA-pro the most specific.

Integrated analysis of prostate cancer for the identification of biomarkers correlated to recurrent disease. *J. Lindberg[1,2], D. Klevebring[1,2], W. Liu[3], O. Laurin[4], M. Neiman[1,2], J. Xu[3], P. Wiklund[4], F. Wiklund[1], L. Egevad[5], H. Grönberg[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 2) Science for life laboratory, Stockholm, Sweden; 3) Center for Cancer Genomics, Wake Forest University School of Medicine, NC, USA; 4) Department of Urology, Division of Surgery, Karolinska Hospital, Stockholm, Sweden; 5) Department of Pathology and Cytology, Karolinska University Hospital, Stockholm, Sweden.

Background: Prostate cancer (PC) is the most common type of cancer accounting for ~35% of annual male cancer incidents and although the five-year survival rate is 75%, PC is the most frequent cause of death from cancer in Sweden. One of the main problems with treatment of PC is the lack of informative biomarkers for diagnosis and prognosis. PSA is a biomarker present in serum that has been used to monitor and diagnose PC patients for more than a decade, but the molecule has several drawbacks with massive unnecessary treatment as a consequence. Here we report on the current progress of an analysis of a biobank of PC tissues with the overreaching goal of identifying biomarkers for aggressive disease. We have taken the approach of 1) Mapping the somatic variation landscape in PC with focus on aggressive disease. 2) Evaluating circulating tumor DNA as a personalized biomarker in PC. 3) Integrating RNAseq data with the somatic mutation data for the identification of plausible protein biomarkers. 4) Evaluating the potential protein biomarkers both in tumors and plasma. Current results: So far we have extracted RNA/DNA and proteins from 110 PCs with >3 years of follow up and >70% of tumor content. Whole-exome sequencing combined with CNV data on 21 tumors from 19 individuals demonstrates the somatic variation landscape of PC to be as heterogeneous as for other solid tumors. Although few genes were recurrently mutated, significantly overrepresented themes related to chromatin modification, protein ubiquitination and ion transport, among others, were identified. Also, in-depth analysis of multiple tumor loci from one prostate indicates the presence of multiple independent tumors, with potential implications for sampling and biomarker discovery.

A General Statistical Approach to Somatic Mutation Discovery in Cancer Genome Sequence. *P. Liu, X. Hua, H. Xu, S. Park, Y. Lu.* Dept Physiology and Cancer Center, Medical College of Winconsin, Milwaukee, WI.

Cancers are caused by the accumulation of genomic alterations. Next-generation sequencing (NGS) technologies have revolutionized cancer genomics research by providing an unbiased and comprehensive method of detecting somatic cancer genome alterations, including nucleotide substitutions, small insertions and deletions, copy number alterations, and chromosomal rearrangements. However, substantial statistical and computational challenges still exist for analyzing NGS data. Here, we proposed a general statistical model for inference of somatic mutations and estimation of DNA contamination using NGS data. The proposed new approach possesses two prominent statistical properties. First, the method can jointly call somatic variants from multiple tumor samples. Second, the DNA contamination, commonly existing in tumor sequencing, is incorporated into our statistical models. We derived an efficient EM algorithm to obtain the maximum likelihood estimates of sequencing error rate, somatic mutation status and DNA contamination rate. Simulation results showed that these estimations are unbiased in our model. When incorporating DNA contamination rate into the model, our approach further increases 5-10% power as compared with conventional methods. As a result, we developed C routines to implement our approach. The program is user-friendly and can simultaneously handle hundreds of Binary Alignment/Map (BAM) files - the compressed binary version of the Sequence Alignment/Map, with multiple threads from cancer sequencing projects. To demonstrate its utility, we applied our approach to the analysis of 201 lung cancer exomes from The Cancer Genome Atlas (TCGA).

Cell-based models have shown that response to chemotherapy has a heritable component. We hypothesized that to identify loci associated with treatment outcome, we should focus on cases known to have had the standard chemotherapy for epithelial ovarian cancer. We therefore performed a two-stage genome-wide association study (GWAS) of progression free survival (PFS) following first line carboplatin/paclitaxel chemotherapy in ovarian cancer cases. In the first stage, we genotyped (Illumina Omni1) 183 Australian cases selected using an extreme phenotype design, and also included data on 134 cases from the TCGA and 68 from Mayo Clinic. In this stage, 260 cases had `standard' treatment (“primary” group: at least 4 cycles of carboplatin 5-6 AUC and paclitaxel 135-175 mg/m2 every three weeks) and 125 cases (“secondary”) had an unknown amount of carboplatin/paclitaxel chemotherapy. In the 2nd stage we genotyped 156 of the top ranking genotyped and imputed SNPs in 4660 cases (1080 `primary' and 1433 `secondary') from 11 sites in OCAC. The additive allelic association with the PFS was assessed in a Cox Proportional Hazards model, adjusting for study site, histological subtype, grade, stage and residual disease. For the SNPs with low minor allele frequencies, we ran permutations to correct the asymptotic p-values. One SNP clearly replicated in the 2nd stage. The associations in both stages were strongest in the “primary” group (1st stage results for this imputed SNP: hazard Ratio (HR) per minor allele=6.30, 95% CI=[4.26, 9.30], two-sided asymptotic p-value=1.88e-6, permuted p-value= 4.46e-5; 2nd stage: HR per minor allele=3.37, 95% CI=[2.48, 4.62], one-sided asymptotic p-value=5e-5, permuted p-value=2.9e-4; meta-analysis p-value corrected by permutation=1.7e-7). Furthermore, an independent cell-based GWAS conducted using HapMap lymphoblastoid cell lines showed that a more common SNP (MAF~4.5%) in moderate LD with our reported SNP (r2~0.28), was associated with carboplatin sensitivity (p-value=9e-3). Both these SNPs are located in a gene on chromosome 9 that is known to be associated with high-density lipoprotein cholesterol. We are now conducting additional experiments to evaluate the biological relevance of this gene with respect to treatment outcome, including the potential role of cholesterol metabolism as a determinant of response to chemotherapy. Our findings may provide some insight into the suggested role of statins in improving outcome for ovarian cancer.

The role of miRNAs in Cyclo-oxygenase-2 mediated breast cancer metastasis. *M. Majumder, L. Dunn, P.K. Lala.* Department of Anatomy and Cell Biology, The University of Western Ontario, London, Ontario, N6A 5C1, Canada.

Over-expression of the inflammation associated enzyme Cyclo-oxygenase (COX)-2 in breast cancer patients promotes tumor progression and metastasis by multiple mechanisms. MicroRNAs (miRNAs) are small regulatory RNAs that are emerging as biomarkers for cancer. Identification of miRNAs regulated by COX-2 will help to dissect post-transcriptional regulation. We examined the consequences of introducing COX-2 gene into COX-2-ve, ER+ve, non-metastatic MCF-7 human breast cancer cell line named MCF-7-COX-2. When MCF-7-COX-2 cells compared with empty vector-transfected MCF-7-mock cells showed (1) EMT, (2) higher proliferative, migratory and invasive abilities, (3) increased vascular mimicry, (4) increased in stem like cells population with higher expression of stem cell markers in vitro. We conducted differential gene and miRNA micro arrays in MCF-7-mock vs. MCF-7-COX-2 cells, with Affymatrix Human Gene Array 1.0 ST and Affymatrix Genechip miRNAs Array, expression micro arrays. ANOVA with alpha value 0.05 was used to determine associated probe sets followed by a Benjamini and Hochberg Multiple testing correction to reduce the false positive rate. For combined mRNA and miRNA analysis, correlation coefficient (±0.99) was fixed to determine up and down regulated miRNAs with their target gene of expression in MCF-7-COX-2 cell line compared to MCF-7-mock. We have identified two miRNAs (miR-526b and miR-655) that are up-regulated in MCF-7-COX-2. These two COX-2 up-regulated miRNAs were shown to down-regulate fourteen target genes linked with tumor-suppressor functions. We hypothesize that the COX-2-up-regulated miRNAs, are important for COX-2 mediated metastasis in human breast cancer. To test this, various COX-2 disparate human breast cancer cell lines were used to examine COX-2 functions, and to quantify miRNA expression with Taqman miRNA expression assay. COX-2 expression at mRNA level was directly related to expression of mir-655. We are now testing the metastatic abilities of MCF-7-COX-2 cell line in vivo in NOD/SCID/GUSB null mice to measure lung metastasis (identified by GUSB staining of cancer cells). We shall test whether knocking down of miRNAs in COX-2 over-expressing cells (1) can abrogate COX-2 mediated functions in vitro, (2) experimental lung metastasis and (3) find correlation of COX-2 and miRNAs expression in fresh/frozen breast cancer specimens that can personalize diagnostic and therapeutic approaches after surgery.

P53 isoforms are regulated by ETV6, a transcription factor involved in childhood acute lymphoblastic leukemia. *C. Malouf[1,2], J. Larose[1], S. Langlois[1], B. Neveu[1,2], D. Sinnett[1,3].* 1) Division of Hemato-Oncology, Research Center Sainte-Justine University Health Center, Montreal, Canada, H3T 1C5; 2) Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Canada, H3T 1J4; 3) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Canada, H3T 1C5.

Introduction. Pre-B acute lymphoblastic leukemia (ALL) is the most frequent pediatric cancer. Around 25% of patients carry the translocation t(12;21) that leads to the expression of the ETV6-AML1 chimera. This chimera alone is not sufficient to the development of leukemia. Notably, patients carrying the t(12;21) often present a deletion of the short arm of the non-translocated chromosome 12. This results in the inactivation of ETV6, an Ets transcriptional repressor with very few known transcriptional targets. We propose that ETV6 participates in childhood leukemogenesis through the deregulated expression of its transcriptional targets. **Experimental method**. In previous studies, we identified TP53 as a putative transcriptional target of ETV6. The TP53 classic promoter is responsible for the transcription of the p53 isoforms, whereas the TP53 alternative promoter regulates the transcription of the Δ133p53 isoforms. To understand the ETV6-mediated transcriptional regulation of TP53, we used *in vitro* gene reporter assays and *in vivo* chromatin immunoprecipitations. We also measured the expression of the p53-isoform transcripts by nested PCR in a cohort of leukemia patients. **Results**. ETV6 represses the transcription of both the TP53 classic and alternative promoters. The transcriptional regulation requires a region close to the basal promoters, along with both functional domains of ETV6: the Pointed domain (PNT) implicated in oligomerization and protein interactions and the DNA-binding domain (ETS). In the TP53 classic promoter, ETV6 interacts with chromatin in a region comprising three consensus Ets-Binding Sites (EBS) which are essential to the ETV6-mediated transcriptional repression. However, the consensus EBS of the TP53 alternative promoter were not recognized by ETV6. Since we didn't observe an enrichment of ETV6 on the TP53 alternative promoter, we propose that ETV6 could sequester transcription factors involved in Δ133p53 expression. Finally, we measured the expression of p53 isoforms in patients with pre-B ALL; although the p53 isoforms were down-regulated, we observed an up-regulation of the Δ133p53 isoforms. **Conclusion**. ETV6 regulates the transcription of all p53 isoforms using molecular mechanisms that are adapted to the target promoter. This study is the first to report a deregulated expression of the p53 isoforms in childhood leukemia and to suggest the implication of Δ133p53 in leukemogenesis.

Fine needle aspiration biopsy (FNAB) and aCGH in uveal melanoma. *D. Martinet[1], A. Schalenbourg[2], B. Rapin[1], L. Zografos[2], J.S. Beckmann[1], A.P. Moulin[2].* 1) Service of medical genetics, Lausanne, Lausanne, Switzerland; 2) Pathology,Ophthalmology, Jules Gonin Eye Hospital, Lausanne, Switzerland.

Genomic alterations in uveal melanoma are of prognostic value in terms of patient survival. We evaluated in this context the reliability of fine needle aspiration biopsy (FNAB) in molecular chromosomal analysis of uveal melanoma. High resolution aCGH analysis was conducted in 21 cases of uveal melanoma following enucleation. In 16 cases, 25G FNAB was performed immediately after enucleation. The results of CGH array from FNAB perfectly correlated with those arising directly from the tumor after section of the eye. In only one case (6%), there was insufficient DNA for array CGH analysis. Isolated monosomy 3 was present in 1 case; monosomy 3, 8q gain in 5 cases;, monosomy 3, 8q gain and 1p loss in 4 cases, monosomy 3, 6p gain, 8q gain and 1p loss in 3 cases; 6p gain only in 3 cases; 6p gain and 8q gain in 3 cases; no alteration on chromosomes 1, 3, 6 and 8 in 2 cases. FNAB is a reliable technique and provides enough tissue for the analyses of the entire genome, allowing the prospective use of this technique in uveal melanoma patients without enucleation. Our data do not confirm the hypothesis that 6p gain and monosomy 3 are mutually exclusive and represent different sequences in the pathogenesis of uveal melanoma.

Clinical laboratory experience of gene expression profiling of 2,384 solid tumors. *M.J. McGinniss, A. Ghazalpour, M. Hadlock, J. Garcia, N. Marcus, Y. Hosohata, J. Zarkovic, D. Jacquin, D. Flood, K. Wiste, K. Swetel, B. Toussaint, L. Teets, R.P. Bender.* Molecular Diagnostics, Caris Life Sciences, Phoenix, AZ.

Background: Optimizing therapeutic selections for cancer patients using the molecular profile of their tumor is an unmet need. Currently, many providers use results of tumor profiling by platforms including IHC, FISH and mutational analyses to identify potential cancer treatments. Gene expression profiling with microarrays also has the potential to help classify solid tumor subtypes and assist with therapy selections based on the under or over-expression of particular transcripts. Methods: Solid tumor samples are assessed by board-certified pathologists to ensure the presence of at least 20% tumor nuclei. Total RNA is extracted from tumor tissues (FFPE, frozen and RNAlater-preserved tissues). In addition, extracted RNA is verified to be of sufficient quality (using spectrophotometric metrics and qPCR results on a housekeeping gene RPL13a). The RNA sample is then subjected to a whole genome (29,285 transcripts) microarray analysis using Illumina cDNA-mediated annealing, selection, extension and ligation (DASL) process with the HumanHT-12 v4 beadChip (Illumina Inc., San Diego, CA). After direct hybridization and scanning of the bead array, the expression of a subset of 88 transcripts are then compared to tissue-specific normal control pools and the statistical significance of the difference between the patient tumor sample and control is determined. Results: The median Ct value from the RPL13a qPCR results for both frozen samples (N=70) and RNAlater preserved samples (N=851) was 24. The median Ct value for FFPE samples (N=1463) was 27. The ability of this assay to detect expression changes is directly proportional to the amount of tumor nuclei present in the patient sample. Dilution experiments showed that samples with 20% tumor nuclei are ~65% concordant for gene expression information compared to samples with >95% tumor nuclei with an R-squared value >0.99. Our intra-assay variability (same chip; same operator) was extremely low and the R-squared value was 0.99. The inter-assay variability (different chip; different operators) was somewhat lower with R-squared value of 0.93. The expected variability with internal proficiency (different reagent lots; different months; different operators) was >0.8. Conclusions: This microarray assay has been a reliable and robust method to perform gene expression profiling on routine solid tumor samples, including FFPE, submitted for clinical molecular profiling.

Genome-wide transcriptional sequencing identifies novel mutations in metabolic genes in human hepatocellular carcinoma (HCC). *D. Meerzaman[1], C. Yan[2], B. Dunn[3], M. Edmonson[1], R. Finney[2], C. Cultraro[1], L. Dong[1], Z. Yang[1], Y. Hu[1], J. Kelley[1], H. Zhang[1], N. Park[4], K. Buetow[1,2].* 1) NCI/LPG, NIH, Bethesda, MD; 2) NCI/CBIIT, Rockville, MD; 3) NCI/DCP, Bethesda, MD; 4) University of Ulsan College of Medicine, Asan Medical Center, Seoul, Korea.

Hepatocellular carcinoma (HCC) is the fifth most common cancer and the third most common cause of cancer mortality in the world. Although the association of HCC with chronic liver disease is well established, the exact etiology of HCC remains undefined. Here, we report the results of next-generation transcriptome sequencing from three human hepatocellular carcinoma tumor/tumor-adjacent pairs. RNA sequencing was carried out using the Illumina Solexa Genome Analyzer generating approximately 240 million 75-mer reads for all six samples. Sequence reads were mapped to hg18 using BWA and Bambino, an in-house tool. Expression values were normalized with the RPKM method. We identified 4,513 up-regulated genes and 1,182 down-regulated genes in tumor compared to matched normal samples. This differential gene expression was further confirmed using a large data-set containing 434 normal liver and tumor samples. Network analysis of expression data identified the Aurora B signaling, FOXM1 transcription factor network and Wnt signaling pathways as altered in HCC. Our mutation analysis revealed 30 mutations that were validated using Sanger sequencing. In addition to known driver mutations such as TP53 and CTNNB1, our mutation analysis also identified six non-synonymous mutations in genes implicated in metabolic processes. Furthermore, five of these mutated genes are known to be involved in metabolic diseases such as diabetes and obesity: IRS1, HMGCS1, ATP8B1, PRMT6 and CLU. The data presented here strongly suggest that alteration of metabolic genes is highly associated with the development and progression of liver cancer and will provide further insight into etiology liver cancer.

Molecular Characterization of Adeno-Pituitary Adenoma: Familial Isolated Prolactinoma. *F.M. Melo, L. Bastos-Rodrigues, M.S. Sarquis, L. De Marco.* UFMG - Universidade Federal de Minas Gerais, Belo Horizonte, MG., Brazil.

Pituitary adenomas are benign neoplasms that arise from the expansion of single cells from the adeno-pituitary. These tumors comprise 10% to 15% of all intracranial tumors. The pathogenic mechanisms of these tumors can be either genetic or epigenetic changes, resulting in the deregulation of cell cycle, signaling defects or loss of tumor suppressor factors. The prolactinoma is the most frequent pituitary adenoma, and may cause infertility and amenorrhea-galactorrhea syndrome in females. However, familial cases are rare and poorly characterized. Therefore, the propose of this work is to perform molecular characterizations of a family that carries prolactinoma. For this, we surveyed mutations described in two tumor suppressor genes (AIP and MEN1). We also evaluated a specific mutation, p.Gly2019Ser, in the gene LRRK2 associated with the greater propensity of tumors in patients with Parkinson's disease. For this study, genomic DNA from two patients diagnosed with prolactinoma, and two healthy relatives were extracted from peripheral blood samples. Sequencing was performed for the six exons of AIP and the exon 41 of LRRK2. Experiments with MEN1 are underway. No mutations were detected in the exons 1, 3, 4 and 6 of the AIP gene. Exons 2 and 5 are in review process. Two polymorphisms (p.Gln165Lys, p.Gln307Pro) were identified in all samples, which demonstrates the reliability of the results with the data already published. Mutations in LRRK2 were not detected. Considering the related results, no correlations were detected between mutations in the selected genes and prolactinoma development. To complement this work we will apply, in the near future, exoma sequencing in order to identify other mutations that can be correlated to the development of prolactinomas in isolated familial cases.

1203T

Identifying women at increased risk of breast cancer: Can we use genotyping at low penetrance loci? *C. Merrick[1], J. Dunlop[2], L. Baker[1], E. Gellatly[1], A. Martin[3], P. Quinlan[1], R. Tavendale[1], A.M. Thompson[1], C. Palmer[1], M. Reis[4], J.N. Berg[1,3].* 1) University of Dundee, Ninewells Hospital, Dundee, DD1 9SY, United Kingdom; 2) East of Scotland Regional Genetics Unit, Ninewells Hospital, Dundee, DD1 9SY, United Kingdom; 3) NHS Tayside, Ninewells Hospital, Dundee, DD1 9SY, United Kingdom; 4) Tayside Breast Cancer Family Clinic, Ninewells Hospital, Dundee, DD1 9SY, United Kingdom.

Background: Most inherited predisposition to breast cancer is attributable to low penetrance susceptibility loci, a number of which have been identified through genome-wide association studies. Although individually each locus has a small effect, combining data from multiple loci would be expected to provide more risk information. We investigated the size of risk determination that can be achieved using genotyping at 18 loci. We then calculated its effect when combined with risk estimated from family history alone in terms of management under UK guidelines, where a woman who has a 10 year risk of 3% or greater requires additional breast screening from a younger age. **Methods**: Genotyping for 18 loci was carried out in 253 women at increased risk of breast cancer due to a positive family history and 118 matched controls. The relative risks conferred by genotype at the 18 loci were combined under a log-additive model and transformed into a log-polygenic risk. The BOADICEA risk estimation tool was used to calculate breast cancer risk due to family history. **Results**: Both the increased risk and control groups demonstrated a normal distribution of log-polygenic risk with similar variance. There was a significantly higher mean in the increased risk compared to the control group (mean = 0.1313 and 0.0874 respectively, P = 0.007). No significant correlation was found between polygenic risk calculated from genotype data and the family history risk estimated using BOADICEA. When polygenic risk was combined with family history risk there was significant reclassification of risk for those with a family history. 36.76% moved into a higher risk category while 3.68% moved into a lower risk category. **Conclusions**: Our data suggests that genotyping will be clinically relevant for estimating breast cancer risk. Individuals with a family history overall have a higher genotype risk than the population. The lack of correlation of genotype risk with BOADICEA risk suggests that the two risk estimates can be considered independently. By combining genotype with family history data, we demonstrated a significant reclassification of risk for individuals with a family history, with better identification of women in this group requiring intervention.

1204T

Understanding the role of TRIM8, a new p53 target gene that modulates p53 activity, in the progression of glioma. *L. Micale[1], M.F. Caratozzolo[2], C. Fusco[1], B. Augello[1], M.N. Loviglio[1], M.G. Turturo[1,5], G. Cotugno[1], T. Lopardo[3], F. Galli[3], S. Cornacchia[2], F. Marzano[2], A.M. D'Erchia[2], L. Guerrini[3], G. Pesole[4], E. Sbisà[3], A. Tullo[2], G. Merla[1].* 1) Medical Genetics Unit, IRCSS, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Foggia, Italy; 2) Institute for Biomedical Technologies , ITB, Bari, Italy; 3) Department of Biomolecular Sciences and Biotechnologies, Milan; 4) 5Institute of Biomembranes and Bioenergetics, IBBE, Bari; 5) Telethon Institute of Genetics and Medicine, TIGEM, Napoli.

Impairment of p53 function has a crucial role in tumor evolution. p53 inactivation occurs through alteration of p53 function by mutations and deregulation of signaling pathways or effectors molecules that regulate p53 activity. The stabilization and activation of p53 are crucial in preventing cells from becoming cancerous. Thus, one of the most important challenges for the development of improved cancer therapies is the discovery of additional p53-inactivating pathways or p53 modulators. We describe a previously unknown function for TRIM8, as a new p53 target gene that modulates the p53-mediated tumour suppression mechanism. We showed that, under stress conditions, such as UV treatment, p53 induces the expression of TRIM8, which in turns interacts with and stabilizes p53. The stabilization of p53 was paralleled by an increase of Ser15 and Ser20 phosphorylated p53 level, a marker of the activation status of p53 for cell cycle arrest activity. Furthermore, overexpression of TRIM8 regulates the p53 transcriptional activity by increasing p21 and GADD45 mRNA levels, that result in inhibition of cell cycle progression. Concurrently, TRIM8 overexpression decreases MDM2 protein levels suggesting that TRIM8-mediated p53 stabilization occurs through MDM2 degradation. TRIM8 is highly expressed in human brain and it maps to 10q24.3, a region proposed to contain tumor suppressor genes involved in gliomas. By analyzing approximately 100 human glioma cell lines we showed that TRIM8 expression is strongly under expressed in these tumors, correlating with the tumor histological grade. Intriguingly, the restoring of TRIM8 expression level in U87 glioma cell line enhances the stabilization of endogenous p53 protein level and induces the suppression of cell proliferation, as revealed by western blot and MTT assays. Moreover we assessed the molecular mechanisms responsible for TRIM8 downregulation, revealing TRIM8 LOH and hypermethylation of CpG islands. Finally we found that in glioma samples TRIM8 mRNA level anti-correlates with miR-17 expression, a microRNA involved in glioma progression. Consistently, target prediction tools and luciferase assay showed that miR-17 targets 3'UTR-TRIM8, resulting in TRIM8 downregulation. Collectively, our observations suggest the existence of a new p53-TRIM8 feedback-loop mechanism and support the hypotheses that TRIM8 might participate to the development of gliomas through a molecular modulation of p53.

Functional Polymorphism in Promoter Survivin Gene and Risk of Urothelial Bladder Carcinoma in North Indian Population. *R.D. Mittal, P. Jaiswal, A. Mandhani, T. Mittal, R. Kapoor.* Urology & Renal Transplantation, Sanjay Gandhi PGI, Lucknow, Uttar Pradesh, India.

Survivin is a member of novel inhibitor of apoptosis protein family that is expressed in human cancers and not normal tissues. The molecular detection of bladder cancer by targeting of Survivin as a novel molecular marker may be useful as it plays an important role in the occurrence and progression of cancer. We examined whether -31G>C, -644T>C, -625G>C, -1547 A>G and -241C>T was related to the risk of developing bladder carcinoma (BC) in a case-control population from Northern India which consisted of 200 patients with BC and 200 healthy controls. This polymorphism was genotyped by Polymerase Chain Reaction- Restriction Fragment Length Polymorphism (PCR-RFLP). The genetic associations with the occurrence and progression of BC were estimated by logistic regression. We observed a statistically significant increased occurrence of BC risk associated with the variant CC genotype of Survivin-31G>C (P = 0.021; OR= 2.61; 95% CI (1.16-5.87).We also observed hetero genotype of Survivin -625G>C to be at risk (p=0.019), while variant allele GG demonstrated 1.6 fold increased BC risk. The variant genotype in other polymorphic site of Survivin (-1547 A>G) was significantly associated with BC risk (p=0.047). In case of Survivin-241C>T the risk genotype for BC risk was hetero (p=0.035). Furthermore, the haplotype analysis revealed that G-G-C-A-C haplotype had BC risk. Smoking significantly modulated the risk in patients with Survivin 1547-A>G polymorphism. A significant association was observed for the Survivin -644 T>C (p=0.012) and for Survivin- 625 G>C with GC+CC combination (p=0.003) and GC genotype (p=0.01) with the severity of BC (as measured by tumor-node-metastasis staging system). Variant as well as hetero genotype of Survivin-31G>C was associated with risk of recurrence (HR = 0.22 and 0.35) in superficial BC patients receiving BCG treatment thus showing least survival (log rank= 0.004).Our findings suggested that the functional polymorphism -31C>G,-625G>C,-1547A>G and -241C>T in the promoter of Survivin gene may play a significant role to intercede the susceptibility to BC in North Indian population Acknowledgement: Financial support from Council of Scientific and Industrial Research (CSIR) and Department of Science and Technology (DST).

CREB3 and STK11 show different gene expression profiles in benign and malignant salivary gland cancers. *N. Mohammadi Ghahhari[1], M. Kadivar[1], A.R. Kamyab[1], M.T. Khorsandi Ashtiani[2], H. Mohammadi Ghahhari[3].* 1) Department of Biochemistry,Pasteur Institute of Iran, Tehran, Iran; 2) 2. Otorhinolaryngology Research Center, Amir-Alam Hospital, Department of Otolaryngology-Head and Neck Surgery, Tehran University of Medical Sciences, Tehran, Iran; 3) 3. Department of Otorhinolaringology and Head & Neck Surgery, Imam Reza Hospital, Tabriz University of Medical Sciences, Tabriz, Iran.

Introduction:Salivary gland cancers (SGCs) are heterogeneous neoplasms showing various histopathological characteristics with uncertain prognosis for their patients. Unfortunately, because of their rarity, only few studies have been performed to investigate molecular mechanisms involved in their tumor formation and progression. In the present study, we aimed to evaluate the expression level of two genes including STK11 and CREB3 which are supposed to play roles in both pro- and anti-apoptotic pathways in the cell. Materials and methods:In the study, a total of 23 fresh tissue specimens were obtained from patients having SGCs comprising of 11 pleomorphic adenomas and one sample of each warthin's tumor (WT), benign adenomatous tumor (BAT), cystic parotid adenoma (CPA), low grade mucoepidermoid carcinoma (MEC), small cell carcinoma (SCC), clear cell carcinoma (CCC) and one with no remarkable diagnosis (Non Tumor), respectively. Five normal tissue samples (NR) were also included in the study. The mean age of patients was 34 and none of them underwent radiotherapy or chemotherapy before surgery. After RNA isolation and cDNA synthesis, we performed quantitative Real-Time PCR for all samples with specific primers. RNA polymerase-II gene was selected as an endogenous control. Subsequently, Real-Time PCR data was analyzed using the comparative threshold cycle ($\Delta\Delta$CT, ratio=2 -$\Delta\Delta$CT) and statistical methods. Results:Statistical analysis showed the CREB3 gene expression percent for NRs, PAs, WT, BAT, CPA, Not Tumor, MEC, SCC and CCC were calculated as 100.5±6.8, 101.7±7.5, 91.4±24.1, 85.6±3.1, 77.8±6.9, 105.2±3.5, 158.1±32.2, 114.1±21.7 and 114.7±7.7, respectively. Moreover, the gene expression percent for STK11 gene was 98±1.6 in normal tissues and 29.4±10.0 in PAs, 78.8±10.6 in WT, 785.3±74.7 in BAT, 10.9±8.6 in CPA, 62.7±16.9 in Not Tumor, no expression in MEC, 202.1±37.4 in SCC and 3.4±1.8 in CCC. Discussion:To our knowledge, this is the first report that the expression levels of STK11 and CREB3 have been quantified in benign and malignant SGCs using qReal-Time PCR method. Based on tumor suppressor role for CREB3 gene, we may conclude that all tumors show it by having small changes in gene expression level. STK11 gene has responsibilities as tumor suppressor and oncogene in the cell. Therefore, in PAs, WT, CPA, Not Tumor, MEC and CCC it has partially lost its tumor suppression role. However, it indicates very strong oncogenic function in BAT and SCC.

Systematic Meta-Analysis for Common Low Penetrance Genes in Colorectal Cancer. *Z. Montazeri[1], E. Theodoratou[2], J. Little[1], H. Campbell[2].* 1) Epidemiology and Community Med, Ottawa University, Ottawa, Canada; 2) centre for Population Health Science, The University of Edinburgh, UK.

To identify genetic variance influencing colorectal cancer (CRC), we conducted systematic reviews and meta-analysis for a set of genes which were identified in genome wide association studies (GWAS). To date, 15 common genetic variants influencing risk of CRC have been reported from GWAS for colorectal cancer. We identified and extracted data from published studies up to 31 March 2011. In addition, unpublished data from the Scotland GWAS (SOCCS) and/or Ontario GWAS (ARCTIC) were included in the analyses. We carried out meta-analysis to derive summary effect estimates for 18 polymorphisms in 15 genes; and obtained summary crude odds ratios and 95% CI for recessive, additive and one dominant model for variants that were identified from GWAS. We applied either the fixed effect model or in the case of heterogeneity the random effect model. Heterogeneity was quantified by calculating the Q statistic; we also calculated the I^2 heterogeneity metric. The statistical power of each meta-analysis was estimated. In assessing the credibility of genetic association, we consider the Venice criteria and the Bayesian False Discovery Probability (BFDP). We classified the genetic association in 3 categories as positive, less credible positive and negative. Furthermore, we applied the model free meta-analysis approach for those SNPs that were identified as “positive”. Two SNPs at 8q24 locus showed positive association irrespective of genetic model considered (OR: 1.45; 95% CI (1.39-1.51) for rs6983267 and OR: 1.32; 95%CI: (1.22-1.42) for rs10505477) which has been found to be associated with other types of cancer; whereas SMAD7 was inversely associated with CRC with OR: 0.75; 95%CI: (0.71, 0.79). The associations for other variants were also observed and categorized.

About 90% of adult kidney cancers are renal cell carcinoma (RCC), the majority of which are clear cell adenocarcina (ccRCC) which can be further classified by genomic profiling. Comparative genomic hybridization was used to identify alterations in tumors from patients enrolled in a large case-control study of RCC in Central Europe. Associations with histopathology, occupational exposures, and genetic risk factors were evaluated based on previously observed associations. Of 1097 cases in the final study, 524 RCC cases (48%) diagnosed from hospital reports provided frozen tumor biopsies. Of these, 415 biopsies were confirmed with ccRCC. Tumors were macrodissected, DNA extracted. Scanning and OncoBAC arrays were comprised of 2464 BACs selected at approximately megabase intervals along the genome, printed in quadruplicate. Multivariate regression and polynomial models were used to identify associations between chromosomal regions and patient/tumor characteristics. The most frequent chromosome alterations were: 3p-(92.2%), 14q-(46.5%), 8p-(38.1), 4q-(35.4%), 9q-(32.2%), 9p(31.6%)-, 6q(30.6%)-, 3q-(29.2%), 10q-(25.8%), 13q-(24.3%), 1p-(23.6%) and 5q+(60%), 7q+(39.5%), 7p+(30.6%), 5p+(26.3%), 20q+(25.3%), 12q+(24.6%), 12p+(22.7%).In multivariate analyses, only VHL inactivation [through promoter hypermethylation and sequence alteration] was associated with 3p- (OR=1250(95% CI:476-3125) compared to VHL wild type cases. The frequency of clonal losses differed significantly between VHL wild type, hypermethylated and genetically altered cases at regions on 3p, distal and proximal to the FHIT gene locus (3p14.3). Grade was associated with 1p-, 4q-, 6q-, 8p-, 9p-, 9q-, 13q-, 14q-, and 5p+, 7p+, 7q+, 12q+. Stage was associated with 1p-, 9p-, 9q-, 10q-, 13q- and 12p+, 12q+, 20q+. Males had significantly more alterations compared to females on 3q-, 9p-, 9q-, 13q-, 14q- and 7q+, 12p+, 12q+, and 20q+ independently of stage or grade. Cases without a family history of cancer had significantly more alterations and breakpoints compared to those that did. This is the first study of its size to conduct multivariate analyses of chromosomal alterations with detailed information on patient/tumor characteristics and risk factors. We identified case heterogeneity by loss of clones on 3p that varied by the presence and mechanism of VHL gene inactivation. They also suggest that male cases may be more genetically instable than female cases, and may be more aggressive.

Evaluation of circulating tumor DNA as marker for decease progression in breast and prostate cancer. *M. Neiman[1,2], J. Lindberg[1,2], D. Klevebring[1,2], T. Nordström[1,3], L. Eriksson[1], L. Nygård[4], F. Celebioglu[4], K. Czene[1], P. Hall[1], H. Grönberg[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Solna, Sweden; 2) Science for life laboratory, Stockholm, Sweden; 3) Danderyds Hospital, Danderyd, Sweden; 4) Stockholm South General Hospital, Stockholm, Sweden.

In the western world, breast and prostate cancer are the most common forms of cancer in women and men respectively. Of all reported cancer cases in men in Sweden 2009, 35.7 % were prostate cancer and for breast cancer in women the corresponding figure was 28.7 % . One of the biggest challenges in cancer treatment is monitoring disease progression in diagnosed patients such as tumor aggressiveness and treatment response. In cancer, circulating tumor miRNA and DNA have been correlated to both early detection and prognosis. Since the half-life of circulating DNA in blood is less than 30 min, it has been successfully used to monitor treatment outcome. Structural rearrangements in the tumor genome can be identified through whole genome sequencing. The breakpoints of these rearrangements can be used targets for a qPCR assay making it possible to detect single tumor DNA molecules in milliliters of plasma. When dissecting heterogeneous tumors, such as prostate or breast cancer tumors, it is difficult to get material consisting of more than 70% tumor cells, which is desired for tumor sequencing. To circumvent this issue, we use Laser Capture Microdissection (LCM) prior to DNA extraction. The amount of DNA that can be extracted from microdissected tumor tissue is however limited. In order to be able to perform Illumina sequencing from these small amounts of DNA it is not possible to use the standard sample preparation protocols. We have developed an alternative sample preparation protocol making it possible to prepare sequence ready libraries from minute amounts of DNA. The yield is around 30 times higher than when using the standard protocol. Using this new protocol we are able to sequence DNA from microdissected material and fine-needle biopsies. We have collected plasma and tumor tissue from prostate and breast cancer patients that underwent surgery at Karolinska Univeristy Hospital and Stockholm South General Hospital respectively. From each patient, whole genome sequencing is carried out on both tumor and germline DNA to identify tumor-specific rearrangements which can be monitored using individualized qPCR assays. Tumor DNA amounts are measured in plasma samples collected at multiple time points during treatment.

Molecular profiling of inherited colorectal cancer syndromes by genomic analysis of normal tissue. *D. Neklason[1,2], B. Milash[1], L. Frey[1,3], M. Done[1], N. Sargent[1], T. Berry[1], T. Tuohy[1], R. Burt[1,4].* 1) Huntsman Cancer Inst, Univ Utah, Salt Lake City, UT; 2) Dept of Oncological Sciences, Univ Utah, Salt Lake City, UT; 3) Dept of Biomedical Informatics, Univ Utah, Salt Lake City, UT; 4) Dept of Medicine, Univ Utah, Salt Lake City, UT.

Current technologies are only able to provide genetic diagnosis on 20 to 90% of index cases depending on the gene and syndrome. We hypothesize that a diagnostic test can be developed based on gene expression in normal tissue from the end organ tissue of a disease. The mRNA from the mutated gene may be unchanged in many cases, but the downstream effects due to a nonfunctional protein may have a detectable readout. A diagnostic test is under development for the inherited colorectal cancer syndromes based on a genome-wide analysis of mRNA expression in normal colonic epithelial biopsies obtained during endoscopy. The utility of this method is to properly classify patients where genetic diagnosis is incomplete and suggest molecular pathways that are shared and differentiate the syndromes. RNA was extracted from fresh colonic biopsies. Agilent 44K whole genome microarrays were run on 7-10 normal colon tissue samples from control, FAP, AFAP, Cowden syndrome, hyperplastic polyposis (HPP), and HNPCC patients. Microarray data were normalized and log-transformed for analysis by four methods. We applied a SAM-like method using GeneSifter software with a t-test. Diagnostic genes for each syndrome were selected based on p-value and relative expression level compared to control. Differentially regulated genes were also selected using a rank product analysis. Paired genes that create a distinct convex hull, relative to either controls or all other syndromes, were identified and selected for maximal separation between the groupings. Finally, classification models were used to create decision tree classifiers with area under the ROC curve to separate the syndromes. Gene transcripts selected by each of these methods were confirmed by RTqPCR. The mRNAs from causative genes are decreased in most normal colonic tissues from Cowden syndrome (PTEN), HNPCC (MLH1), and a small subset of AFAP and FAP (APC) patients, presumably through nonsense mediated decay. Cowden syndrome can be diagnosed by differential expression of CLIC6, MFAP5, and possibly ADRA1. HNPCC has been initially characterized by expression of KIAA1804 and KIT. For AFAP and FAP, molecular diagnosis will likely involve multiple markers, including TTC12, NKD1, ANPEP. These initial results indicate that molecular differences can be identified in normal tissue from individuals harboring a single genetic mutation. This strategy offers promise as a diagnostic tool, especially when conventional genetic diagnosis fails.

1211T

Replication of susceptibility loci for lung cancer in a French Canadian population. *J.D.U. Nguyen[1], M. Lamontagne[1], C. Couture[1], M. Laviolette[1], Y. Bossé[2], The Merck-Laval-UBC-Groningen Lung eQTL consortium.* 1) Centre de recherche Institut universitaire de cardiologie et de pneumologie de Québec, Laval University, Quebec, Canada; 2) Department of Molecular Medicine, Laval University, Quebec, Canada.

Recent genome-wide association studies (GWAS) have identified three genetic loci reproducibly associated with lung cancer: 15q25, 5p15 and 6p21. The aim of this study was first to test whether these loci are also associated with lung cancer in a French Canadian population and then to identify the causal genes in these regions using lung expression quantitative trait loci (eQTL) data. More than a million single-nucleotide polymorphisms (SNP) were genotyped in 420 patients undergoing lung cancer surgery. Genetic association tests were restricted to SNPs previously associated with lung cancer on chromosomes 15q25, 5p15, and 6p21. The allele frequencies of seven uncorrelated SNPs were compared to a control group of 3,151 individuals of European ancestry. Genome-wide gene expression profiles of 409 non-tumor lung tissues from the same lung cancer patients were measured to identify eQTLs. SNPs rs8034191 and rs8042374 on chromosome 15q25 were significantly associated with lung cancer (p = 2.91E-6 and 0.006, respectively). SNP rs2736100 on chromosome 5p15 was specifically associated with a histological subtype of cancer, adenocarcinoma (p = 0.004). The single SNP (rs3131379) tested on chromosome 6p21 was also associated with lung cancer (p = 0.032). Genetic variants that were associated with lung cancer on 15q25 were also associated with the expression levels of the gene CHRNA5 located in the same chromosomal region (p = 2.23E-22 for the strongest eQTL). This study confirms the three susceptibility loci for lung cancer in a French Canadian population and also suggests that the risk alleles on chromosome 15q25 confer susceptibility for lung cancer by modulating the expression levels of CHRNA5 in the lungs.

Early insights from whole-exome analysis of early-onset, multiple-case breast cancer pedigrees. *T. Nguyen-Dumont[1], D.J. Park[1], F. Odefrey[1], F. Hammet[1], Z.L. Teo[1], D.E. Goldgar[2], S.V. Tavtigian[3], B.J. Pope[4], A. Lonie[4], M.C. Southey[1], BCFR, BRCAX Consortium.* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria, Australia; 2) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, Utah, USA; 3) Department of Oncological Sciences, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, Utah, USA; 4) Victorian Life Sciences Computation Initiative, Victoria, Australia.

Germline mutations in known susceptibility genes explain a relatively small proportion of the heritable risk for breast cancer (BC) (30-35%). In this study, we aim to identify genes in which variants could account for the majority of the unexplained residual familial aggregation of BC. We are applying whole-exome capture followed by massive parallel sequencing (XC-MPS) to analyze highly selected, early-onset, multiple-case BC pedigrees from international resources, which have been previously screened for mutations in known BC susceptibility genes. We have used the SeqCap EZ Human Exome Library v2.0 kit (Nimblegen), and the SOLiD4 platform (Life Technologies) to sequence coding regions and proximal intronic splice consensus sequences in pairs of affected young women more distantly related than first cousins, within each pedigree. The exomes of 20 individuals from 10 families have thus far been analyzed. We have developed an in-house bioinformatics analysis pipeline based on peer-recognized Bioscope, SAMtools, Picard, GATK, BEDtools and IGV software, and the human genome reference hg19. Our initial analysis strategy filters out variants listed in dbSNP131, and filters for SIFT-predicted damaging variants. We have developed novel data filtering approaches to markedly increase specificity over conventional pipelines, without compromising sensitivity. The great majority (86%) of candidate genetic variants identified through our XC-MPS pipeline prove to be genuine via Sanger sequencing. We have identified rare, predicted protein damaging variants in 168 genes with key roles in disease-relevant pathways such as DNA repair and replication, cell cycle checkpoints, centromere function, telomere maintenance, chromosome stability and estrogen signaling. Despite observing 6 core DNA repair genes exhibiting a protein-truncating mutation or disruption to a core splice site consensus sequence, we have not, to date, observed such a potentially “catastrophic variant” to be shared by both analyzed members of the same pedigree. XC-MPS has revealed the extensive genetic variation present in human exomes. The proportion of variation with plausible relevance to disease predisposition is considerable and further work is required to characterize the true BC predisposition genes. Our findings suggest that a substantial proportion of the currently unexplained familial risk for BC might be explained by combinations of rare genetic variants that together confer high risks for BC.

1213T

Diagnostic improvement of thyroid nodules cytology by determination of three genes expression profile. *V. Novik[1,2], G. Molina[3,4], A. Vasquez[4], R. Ceriani[4], M. Fuentes[4], C. Weisntein[4], C. Henríquez-Roldán[5], G. Arístides[6], D. Navarrete[1], F. Brusco[7], G. Lezana[7], A. Lobos[8,9].* 1) Departamento de Medicina. Escuela de Medicina, Universidad de Valparaíso, Valparaiso, Región de Valparaíso, Chile; 2) Facultad de Medicina. Universidad Nacional Andres Bello. Sede Viña del Mar; 3) Unidad de Genética Forense, Servicio Médico Legal de Valparaíso, Valparaíso, Chile; 4) Facultad de Farmacia. Universidad de Valparaíso; 5) Centro de Estudios Estadísticos. Universidad de Valparaíso; 6) Hospital Eduardo Pereira, Valparaíso; 7) Hospital Naval Almirante Nef. Viña del Mar; 8) Hospital Gustavo Fricke. Viña del Mar; 9) Departamento de Cirugia, Universidad de Valparaíso.

Thyroid cancer represents only 1% of total amount of cancer. However, thyroid nodules are frequent. 5%-10% of the total population will develop a thyroid nodule during they life. Most of these will be benign. Currently, fine-needle aspiration biopsy (FNAB), represents the most important initial test for diagnosing malignancy. The result of the FNAB cytology can be classified as benign (70% of cases), malignant (5% to 10%), indeterminate or suspicious (10% to 20%), or nondiagnostic (10% to 15%). Although nondiagnostic FNABs can be repeated, the indeterminate or suspicious group presents a dilemma for the clinician. Patients with a non diagnostic FNAB must undergo a thyroidectomy with a diagnosis objective. MET, FN1 and TPO genes have been determined as consistent differential gene expression markers between malignant and non-malignant tissue in thyroid nodules. These candidates should help to develop a panel of markers with sufficient sensitivity and specificity for the diagnosis of thyroid tumors in a clinical setting. Twelve preoperative samples of FNAB from patients with a thyroid nodule, were obtained. All patients were undergoing to a thyroidectomy with a diagnostic or therapeutic objective. An informed consent were accepted and signed by the patients. The expression of MET, FN1 and TPO genes were determined by quantitative real time PCR (Fret probe, ROCHE), using G6PDH to normalize. A general index including the expression of the three genes were determined using main components analysis. The index was compared with the histopathology of the surgery biopsy (Gold Standard). A sensitivity of 100% and a specificity of 71,4% was obtained for malignancy state. The pre-operatory diagnosis could be improved in a 36%. The thyroidectomies with diagnosis objective in these group of patients was 41,7%. These unnecessary surgeries could be avoided using molecular genetics results in the cytology of thyroid nodules. The molecular diagnosis with this 3 gene model might be a reliable test to preoperatively diagnose the malignant potential of thyroid nodules. FONIS SA07I20066.

Li-Fraumeni syndrome: retesting archival DNA samples identifies previously unrecognized germline *p53* mutations. *A. Novokmet[1,2], B. Baskin[4], P. Ray[2,3], D. Malkin[1,2].* 1) Hematology/Oncology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Molecular Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Clinical Genetics, Uppsala University Hospital, Uppsala, Sweden.

Background: Li-Fraumeni syndrome (LFS) is a familial cancer predisposition syndrome that results from germline alterations in the *p53* gene. Unlike other cancer predisposition syndromes, LFS predisposes to a wide range of cancers including premenopausal breast cancer, sarcomas, brain tumors, adrenocortical carcinomas, and others. Over the past 20 years, the criteria for LFS have expanded beyond the classical definition, resulting in an increased number of individuals being tested. Additionally, technological advances have facilitated discovery of previously occult alterations. Upon review of samples received by our laboratory for *p53* analysis between 1991 and 2004, we identified 71 samples for retesting. **Methods:** We queried our extensive Cancer Genetics database, containing more than 4100 individuals, for banked blood-derived DNA samples that had undergone *p53* mutation analysis prior to April, 2004 and were found not to have an alteration. Diagnosis and/or family history were confirmed to meet the classical, Birch, or Chompret criteria for LFS. Seventy-seven patient samples were retrieved and of those, 71 were of sufficient quality and quantity for analysis. The samples were submitted to the Hospital for Sick Children's Molecular Genetics Laboratory for analysis. **Results:** Of the 71 samples submitted for *p53* analysis, 8/71 were found to harbor a *p53* germline alteration (Cys229Arg, Val157Ile, Tyr236X (n=2), Thr125Thr, Arg213Gln (n=2), and deletion exons 10-11), 1/71 was found to be wildtype, and the remaining 62/71 were found to harbor a presumed non-disease-causing codon 72 polymorphism (Arg72-Arg, Pro72Arg). Three of the five alterations (Cys229Arg, Val157Ile, Tyr236X) have previously been identified in somatic tissues (http://www-p53.iarc.fr); however, this is the first report of their occurrence in the germline. **Conclusions:** Advances in technology have allowed detection of a higher frequency of *p53* alterations and have facilitated the identification of a *p53* alteration in eight individuals who were previously found to be wildtype. Positive findings are important for affected individuals with respect to risk of development of second malignancies and for other at-risk family members, given an overall lifetime cancer risk of 85% in individuals with LFS. These findings stress the importance of banking DNA for possible future retesting in anticipation of advances in technology.

1215T

Expression of human endogenous retroviruses in childhood acute leukemia cells. *J. Nowak[1], K. Nowicka[1], J. Rembowska[1], D. Januszkiewicz[1,2].* 1) Inst Human Gen, Polish Academy Sci, Poznan, Poland; 2) Department of Paediatric Oncology, Hematology and Transplantology Poznan University of Medical Sciences, Poznan, Poland.

Human endogenous retroviruses sequences(HERVs) constitue 8% of the whole human genome. The complete structure of HERVs contains gag, pol, env and primer binding site flanked by Long Terminal repeats (LTRs). The majority of HERVs are not complete and its individual sequences are spread throughout the genome often in more than one copy. The majority of HERVs are defective due to mutations, deletions and insertions. There are reports indicating the participation of HERVs in etiopathogenesis of autoimmune diseases and cancer. In order to learn the importance of HERVs in leukemogenesis we investigated the expression of gag, pol and env genes of HERV K, H, W and E in acute leukemias in children. RNA was isolated from PBL of 120 acute lymphoblastic leukemia (ALL) patients, 40 acute myeloblastic leukemia children and 20 healthy individuals. HERVs gene expression was studied by real-time PCR and the results were normalized to reference gene expression and to expression of all studied genes in PBL. In ALL the high expression of gag, pol and env only of HERV-K has been found. The expression of other studied HERVs in ALL was similar to that in PBL. In AML cases, among studied HERVs, the expression of HERV-E differs significantly in comparison to ALL and PBL. Preferential gag, pol and env expression of HERV-K in ALL and HERW-E in AML strongly suggests the contributions of these HERVs in pathogenesis of acute leukemias in children. Determination of specific role of HERVs in leukemias warrants futher investigations. The work has been sponsored by Ministry of Science and Education grant No 401195339.

Detecting copy number aberrations in tumours using SNP array technology: A comparison of several available methods. *K. Oros Klein[1], S. Arcand[2], A. Birch[3], D. Provencher[4,5], J. Squire[6], A.M. Mes-Masson[4,5], P.N. Tonin[2,3,7], C.M.T Greenwood[1,8,9].* 1) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, QC; 2) The Research Institute of the McGill University Health Centre, Montreal, QC; 3) Department of Human Genetics, McGill University, Montreal, QC; 4) Centre de recherche du Centre hospitalier de l'Université de Montréal, Montreal, QC; 5) Institut du cancer de Montréal, Montreal, QC; 6) : Department of Pathology and Molecular Medicine, Queen's University, Kingston, ON; 7) Department of Medicine, McGill University Montreal, QC; 8) Department of Oncology, McGill University, Montreal, QC; 9) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, QC.

In a well-defined set of ovarian cancer tumour samples and ovarian cancer cell lines of the serous histopathological subtype, we have compared the performance of several methods for inferring copy number aberrations (CNAs) from high-density SNP data derived using the Illumina 610-Quad BeadChip array. Inference about CNAs in tumours and cell lines is made more difficult by (a) the presence of normal tissue mixed with tumour tissue, (b) clonal variation between cells in the same tumour, and (c) aneuploidy. Analysis methods have evolved with time to allow for several of these factors. We compared the performance of 4 algorithms, dChip (Zhao et al. 2004, Cancer Res), GenoCNA (Sun et al. 2009, Nucleic Acids Res), GAP (Popova et al., 2009, Genome Biol) and OncoSNP (Yau et al. 2010, Genome Biol), where each of these methods bases inferences of CNAs on both the total intensity and the balance of the signals derived from the two alleles for each SNP marker. We have analyzed serous ovarian tumours representing differences in disease from benign and low malignant potential (LMP) tumours to the more aggressive high grade carcinomas, several well characterized ovarian cancer cell lines, as well as matched blood samples from some patients. Spectral Karyotyping (SKY) analysis is available for the cell lines to validate inferences. As expected there appeared to be an increase in CNVs with more aggressive disease, as has been reported by other groups. We find that for highly-rearranged genomes, that OncoSNP and GAP accurately identified changes in ploidy and regions with copy number gains and losses, although the exact copy number appears to be difficult to estimate. However, for genomes from benign or LMP tumours, we found that these two algorithms called far too many alterations than were expected for these tumour types which are known to exhibit either no or modest levels of chromosomal instability. For all algorithms, the inference about loss of heterozygosity appeared unstable. Although algorithms for CNA inference are rapidly evolving, there is still room for further improvement.

INTRODUCTION: MicroRNAs (miRNAs) are an important class of gene regulators, acting on several aspects of cellular function such as differentiation, proliferation, apoptosis, etc. Circulating miRNAs were found to exist in plasma in a highly stable form, and aberrantly expressed in many human diseases. The expression levels of circulating miRNAs are estimated by quantitative real-time polymerase chain reaction (RT-qPCR), however, the accuracy of the results is largely dependent on proper data normalization. Despite increasing miRNA expression studies in leukemia, specifically ALL-B, no previous report identification suitable reference genes for normalization in plasma samples have been reported. In this study we identify the most stable reference microRNAs using a high-throughput approach in ALL-B plasma samples. The candidate references miRNAs were validated using miR-223 as the target miRNA, which has been previously reported as down expressed in ALL. METHODS: Plasma samples from 32 ALL-B patients and 5 healthy controls were analyzed. RNA was isolated and miRNAs profiling was determined in 13 ALL-B patients and 5 controls by qRT-PCR TaqMan Low Density Array and data were analyzed. The most stably expressed miRNAs were obtained with the mean expression value of all miRNAs and identify those that resemble the mean. These candidate miRNAs were validated by qRT-PCR SyberGreen analysis in the plasma of 32 ALL-B patients and 5 controls and the relative expression of miR-223 was determined. RESULTS: We selected 3 miRNAs (miR-101, miR-106a and miR-26b) that were most similar to the mean expression and were the most stable based in the geNorm algorithm. We evaluated these candidate normalizers and obtained low stability values of the individual genes indicating great gene stability. Similarity index of expression across the sample set was 97% and presented significance positive correlation. We obtained a statistic significance difference between all ALL-B samples and controls for the miR-223 expression. CONCLUSION: In previous studies, miRNA expression was estimated by relative quantification using U6, RNU44, 18S and miR-16 as internal controls, however they are not miRNAs, except miR-16, and may not be representative of the miRNA fraction. Our study identified suitable reference genes for qRT-PCR analysis of circulating miRNAs in ALL-B patients. For this study, the best combination of stably expressed genes was miR-101, miR-106a and 26b in ALL-B samples.

1218T

Methylation profile analysis of DNA repair genes in hepatocellular carcinoma with MS-MLPA. *O. Ozer[1], B. Bilezikci[2], S. Aktas[3], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Pathology, Baskent University Faculty of Medicine, Ankara, Turkey; 3) Department of General Surgery, Baskent University Faculty of Medicine, Ankara, Turkey.

Hepatocellular carcinoma (HCC) is one of the rare tumours with well-defined major risk factors. Frequently seen factors include environmental agents like Hepatitis B and C, alcohol, aflatoxins and other etiological agents. The multifactorial etiology of HCC can be explained by its complex molecular pathogenesis. A wide range of genetic changes; including gene expression changes, mutations, and loss of heterozygosity and promoter hypermethylation; has been reported in HCC. Methylation specific - multiplex ligation dependent probe amplification (MS-MLPA) is a newly developed diagnostic tool which enables to detect methylation profiles of multiple genes at the same reaction. In a previous study, reduced expression of DNA repair genes has been reported in HCC samples but the mechanism was not explained. In the current study, methylation status of seven genes involved in DNA repair mechanisms, namely MLH1, PMS2, MSH6, MSH2, MGMT, MSH3 and MLH3, was investigated in formalin fixed paraffin embedded tumour tissue samples from HCC patients, using the MS-MLPA method and the results were correlated with available clinical findings. The most common etiological factor in these cases was the presence of hepatitis B alone (47.2%). Among the 56 cases that were studied, promoter methylation was detected in at least one of the genes in 27 (48.2%) cases, only in one gene in 13 (23.2%) cases and in more than one gene in 14 (25%) cases. Methylation was detected in all of the genes studied only in one (1.8%) patient. Of the seven genes investigated, methylation was the most frequently observed in MSH3, in 14 (25%) cases. Methylation of at least one gene was significantly more frequent in patients with single tumours than multifocal tumours. There were significant differences regarding hepatitis B status, Child class, tumour number, grade and TNM stage in cases where PMS2 methylation was detected. To our knowledge, this is the first study investigating the methylation profile of seven DNA repair genes in HCC samples. Our results suggest that methylation of genes involved in mismatch repair may be responsible in the pathogenesis of HCC. Evaluating changes in multiple genes in these pathways simultaneously would be more informative. Despite being a robust and relatively inexpensive method, the MS-MLPA assay could be more extensively applied with improvements in the currently intricate data analysis component.

No evidence that *FAN1 R377W* or *R507H*, identified via exome sequencing in multiple-case, early-onset breast cancer families, influence breast cancer risk. *D.J. Park[1], F. Odefrey[1], F. Hammet[1], G.G. Giles[2], L. Baglietto[2], J.L. Hopper[3], D.F. Schmidt[3], E. Makalic[3], O.M. Sinilnikova[4], D.E. Goldgar[5], M.C. Southey[1], ABCFS, MCCS.* 1) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Melbourne, Victoria, Australia; 2) Cancer Epidemiology Centre, The Cancer Council Victoria, Melbourne, Victoria, Australia; 3) Centre for Molecular Environmental Genetic and Analytical Epidemiology, School of Population Health, The University of Melbourne, Carlton, Victoria, Australia; 4) Unité Mixte de Génétique Constitutionnelle des Cancers Fréquents, Hospices Civils de Lyon/Centre Léon Bérard, Université de Lyon, Lyon, France; 5) Department of Dermatology, University of Utah School of Medicine, Salt Lake City, Utah, USA.

Massively parallel sequencing is increasingly being applied to the study of complex human disease. Our primary interest is to characterise previously undescribed contributions to the heritable component of human cancers. To this end, we applied whole-exome capture followed by massively parallel sequence analysis to the germline DNA of greater than third-degree affected relatives from multiple-case, early-onset breast cancer families. Prior testing for variants in known breast cancer susceptibility genes in these families failed to identify causal mutations. After analysing four of these pedigrees, we identified two different variants in the DNA damage repair gene *FAN1* (*R377W*, chr15:31197995 C>T and *R507H*, chr15:31202961 G>A [hg19]) which were not present in dbSNP131. *FAN1 R377W*, predicted to be damaging by SIFT and PolyPhen2, was present in all six tested members of the first family with cancer (five with breast cancer, one with malignant melanoma). *FAN1 R507H*, predicted to be damaging by SIFT but benign by PolyPhen2, was observed in one of two tested members of the second family with breast cancer. We genotyped *FAN1 R377W* and *R507H* sites across 1417 population-based cases and 1490 unaffected population-based controls (frequency-matched for age). These variants were rare in the Australian population (minor allele frequencies of 0.0064 and 0.010, respectively) and were not associated with breast cancer risk (OR=0.80, 95% CI[0.39-1.61], p=0.50 and OR=0.74, 95% CI[0.41-1.29], p=0.26, respectively). Analysis of breast cancer risks for relatives of case and control carriers did not find evidence of an increased risk. Despite the biological role of *FAN1*, the plausibility of its role as a breast cancer predisposition gene, and the possible deleterious nature of the identified variants, these two variants do not appear to be causal for breast cancer. More extensive genetic analysis of *FAN1* in future studies will further explore its possible role as a breast cancer susceptibility gene.

Analysis of *IKZF1* splicing variants, and expression of *CASP8AP2* and *H2AFZ* in childhood acute lymphoblastic leukemia. *P. Perez-Vera[1], R. Juarez-Velazquez[1], A. Reyes-Leon[1], C. Salas[1], A. Medrano[1], R. Paredes[2], R. Cardenas[2], G. Lopez-Hernandez[3], P. Navarrete[1], A. Lopez[4], A. Carnevale[5], R. Ortiz[6].* 1) Human Genetics Dept, Instituto Nacional de Pediatria, Mexico, D.F; 2) Hemato-Oncology Dept, Instituto Nacional de Pediatría, Mexico, D.F; 3) Hematology Dept, Hospital del Niño Poblano, Puebla; 4) Gastroenterology Dept, INCMNSZ, Mexico, D.F; 5) INMEGEN, Mexico, D.F; 6) Universidad Autonoma Metropolitana-Iztapalapa, Mexico, D.F.

Treatment improvement in childhood acute lymphoblastic leukemia (ALL) depends on the assessment and identification of molecular markers associated with response to therapy. Gene expression analyses of lymphoblast at diagnosis have identified several genes with potential prognostic significance. The dominant-negative isoforms of *IKZF1* and low *CASP8AP2* and *H2AFZ* expression levels are considered independent predictors of adverse outcome. The aim of this study was detecting *IKZF1* splicing variants and determining the *CASP8AP2* and *H2AFZ* expression levels, in order to know their association with conventional prognostic factors or if may influence the early response to treatment. This was a prospective study performed in a group of ALL children. Bone marrow samples were collected from 66 ALL pediatric patients at diagnosis, attended at the Instituto Nacional de Pediatría and Hospital del Niño Poblano in Mexico, between 2008 and 2010. Total RNA was extracted from mononuclear cells; nested RT-PCR was performed for analyzing *IKZF1*'s isoforms expression. Quantitative-PCR method was used for evaluating expression levels of *CASP8AP2*, *H2AFZ* and the endogenous control *ABL1*. Fifty-four patients were diagnosed with B-ALL, 18 patients showed adverse conventional prognostic factors (age <1 or >10 years old, WBC count higher than $50x10^9$/L, presence of *BCR-ABL1* fusion). Sixteen of them presented dominant-negative variants of *IKZF1* or low expression of *CASP8AP2* or/and *H2AFZ*, one of these patients died. In 36 patients conventional adverse factors were not found, however, up to date 4 have died and all of them presented adverse expression-levels or non-functional isoforms. Twelve patients showed T-ALL, in 10 cases low expression levels of *CASP8AP2* were detected; in addition all patients showed low levels of *H2AFZ*. To date, 7 out of 10 patients with low levels of both genes relapsed and died. In the studied patients, dominant-negative variants Ika6 and Ika8 were identified, as well as low expression levels of *CASP8AP2* and *H2AFZ*. Although the results suggest that these markers could be potential prognostic factors, in B-ALL long-term survival analysis is required to demonstrate it. In contrast, in T-ALL low expression of *CASP8AP2* and *H2AFZ* showed association with relapse and patient's death. Measurement of these markers at diagnosis could be able to detect patients prone to therapy failure. Acknowledgment: CONACYT SALUD-2006-C01-44402 and scholarship 165427 to RJ-V.

microRNA regulation of cell viability and drug sensitivity in lung cancer. *A. Pertsemlidis[1,4], L. Du[1], C. DeSevo[2], R. Borkowski[2], M. Baker[2], A. Gazdar[1,3,4,6], J. Minna[1,4,5,6].* 1) Simmons Comprehensive Cancer Center, UT Southwestern Medical Center, Dallas, TX; 2) Graduate School of Biomedical Sciences, UT Southwestern Medical Center, Dallas, TX; 3) Department of Pathology, UT Southwestern Medical Center, Dallas, TX; 4) Department of Internal Medicine, UT Southwestern Medical Center, Dallas, TX; 5) Department of Pharmacology, UT Southwestern Medical Center, Dallas, TX; 6) Hamon Center for Therapeutic Oncology Research, UT Southwestern Medical Center, Dallas, TX.

Lung cancer is the leading cause of cancer-related deaths, with the majority of deaths due to failed therapy from tumor drug resistance. Third-generation chemotherapeutic agents represent the standard first-line treatment for advanced small cell (SCLC) and non-small cell (NSCLC) lung cancer patients. Response rates are poor (20-40%) with a median survival of 8-10 months. In an unbiased and comprehensive approach, we have combined a high-throughput screening platform with a library of chemically synthesized microRNA mimics and inhibitors. We have used this platform to identify mimics and inhibitors that reduce cell viability in general, and those that specifically sensitize cells to paclitaxel. We have identified several miRNAs for which over-expression or inhibition has a dramatic and selective effect on cell viability or drug response. Using in vitro approaches, we have demonstrated that over-expression of miR-337-3p sensitizes NSCLC cells to taxanes. By combining in vitro and in silico approaches, we identified STAT3 and RAP1A as direct targets that mediate the effect of miR-337-3p by enhancing taxane-induced arrest in the G2 phase of the cell cycle. We have also identified an inhibitor of miR-139-5p as a potent and selective regulator of SCLC cell viability. Inhibiting miR-139-5p decreases SCLC cell viability by over 80%, but has a minimal cytotoxic effect on that of NSCLCs or immortalized human bronchial epithelial cells. Increasing levels of miR-337-3p and inhibiting miR-139-5p may therefore provide novel therapeutic tools for the treatment of NSCLC and SCLC lung tumors, respectively.

1222T

Lung adenocarcinoma and squamous cell carcinoma develop through distinct genomic and epigenomic pathways. *L. Pikor[1], W.W. Lockwood[1,2], I.M. Wilson[1], B.P. Coe[1,3], R. Chari[1,4], K.L. Thu[1], C.E. MacAulay[1], S. Lam[1], W.L. Lam[1].* 1) Integrative Oncology, BC Cancer Research Center, Vancouver, British Columbia, Canada; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 3) Department of Genome Sciences, University of Washington School of Medicine, Seattle, WA, USA; 4) Department of Genetics, Harvard Medical School, Boston, MA, USA.

Non-small cell lung cancer (NSCLC) has traditionally been regarded as a single disease in terms of systemic therapy; however, recent evidence suggests that adenocarcinoma (AC) and squamous cell carcinoma(SCC), the two major subtypes of NSCLC, respond differently to both molecular targeted and newly developed chemotherapies. Identifying the molecular differences between these tumor types will therefore have a significant impact on novel treatment design and stratification, with the potential to improve the dismal outcome associated with lung cancer. An integrative analysis of genome-wide DNA copy number, methylation and gene expression profiles was performed on 261 primary NSCLC tumors (169 AC and 92 SCC) to identify subtype-specific molecular alterations. Ingenuity Pathway Analysis was used to define the canonical pathways and gene networks driving subtype development. Principle Component Analysis in multiple independent datasets was performed to assess the contribution of genes to disease phenotype and survival analysis was employed to identify genes associated with NSCLC prognosis that could better determine patient outcome. Characterization of AC and SCC genomic and epigenomic landscapes revealed 778 altered genes, with corresponding gene expression changes that are selected for during lung tumor development in a subtype-specific manner. Analysis of over 200 additional NSCLCs confirmed that these genes are responsible for driving the differential development and resulting phenotypes of AC and SCC. Importantly, we identified key oncogenic pathways disrupted in each subtype that likely serve as the basis for differential behaviors in tumor biology and clinical outcomes. Downregulation of HNF4(target genes was the most common pathway specific to AC, while SCC demonstrated disruption of numerous histone modifying enzymes as well as the transcription factor E2F1. In silico screening of candidate therapeutic compounds based on subtype-specific pathway alterations identified HDAC and PI3K inhibitors as potential treatments tailored to lung SCC. Our findings suggest that AC and SCC are distinct disease entities that develop through divergent molecular pathways, and should therefore be treated as such. Furthermore, the gene networks and signaling pathways identified through our analysis provide a rationale for elucidating the mechanisms underlying subtype development and differentiation, and developing subtype specific therapeutic strategies.

Genetic testing and immunohistochemistry for SDHB in phaeochromocytoma-paraganglioma syndromes: The South Australian experience. *N. Poplawski[1,2,3], A. Duszynski[2], L. Rawlings[4], J. Seymour[4], D. Benn[5], A. Gill[6,7].* 1) Familial Cancer Unit, Women's and Children's Hospital, North Adelaide, South Australia, Australia; 2) Familial Cancer Unit, Genetics and Molecular Pathology Directorate, SA Pathology (WCH site), North Adelaide, South Australia, Australia; 3) University of Adelaide, Adelaide, South Australia, Australia; 4) Genetics and Molecular Pathology Directorate, IMVS (Frome Road Site), Adelaide, South Australia, Australia; 5) Cancer Genetics, Kolling Institute of Medical Research, Royal North Shore Hospital, St Leonards, New South Wales, Australia; 6) Department of Anatomical Pathology, Royal North Shore Hospital, St Leonards, New South Wales, Australia; 7) University of Sydney, Sydney, New South Wales, Australia.

INTRODUCTION: Most phaeochromocytomas and paraganglioma occur sporadically, but some occur as part of a hereditary cancer syndrome caused by mutations in one of a number of genes.

AIM AND METHODS: A retrospective review of germline genetic testing (VHL, RET and succinate dehydrogenase subunit genes SDHB, SDHC and SDHD) and immunohistochemical staining for SDHB in tumour tissue (SDHB-IHC), in patients referred to the South Australian Familial Cancer Unit with an adrenal phaeochromocytoma (PC) and/or paraganglioma (PGL).

RESULTS: Between January 1999 and May 2011, 21 probands were referred to and fully assessed by our service. Three patients presented with phaeochromocytoma and other personal and family features of multiple endocrine neoplasia type 2; all had RET mutations identified. The only patient with familial PC had a VHL mutation identified. Of the 8 with an apparently sporadic unilateral PC, only 1 had a mutation identified; a 30 year old man with an SDHB mutation who developed a head-and-neck PGL 14 years after the PC. SDH mutations were identified in 2 of 4 who presented with an apparently sporadic head-and-neck PGL (1 SDHD and 1 SDHC), 2 of 3 who presented with an apparently sporadic malignant abdominal PGL (both SDHB) and none of 2 who presented with familial head-and-neck PGL.

Tumour tissue was available from 16 probands and SDHB-IHC was abnormal in all probands with an SDH mutation (5/5; 100%), 0/1 with a VHL mutation and 2/10 (20%) with no identified mutation (both presented with familial head-and-neck PGL). Tissue was unavailable for testing in the remaining 4 patients.

CONCLUSION: Our experience supports using SDHB-IHC as a tool to triage genetic testing (see references).

Integrated epigenetics of human breast cancer subtypes: synoptic investigation of targeted genes, microRNAs and proteins upon demethylation treatment. *R. Radpour[1], Z. Barekati[1], C. Kohler[1], M.M. Schumacher[2], T. Grussenmeyer[3], P. Jenoe[4], J. Bitzer[5], I. Lefkovits[3], F. Staedtler[2], X.Y. Zhong[1].* 1) Laboratory for Gynecological Oncology, Women's Hospital/ Department of Biomedicine, University of Basel, Switzerland; 2) Biomarker Development, Novartis Institutes of BioMedical Research, Novartis Pharma AG, Basel, Switzerland; 3) Department of Biomedicine and Department of cardiac surgery, University hospital Basel, Switzerland; 4) Biozentrum, University of Basel, Switzerland; 5) Department of Obstetrics and Gynecology, Women's Hospital, University of Basel, Switzerland.

The contribution of aberrant DNA methylation in silencing of tumor suppressor genes (TSGs) and microRNAs has been investigated. Since these epigenetic alterations are reversible, it became of interest to determine the early and late effects of the 5-aza-2'-deoxycytidine (DAC) demethylation therapy in breast cancer within different molecular levels. Here we investigate a synoptic model to predict complete DAC treatment effects at the level of epigenome, transcriptome, and proteome for several human breast cancer subtypes. The present study assessed an effective treatment dosage based on the cell viability, cytotoxicity, apoptosis and methylation quantification assays for different breast cancer cell lines. Using the optimal treatment dosage, a highly aggressive and a non-aggressive lines were investigated at various time points using omics approaches such as MALDI-TOF MS, mRNA- and microRNA expression arrays, 2-D gel electrophoresis and LC-MS-MS. Complete molecular profiles of the studied subtypes including the biological interactions and possible early and late systematic stable or transient effects of the methylation inhibition were determined in depth. Beside the activation of several epigenetically suppressed TSGs, we also showed significant dysregulation of some important oncogenes, oncomirs, oncosuppressors miRNAs as well as drug tolerance genes/miRNAs/proteins in breast cancer related pathways. In present study, the results give new therapeutic clues based on chemical modification of the pathological methylation patterns in breast cancer as well as investigation of some new molecular DAC targets and involved pathways. The presented approach might become a useful epigenetic treatment model for other human solid tumors in management of cancer patients.

1225T

polymorphism of TYMS in Mexican breast cancer patients. *A. Ramos[1,2], A. Solorzano[1], LE. Figuera[1], AM. Puebla[3], MP. Gallegos[1].* 1) IMSS, CIBO, Guadalajara, Jalisco, Mexico; 2) Doctorado en Farmacologia, UdeG; 3) Laboratorio de Inmunofarmacologia, CUCEI. UdeG.

Thymidylate synthase (TYMS) catalyzes the reductive methylation of dUMP to form dTMP, which are essential for cell proliferation. Has been show that patients high levels of TYMS are no respond to 5-fluorouracil. The polymorphisms 2R/3R in 5'untranslated region (5'UTR) of TYMS gene contains repeated of a 28 bp sequence. The alleles with two repeat (2R), have low translational efficiency of TYMS mRNA than three (3R) repeats with greater translational efficiency. In the present study we describe to frequency of 2R/3R polymorphism of TYMS gene breast cancer patients and woman health controls from Mexico. In a case-control study of 110 breast cancer patients and 251 controls we observed a frequency of 34.5% (38/110) and 27.8% (70/251) of 3R/3R genotype; 13.5% (152/110) and 16% (40/251) of 2R/2R genotype, and heterozygous genotypes were: 1%(1/110) and 0.8% (2/251) of 1R/2R, 2% (2/151), and 0.8% (2/252) 2R/4R genotype, 1% (1/151) and 1.2% (3/251) of 3R/4R genotype and 48% (53/151) and 53% (134/252) of 2R/3R genotype in cases and controls respectively, without to be statistically different ($p>0.05$). These results suggest that the 2R/3R polymorphism on the TYMS promoter is not associated with Mexican breast cancer patients.

1226T

Rhesus macaque as an animal model for hereditary non-polyposis colorectal cancer. *M. Raveendran[1], P. Gillespie Jr[3], D.W. Brammer[4], D.P. Young[3], J.G. Gelovani[3], J. Rogers[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Experimental Diagnostic Imaging, The University of Texas MD Anderson Cancer Center, Houston, TX; 4) University of Houston, Houston, TX.

Rhesus (Macaca mulatta) have been used as an animal model to study several human diseases, e.g., coronary heart disease, osteoporosis, diabetes mellitus. There are only few reports that show the incidence of colon cancer in rhesus, and detailed genetic studies are lacking. Colon cancer is the third most common form of cancer diagnosed in the United States and second leading cause of cancer death. Diagnosing colon cancer at early stage can reduce the incidence of advanced stage tumors and therefore reduce the mortality. Defects in the MLH1 gene account for the majority of cases of hereditary non-polyposis colorectal cancer (HNPCC-Lynch syndrome). In this study we sequenced the full length of the rhesus MLH1 gene, exons 1 to 19, promoters, introns and UTRs in 18 rhesus samples using Sanger sequencing methods. We used PET-CT images and colonoscopy to confirm the colon cancer in our study animals. We identified 124 SNPs and three of them are in coding regions. Two of these coding SNPs are non-synonymous. A total of 47 SNPs were found to be shared in monkeys with known colon cancer (n = 4) and were absent in normal animal (n = 1) and animals of unknown disease status (n=13). We also identified a two base pair deletion in the promoter region of colon cancer monkeys. These SNPs and the deletion will be useful as screening markers prior to the development of “detectable” tumors in rhesus, which in turn can be used as an animal model to study the onset and progression of colon cancer in a suitable animal model.

1227T

Identification of a BRCA2 truncating mutation in a hereditary prostate cancer case with a family history of breast and ovarian cancer through next-generation sequencing. *A.M. Ray[1], K.A. Zuhlke[1], C.M. Robbins[5], W.D Tembe[5], J. Xu[6], S.L. Zheng[6], J.D. Carpten[5], E.M Lange[3], W.B. Isaacs[4], K.A. Cooney[1,2].* 1) Department of Internal Med, Hem/Onc, University of Michigan Medical School, Ann Arbor, MI; 2) Department of Urology, University of Michigan Medical School, Ann Arbor, MI; 3) Department of Genetics, University of North Carolina School of Medicine, Chapel Hill, NC; 4) Department of Urology, The Johns Hopkins University School of Medicine, Baltimore, MD; 5) Translational Genomics Research Institute, Phoenix, AZ; 6) Center for Cancer Genomics and Center for Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC.

Prostate cancer (PCa) is the most commonly diagnosed cancer and the second leading cause of cancer deaths among American men. Family history is a known PCa risk factor, with ~10% of all PCa cases assumed to be hereditary. The hereditary breast cancer (BrCa) gene BRCA2 has previously been associated with an increased risk of PCa, especially early-onset PCa. Here we used targeted next-generation sequencing to examine multiple candidate PCa susceptibility genes in probands from 94 hereditary PCa families from the University of Michigan and Johns Hopkins University. A BRCA2 truncating mutation, K3326X, was identified in 1 individual with a family history of breast and ovarian in addition to prostate cancer. Analysis of the family revealed the mutation was also carried by 2 brothers and 1 maternal cousin of the proband with PCa as well as 2 maternal cousins with BrCa and 1 with bladder cancer. Additionally, 1 brother and 1 maternal cousin with PCa, 1 niece with melanoma and 1 unaffected maternal cousin were not carriers. Further screening of 917 Caucasian, early-onset PCa cases and 909 Caucasian, screened controls revealed an additional 18 affected and 17 unaffected carriers. K3326X has been previously associated with increased risk of both lung (OR=1.72) and pancreatic cancer (OR= 4.84) as well as Fanconi Anemia. However, to our knowledge, this is the first report of K3326X in a hereditary PCa family. Further investigation is needed to determine the exact role of K3326X in prostate and other cancers.

High Prevalence of Germline p53 Mutations Among a Consecutive Series of Unselected Patients with Adrenal Cortical Carcinoma. *VM. Raymond[1], JN. Everett[1], JL. Long[1], T. Else[2], GD. Hammer[2], SB. Gruber[1,3,4].* 1) Department of Internal Medicine, University of Michigan, Ann Arbor, MI; 2) Department of Metabolism, Endocrinology and Diabetes, University of Michigan, Ann Arbor, MI; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Epidemiology, University of Michigan, Ann Arbor, MI.

Introduction: Adrenocortical carcinoma (ACC) is a rare, aggressive tumor which when diagnosed in children prompts an evaluation for Li Fraumeni Syndrome (LFS) due to germline p53 mutations. The Chompret criteria advocate for p53 genetic testing in individuals with ACC regardless of age at diagnosis or family history. The University of Michigan Multidisciplinary Adrenal Cancer Clinic (UMMACC) is a Center for Excellence in ACC diagnosis, treatment and management, a referral center for ACC patients internationally and evaluates greater than 25% of all ACC patients in the United States. To date, no prospective studies quantifying the prevalence of LFS in unselected cases of ACC have been performed. Methods: Patients were recruited through the UMMACC between December 2009-April 2011. All patients with a personal history of ACC were eligible and offered a genetic consultation, p53 genetic testing and participation in an IRB approved Cancer Genetics Registry. Genetic testing was performed at a CLIA certified clinical laboratory via sequencing and gene dosage analysis or MLPA for large deletions, duplications and rearrangements. Results: Ninety-one patients were evaluated in the UMMACC during the study timeframe. Seventy patients underwent genetic consultation (76.9%) and 36 of 70 (51.4%) pursued p53 genetic testing. Primary reason for not pursuing testing was insurance coverage concerns due to out-of-network location of UMMACC (27 of 34). Seven patients declined genetic testing (10%). Three individuals were positive for deleterious missense mutations: p.V272M, diagnosed at 68; p.R181H diagnosed at 52; p.R158H diagnosed at 3. One individual, diagnosed at 47, was positive for a novel variant of uncertain significance (c.G>T 207bp upstream from exon 1)(4 of 36, 11.1%). No positive patients met Classic Li-Fraumeni or Li-Fraumeni-like criteria. The average age at diagnosis in the cohort testing negative for p53 mutations was 44.2. No patients met Classic LFS diagnostic criteria. Three patients met Birch criteria and 2 patients met Eeles criteria. Conclusions: This prospective series of unselected patients with ACC demonstrates that LFS is under recognized within this population. Germline p53 testing in all patients with ACC yields an 11.1% diagnostic yield for LFS. The majority of patients were interested in a genetic consultation (76.9%) and genetic testing (90%). All patients with ACC, regardless of family history should be offered p53 genetic testing.

DNA repair pathways and lymphoma susceptibility. *J. Rendleman[1], Y. Antitpin[2], B. Reva[2], J. Przybylo[2], A. Dutra-Clarke[2], A. Heguy[2], K. Huberman[2], O. Paltiel[3], D. Ben-Yehuda[3], J. Brown[4], C. Sander[2], R.J. Klein[2], K. Offit[2], T. Kirchhoff[2].* 1) NYU School of Medicine, New York University, New York, NY, USA; 2) Memorial Sloan-Kettering Cancer Center, New York, NY, USA; 3) Hadassah University, Jerusalem, Israel; 4) Dana Farber Cancer Center, Harvard University, Boston, MA, USA.

The inherited factors contributing to the development of lymphoma remain largely unknown. The molecular and genetic evidence points to DNA repair as a candidate molecular network involved in lymphomagenesis. Several studies have attempted to relate DNA repair pathways with lymphoma risk, but the power or smaller scope of selected candidates were usually the major limitations of these prior efforts. In this study we have conducted a case/control association analysis of lymphoma risk based on the large systematic screen of common genetic variation in the complex DNA repair networks. We have applied bioinformatics approaches for a more unbiased selection of candidate genes. Using these strategies, we have selected >450 genes involved in more than 25 DNA repair processes. For the genetic variants, we have focused on tagging single nucleotide polymorphisms (tSNPs), capturing the common variation (MAF>0.05) of 450 selected genes in European population, used primarily in the study. In order to reduce the number of variants in the association screen, all the tSNPs were uncorrelated with r2<0.6, yielding the selection of ~ 1500 SNPs tagging the common variation in these 450 genes. The 1500 SNPs were genotyped in 2 phases in 2500 lymphoma cases and 2500 controls, both of European ancestry using the Sequenom iPLEX methodology. Here we report the results of phase 1 of the study, involving 531 SNPs in 87 DNA repair target genes genotyped in 2500 Lymphoma cases and 2500 controls, both of European ancestry. In phase 1, we have identified several loci associated with the lymphoma risk in pooled or lymphoma subtype-specific analyses. The preliminary results of NHL scan points to a locus on chromosome 11 with 3 independent SNPs showing the significant associations (OR=1.522, 1.451, .7342; p=1.61E-5, 7.9E-5, .0014). NHL associations were also seen on chromosome 15 (OR=1.821, p=.00032), chromosome 8 (OR=.5001, p= .0016), and chromosome 10 (OR=.7045, p=.0023). Significant associations were also confirmed for common and rare haplotypes surrounding these loci, using the imputed data from HapMap Phase 2 and 1000 genomes. While finalizing the second phase of this large scan, we also address the epistatic effects of SNPs and haplotypes in the different components of DNA repair machinery targeted in the study. The further validation of associations identified here will be necessary in larger and independent subsets, possibly as part of International consortia.

High quality genotyping data from FFPE tumor samples. *B. Riley-Gillis[1], R. Benayed[1], A. Helm[2], K. Gunderson[2], J. Izzo[2], D. Pokholok[2], J. Le[2], C. Fishman[2], J. Garsetti[2], M. Martin[1].* 1) Translational Research Sciences, Roche, Nutley, NJ; 2) Illumina, San Diego, CA.

Formalin-fixed, paraffin-embedded (FFPE) tumor samples are an invaluable resource for cancer research, drug development, and diagnosis. However, utilizing these samples is complicated by the nucleic acid degradation and base modification that occurs during the fixation and storage processes. In this study, we use the Illumina platform to assess the feasibility of genotyping tumor FFPE DNA for targeted and whole genome association studies. Matched fresh frozen (FF) and FFPE ovarian cancer samples were compared on two platforms: custom GoldenGate genotyping and Infinium OmniExpress with FFPE DNA restoration.

The GoldenGate genotyping technology does not involve an initial whole genome amplification step, therefore is not as susceptible to the effects of degraded DNA. At the recommended input DNA concentration of 250ng, concordance between FF and FFPE samples was greater than 99.7%. Over a range of DNA input concentrations, we found concordant genotyping results for FFPE samples down to 50ng of input DNA (concordance with FF >97%).

Illumina's Infinium FFPE DNA Restoration protocol repairs damaged DNA prior to whole genome amplification. The five matched FF and FFPE samples were restored and genotyped on the OmniExpress array, which includes >693,000 genomic markers and coverage of 97% of the cancer genes identified by the Sanger Cancer Genome Project. The restored FFPE samples had call rates between 92% and 97% and concordance between FF and restored FFPE samples was greater than 99.8% for all five samples.

The results indicate that DNA from FFPE tumor samples can be successfully genotyped and yield high quality genotyping data on both custom and genome-wide genotyping platforms. The next step for this project includes testing the FFPE restoration protocol on a custom Infinium iSelect panel containing ~3000 somatic mutations, CNVs and fusion genes. The ability to capture the significant information available in FFPE samples will be critical to deepen the disease understanding through identification of variants in drug targets and pathways driving tumorigenesis and progression. Additionally, baseline assessment of tumors from patients in clinical trials using custom genotyping platforms is necessary to define tumor mutations, stratify patient populations and evaluate or predict therapy response.

1231T

BRCA1 and _BRCA2_ large genomic rearrangement testing in a large cohort of hereditary breast/ovarian cancer patients: prevalence and mutation profiles in risk-stratified patient groups of different ethnicities. *B. Roa, E. Rosenthal, C. Arnell, L.A. Burbidge, W. Geary, J. Schoenberger, J. Trost, R. Wenstrup, T. Judkins.* Myriad Genetic Laboratories, Inc., Salt Lake City, UT, USA.

Large rearrangements in *BRCA1* and *BRCA2* make up a significant proportion of mutations in hereditary breast and ovarian cancer (HBOC). Since August 2006 our laboratory has offered clinical testing for deletions and duplications in *BRCA1* and *BRCA2* using the BRAC*Analysis* Rearrangement Test (BART). Nearly 64,000 patients have received BART testing, revealing a broad spectrum of large rearrangements in both *BRCA1* and *BRCA2*. To characterize the mutation profile of *BRCA1/2* within this referral testing cohort, results from a defined subset of patients were stratified by mutation type (sequencing vs. large rearrangements), prior risk, and patient ethnicity. Among patients tested between July 2007 and April 2011, a subset of 25,535 received BART testing automatically because they met high-risk criteria; 22,925 did not meet high-risk criteria but ordered elective BART at the same time as *BRCA1/2* sequencing. The overall *BRCA1/2* mutation prevalence among high-risk patients was 23.8% compared to 8.2% for the elective group. High-risk patients showed a mutation profile of 90.1% sequencing mutations vs. 9.9% large rearrangements. The corresponding mutation profile in the elective group was 94.1% vs. 5.9%, with significantly fewer large rearrangements in this group versus the high-risk group ($p << 0.001$). Possible explanations for this difference may include bias introduced by the high proportion of large rearrangements found in *BRCA1*, which is more penetrant than *BRCA2*. Results were correlated to eight self-reported ethnic groups to characterize the mutation spectrum. This analysis included only patients who self-reported one ethnicity. In the Western/Northern European group, 9.7% of mutations in high-risk patients were large rearrangements vs. 5.9% in the elective group. Among Latin American/Caribbean patients, large rearrangements accounted for 20.6% of mutations in the high-risk group and 12.8% in the elective group, indicating more large rearrangements in this ethnic group overall ($p << 0.001$, $p = 0.02$). Those reporting African ancestry showed the highest positive rate for sequencing mutations but large rearrangements contributed only 8.3% and 1% of all mutations in the high-risk and elective groups, respectively. Large rearrangements are a significant contributor to the overall spectrum of mutations, and show ethnic-specific variation in their contribution to the *BRCA1* and *BRCA2* mutation profile.

1232T

Elucidation of the role of miR-302 in the induction of TGF-beta signaling pathway in tumor cells. *S. Rohban[1], M.R Rafiee[2], A. Malekzadeh Shafaroudi[2], M. Malakootian[1], N. Ghorbanmehr[1], S.J. Mowla[1].* 1) Department of Molecular Genetics, Faculty of Biological Sciences, Tarbiat Modares University, Tehran, Iran; 2) Nanomedicine and Tissue Engineering Center, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

According to the “stem cell origin of cancer” hypothesis, tumors include a small subpopulation of cancer cells which is characterized by stemness properties and is responsible for sustained tumor growth, metastasis and resistance to therapy. Recently, studies have identified the expression of a subset of embryonic stem cell (ESC)-like gene expression signature in invasive, poorly differentiated tumor cells. However, the underlying molecular mechanisms by which these genes contribute to stem cell-like phenotypes shown by many tumors, are not yet fully understood. Here we report the expression of miR-302 family of microRNAs, which are expressed at high levels in ESCs, in the malignant brain tumor tissues and cell lines, combined with transcriptional activity of its cloned promoter in a small subpopulation of tumor cells. Interestingly, by overexpression of miR-302 in these tumor cells, the expression of components of TGF-) signaling pathways, such as TGF) -1, TGF) -2 and TGF) receptor 2, together with several pluripotency markers, was overexpressed in the cells. Moreover, the expression level of miR-141 which can act as translational repressor of TGF-) signaling, was decreased in the transfected cells. Taken together, our data suggest that miR-302 may play a role in cancer stem-like cell behavior, such as self-renewal and maintenance of an undifferentiated state of tumor cells. In addition the effect of miR-302 overexpression on inducing TGF-) pathway, may reflect its probable role in epithelial-to-mesenchymal transition in migrating cancer stem cells. These observations provide important concepts to develop new strategies to target cancer stem cell subpopulation in tumors.

1233T

Large deletions of the APC-gene region in familial adenomatous polyposis patients and the effect on the expression from promoter 1A and 1B. *A. Rohlin[1], Y. Engwall[1], K. Fritzell[2], J. Björk[2], M. Nordling[1].* 1) Department of Molecular and Clinical Genetics, Institute of Biomedicine, Sahlgrenska Academy at University of Gothenburg, Gothenburg, Sweden; 2) The Swedish Polyposis Registry, Department of Medicine, Karolinska Institute, Stockholm, Sweden.

Familial adenomatous polyposis (FAP) is caused by dominant inheritance of germline mutations in the adenomatous polyposis coli (APC) tumour suppressor gene. In classical FAP, mutation carriers develop hundreds to thousands of adenomas in the large bowel and untreated carriers inevitably develop colorectal cancer (CRC) at an early age. A milder form of FAP also exists referred to as attenuated polyposis (AFAP). The APC gene (5q21-q22) encodes several tissue specific transcripts and two promoter regions have been identified 1A and 1B. In this study 54 families with FAP or AFAP were screened for mutations in APC. A deleterious mutation was found in 97% of families with FAP and 26% of families with AFAP. The screening method used to detect mutations in the exons of APC was sequencing. Multiplex Ligation-dependent Probe Amplification (MLPA) was used for detection of larger deletions and duplications. Seven families, among these the largest FAP family in Sweden including 150 individuals of whom 59 are affected, harboring deletions including part or the whole of the APC gene region and/or the promoter region were further investigated. The methods used to characterize the deletions were copy number- and expression analyses using the Affymetrix® Genome-Wide Human SNP Array 6.0 and GeneChip® Human Exon 1.0. Q-PCR (Taqman) was also used for extensive RNA investigations of the APC transcripts using five different probes, one specific for transcripts from promoter 1B, two for promoter 1A and two for the overall expression. Differences in expression from the promoter 1A and 1B were found among the patients given more insight into the regulation of the APC gene in the FAP patients. In families displaying a classical FAP phenotype with no deleterious mutation identified, screening for CNVs in the regulatory regions of APC should follow the initial screening of the coding region as mutations located upstream of promoter 1A could be a possible causative alteration.

An integrated (epi)genomic approach reveals the role of retinoic acid in cell fate determination. *S. Rossetti, N. Visconti, J. Fischer, N. Sacchi.* Dept Cancer Genetics, Roswell Park Cancer Inst, Buffalo, NY.

The coordinated expression of gene networks in numerous physiological, developmental, and metabolic processes can be ascribed in large part to a superfamily of ligand-inducible transcription factors, the nuclear receptors (NRs). Ligand-binding imparts changes in the NR structure and consequently modulates the recruitment of coactivator/corepressor complexes that are necessary for modifying the chromatin environment at multiple NR direct gene targets. Retinoic acid (RA) a master ligand of prenatal and postnatal developmental processes acts through retinoic acid receptors (RARs). RA can induce or suppress growth in cells with different histotype. Intriguingly, we found that RA can exert a dual action on cell growth within the same cell context. To identify the mechanism at the basis of this dual action, we used an integrated (epi)genomic approach. Unexpectedly, from this analysis it emerged that gene networks and pathways are differentially regulated by RA paradoxically through the very same RA receptor. This work was funded by R01 CA127614 (NS).

Evaluation of polymorphisms *GSTP1* A313G and *GSTP1* C341T in patients with head and neck squamous cell carcinoma. *A. Russo[1], P.F. Francelin[1], M.A. Palmejani[1], A.L. Galbiatti[1], M.T. Ruiz[1], T.P. Gueroni[1], J.V. Maniglia[2], E.C. Pavarino[1], E.M. Goloni-Bertollo[1].* 1) Genetics and Molecular Biology Research Unit - UPGEM, Faculdade de Medicina São José do Rio Preto - FAMERP , São José do Rio Preto, SP, Brazil; 2) Otorhinolaryngology and Head and Neck Surgery Department of the Faculdade de Medicina São José do Rio Preto - FAMERP, São José do Rio Preto, SP, Brazil.

Introduction: Head and neck cancer is responsible for significant morbidity and mortality, represents the sixth leading cause of cancer death worldwide, and is one of the most prevalent tumor in Brazil. Variations of activation and detoxification of chemical compounds in the xenobiotics metabolism are involved in tumorigenesis, even as polymorphisms in genes of the glutathione S-transferase superfamily, which act in phase II of this metabolic pathway. **Aim:** To investigate the frequency of *GSTP1* polymorphisms A313G (rs1695) and C341T *GSTP1* (rs1138272) in patients with head and neck cancer (case group) and compare with subjects with no history of cancer (control group) to evaluate the association between these polymorphisms and the risk factors and the histopathologic characters of the tumor. **Methods:** Were included 783 individuals, 264 patients and 519 controls. Molecular analysis was performed by PCR-RFLP. For statistical analysis we used the chi-square and multiple logistic regression. **Results:** Results showed that age ⁄ 48 years (OR=12.37; IC 95% 7.89-19.38; p<0.0001), smoking (OR=4.21; IC 95% 2.71-6.55; p<0.0001) and alcoholism (OR=1.65; IC 95% 1.07-2.55; p=0.023) were predictors for the development of cancer of the head and neck, while the *GSTP1* A313G polymorphism was more frequent in control individuals (OR=0.61; IC 95% 0.42-0.90; p=0.013). The clinical pathological parameters were not associated with the presence of the polymorphisms studied. **Conclusion:** In conclusion, the presence of *GSTP1* A313G variant is associated with decreased risk for head and neck cancer and age⁄ 48 years, male gender and tobacco and alcohol consumption are associated with increased risk for developing this disease. **Financial Support:** FAPESP, CNPq and CAPES; support: FAMERP/FUNFARME.

Study of P53 gene mutations in promoter and exons 2-11 in gastric cancer by PCR-SSCP in a province of Iran. *j. saffari chaleshtori[1], M. Moradi[2], E. Farrokhi[2], M.A. Tabatabaieefar[2], M. Taherzadeh Ghahfarokhi[1], G. Mobini[2], F. Shayesteh[2], F. Azadegan[2], G. Rahimian[2], H. Nazem[3], M. Hashemzadeh Chaleshtori[2].* 1) Payame Noor Univ. Tehran & Cellular and Molecular Research Center Shahrekord Univ. of Med.Sci. Iran. Shahrekord. Islamic Republic of Iran; 2) Cellular and Molecular Research Center Shahrekord Univ. of Med.Sci. Iran. Shahrekord. Islamic Republic of Iran; 3) Payame Noor Univ. Tehran Islamic Republic of Iran.

Background and aim: Gastric cancer is one of the most important human cancers and is the second cause of cancer death worldwide after lung cancer. Genetic factors including oncogens and tumor suppressor genes always contribute to the progression of this cancer. The P53 tumor suppressor gene has a main role in genomic stability and DNA repair. The aim of this study was to determine the P53 gene mutations in gastric cancer specimens in Chaharmahal Va Bakhtiari Province, in southwest Iran. Methods: in this descriptive lab based study, we screened the promoter and exons of P53 gene for mutations in 38 paraffin embedded gastric cancer specimens. DNA was extracted following the standard phenol chloroform protocol. The P53 gene mutations were determined using PCR-SSCP procedure. Results: Our study revealed no P53 gene mutation in promoter and exons 2-11 in the gastric cancer subjects studied. Conclusion: While P53 gene mutations have been reported as the most frequent genetic alterations and are found in about 50% of the human malignancies, no mutation was detected in this study. This might be due to small sample size or mutations on other genetic or epigenetic factors.

1237T

A genome-wide association study of early onset prostate cancer: Increased genetic burden among young cases. *C.A. Salinas[1], E.M. Lange[2,3,4], K.A. Zuhlke[1], A.M. Ray[1], Y. Wang[2], Y. Luo[3], W.B. Isaacs[5], S.L. Zheng[6,7], K.A. Cooney[1,8,9].* 1) Dept. Internal Medicine, University of Michigan Medical School, Ann Arbor, MI; 2) Dept. Genetics, University of North Carolina, Chapel Hill, NC; 3) Dept. Biostatistics, University of North Carolina, Chapel Hill, NC; 4) Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC; 5) Dept. of Urology, Johns Hopkins Medical Institutions, Baltimore, MD; 6) Center for Cancer Genomics, Wake Forest University School of Medicine, Winston-Salem, NC; 7) Center for Genomics and Personalized Medicine Research, Wake Forest University School of Medicine, Winston-Salem, NC; 8) Dept. Urology, University of Michigan Medical School, Ann Arbor, MI; 9) University of Michigan Comprehensive Cancer Center, Ann Arbor, MI.

At least 30 common loci associated with prostate cancer (PC) have been identified by genome-wide association studies (GWAS). Although early age at diagnosis is a recognized marker of genetic susceptibility in several hereditary cancers almost all GWA studies have been conducted in older populations. Men diagnosed with PC at ≤55 years, i.e., early onset PC, may provide increased power to detect novel loci that influence PC incidence. Data from 931 early onset PC cases and 2,985 controls of European descent were analyzed in a first-stage GWAS of PC (n=458,162 single-nucleotide polymorphisms or SNPs). Cases were diagnosed with PC at a mean age of 49.8 years and the majority had low-grade (81% Gleason score ≤7=3+4), localized (81%) disease. Controls were unrelated individuals from Illumina's iControlDB database. Cases were genotyped with the Illumina HumanHap610-Quad Genotyping BeadChip platform. Logistic regression models, adjusted for principal components to account for ancestry, were used to test the association between PC and individual SNPs, assuming a multiplicative genetic model. Overall, no novel SNPs attained genome-wide significance and only rs6983267 ($p=6.07x10^{-9}$) remained significant after correction for multiple tests. Of 23 previously reported PC-associated SNPs, 18 were nominally significantly associated with PC (p<0.05) in our GWAS, with all 23 having a direction of effect consistent with prior findings. We are currently performing genotype imputation and selection of SNPs for Stage 2 genotyping on an independent sample of early onset cases and controls. Compared to older Cancer Genetic Markers of Susceptibility (CGEMS) study cases (>55 years at diagnosis), cases diagnosed with early onset PC had a significantly greater number of risk alleles across 18 previously reported PC-associated SNPs ($p=3.6x10^{-3}$). In a combined analysis of CGEMs and early onset PC cases, the burden of risk alleles carried by each case was significantly related to age at diagnosis, with an average 25.1 (standard deviation=3.2), 24.1 (4.2), 23.8 (3.8), 23.4 (3.2), 23.2 (3.1) and 22.3 (4.7) risk alleles in cases aged 35-44, 45-54, 55-64, 65-74, 75-84 and 85+ years at diagnosis, respectively ($p_{trend}=2.6x10^{-5}$). SNPs identified in older PC cases had stronger associations in men diagnosed with early onset PC. This demonstrates the potential for identifying PC-associated genetic variants by focusing on men with early onset disease.

Investigation of expression level of MDR1 in Iranian colorectal cancer (CRC) patients. *s. samanian[1], f. mahjoubi[1], b. mahjoubi[2], r. mirzaee[2], r. azizi[2].* 1) National Institute of Genetic Engineering and Biot, tehran, Iran; 2) HAZRAT Rasool Hospital, TehranUniversity of Medical Sciences and Health Care Services.

Purpose: Chemotherapy is one of the most effective treatments for cancer patient but resistance to chemotherapy limits the effectiveness of this useful treatment. Multi drug resistance (MDR) is a phenomenon in which tumor cells become resistant to many structurally and functionally different drugs. Drug resistance can occur at many levels including drug activation, alteration in drug target, DNA repair, apoptosis, drug uptake and increasing drug efflux. ABC transporters super-family is the most important mechanism among all of them. These are trans-membrane proteins that their over expression increase the level of drug afflux by using ATP molecules. Methods used: We investigated the expression level of MDR, one of the ABC transporters' members in 60 Iranian patients diagnosed with colorectal cancer (CRC) employing real time RT-PCR Materials and Methods. Tumor and adjacent normal tissues from 60 Iranian patients with colorectal cancer were assessed for the expression level of MRP1 by Real Time RT-PCR. Result: The project was approved by the local ethical committee of National Institute for Genetic Engineering and Biotechnology (NIGEB) and written informed consent was obtained from all cases. Tissue specimens (tumor and normal tissue adjacent to tumor) were collected from Hazrat Rasool hospital between 2008and September 2010, Histological diagnosis was confirmed for all samples. We found that the expression of MDR1 increased significantly in cancerous regions of these CRC patients compared with their adjacent normal tissues. Furthermore, we demonstrated that the MDR1 expression was dependent on the histological grading. Conclusion: Our results suggest that MDR1likely have an effect on the clinical response to treatment in CRC patients.

Heat Shock Protein Polymorphism and the Risk of Development of Hepatocellular Carcinoma in Chronic Liver Disease Patients from India. *M.P. Sarma, M. Asim, S. Medhi, P. Kar.* Medicine, Maulana Azad Medical College,University of Delhi, New Delhi, Delhi, India.

INTRODUCTION Genetic variation has been suspected to influence the variable risk of hepatocellular carcinoma (HCC) in which numerous familial HCC clusters has been reported. Functionally significant polymorphisms have been noted in the HSP70-Hom and HSP70-2 genes. HSP70 have been shown to mediate tumorigenesis through inhibition of apoptosis and replicative senescence. AIMS & METHODS The aim of this study was to investigate the potential role of HSP70-Hom and HSP70-2 polymorphisms and the subsequent risk of HCC in chronic liver disease (CLD) patients. Patients diagnosed as HCC with HBV and/or HCV as the main etiology were included in the study. The EASL diagnostic criteria for HCC were followed (Bruix et. al 2001). A total of 75 HCC cases were included in the study of which 35 were positive for HBV and 40 for HCV. An equal number of HBV and HCV related chronic hepatitis cases were also included as controls in which 32 were positive for HBV and 43 were positive for HCV. HSP70-Hom and HSP70-2 polymorphisms were analysed by PCR-RFLP method. The statistical program “EPIINFO” (version 5.0; USD Incorporated 1990, Stone Mountain, Georgia) was used for these analyses. RESULTS HSP70-Hom gene polymorphism was found to be a risk factor for HCC compared to chronic hepatitis irrespective of the etiology of liver disease OR 15.17(3.35-95.35); p= 0.001.On the other hand HSP70-2 gene polymorphism was also found to be a risk factor for HCC compared to chronic hepatitis irrespective of the etiology of liver disease OR 2.36(1.29-4.36); p= 0.002. CONCLUSION: The findings indicate that patients with chronic hepatitis B/ C virus infection who harbor these SNPs represent a high-risk group for HCC and need intensive surveillance for early detection of HCC.

1240T

Single nucleotide polymorphisms in E-cadherin gene confer risk to breast cancer. *V. Satti[1], N. Tipirisetti[1], S. Govatati[2], K. Lakshmi Rao[3], R.R. Digumarti[4], M. Bhanoori[2], M. Deenadayal[5].* 1) Department of Genetics, Osmania University, Hyderabad,; 2) Department of Biochemistry, Osmania University, Hyderabad,; 3) Centre for Cellular and Molecular Biology (CCMB), Hyderabad,; 4) Nizams Institute of Medical Sciences, Hyderabad,; 5) Infertility Institute and Research Centre (IIRC), Secundrabad, INDIA.

Cadherins constitute superfamily of integral membrane glycoprotein's that mediate and regulate Ca2+ dependent homophilic cell-cell adhesion and modulate a wide variety of processes, including cell polarization, migration and cancer metastasis. E-cadherin (CDH1) is an epithelial cellular junction protein expressed in almost all epithelial cells and plays an important role in the maintenance of epithelial development, organization, and cell integrity Reduced CDH1 expression promotes malignant transformation, tumor invasion, and metastasis confirming its role in the suppression of cellular mobility. The present study is an attempt to evaluate the role of CDH1 in the development and progression of breast cancer through SNP analysis. Three SNPs of CDH1 gene viz: -160 C/A, 347 G/GA (located upstream from the transcriptional start site of the CDH1) and +54 C>T transition (located after the stop codon) were analyzed through PCR followed by sequencing. Further the -347G/GA (insertion mutation) SNP was confirmed by RFLP analysis. Blood samples were collected from 101 Breast cancer patients and 250 healthy individuals from department of oncology, NIMS hospital, Hyderabad, India and Infertility Institute and Research Centre (IIRC), Hyderabad, India respectively after ethical committee approval of the hospital and the institute. Elevated risk was observed for -347GA/GA, -160 AA and +54 TT genotypes for development of breast cancer. Further haplotype analysis confirmed that -347GA/-160A/+54C and -347GA/-160A/+54T haplotypes were significantly associated with breast cancer. In conclusion, CDH1 haplotypes may jointly modify the risk of breast cancer development in south Indian women. The lower transcriptional efficiency and m RNA instability associated with these SNP might explain the significant association. The loss of CDH1 protein may also promote tumor initiation through release of b catenin, potentiating the canonical Wnt signaling pathway, or by modulating mitogenic signaling, such as EGF-induced cellular proliferation. To the best of our knowledge, this is the first study from Indian population that reveals the correlation between CDH1 polymorphisms and the risk of developing breast cancer.

1241T

Genomic characterization of bladder cancer initiation and development. *S. Scherer[1, 2], T. Majewski[3], J. Bondaruk[3], D. Muzny[1], J. Drummond[1], L. Trevino[1], J. Niu[1], S. Zhang[3], J. Reid[1], K. Baggerly[4], I. Newsham[1], C. Dinney[5], B. Grossman[5], W. Zhang[3], M. Wang[1], Y-Q. Wu[1], M. Morgan[1], D. Wheeler[1, 2], B. Czerniak[3], R. Gibbs[1, 2].* 1) HGSC, Baylor Col Med, Houston, TX; 2) Mol & Human Gen, Baylor Col Med, Houston, TX; 3) Pathology, UT MD Anderson Cancer Ctr, Houston, TX; 4) Bioinformatics and Comp. Bio., UT MD Anderson Cancer Ctr, Houston, TX; 5) Urology, UT MD Anderson Cancer Ctr, Houston, TX.

We are characterizing the two primary paths of bladder cancer development by combining tumor-normal exome sequencing, RNA-seq and epigenetic analysis in an effort to understand the earliest proliferative events and subsequent progression of the disease. Bladder cancer generally presents as either papillary with relatively high recurrence rates or invasive, and in at least 15% of cases, progresses from the former to the latter. The physiology of resected bladder tissue presents a landscape to employ a unique strategy known as whole organ histologic and genetic mapping. The resected tissue is laid flat and divided into one-centimeter squares over the entire surface. Each square is characterized histologically by a pathologist and then processed to isolate both RNA and DNA. As the tissue blocks range from normal urothelium to carcinoma in situ to invasive transitional cell carcinoma, so too, the underlying mutation profile shifts ahead of these changes from incipient field effects to somatic small scale mutations and finally to larger numbers of mutations and chromosome rearrangements. Previous efforts using SNP mapping at a limited number of loci identified “forerunner genes,” which when mutated, provided proliferative advantage ahead of subsequent mutations in nearby known tumor suppressors. We are now extending these efforts using a combination of NimbleGen whole exome capture and SOLiD sequencing of three tumor-normal pairs on one tissue block per cystectomy. Preliminary analysis revealed mutations present in both the oncogenic RAS-ERK-MAPK signaling pathway and the tumor suppressor p53 regulatory pathway while no variants are observed in Ras, ERK or p53 directly. We are currently expanding these analyses in three ways: we are generating sequencing data on another four tissue blocks per cystectomy, we now have another six whole exome tumor-normal pair datasets generated on the Illumina Hi-seq platform and these results are being augmented by both transcriptome and epigenomic analyses. We believe these results will result in biomarker identification, identification of pathways and therapeutic targets and greater understanding of tumor initiation and development that may be applied to other cancers.

1242T

Proteomic and pathway analyses reveal a network of inflammatory genes associated with differences in skin tumor promotion susceptibility in DBA/2 and C57BL/6 mice. *J. Shen[1], E.L. Abel[1], J.M. Angel[2], P.K. Riggs[3], J. Repass[1], S.C. Hensley[1], L.J. Schroeder[1], A. Temple[1], A. Chau[1], S.A. McClellan[2], K. Lin[1], M.D. Ward[4], O.J. Semmes[4], M.D. Person[2], J. DiGiovanni[2,5].* 1) Department of Molecular Carcinogenesis, Science Park, The University of Texas M.D. Anderson Cancer Center, Smithville, TX 78957; 2) Division of Pharmacology and Toxicology, College of Pharmacy, The University of Texas at Austin, Austin, TX 78712; 3) Department of Animal Science, College of Agriculture and Life Sciences, Texas A&M University, College Station, TX 77834; 4) The Leroy T. Canoles Cancer Research Center, Eastern Virginia Medical School, Norfolk, VA 23507; 5) Department of Nutritional Sciences, College of Natural Sciences, The University of Texas at Austin, Austin, TX 78712.

Genetic susceptibility to two-stage skin carcinogenesis is known to vary significantly among different stocks and strains of mice. In an effort to identify specific protein changes or altered signaling pathways associated with skin tumor promotion susceptibility, a proteomic approach of two-dimensional (2-D) gel electrophoresis and mass spectrometry was used to examine and identify proteins that were differentially expressed in epidermis between promotion-sensitive DBA/2 and promotion-resistant C57BL/6 mice following treatment with the phorbol ester, 12-O-tetradecanoylphorbol-13-acetate. We identified 19 differentially expressed proteins of which 5 were the calcium-binding proteins including annexin A1, parvalbumin (, S100A8, S100A9, and S100A11. The differential expression of two of these calcium-binding proteins, S100A8 and S100A9, was further examined and validated by the following methods: i) one-dimensional (1-D) Western blot analysis; ii) 2-D Western blot analysis; iii) immunohistochemical analysis; and iv) quantitative real-time PCR. Further analyses revealed that S100A8 and S100A9 protein levels were also similarly differentially up-regulated in epidermis of DBA/2 vs C57BL/6 mice following topical treatment with two other skin tumor promoters, okadaic acid and chrysarobin. Pathway analysis of all 19 identified proteins from the present study suggested that these proteins were components of several networks that included inflammation associated proteins known to be involved in skin tumor promotion (e.g. TNF-(, NF2B). Follow-up studies revealed that Tnf(, Nfkb1, Il22, and Il1(mRNAs were highly expressed in epidermis of DBA/2 (>2.5 fold, $p<0.05$) compared with C57BL/6 mice. Taken together, the present data suggest that differential expression of genes involved in inflammatory pathways in epidermis may play a key role in genetic differences in susceptibility to skin tumor promotion in DBA/2 and C57BL/6 mice.

A Novel Deletion of MEN1 Gene in a Large Family of Multiple Endocrine Neoplasia Type 1 (MEN1) with Aggressive Phenotype. *Y. Shi[1], H. Raef[2], M. Zou[1], E. Baitei[1], R. Al-Rijjal[1], N. Kaya[1], M. Al-Hamed[1], D. Monies[1], N. Abu-Dheim[1], H. Al-Hindi[3], M. Al-Ghamdi[3], B.F. Meyer[1].* 1) Genetics, King Faisal Specialist Hospital and Research Centr, Riyadh, Saudi Arabia; 2) Medicine,King Faisal Specialist Hospital and Research Centr, Riyadh, Saudi Arabia; 3) Pathology, King Faisal Specialist Hospital and Research Centr, Riyadh, Saudi Arabia.

Context: The MEN1 syndrome is associated with parathyroid, pancreatic, and pituitary tumours caused by mutations in the MEN1 gene. In general there is no genotype-phenotype correlation. Objectives: To characterize a large family with MEN1 with aggressive tumour behavior: malignant pancreatic endocrine tumours were present in 5 affected subjects and were the presenting features in 3 subjects. Design: The coding region of MEN1 was sequenced. The gene copy number analysis was performed by multiplex ligation-dependent probe amplification (MLPA) and array comparative genomic hybridization (aCGH).The loss of heterozygosity (LOH) in the tumour tissue was studied by microsatellite analysis. Insulin-like growth factor II (IGF-II) and CDKN1C/ p57KIP2 expression were investigated by immunohistochemistry. Results: Mutation screening by PCR-sequence analysis of patients' peripheral blood DNA did not reveal any mutation in the MEN1 or CDKN1B gene. Gene copy number analysis by multiplex ligation-dependent probe amplification (MLPA) and array comparative genomic hybridization (aCGH) demonstrated a novel monoallelic deletion of 5 kb genomic DNA involving MEN1 promoter, exon 1 and 2. LOH analysis indicated somatic deletion of maternal chromosome 11 including MEN1 locus (11q13) and 11p15 imprinting control regions (ICR). Methylation analysis of ICR demonstrated ICR1 hypermethylation and ICR2 hypomethylation in the tumour specimens. ICR1 and ICR2 control the expression of IGF-2 and CDKN1C/ p57KIP2, respectively. Immunohistochemistry analysis showed that the expression of paternally expressed IGF-2 was up-regulated and the maternally expressed CDKN1C/ p57KIP2 was lost in the pancreatic endocrine tumours. Conclusions: Gene copy number analysis by MLPA should be considered in patients with negative conventional mutation screening. Although large MEN1 deletion causes MEN1, disruption of imprinted CDKN1C/ p57KIP2 and IGF-2 expression may contribute to tumour progression and aggressive phenotype.

1244T

Genetic alterations in FGFR3 and RAS reveal mutual exclusiveness of these genetic events in urinary bladder cancer. A study in Kashmiri population. *M.A. Siddiqi[1], A.A Pandith[1], Z.A Shah[1], N.P Khan[2], M.S Wani[3].* 1) Immunology & Molecular Medicine , Sherl Kashmir Institute of Medical Sciences, Srinagar, Kashmir, India; 2) Clinical Biochemistry, Sherl Kashmir Institute of Medical Sciences, Srinagar, Kashmir, India; 3) Urology, Sherl Kashmir Institute of Medical Sciences, Srinagar, Kashmir, India.

Urothelial cell carcinoma (UCC) is a common malignancy. Worldwide, it is the seventh most prevalent cancer, accounting for 3.2% of all malignancies. The highest incidence is seen in industrialized countries and geographic areas where infection with Schistosoma haematobium is endemic. Men have a higher risk of bladder cancer than women, by a rate ratio of at least 3:1. We conducted a detailed study of the bladder cancer cases registered from 2005 to 2010 in the only tertiary care hospital in Northern India. This study revealed that bladder cancer ranks as the 7th leading cancer and accounts for 5.9% of all prevalent cancers in the Kashmiri population. Thus aim of this study was to analyze the frequency and association of FGFR3 and RAS gene mutations in UCC. We analyzed the mutations of FGFR3 gene and RAS gene family (HRAS, NRAS, and KRAS) to explore the association of FGFR3 & RAS gene alterations as two genetic events in the development of UCC. DNA of tissue specimens of 65 consecutive patients was examined. The DNA preparations were evaluated for the occurrence of FGFR3 and RAS gene mutations by PCR-SCCP and DNA sequencing. Somatic mutations of FGFR3 gene aggregated to 32.30% (21 of 65). The pattern and distribution of FGFR3 mutations were significantly associated with low grade/stage ($p<0.05$). The overall mutations of RAS genes aggregated to 21.5% and showed no association with any clinic-pathological parameters. In total, 53.8% (35 of 65) of the tumours studied had mutation of either a RAS or FGFR3 gene. RAS and FGFR3 mutations were totally mutually exclusive and are thought to reflect activation of the same pathway by either event. Unlike FGFR3 mutation, no obvious relationship of mutation of a RAS gene with tumour grade of stage has been found. FGFR3 and RAS are in the same signal transduction pathway, which might be a possible explanation for the hypothesis of mutual exclusiveness of mutations in these genes in this study. Thus we conclude that FGFR3 and RAS are mutually exclusive genetic events in UCC, suggesting that both provide the same selective advantage most likely activation of MAPK pathway.

1245T

Transcriptome Based Bioinformatic Analysis of a Unique Ovarian Cancer Model. *S.N. Smillie[2], K. Gambaro[2], D. Provencher[4,5], A.-M. Mes-Masson[5,6], P.N. Tonin[1,2,3].* 1) The Research Institute of the McGill University Health Centre, Montreal, Canada; 2) Department of Human Genetics, McGill University, Montreal, Canada; 3) Department of Medicine, McGill University, Montreal, Canada; 4) Division de gynécologie oncologique, Université de Montréal, Montréal, Canada; 5) Centre de Recherche du Centre Hospitalier de l'Université de Montréal / Institut du cancer de Montréal, Montréal, Canada; 6) Department of Medicine, University of Montreal, Montreal, Canada.

Ovarian cancer (OC) is the 5th most deadly female malignancy in Canada with an average 5-year survival rate of 30%. Women are diagnosed at an advanced stage where current therapies are ineffective due to poor screening strategies and a paucity of information regarding the etiology and pathology of the disease. Previously in our laboratory, a unique chromosome transfer technique was applied to OV90, a well-characterized, aggressive OC cell line possessing molecular genetic features commonly observed in high grade serous OC (HGSOC). The derived OV90 hybrids exhibited complete suppression of tumourigenicity and transcriptome analysis revealed that molecular networks characteristics of OC were affected. Current research has expanded the scope of this work to integrate higher density Affymetrix GeneChip expression arrays and a larger sample of independently derived normal ovarian surface epithelial brushings (NOSE) and HGSOC samples. These results have provided support to previous findings from our group (>22% of top candidates recapitulated) and identified additional molecular pathways that are transcriptionally altered both in our cell line model and between NOSE and HGSOC samples. The approach seeks to elucidate the biological mechanisms behind the abrogation of tumourigenicity observed in our model as it relates to HGSOC - the most common type of OC. The complement to this approach has been to investigate genes that exhibit differential expression between NOSE and HGSOC samples, but have stable expression levels in our model. Here we aim to identify pathways underlying the ability to grow indefinitely in culture, a feature retained in our model and one representative of immortalization, an essential phenotype of cancer. Of 153 candidate genes, 43 have been previously identified in cancer, 17 in OC. The integration and utilization of numerous bioinformatics resources and programs has yielded a systematic approach to candidate selection. Top candidates have been identified and steps to validate via qRT-PCR, immunohistochemistry and in vitro assays have been initiated. The characterization of this model aims to address fundamental aspects of OC biology with the hopes of improving our ability to treat and prevent this disease.

Germline RAD51C mutations in breast and ovarian cancer susceptibility. *F. Soubrier[1], N. Davids[1], A. Fajac[2], C. Colas[1], M. Eyries[1], F. Cornelis[3], A. Cortez[4], R. Rouzier[5], S. Uzan[5], JP. Lefranc[6].* 1) Oncogénétique moléculaire, GH-Pitié-Salpêtrière-APHP, PARIS, France; 2) Histologie Biologie Tumorale, Hôpital TENON-APHP, Paris, France; 3) Anatomo-Pathologie, Hôpital Jean Verdier-APHP, Paris, France; 4) Anatomo-Pathologie, Hôpital Tenon-APHP, Paris, France; 5) Chirurgie Gynécologique, Hôpital Tenon-APHP, Paris, France; 6) Chirurgie Gynécologique, GH-Pitié-Salpêtrière-APHP, Paris, France.

Mutations in the two major susceptibility genes BRCA1 and BRCA2 account for about 16% of familial breast cancers (Van der Groep et al). Genetic factors are mostly unknown for the remaining 84%. Several other genes might explain unelucidated family cases. In the case of breast cancer, deleterious mutations in few genes involved in the Fanconi complex and in the Fanconi-BRCA DNA repair pathway are responsible for Fanconi anemia at the homozygous state and breast cancer susceptibility at the heterozygous state (BRCA2, PALB2, BRIP1). RAD51C plays an important role in the double-strand break repair pathway and, a biallelic missense mutation in the RAD51C gene was found in a Fanconi anemia-like disorder (Somiyajit et al). Subsequently, six monoallelic pathogenic mutations were identified after screening 480 BRCA1/2 negative breast and ovarian cancer pedigrees (Meindl et al). Several reports were unsuccessful to replicate results of the Meindl's study. To investigate whether germline mutations in RAD51C are associated with an increased risk of developing breast and ovarian cancer, we screened, by sanger sequencing of the coding sequence, 92 index cases of breast and ovarian families from French or European origin, and negative for BRCA1/2 mutations. Mutation screening revealed two novel splice mutations flanking exon 7, one donor mutation at position +5 (c.965+5A>G), and one acceptor at position -2 (c.905-2A>C). Either the wild-type exon 7 and its flanking regions, or the two mutated sequences were introduced into the pSPL3 splicing reporter plasmid, and transfected into HeLa cells. The RT-PCR analysis of the transfected cells showed that both mutations induced the loss of exon 7 in the mature transcript, and introduced a frameshift and a codon stop at position 363. This result was confirmed by RT-PCR of the mRNA isolated from blood cells of one index case. One mutated patient presented with an invasive serous ovarian cancer and the other one an invasive endometrioid ovarian carcinoma, and in both cases, several cases of breast cancer were present in the relatives. In our study we found 2 pathogenic mutations among 92 families screened which corresponds to a 2,2 % frequency, a frequency higher than in Meindl et al. Our results confirm that RAD51C is a susceptibility gene for ovarian and breast cancer and that this gene should be screened for mutations in families with multiple breast/ovary cancers.

Whole Exome Sequencing of Pre- and Post-treatment Glioblastoma Multiforme. *K. Squire[1], A. Lai[2], S.F. Nelson[1].* 1) Human Genetics, UCLA, Los Angeles, CA; 2) Neuro-Oncology, UCLA, Los Angeles, CA.

Glioblastoma mulitforme (GBM) is the most common and aggressive type of primary malignant brain tumor in adults. The standard treatment for GBM is radiotherapy (RT) combined with the alkylating agent temozolomide (TMZ). Despite treatment, GBM remains incurable, with median overall survival under 18 months. Efforts to gain a molecular understanding of GBM have focused on characterization of the untreated tumor. However, RT/TMZ treatment can induce an expanded mutational spectrum potentially involving point mutations, chromosomal aberrations and epigenetic changes. This expanded mutational spectrum within relapsed tumors may contain `driver' aberrations associated with resistance to RT/TMZ. To explore this hypothesis, we are conducting whole-exome sequencing of pre- and post-treatment GBM tumors and matched normal blood samples. In an illustrative sample, copy number analysis based on exome sequencing showed significant amplification of a region containing EGFR on chromosome 7 and loss of chromosome 10 in both tumors, but little difference between the tumors at the chromosomal level. We discovered 1428 and 1779 somatic SNVs/indels in the pre- and post-treatment tumors, respectively, with 1071 shared mutations. Comparing the tumors, we discovered 31 novel non-synonymous, protein-altering SNVs and 5 novel frameshift-causing indels in 31 genes the recurrent tumor, including EGFR, SUFU, and C9orf72. Most novel variants were not detected in the pre-treatment tumor but enrichment of the variants was observed consistent with clonality and a heterozygous state in the recurrent tumor. These findings suggest a selective advantage for the post-treatment haplotypes as heterozygous mutations, although not proven here. SNVs of interest include 3 EGFR variants on the amplified allele. One EGFR variant (R521K) is heterozygous in the blood genome, and both tumors show a gross amplification of the reference allele, typical of DNA amplifications. A second EGFR mutation (R324L) is non-existent in germline, appears in the initial tumor, and is virtually eliminated in the post-treatment tumor, suggesting that the treatment selected against this mutation. In contrast, an EGFR C620Y mutation was also absent in germline, but is strongly present in the initial tumor, and has been highly selected for in the post-treatment tumor. These results begin to highlight the mutational changes between pre- and post-treatment GBM tumors and may inform future prognosis and treatment of GBMs.

1248T

Role of genetic variants of ESR1, ESR2 and PGR in susceptibility to gallbladder cancer. *A. Srivastava[1], K. Sharma[1], S. Misra[2], A. Kumar[3], N. Srivastava[4], B. Mittal[1].* 1) Genetics, Sanjay Gandhi Post Graduate Institute of Medical Science, Lucknow, UP; 2) Surgical Oncology, Chhatrapati Shahuji Maharaj Medical University, Lucknow, UP; 3) Surgical Gastroenterology Sanjay Gandhi Post Graduate Institute of Medical Science, Lucknow, UP; 4) Physiology, Chhatrapati Shahuji Maharaj Medical University, Lucknow, UP.

Rationale: Gallbladder cancer (GBC) shows one of the highest incidence and mortality rates in regions of Northern India. GBC is more common in females, suggesting that sex hormones may play a noteworthy role in the etiology of the disease. The intracellular action of estrogens and progesterone is regulated by the estrogen and progesterone receptors. Therefore, the present study was planned to investigate the associations of common genetic variants in estrogen (ESR) and progesterone (PGR) receptor genes with risk of GBC. Methods: The case control study included subjects who completed an interview and provided blood, which totaled 243 GBC cases, 230 gallstone cases and 220 healthy subjects from North India. The study examined whether polymorphisms of ESR1 IVS1-397T>C (rs2234693), IVS1-351A>G (rs9340799) and Ex4-122C>G (rs1801132), ESR2 -789T>G (rs1271572), Ex6-1082G>A (rs1256049) and variant of PGR Ins/del (rs1042838) are associated with GBC susceptibility. Genotyping was carried out by PCR-RFLP. Statistical analysis was performed by using SPSS ver16. Results: We found that the ESR1 IVS1-397 TT, IVS1-351 GG and ESR2-789 GG genotypes were significantly associated with an increased risk of GBC (Odds Ratio [OR] 2.4, 2.5, 2.0 respectively) and gallstone disease (OR; 2.9 2.0 1.8 respectively) as compared to healthy controls. In contrast, ESR1 Ex4-122C>G and ESR2 Ex6-1082 G>A showed no significant association with GBC and gallstone disease either by allelic or genotypic frequencies. Furthermore, ESR1 T,G,C (OR; 3.0) and T,G,G (OR; 2.0) haplotypes and ESR2 C,G haplotype (OR; 2.2) also showed increased risk for GBC. In PGR, the insertion variant conferred low risk for both GBC (OR; 0.4) and gallstone disease (OR; 0.5). The protective effect of PGR variant (rs1042838) was nullified by ESR1 T,G,C/T,G,G haplotypes in dose dependent manner. Conclusion: Our findings suggest that common variants in hormone-receptor genes ESR1 (rs2234693-rs9340799), ESR2 (rs1271572) and PGR (rs1042838) are associated with risk of gallbladder cancer as well as gallstone disease. Acknowledgements: The study was supported for financial assistance by ICMR, CSIR, DST and DBT, Government of India.

De novo germline genetic alterations in cancer susceptibility. *Z. Stadler[1], S. Shah[1], B. Yamrom[2], J. Vijai[1], D. Esposito[2], D. Levy[2], J. Kendall[2], K. Sarrel[1], N. Hansen[1], M. Robson[1], N. Kauff[1], D. Feldman[1], G. Bosl[1], L. Norton[1], M. Wigler[2], K. Offit[1].* 1) Memorial Sloan Kettering Cancer Center, New York, NY; 2) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Objective: Genomic structural variations, such as copy number variants (CNVs), contribute significantly to inter-individual genetic variation and have been implicated in susceptibility to neurocognitive disorders. The objective of this study is to determine if de novo CNVs also play a role in cancer susceptibility. Methods: We performed CNV analysis, using 2.1M NimbleGenHD arrays, on a unique ascertainment of DNA samples from “trios”-probands with early-onset cancer and their unaffected biologic parents. Custom algorithms encompassing a series of normalizations including local intensity normalization, lowess normalization and finally archival normalization that adjusts sample hybridizations to a large data set of “standard-standard” hybridizations were used to capture de novo regions. De novo events were characterized and validated with TaqMan copy-number assays for deletions/amplifications. Unaffected siblings of affected probands served as controls for our case-parent trios. Results: In the first 42 testicular germ cell tumor (TGCT) case-parent trios to have undergone analysis, we have identified 5 de novo events affected probands, a rate that exceeds expected background de novo rates for such events. All events occurred outside known regions of common copy-number polymorphisms, and included 3 amplifications and 2 deletions, ranging in size from 23kb to 400kb. Some regions were found to overlap somatic alterations previously described in testicular tumor samples. In one young man with non-seminomatous testicular cancer (NSGCT), two regions, an 80kb amplification on chr3 and a 23kb deletion on chr4 were identified. Another young man with NSGCT was found to harbor a very large deletion, spanning over 400kb, on chr6. Conclusions: Our preliminary data suggests a role for de novo germline deletions and amplifications in cancer susceptibility; however, further validation of results, expansion of the TGCT ascertainment, and assessment in other cancer types is still ongoing. These results mark one of the very first studies focused on the role of de novo mutations as a mechanism of cancer causation and could potentially represent a new paradigm in our understanding of cancer genetics that could have broad applications in terms of cancer risk stratification and cancer prevention.

Triple negative breast cancers form an aggressive subtype of breast cancer with poor survival. However, little is known about the etiological factors that promote the initiation and development of this form of breast cancer. Commonly inherited breast cancer risk factors identified through genome wide association studies display heterogeneity of effect among breast cancer subtypes defined by estrogen receptor and progesterone receptor status. In this large study of genetic susceptibility to triple negative breast cancer by the Triple Negative Breast Cancer Consortium (TNBCC), 22 common breast cancer susceptibility variants were investigated in 2,980 Caucasian women with triple negative breast cancer and 4,978 healthy controls. Six single nucleotide polymorphisms (SNPs) were highly significantly associated with risk of triple negative breast cancer: rs2046210 (ESR1) (p=4.38 x 10-7), rs12662670 (ESR1) (p=1.13 x 10-4), rs3803662 (TOX3) (p=3.66 x 10-5), rs999737 (RAD51L1) (p=2.96 x 10-4), rs8170 (19p13.11) (p=2.25 x 10-8) and rs8100241 (19p13.11) (p=8.66 x 10-7). These results provide convincing evidence of genetic susceptibility for triple negative breast cancer.

Effects of phytochemicals on Nickel and Chromium induced DNA damage. *A.R. Patel[1], S.S. Chettiar[2], D.D. Jhala[3], M.V. Rao[3].* 1) Molecular cell Biology, Iladevi Cataract and IOL Research Centre, Ahmedabad, Gujarat, India; 2) Department of Biotechnology, Shree Ramkrishna Institute of Computer Education and Applied Sciences, M.T.B. College Campus, Athwalines, Surat, Gujarat, India; 3) Department of Zoology, School of Sciences, Gujarat University, Ahmedabad, Gujarat, India.

Purpose: Curcumin and Andrographolide are the phytochemicals of medicinal plants Curcuma longa and Andrographis paniculata were investigated to evaluate its ameliorative potential against Nickel (Ni) and/or Chromium (Cr) exerted effects. Ni and Cr compounds are exposed to human population by numerous paths. Hence, this study was undertaken to establish potent herbal antidote against these metal ions. Methodology: In the present study, we report the cytogenetic variations in lymphocyte cultures after exposure to Cr and Ni in the form of potassium dichromate (K2Cr2O7, 1.36 X 10-6M) and nickel chloride (NiCl2, 4.216 X 10-5M) respectively in vitro for 24 and 69 hours exposures and phytochemicals Curcumin (3.87 X 10-7M) and Andrographolide (0.4 x 10-6M) were cosupplemeted. The genotoxic effects of the compounds were analyzed by scoring of genotoxic endpoints like chromosomal aberration, comet assay, and markers of oxidative stress. A known mutagen ethyl methane sulfonate (EMS) was also used as a positive test control. Results: Results revealed that the both curcumin as well as andrographolide significantly reduced chromosomal aberrations and also there was reduction in the comet tail length in these phytochemical supplemented cultures. Cultures supplemented with curcumin showed 92 % where as andrographolide showed 88% amelioration. Exposure dependent effect of the phytochemicals were noticed, results suggested that these phytochemicals showed better effects in the longer (69hrs.) exposure intervals. Conclusion: Curcumin and Andrographolide, medicinal phytochemicals showed protective effect on the DNA damage induced by the Ni and Cr in peripheral blood lymphocyte cultures. Curcumin is more potent ameliorative agent than the andrographolide at this concentration.

1252T

Detecting Chromosomal Inversions Using Chromatid Paints- Use for Synteny Among the Hominidae. *F.A. Ray[1,2], E. Zimmerman[2], M.N. Cornforth[3], J.S Bedford[1,2], E.H. Goodwin[2], S.M. Bailey[1,2].* 1) Department of Environmental and Radiological Health Sciences, Colorado State University, Fort Collins, CO 80523; 2) KromaTiD Inc., 515 E. Laurel St., Fort Collins, CO 80524; 3) Department of Radiation Oncology, University of Texas Medical Branch, Galveston, TX 77555.

There is no suitable method to routinely detect inversions smaller than a typical metaphase chromosome band (i.e. 10Mb). A chromosomal inversion is an intrachromosomal aberration initiated by misrepair of two double strand breaks and resulting in a segment of DNA within a chromosome being oriented in the opposite direction from the rest of the DNA molecule. We have developed a new methodology to improve inversion detection that involves design of strand specific fluorescent probes that when combined with strand specific removal of the nascent DNA strands (using Chromosomal Orientation- Fluorescence In Situ Hybridization(CO-FISH)) allows hybridization to only one of the remaining two DNA strands within the chromosome. Thus, probes hybridize to an unaltered chromatid producing a fluorescent `chromatid paint' and a chromatid with an inversion produces an easily detectable fluorescence signal switch from one chromatid to the other. For the first chromatid paint, human chromosome 3 was chosen. Hybridization targets, regions of unique DNA, were designed to be located at 1Mb intervals along the length of the four contigs making up chromosome 3. A total of 195 fluorescent probes, along the length of chromosome 3 were developed and tested individually. The probes were then combined and hybridized to cells derived from normal humans. The result in every case has been a fluorescent paint appearing on one chromatid and not the other in both chromosome 3 homologs. To date, no constitutive inversions have been observed in cells from different humans (0/12). The chromatid paint was also hybridized to cells from a patient with one normal chromosome 3 and a known inversion on the other homolog. One homolog produced a clear signal switch at the known breakpoints and the normal homolog did not, clearly demonstrating the ability of chromatid painting to detect inversions. The ability to detect a 1Mb inversion was demonstrated using a chromatid paint with one probe complementary to the rest. It is also important to include inversions as an informative class of evolutionary changes in genome structure. The human chromosome 3 chromatid paint was hybridized to cells from the great apes; chimpanzee, gorilla and orangutan. In each case the chromatid paint hybridized to the corresponding chromosome 3 only. A large inversion observed in orangutan chromosome 3 will be described and the potential of chromatid painting for synteny studies will be further elucidated.

Implementation of whole genome copy number-SNP arrays in a clinical reference laboratory: expanding the possibilities for molecular karyotyping. *T. Sahoo, R. Owen, L.P. Ross, M.M. Elnaggar, P.H. Kohn, M.H. Haddadin, F.Z. Boyar, L.W. Mahon, B.T. Wang, C.M. Strom, A.L. Anguiano.* Quest Diagnostics Nichols Institute, San Juan Capistrano, CA.

Microarray-based technologies have enhanced the identification of chromosomal abnormalities. The transition from BAC and oligonucleotide-based array comparative genomic hybridization (aCGH) to whole-genome oligonucleotide single-nucleotide polymorphism (oligo-SNP) arrays for postnatal and prenatal constitutional studies is already a reality. Oligo-SNP arrays enable simultaneous high-resolution interrogation of both copy number variations (CNVs) and copy neutral segments of homozygosity (SOH). Our experience using a whole-genome oligo-SNP array to characterize constitutional abnormalities is presented. Since implementation of the Affymetrix SNP Array 6.0 at Quest Diagnostics, >1386 samples submitted for evaluation of constitutional disorders have been analyzed. During the same period, 2642 cases were analyzed with a proprietary, whole-genome BAC aCGH platform. Based on analytical, genomic, and clinical metrics, oligo-SNP revealed clinically significant abnormalities in 178 (13%) cases, findings of unclear clinical significance in 193 (14%), and single or multiple SOH in 48 (3.4%). The clinically significant abnormalities included 168 cases with pure CNVs and 10 with both CNVs and SOH or uniparental disomy. Interpretation of findings of unclear clinical significance was based on multiple criteria including gene content, local genomic architecture, overlap with population variants and a systematic evaluation of similar CNVs identified in our laboratory. Parental analysis in 36 oligo-SNP cases revealed 5 to be de novo and 31 to be inherited from a parent. During the same period, BAC aCGH identified clinically significant abnormalities in 250 cases (9.4%) and findings of unclear clinical significance in 166 (6.3%). Parental BAC aCGH in 39 cases identified 7 to de novo and 32 to be inherited from a parent. Additionally, an average of 12-20 recurrent, small, apparently benign CNVs were identified by oligo-SNP per case. Therefore, implementation of the oligo-SNP platform is improving our ability to detect clinically significant alterations. An important initial outcome has been the identification and characterization of several complex chromosomal rearrangements that would be undetectable with conventional methods or earlier array platforms. These data are of profound value in helping identify novel rearrangements, re-define the nature of known microdeletion-microduplication disorders, and deriving a more explicit genotype-phenotype correlation in many cases.

Suggestion for post-zygotic translocation; X-chromosome inactivation spred to autosome with a t(X;15)(p21.1;q11.2) translocation. *S. Sakazume[1,2], H. Ohashi[3], Y. Sasaki[4], N. Harada[4], K. Nakanishi[5], H. Sato[5,6], M. Emi[5,6], K. Endoh[7], Y. Kido[2], T. Nagai[2], T. Kubota[7].* 1) Takasaki, Gunma, Japan; 2) Division of Pediatrics, Dokkyo University Koshigaya Hospital, Koshigaya, Japan; 3) Division of Genetics, Saitama Children's Medical Center, Hasuda, Japan; 4) Department of Molecular Genetic Research and Analysis, Advanced Medical Science Research Center, Mitsubishi Chemical Medience Corporation, Tokyo, Japan; 5) DNA Chip Research Inc., Yokohama, Japan; 6) Department of Neurology, Hematology, Metabolism, Endocrinology and Diabetology, Yamagata University School of Medicine, Yamagata, Japan; 7) Department of Epigenetic Medicine, Faculty of Medicine, Interdisciplinary Graduate School of Medicine and Engineering, University of Yamanashi, Chuo, Japan.

Background: X-chromosome inactivation (XCI) is an essential mechanism in females that compensates for the genome imbalance between females and males. It is known that XCI can spread into an autosome of patients with X;autosome translocations. Methods: The subject was a 5-year-old boy with Prader-Willi syndrome (PWS)-like features including hypotonia, hypogenitalism, and hypo-pigmentation, and developmental delay. G-banding, fluorescent in situ hybridization, BrdU-incorporated replication, human androgen receptor gene locus assay (HUMARA), SNP microarrays, ChIP-on-chip assay, bisulfite sequencing, and real-time RT-PCR were performed. Results: Cytogenetic analyses revealed that the karyotype was 46,XY,der(X)t(X;15)(p21.1;q11.2), -15. In the derivative chromosome, the X and half of the chromosome 15 segments showed late replication. HUMARA showed the two X segments were maternal origin. SNPs confirmed the chromosomes 15 had biparental origin. The DNA methylation level was extremely high in the proximal region from the breakpoint, and the level gradually decreased toward the telomere in the chromosome 15 region. The promoter regions of the imprinted SNRPN and the non-imprinted OCA2 genes were completely and half methylated, respectively. However, no methylation was found in the adjacent imprinted gene UBE3A, which contained a lower density of LINE1 repeats. Conclusions: Our findings suggest that XCI spread into the paternal chromosome 15 leading to the aberrant hyper-methylation of SNRPN and OCA2 and their decreased expression, which contributes to the PWS-like features and hypo-pigmentation. To our knowledge, this is the first report in which the DNA methylation level is demonstrated in an autosome subject to XCI. The methylation status of SNRPN is complete in this patient. Uncommon hypermethylation is suspected in paternal SNRPN in the patient. We assume that, in the derivative chromosome, X region is maternal and 15q is paternal. The derivative chromosome isolation is inevitable step for the verification of post-zygotic translocation.

Identification of Chromosomal Alterations in Autism Patients. *K. Sasikala[1], V. Balachandar[1,2].* 1) Human Molecular Genetics, Bharathiar University, Coimbatore, India; 2) Thiruvalluvar University, Vellore, india.

Autism is a complex neurobiological disorder that typically lasts throughout a person's lifetime. It is part of a group of disorders known as autism spectrum disorders (ASD). It is often associated with other conditions, such as disorders of the CNS (tuberous sclerosis), developmental delay, attention deficit, epilepsy, and anxiety and mood disorders. At the current time, the exact causes of autism remain elusive, but researchers increasingly believe that both genetics and environment play a role. The prime aim of the present study was to identify the chromosomal aberrations with autism patients in Coimbatore region. In order to investigate the possible cytogenetic damage in autism patients, peripheral blood lymphocyte culture (PBLC) method was carried out on the lymphocytes of 45 autism patient samples and equal number of controls was selected, based on the detailed questionnaire. An autism child has been followed up regularly at frequent intervals of 4-6 weeks both by the paediatrician and child psychologist. Parameters during follow up included enquiry into the parents' assessment of the child as a whole, level of hyperactivity after behavioural and pharmacological intervention. For karyotyping, 100 complete metaphase cells from each subject were evaluated using Trypsin - Giemsa Banding method. In our study chromosomal alterations were frequently observed in chromosomes 2, 3, 8, 16 and X (2q32, 3q25-q27, 16p13, Xp22, and Xq13). In conclusion, in this pilot study, we observed the chromosomal instability in peripheral blood lymphocytes may be a potential biomarker in autism patients. Identification of cytogenetic abnormalities is not only important for providing a cause for the autism in a single individual but is also critical for accurate counselling regarding recurrence risks to parents and family members.

Molecular cytogenetic characterization of partial deletion Xq and duplication Xp in a patient with premature ovarian failure. *S.H. Shim[2], M.K. Kim[1], S.H. Park[2], J.E. Park[2], Y.H. Cho[3], D.H. Cha[1,2], T.K. Yoon[1].* 1) Department of Obstetrics and Gynecology; 2) Genetics Laboratory, Fertility Center of CHA Gangnam Medical Center, CHA University, Seoul,135-081, Korea,; 3) Department of Medical Genetics, College of Medicine Hanyang University, Seoul, 133-791, Korea.

A 26-year-old female was initially suspected as premature ovarian failure (POF) syndrome because of amenorrhea and high levels of serum FSH and LH, 85.21mIU/ml and 25.05mIU/ml, respectively. Numerical or structural abnormalities of an X chromosome and FMR1 premutation were well known genetic causes of this syndrome. Chromosome analysis with high-resolution GTG banding technique was carried out and her karyotype was apparently 46,XX normal female. FMR1 gene analysis was performed by polymerase chain reaction (PCR) and Southern blotting. The PCR result was normal and one allele in the normal range of (CGG)n repeats was detected. However, Southern blot analysis showed an unusual pattern, no size expansion nor methylated allele detected, which was normal male pattern not female. To figure out this unusual result, multiplex ligation-dependent probe amplification (MLPA) with the subtelomeric region specific probe set (P070) was carried out and the result showed the trisomy Xp and monosomy Xq. This result was confirmed by fluorescent in situ hybridization (FISH) with the TelVysion Xp/Yp and Xq/Yq probes. One of the X chromosomes had two Xp signals on both ends of the X chromosome and no Xq signal. Her family members were also investigated. Her mother is 50 years old and showed no signs of POF syndrome and her 24-year-old younger sister showed normal regular menstruation and normal serum FSH and LH level. Both of them showed apparently normal 46,XX karyotype like the proband. However, FISH analysis showed the mother had a pericentric inversion between Xp22.3 and Xq27 and her younger sister had the same X chromosome abnormality as that of the proband. From these results, the proband's karyotype was 46,X,rec(X)dup(Xp)inv(X)(p22.3q27)mat. To characterize the exact chromosomal regions and genes involved, array based comparative genomic hybridizations (array CGH) using the 135K NimbleGen Whole-Genome Array are applied and the results are pending. Although, the proband's sister does not show any signs and symptoms of POF at this moment, appropriate genetic counseling and clinical follow-up is required.

1257T

A 3.44 MB interstitial duplication of chromosome 3 with no apparent phenotype detected by SNP array. *M. Thangavelu[1], J.H. Tepperberg[2], J. Hume[3], B. Huang[1].* 1) Genzyme Genetics, Orange, CA; 2) LabCorp, NC; 3) Newton-Wellesley Hospital, Newton, MA.

Prenatal cytogenetic studies on amniocytes referred for abnormal sequential screening (1:35 risk Down syndrome and 1:18 risk trisomy 18) and fetal MCA, including heart defect and IUGR on ultrasound, revealed the following karyotype: 47,XY,+mar[10]/46,XY[5]. Whole genome SNP microarray to characterize the marker, revealed an interstitial duplication of a minimum size of 3.443 MB of material from the short arm of chromosome 3 (BP linear position was from 74, 756, 515 to 78, 199, 925 including the gene ROBO2). FISH studies showed that the marker did not contain chromosome 3 material but was derived from the pericentromic region of chromosome 11. Maternal studies showed that the duplication of chromosome 3 material was maternally derived, with insertion of the duplicated material from the short arm on to the long arm of chromosome 3. The pregnancy ended in fetal demise around 20 week gestation. This case illustrates a number of issues to be considered prior to offering and performing microarray; (1) need for parental studies and (2) unexpected findings and (3) the need for appropriate genetic counseling. Irrespective of the size of the duplication/deletion parental follow up studies are important. Unexpected findings in normal individuals may not be entirely benign, because of the potential role of other factors (genetic and non genetic) in the expression of the phenotype. Also, one should be mindful that due to lack of previously documented/reported information satisfactory interpretation may not be feasible in some instances. All these aspects need to be addressed during genetic counseling prior to offering microarray so that the patient is fully aware that the testing may be a lengthy process and may not offer a definitive answer in all cases. When a definitive answer is not available, patients should be prepared to revert to the available phenotype (ultrasound findings) in making a decision. Detailed analysis and documentation of additional cases with copy number variation of relatively large segments with no apparent clinical phenotype will provide valuable information for genetic counseling, as microarray testing gains importance as a powerful tool in genetic diagnosis. Cytogenetic study of petrol pump workers occupationally exposed to Benzene. *R.P. Thumbar, P.K. Gadhia.* Department of Biosciences, Veer Narmad South Gujarat University, Surat, Gujarat, India.

Abstract: Petrol has become one of the basic needs of common men. To supply and distribution, there are many industries involved, refinery to petrol pump station. Out of these industries petrol pumps are the only place where petrol fume is directly exposed to maximum numbers of individuals who refill petrol to vehicles. Petrol is not a chemical but mixture of aliphatic hydrocarbons and antiknock agents; aromatic hydrocarbons such as benzene and toluene. Benzene is now proven leukemogen. The concentration of benzene in petrol differs according to mandatory regulation. In developed countries like Europe, Australia and USA, the concentration of benzene in petrol is less than 1%, where as in developing countries like India the concentration of benzene is approximately 3-5%. So it is important to measure the genotoxic risk factor of petrol pump attendants who are serving 8 - 12 hours according to their shift at benzene containing work atmosphere. Methodology: In present study, we have considered smoker (n=25) and non smoker (n=25) petrol pump attendants as a study group where as their respective smokers (n=25) and non smokers (n=25) control individuals, who are not exposed to benzene. Sister chromatid exchange, micronuclei and chromosomal aberration were carried out form blood by peripheral blood lymphocyte culture for genotoxic evaluation. Mitomycin C was used to add in other set of culture vials, as a positive control. Urinary phenol and t,t - muconic acid (HPLC) measured as urinary benzene biomarkers. Result: Micronuclei frequency in smoker petrol pump attendants was seen to be increased ($p< 0.05$) significantly as compared to control. Whereas other cytogenetic parameters such as, SCE and chromosomal aberrations were did not show any significant difference. Urinary phenol and t,t - muconic acid concentration in smokers and non smoker petrol pump workers was found to be significantly increased respectively ($p< 0.05$) and ($p<0.01$) than controls. Conclusion: Increased urinary phenol and t,t - muconic acid in petrol pump attendants ensure the exposure of benzene in work area. Chromosomal endpoints did not show any significant difference in petrol pump attendants than the respective controls, exceptionally micronuclei study showed significant increase in micronuclei frequency of smoker petrol pump attendants than control. Thus, other cytogenetic parameters such as comet assay, FISH etc with cohort study are needed to reach to any concrete conclusion.

1259T

Cytogenetic analysis in material from abortions in couples with recurrent first-trimester miscarriages. *C. Uria Gomez[1, 2], G. Arteaga Ontiveros[1], A. Rodríguez Gómez[1].* 1) Genecon Diagnostico Laboratorio, Toluca Edo. de Mexico, Mexico; 2) Facultad de Medicina UAEM.

The cytogenetic analysis of fetal tissue from spontaneous abortions shows that 50-60% of them were caused by abnormal karyotype. The most frequent chromosomal abnormality is trisomy 16. The aim of this study was to know the frequency of chromosomal aberrations in patients with recurrent miscarriages. Cytogenetic analysis was performed in 100 samples of miscarriage in women with at least 2 first trimester spontaneous abortions. The samples were processed by the explant technique and enzyme digestion using trypsin and collagenase. Cultures were incubated at 37ºC with an atmosphere of 5 % CO_2 and harvested with the usual technique. The chromosomal analysis was performed with GTG banding technique. The cytogenetic results, along with clinical data including gestational age at the time of the miscarriage and maternal age were compiled in a database. The incidence of specific chromosome abnormalities was determined. Cytogenetic results were obtained for 71 cases (71 %), of which 22 (31 %) showed chromosome abnormalities. The most frequent chromosomal aberration was trisomy, detected in 17 cases. The most common autosomal trisomy was that of chromosome 18 (4 cases), followed by trisomy 22 (3 cases) trisomy 13 (2 cases) and trisomy 21 (2 cases). We found other trisomies involving chromosomes 4, 10, 14, 15, 16, and 20, some of them showed mosaicism with a normal cell line. Triploidy was identified in one case, and tetraploidy was detected in one case. A balanced translocation was identified in one case. Trisomy 4 and 10 were detected in earliest gestational age. Of the 100 samples received, 13 of them there was no cell growth and 16 were discarded because they showed bacterial contamination. Our success rate in cell growth, removing the contaminated samples, is 81.6%. This percentage is acceptable according to data reported in literature. Of the 49 samples that were normal, 37 had a karyotype 46,XX and the remaining 12 were 46,XY. The cytogenetic study of abortions is difficult because the study material on occasion is not the most suitable for cell culture, and that may have contamination, maceration or after formalin fixation. Cytogenetic analysis in spontaneous abortions is very important, especially when it has a history of previous losses.

1260T

Fetoplacental discrepancy with normal karyotype in amniotic fluid and two different cell lines in placenta: A case report. *G. Velagaleti[1], K. Higby[2], E. Williamson[1], C. Mendiola[1], V. Ortega[1].* 1) Department of Pathology, University of Texas Health Science Center, San Antonio, TX; 2) Center for Maternal and Fetal Care, San Antonio, TX.

We present a case of fetoplacental discrepancy in a second-trimester fetus with normal karyotype in amniotic fluid and two different Robertsonian translocations in placenta, one balanced and one unbalanced. A 41-year-old woman of Middle-Estern origin, gravida 2, para 1 underwent amniocentesis at 16-weeks gestation due to advanced maternal age. Prenatal aneuvysion testing showed a signal pattern consistent with normal female chromosomes while amniotic fluid showed a normal 46,XX karyotype. Interestingly the karyotype also showed a homozygous inv(9) in all the cells analyzed. Although the inv(9) is considered a polymorphic variant, due to the homozygous nature, parental chromosome studies were suggested. Both parents showed the inv(9) in thier respective karyotypes, thus suggesting the biparental inheritance of the homozygous inv(9) in the fetus. Fetal ultrasound was normal and didnot show any unusual findings. The mother presented to the clinic four weeks later with an intrauterine fetal demise. Although cultures were initiated from fetal, cord and placental tissues, growth was obtained only from placental tissue. Chromosome analysis showed two different cell lines, a balanced (15;21) Roberstonian translocation in 11 cells and an unbalanced (21;21) Robertsonian translocation in 9 cells. The karyotype was interpreted as mos 45,XX,inv(9)(p11q13)x2,der(15;21)(q10;q10)[11]/46,XX,inv(9)(p11q13)x2,+21,der(21;21)(q10;q10)[9]. Mother's history is complicated as she is a carrier for the Cystic Fibrosis mutation (ΔF508) and also for the Factor V Leiden. She is also a carrier for the HbD-Los Angeles (33.9%) and HbQ-India (14.7%) variants. She also had a sibling with term stillbirth. Her husband is normal for both CF and Factor V Leiden. Our case appears to be another example of confined placental mosaicism (CPM) with a normal fetal karyotype. However, we could not confirm the possibility that CPM contributed to the IUFD in our case given the complex medical history of the mother.

1261T

Mosaic isodicentric Y chromosome in a patient with mix gonadal dysgenesis. *Z. Yilmaz[1], B. Yuksel[2], O. Ozer[1], F.I. Sahin[1].* 1) Department of Medical Genetics, Baskent University Faculty of Medicine, Ankara, Turkey; 2) Department of Pediatrics, Cukurova University Faculty of Medicine, Adana, Turkey.

Dicentric chromosomes are the most frequently observed structural abnormalities of Y chromosome. The rearranged chromosome has a breakpoint in the long arm with a loss of the short arm except the proximal part, Thus the patients have SRY gene on the chromosome. Dicentric aberrations are unstable during cell division and can generate various types of cell lines. Most reported patients are chromosomal mosaics, generally including a 45,X cell line. Among the cases, a wide range of variation in phenotype, external genitalia, histology, and chromosomal findings was observed. Here, we report a male patient with perineal hypospadias, unilateral cryptorchidism and a mosaic karyotype 45,X [49]/47,X,idic(Y)(q11.2),+idic(Y)(q11.2)[4]/46,X,idic(Y)(q11.2)[47]. We used fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR) to determine the structure and genetic content of the Y chromosome. FISH analyses revealed double SRY signals on the chromosome suggesting isodicentric Y. Whole chromosome probe hybridized with the derivative chromosome only excluding a translocation. According to PCR results, the patient had an amplified SRY region, whereas a total deletion of AZFabcd regions was detected. Our findings and earlier reports emphasize the importance of the use of a combination of cytogenetic and molecular genetic techniques during characterization of a patient with a derivative Y chromosome before any general conclusions can be reached concerning the relative effects of the Y-chromosome abnormality and mosaicism on sexual differentiation.

1262T

Sex chromosome rearrangement and mosaicism in four patients with short stature and ovarian failure. *C. Yu[1], M. Torchinsky[2], O. Abdul-Rahman[2], R. Morris[3], R. Hines[3].* 1) Dept Pathology; 2) Department of Pediatrics; 3) Department of Obstetrics and Gynecology, University of Mississippi Medical Center, Jackson.

Short stature is one of the main clinical features of Turner syndrome either in the mosaic or non-mosaic form. Phenotypic females with Y chromosomal material have an increased risk for gonadoblastomas. Individuals with X/X rearrangement often have secondary amenorrhea and ovarian failure. The phenotypic features varied depending on the chromosome segment involved in the translocation. We report here four female with either mosaicism of idic(Y) or X/X translocation. Case 1. Patient was referred at 5 years of age because of short stature and suspicious of Turner syndrome. On physical examination patient height was 99.4 cm and weight 14.9 kg. Blood chromosome study revealed a mosaic 45,der(X)t(X;Y)(p22.3;p11.3)[10]/ 46,idem,+idic(Y)(q12)t(X;Y)[36] karyotype. A translocation occurred between the X and Y chromosomes and subsequently the derivative Y formed an isodicentric Y chromosome. FISH study confirmed the X/Y translocation and the idic(Y). Case 2. Patient was referred at 15 years of age because of history of short stature. On physical examination the patient height was 139.4 cm and weight was 44.2 kg. Bone age was read as 11 years. Chromosome analysis revealed a mosaic 45,X[43]/ 46,X,dic(Y)(q11.23)[1]/ 47,X,dic(Y)(q11.23)x2[6] karyotype. FISH study confirmed all three cell lines. Case 3. Patient was referred at 21 years of age because of secondary amenorrhea and ovarian failure. On physical examination patient height was 149.8 cm and weight 67.7 kg. Blood chromosome study reveal a 46,X,der(X)t(X;X)(p22.33;q28) karyotype; the derivative X chromosome had a deletion from Xp22.33 to Xpter and a duplication of Xq28 to Xqter. Chromosome study of her 47-year-old phonotypical normal mother revealed that the mother was the carrier of this derivative X and had a mosaic 45,X[2]/ 46,X,der(X)t(X;X)(p22.33;q28)[27]/ 47,XX,+der(X)t(X;X)[1] karyotype. The X/X translocation was confirmed by FISH. Both case 1 and 2 had idic (Y) and positive for the SRY; the timing of mitotic nondisjunction during early embryogenesis and the level of the concurrent 45,X cell line reportedly account for the female phenotype and the Turner stigmata. In case 3, although the patient and her mother had the same rearranged X, the mother was apparently normal. Nonrandom X chromosome inactivation may play an important role between the patient and her mother.

1263T

Pathogenicity of interstitial deletions 14q investigated by CGH microarrays: When the size of the abnormality does not warrant that it is de novo. *M. Beaulieu Bergeron[1], G. Mathonnet[1], V. Désilet[1], J. Gekas[3], M. Sylvain[4], R. Fetni[2], F. Tihy[1], E. Lemyre[1].* 1) Service de Genetique, CHU Sainte-Justine, Montreal, Canada; 2) Departement de Pathologie, CHU Sainte-Justine, Montreal, Canada; 3) Service de Genetique, CHUQ, Quebec, Canada; 4) Service de Neurologie, CHUQ, Quebec, Canada.

We present four cases of interstitial deletions on the long arm of chromosome 14 that were investigated by CGH microarrays (aCGH). In the first two instances, a deletion of approximately 3 Mb in 14q12 was found in two young girls with microcephaly and central nervous systems abnormalities. Patient 1 also presented with cortical blindness, central hypotonia and peripheral hypertonia, as well as clenched fists and flexed limbs. As for patient 2, she also presented with vocal cord palsy that required intubation at birth as well as tracheostomy, seizures and hypotonia. Previous standard cytogenetic analyses had yielded normal results for this patient. aCGH revealed that these two deletions have in common the loss of FOXG1, a gene known to cause a congenital variant of Rett syndrome when in haploinsufficiency. This correlates with the clinical findings, and further analyses by FISH confirmed the deletion to be de novo in both patients. In the two remaining cases, an interstitial deletion in 14q31 was seen on fetal karyotype. In the first pregnancy, amniocentesis was performed for an increased risk of aneuploidy due to soft markers, whereas increased nuchal translucency on ultrasound prompted amniocentesis in the second pregnancy. In both cases, a similar deletion was suspected on parental karyotype, and later confirmed by FISH. aCGH analyses of both fetuses revealed that the deletions in 14q31.1q31.3 were approximately 7 Mb in size, involve respectively 10 et 7 genes, and have in common the loss of 6 genes: TSHR, GTF2A1, SNORA79, STON2, SEL1L and FLRT2. At almost 4-year-old, the first patient presents with minor facial dysmorphisms and normal psychomotor development. The second patient is yet to be born. Based on the patient's and carrier parents' phenotype as well as literature review, mild facial dysmorphisms and mild anomalies of the cognitive development seem to be associated with these deletions. In conclusion, these four cases of interstitial 14q deletions increase our knowledge regarding the phenotypic features associated with those deletions involving regions 14q12 and 14q31. These cases also illustrate the importance of parental analysis when confirming rearrangements seen by aCGH since rather large deletions can either be inherited or de novo and be associated with a phenotype of mild clinical severity.

1264T

Interstitial 21q22.3 Chromosomal Deletion Associated with Intellectual Disability, Behavioral Abnormalities, and Microcephaly in Siblings. *C. Cottrell[1], S. Kulkarni[1,2,3], M. Vineyard[4], M. Shinawi[4].* 1) Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO; 2) Department of Pediatrics, Washington University School of Medicine, St. Louis, MO; 3) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 4) Department of Pediatrics, Division of Genetics and Genomic Medicine, Washington University School of Medicine, St. Louis, MO.

Background: Chromosome 21q22.3 is a gene rich region containing multiple loci associated with human disease. The phenotypic effects of deletions encompassing the 21q22.3 region have not been previously studied. Methods & Results: We present two male siblings with microcephaly and intellectual disability caused by a microdeletion involving chromosomal region 21q22.3. The older sibling is an 11-year-old male with intractable epilepsy, microcephaly, intellectual disability, and aggressive behavior. The 6-year-old sibling also has intellectual disability, microcephaly and was diagnosed with attention deficit hyperactivity disorder. The siblings exhibit some dysmorphic features including relatively large ears, epicanthal folds, smooth philtrum, and widely spaced teeth. The older sibling also has abnormal skin pigmentation. Microarray analysis using the Affymetrix SNP 6.0 platform revealed an approximately 962kb copy number loss [arr 21q22.3(43,832,384-44,793,940)x1] overlapping a region with a single report of copy number variation. The deletion was inherited from an apparently healthy father except for impaired social behavior. A healthy female sibling was not found to carry the deletion. Conclusions: Our data suggest that deletions encompassing chromosomal region 21q22.3 can be associated with microcephaly and neurobehavioral phenotypes. The deleted region encompasses several genes implicated in human disease, including CSTB and TRPM2. Mutations within the CSTB gene have been associated with the autosomal recessive disease, progressive myoclonic 1 epilepsy (EPM1). The effect of CSTB haploinsufficiency in our patients is unclear; however it may be a contributing factor for the intractable epilepsy observed in the older sibling. The TRPM2 gene product functions as a calcium channel receptor and is highly expressed in the human brain. TRPM2 has been previously implicated in bipolar disorder and its deletion may play a role in the neuropsychiatric phenotypes observed in this the family.

1265T

Deletion 1q24q25: four new cases with recognizable phenotype. *M. de Blois-Boucard[1-3], V. Malan[1-3], O. Raoul[1-3], N. Morichon[1], M. Willems[2], S. Nussbaum[1], A. Munnich[2-3], M. Vekemans[1-3], V. Cormier-Daire[2-3].* 1) Cytogenetics laboratory, Necker Hospital, Assistance Publique, Hopitaux de Paris, France; 2) Department of genetics, Necker Hospital, Paris, France; 3) Universite Paris Descartes, Faculte de Medecine, Paris, France.

Deletion of chromosome 1 are very rare and are usually classified as proximal (1q21q25), intermediate (1q24q32)and terminal (1q32qter). Here, we report on four new cases carrying a deletion 1q24q25. All occurred de novo. Three patients were referred to us because they presented with short stature, small hands and feet, facial dysmorphic features and intellectual disability. Skeleton X-rays revealed mesomelic dysplasia and endocrine workup identified a growth hormone deficiency for two patients. One patient was referred prenatally because of intrauterine growth retardation and short extremities detected on ultrasound survey. Using molecular karyotyping (Array-CGH) we are able to characterize the deletions at the molecular level and to define a 9Mb common deleted region. This region encompasses several genes: PRRX1, SERPINC1, DARS2, presumably responsible for the phenotype observed in our patients. When compared to previously published clinical reports, a recognisable skeletal endophenotype could be delineated. It includes specific clinical and radiological features of the limbs and extremities, namely short stature, shortness of the metacarpus, metatarsus and phalanges. Interestingly, a deletion of the homeobox PRRX1 gene is observed in all described patients. Considering that this gene encodes a protein playing an important role in epithelial-mesenchyme interaction during skeletal organogenesis, one may suggest that the PRRX1 gene is causally related to the skeletal endophenotype. As previously suggested, our data confirm that 1q24q25 deletions are probably responsible for a novel recognizable phenotype with specific skeleton features.

1266T

Chromosome microarray analysis and zebrafish studies identify CCDC165 as a new candidate gene for coloboma. *P. Eydoux[1], B. McGillivray[2], K. Schlade-Bartusiak[1], C. Lyons[3], C. Gregory-Evans[4].* 1) Dept Pathology, Children's & Women's Hosp, UBC, Vancouver, BC, Canada; 2) Dept Medical Genetics, Children's & Women's Hosp, UBC, Vancouver, BC, Canada; 3) Dept Ophtalmology, Children's & Women's Hosp, UBC, Vancouver, BC, Canada; 4) Dept Ophtalmology, Eye Care Center, UBC, Vancouver, BC, Canada.

Coloboma is a rare eye malformation resulting from defective closure of the optic fissure, which may result in poor vision. While most cases of coloboma are sporadic, autosomal dominant, autosomal recessive, and X-linked inheritance patterns have been described. Coloboma is a frequent feature of chromosome abnormalities, such as trisomy 13, partial tetrasomy 22 or Wolff-Hirschhorn syndrome, suggesting that coloboma genes may be copy number sensitive. Molecular mechanisms leading to coloboma remain largely unknown. A female patient was referred at 3 years of age because of a unilateral right-sided infero-nasal iris coloboma. Uncorrected vision with HTOV testing was 20/30 each eye. There was good stereopsis and no strabismus. Fundi were unremarkable. Her milestones and growth were entirely normal. There were no dysmorphic features. An MRI was unremarkable in terms of the orbits, optic nerves, and chiasm. There was a small arachnoid cyst just anterior to the supero-lateral right prefrontal gyrus. Her mother was diagnosed with glaucoma at age 14 and had an otherwise normal ophthalmologic examination. Her father had no visual concerns. He has had recurrent renal calculi and is thought to have bilateral ureteral malformations. Chromosome microarray analysis (CMA) identified a de novo 271.8kb deletion at 18p11.22 (chr18:8,642,237-8,914,059), encompassing the CCDC165 gene, which encodes an unknown protein. Parental FISH studies were normal, showing that this abnormality occurred de novo. We performed *in situ* hybridization in the zebrafish, using a Locked Nucleic Acid (LNA) enhanced exon 5-specific probe from this gene. At 24 hours post-fertilization (hpf) we observed high level expression throughout the developing head, whereas at 48 hpf high level expression was restricted to lens, and a lower level expression in the retina and pharyngeal arch. Knock-down experiments of this gene are pending to further support this gene as causing coloboma. Our results show that CCDC165 is an excellent candidate for the occurrence of coloboma in this patient and illustrates the power of this approach for assessment of pathogenicity of copy number losses in patients with malformations.

1267T

Prenatal detection of mosaicism for del(10)(q11.2) caused by a common chromosomal fragile site FRA10G is associated with a normal phenotype. *J. Liao[1,2], M. Sathanoori[1,4], S.A. Yatsenko[1,3,4], U. Surti[1,2,3].* 1) Pittsburgh Cytogenetics Laboratory, Magee-Womens Hospital of UPMC, Pittsburgh, PA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Department of Obstetrics, Gynecology and Reproductive Sciences, University of Pittsburgh School of Medicine, Pittsburgh, PA.

Chromosomal fragile sites are specific loci which exhibit structural instability visible as gaps, constrictions or breaks on metaphase chromosomes exposed to certain cell culture conditions or treated with specific chemical agents. To date, over 120 different fragile sites have been identified in the human genome. They are classified as rare or common based on their frequency in the population. Although common fragile sites are currently considered present in all individuals as an intrinsic part of the normal chromosome structure, they have been implicated as breakpoints in the *in vivo* chromosomal rearrangements found in various cancers. In *in vitro* culture conditions, deletions at fragile sites can also occur. However, the possible implication of common fragile sites at prenatal diagnosis is still poorly documented. Here we report 13 prenatal cases with mosaicism for chromosome 10q deletion identified by karyotype analysis of CVS samples. Percentages of mosaicism range from 4% (2 out of 50 cells) to 24% (12 out of 50 cells). These cases share a similar breakpoint at 10q11.2, where a common fragile site, FRA10G is also located. Clinical follow-ups found normal live births without any phenotypic anomalies for all these cases. Therefore, our results indicate that the prenatal mosaicism of del(10)(q11.2) appears to represent an *in vitro* culture event due to FRA10G fragile site in this region and is not likely to cause any clinical consequences, which may ease the anxiety caused by the similar situation at prenatal diagnosis in the future and eliminate the need for a follow-up amniocentesis if the ultrasound is normal. To our knowledge, it is the first report of an association between this common chromosomal fragile site and a prenatal chromosome structural mosaicism.

1268T

Identification of a recombination hotspot sequence at the breakpoint region of the 22q11 deletion using a yeast model. *T. Ohye[1], H. Inagaki[1], H. Kogo[1], M. Tsutsumi[1], B.S. Emanuel[2], H. Kurahashi[1].* 1) Div Molecular Genetics, Fujita Health Univ, Toyoake Aichi, Japan; 2) Div Human Genetics, Children's Hosp Philadelphia.

Chromosomal microdeletions cause a wide spectrum of genomic diseases such as the 22q11 deletion syndrome, the most frequent genomic disorder with a high frequency of *de novo* occurrences. The deletion breakpoints are mainly located within low-copy-repeats (LCRs). These microdeletions are predominantly mediated by unequal non-allelic homologous recombination during meiosis, while some arise via intra-chromosomal recombination between LCRs. In the current study, we established a yeast model system to identify sequences within the 22q11 LCR that induce the deletion. We studied three candidate sequences from within the LCRs in the 22q11 region, a 1.1 kb minisatellite, a 1.4 kb highly AT-rich repeat region (AT-rich-repeat: ATRR) and the ϒ-glutamyltranspeptidase (GGT) gene sequence. Recombination hotspot sequences for other genomic diseases, neurofibromatosis type 1 (NF1) and Sotos syndrome (SoS), were also used as controls. We inserted the *URA3* gene between two copies of *TRP1* genes, one of which carried the candidate sequence at its center. Homologous recombination between the *TRP1* sequences results in an interstitial deletion with the loss of the *URA3* marker, which can be identified in the presence of 5-FOA. As a result, we determined that the deletion frequency for the ATRR was greater than that for the NF1 or the SoS sequences. Other candidates, the microsatellite and GGT, showed a level similar to that of controls. Next, to investigate the mechanism of deletion, we created a POL1-inducible yeast model under the control of a GAL1 promoter. The deletion frequency of the ATRR-harboring yeast with low POL1 expression was significantly higher than that with high expression. Finally, we tested the ability of the candidate sequences to form non-B DNA structures *in vitro*. T7 endonuclease I, that displays cleavage activity for mismatched DNA, cleaved the plasmid with the ATRR. Our results suggest that potential secondary structures of the ATRR in the 22q11 LCR might cause slow or stalled replication inducing a chromosome deletion via intrachromosomal homologous recombination. This might represent a factor that contributes to the high frequency of *de novo* 22q11 microdeletions.

1269T

Subtelomeric microdeletions 19p13.3 are associated with gastrointestinal dysmotility, multiple congenital anomalies and global developmental delay. *S. Peddibhotla[1], S.W. Cheung[1], P. Stankiewicz[1], F. Probst[1], L.L. Harris[1], G.H. Vance[2], G.H. Scharer[3], L.K. Parsley[3], A. Patel[1].* 1) Baylor College of Medicine, Houston, TX; 2) Indiana University School of Medicine, Indianapolis, IN; 3) University of Colorado School of Medicine, Aurora,CO.

Chromosome 19 has the highest gene density, thus even small aberrations can have significant impact on physical and/or cognitive development. Here, we report five cases with a subtelomeric microdeletion in 19p13.3, ranging in size from approximately 400 kb to 1 Mb, which were identified by high-resolution array CGH. The clinical presentation in these patients was complex and included, gastrointestinal (GI) dysmotility with feeding difficulties, reflux esophagitis and delayed gastric emptying, hearing loss, atrial septal defect, unilateral kidney, global developmental delay, and dysmorphic features. The smallest region of deletion overlap contains approximately 40 genes. We are particularly interested in genes responsible for GI dysmotility, cardiac anomalies, and developmental delay. Disturbances in GI motility often result in decreased provision of enteral nutrition. The etiology of GI dysmotility is not well understood, but is believed to be multifactorial. The various contributing factors to GI tract dysmotility are likely impaired function of enteric nerves and smooth muscles of GI tract, systemic inflammatory response and multiple organ dysfunction. We have identified 12 candidate genes in the subtelomeric region of 19p13.3, which can play a significant role in aspects of the clinical phenotypes observed in these patients.

1270T

Narrowing down Congenital Heart Disease (CHD) critical region boundaries on chromosome 4q according to the phonotypes of a patient with 2q34-qter duplication and 4q34.2-qter deletion. *A. Rashidi-Nezhad[1,2], S.M. Akrami[1], N. Parvaneh[3], F. Farzanfar[4], C. Azimi[4], A. Reymond[2].* 1) Department of Medical Genetics, Tehran University of Medical sciences, Tehran, Iran; 2) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 3) Department of Pediatrics, Children's Medical Center, Tehran University of Medical Sciences, Tehran,Iran; 4) Department of Genetics, Cancer Research Center, Cancer Institute of Iran, Tehran University of Medical Science, Tehran, Islamic Rep. of Iran.

Introduction: Deletions of the distal part of 4q have been reported. The severity of the symptoms is dependent on deletion size. It ranges from minor anomalies in individuals with 4q34 deletion to severe abnormalities in patients with 4q31 deletions. In this report, we describe a patient with 2q34-qter duplication and 4q34.2-qter deletion and compare his phenotype with previous publications allowing to further restricting the HSA4 critical region for Congenital Heart Disease (CHD). Patient: - We present a 10 months boy with developmental delay, growth retardation, hearing problem, facial and non-facial minor anomalies. He was born to a 30 years old mother with a history of recurrent fertility problems. - Methods: - Both G-banded metaphase karyotypes and array CGH were used to map the rearrangements in the proband and his mother. - Results: - Proband genotype was as follow: 46,XY , Dup(2)(q34-q35.2) mat, Del(4)(q34-q37.3) mat.arr 2q34q37.3(209,962,499-242,703,145)×3 mat ,4q34.2q35.2(177,717,642-191,220,565)×1 mat. And his mother karyotype was 46,XX,t(2;4)(q34;q34). Discussion: Our patient is deleted for 13.5 Mb on the distal portion of the long arm of HSA4. A region was suggested to harbor a 10 Mb critical region for CHD and PRS at 4q34.1-4q34.3 (Rossi et.al. 2009). Our patient did not present any of these two symptoms allowing us to propose a shorter 3.1 Mb critical region from 4q34.1 to 4q34.2. The proband also harbors a 32.7 Mb duplication of the terminal end of 2q. Notably, none of the major congenital anomalies, such as congenital heart disease or urinary tract malformations found in more proximal duplications, are present suggesting a critical region from band 2q31 to q34.

Comparison of two different high-resolution genomic arrays, the Affymetrix® Cytogenetics 2.7 versus the Genome-Wide Human SNP 6.0 Array, for diagnosis of CNVs in patients with intellectual disability. *R. Asadollahi[1], B. Oneda[1], S. Azzarello-Burri[1], R. Baldinger[1], A.B. Ekici[2], D. Niedrist[1], A. Reis[2], D. Bartholdi[1], A. Baumer[1], A. Rauch[1].* 1) Institute of Medical Genetics, University of Zurich, Schwerzenbach-Zurich, Zurich, Switzerland; 2) Institute of Human Genetics, University of Erlangen-Nuremberg, Erlangen, Germany.

Array-based comparative genomic hybridization (aCGH) has demonstrated to be a valuable tool in the diagnostics of patients with intellectual disability (ID) and multiple congenital abnormalities (MCAs) due to the high-resolution pangenomic coverage. Diagnostic yield of aCGH depends on the number of array markers and signal to noise ratio of the respective array type. Higher number of markers can increase the resolution for detecting small copy number variants (CNVs). However, detecting higher number of small CNVs may decrease the ratio of clinically significant CNVs to polymorphisms and optimized CNV assays may limit SNP genotyping. Affymetrix® Genome-Wide Human SNP Array 6.0 (1.8 M markers) is widely used to perform high-resolution CNV profiling and to obtain SNP genotyping data for homozygosity mapping, linkage analysis and association studies. On the other hand, Affymetrix® Cytogenetics 2.7 Array (2.7 M markers) is technically optimized for CNV detection with even higher resolution and is still capable to detect stretches of homozygosity. Nevertheless, the 2.7 array is not able to genotype single SNPs. To investigate if the 2.7 array optimized for CNV detection indeed reveals more clinically significant CNVs, we compared CNV results of the two array types in 27 patients with ID and/or MCA. Interestingly, we could identify 5 potentially clinically relevant CNVs of small size (2-48 kb, confidence levels 87%-96%) with the 2.7 array which could not be detected with the 6.0 array. 2 out of the 5 aberrations deleted single exons of known disease genes compatible with the phenotype of the patients and were confirmed as de novo with MLPA. Furthermore, 1 large duplication of 34 Mb in mosaic form was detected by the 2.7 array which was absent in the 6.0 array and could explain the patient's phenotype. FISH studies confirmed the presence of an additional marker chromosome. The optimized design of the 2.7 array by removing commonly false positive or highly variable markers and increasing the markers in critical sites has reduced the number of non-significant results considerably (mean: 44.9 in 2.7 array vs. 231 in 6.0 array without any filter) and simplifies the analysis. In our comparison, no relevant aberration detected with the 6.0 array was missed in the 2.7 array. Our results with at least 11% (3/27) of clinically significant small CNVs or mosaicism missed by the 6.0 array demonstrate the higher diagnostic value of the 2.7 array optimized for CNV detection.

1272T

Familial 5q14.3-5q21.1 duplication associated with microcephaly and developmental delay characterized by Array-Based Comparative Genomic Hybridization. *S. Ebrahim[1,2], D. Stockton[3], R. Chikamane[3], M. Hankerd[2], M. Kristofice[2], J. Wojciechowski[2], A.N. Mohamed[1,2].* 1) Department of Pathology, Wayne State University School of Medicine, Detroit, MI; 2) Detroit Medical Center University Laboratories, Cytogenetics; 3) Division of Genetic & Metabolic Disorders, Children's Hospital of Michigan.

We describe a brother and sister from a non-consanguineous family who have a partial duplication of chromosome 5 long arm documented by chromosomal microarray analysis and confirmed by focus high resolution chromosome and or FISH analysis. Since their parents are phenotypically normal and do not have the duplicated 5q in their blood lymphocytes, the most likely explanation is germ-line mosaicism. A seven year old girl with microcephaly, developmental delay and ventricular septal defect (VSD) was found to have a 12.89 Mb duplication involving chromosome 5q14.3q21.1 long arm region which was confirmed by FISH analysis. This duplication contains at least 44 genes including several developmentally important genes. Parental FISH analysis was performed and neither parent was found to carry a duplication of this region in their lymphocytes. The patient has two younger siblings, a six year old brother and a one year old sister, both of whom have microcephaly and developmental delay but no cardiac defect. Microarray analysis revealed that the six year old brother also had the same dup 5q14.3-q21.1 which was confirmed by focus high resolution chromosome analysis. The one year-old sister has not yet been tested. Parental chromosome analysis was performed and neither parent was found to carry rearrangements involving chromosome 5 or a duplication of this region in their lymphocytes. Partial duplication for chromosome 5q is relatively rare, and is associated with a wide range of phenotypes depending on the size and location of the duplicated region. Generally, it includes hypotonia, dysmorphic features, microcephaly, growth, and psychomotor developmental delay. Our cases represent a novel familial duplication syndrome of chromosome 5q with variable expression of features that include developmental delay, dysmorphic features, and cardiac defect. The clinical variability within the family carrying the same 5q duplication is emphasized by the differing associated anomalies in these siblings, who were discordant for congenital heart disease while both had microcephaly and developmental delay. The presence of the dup 5q in the siblings and the normal parental blood chromosome/FISH results is that one of the parents has germ-line mosaicism.

1273T

Pathogenic chromosomal aberrations in the families with Mental Retardation and developmental delay detected by array-CGH. *V. Kucinskas[1], J. Kasnauskiene[1], Z. Ciuladaite[1], E. Preiksaitiene[1], A. Alexandrou[2], G. Koumbaris[2], P. Patsalis[2].* 1) Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania; 2) Department of Cytogenetics and Genomics, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

The introduction of array CGH into the diagnostic work-up of patients with mental retardation and congenital malformations provides a unique possibility to identify novel microdeletion/ microduplication syndromes, as well as to expand the phenotype, to identify reciprocal products and to elucidate genomic etiology of previously well known conditions and thus allows more accurate and target care and genetic counseling. We report on the results of array-CGH study of 98 karyotypically normal patients with syndromic/ non-syndromic mental retardation/ developmental delay (MR/DD) of unknown origin. The results were confirmed and origin of alterations was revealed by RT-PCR. 15 chromosomal aberrations in 13 patients were considered as pathogenic: 11 de novo (del(2)(q24.2q24.3), del(2)(q27.3), del(4)(q21.22), del(5)(q14.3q14.1), del(5)(q14.3), del(6)(q21), del(16)(q23.1), del(7)(q35q36.1), del(16)(p11.2), dup(5)(q35.3), dup(7)(p22.1)) and 4 inherited (del(16)(p11.2), del(4)(q28.3), del(10)(p14), del(21)(q22.3). The first familial alteration in known pathogenic region was inherited from mother with mild mental retardation, while other three aberrations were inherited from an apparently healthy parent yet have not been reported as polymorphic CNVs in the Database of Genomic Variants. Further molecular analysis is essential to confirm the possibility of incomplete penetrance and variable clinical phenotype in these cases. The efficiency of array-CGH method in our study is 13.3% and demonstrates its successful application in genetic diagnostics of MR/DD. The research was funded by the European Union 7th Framework Programme [FP7/2007-2013] as part of the CHERISH project (www.cherishproject.eu, grant agreement No. 223692).

1274T

Detection of chromosome abnormalities of spontaneous aborted samples using multiple ligation-dependent probe amplification (MLPA). *S.W. Lyu[1], S.R. Sung[2], J.E. Park[2], K.M. Kang[2], M.U. Chin[2], J.W. Kim[1], D.H. Cha[1,2], S.H. Shim[2].* 1) Department of Obstetrics and Gynecology; 2) Genetics Laboratory, Fertility Center of CHA Gangnam Medical Center, CHA University, Seoul, Korea.

Background: About 50% of spontaneously aborted samples shows chromosome abnormalities, mainly numerical abnormalities such as aneuploidies and triploidy. Routine chromosome analyses of aborted samples are performed by tissue culture method. However, this method is labour-intensive and time-consuming and has a significant failure rate (up to 40%) due to poor sample quality. Multiple ligation-dependent probe amplification (MLPA) is a multiplex PCR method detecting abnormal copy numbers of up to 50 different genomic DNA simultaneously. As a molecular cytogenetic method, MLPA can detect various chromosomal imbalances, such as aneuploidies, partial deletions and duplications, depending on the probe set used. Aims: this study aims to evaluate whether the MLPA with subtelomeric probe mix is to be an alternative method of routine chromosome analysis for spontaneous aborted samples. Materials and Methods: Total eighty of abortus samples were examined. The samples were analyzed using both MLPA and routine culture method. Cell culture and conventional chromosome analyses were carried out using standard methods. For MLPA analyses, SALSA70 probe mix which contains probes for subtelomeric regions of all human chromosomes was used. All procedures including multiplex PCR and capillary electrophoresis were performed by manufacturer's protocol. The data were analyzed by the GeneMarker® software and compared with results from routine culture method. Results: Chromosome analyses were performed in 68 cases out of 80. The other 12 (15%) cases were failed to culture. On the other hand, MLPA results were successfully obtained from all 80 cases. The results of sixty four cases were concordant in both MLPA and karyotype results. However, in 4 cases, the results were different from each other due to maternal cell contamination, polyploidy, and mosacism. For 12 culture failed cases, MLPA results showed that seven cases were aneuploidies and the other 5 cases were normal. Conclusion: MLPA is less labour-intensive and more cost-effective than routine karyotype analysis. Moreover, MLPA technique shows a higher success rate and more accuracy than routine karyoptye analysis for abortus samples although MLPA method cannot detect polyploidy (3n or 4n) and balanced translocation.

1275T

Uniparental disomy: Can SNP array data be used for diagnosis? *T. Tucker[1], K. Schlade-Bartusiak[2], P. Eydoux[2], T. Nelson[1], L. Brown[2].* 1) Molecular Genetics Laboratory Dept of Pathology & Lab Medicine Children's & Women's Health Centre of BC; 2) Cytogenetics Laboratory Dept of Pathology & Lab Medicine Children's & Women's Health Centre of BC.

Chromosome microarray analysis (CMA) is recommended as a first tier test for the detection of copy number variants (CNVs) in individuals with developmental delay and autism, replacing disease specific testing using conventional methodologies. In addition to the detection of CNVs, SNP-based CMAs can identify long continuous stretches of homozygosity (LCSH), usually present on multiple chromosomes and associated with consanguinity. When LCSH are restricted to one chromosome, it may reflect UPD; either over the whole chromosome (isoUPD) or segments of the chromosome (heteroUPD). The LCSH in heteroUPD results from recombination during meiosis I (MI). Complete heteroUPD results from a lack of recombination between homologues and on CMA, would have the same appearance as normal biparental inheritance. Several chromosomes have clusters of imprinted genes associated with recognizable syndromes and are therefore sensitive to UPD; developmental delay is a feature of most of these syndromes. Whereas the power of CMA for CNV detection is well documented, very few studies have established the clinical use of CMA for the detection of UPD. To validate the use of Affymetrix 6.0 SNP CMA for the identification of UPD in a clinical laboratory, we retrospectively tested 8 UPD cases identified by conventional polymorphic microsatellite analysis. On CMA, 5 cases showed LCSH limited to a single chromosome, consistent with heteroUPD; the average total LCSH was 29Mb (17Mb-33Mb). Two cases showed complete homozygosity across the entire chromosome, consistent with isoUPD. However, SNP CMA failed to detect one case of UPD; the data showed no LCSH, suggesting a failure of recombination during MI and thus having the appearance of normal biparental inheritance. Recombination during MI is important to ensure proper segregation of the homologous chromosomes, and a failure to recombine at MI may predispose to non-disjunction and, therefore, to UPD. We have demonstrated that UPD will typically be identified by CMA as LSCH. Further, we have confirmed that failure of recombination may result in the inability to detect UPD using CMA. Therefore, a normal SNP CMA result does not exclude the possibility of UPD. Due to the possibility of false negative results, SNP CMA should not be used as a first tier diagnostic test for patients with a clinical diagnosis, or strong clinical suspicion, of a syndrome that may be caused by UPD.

1276T

Mosaic 27.49 Mb 18q terminal deletion with a non-mosaic 461 Kb deletion at the deletion breakpoint. *J. Wang[1], A. Hajianpour[1], B. Huang[2], R. Habibian[1], J. Szymanska[1], H. Zhu[3].* 1) Genzyme Genetics, Monrovia, CA; 2) Genzyme Genetics, Orange, CA; 3) Genzyme Genetics, Westborough, MA.

Chromosome analysis of a 9-day old male with dysmorphic features was reported as normal 46,XY. CGH analysis using Agilent custom 44K oligonucleotide array was performed on the same specimen. A ~38% mosaicism (log2 ratio of -0.304) for a 27.49 Mb terminal deletion of chromosome 18q was detected. Unexpectedly, a log2 ratio of -1 was observed for a 461 Kb sequence at the deletion breakpoint in 18q21.1, indicating a deletion of this region in all cells [arr 18q21.2q21.2(48,585,449-49,046,494)x1,18q21.2q23(49,078,395-76,076,801)x1~2]. A large 18q terminal deletion was subsequently observed cytogenetically in 4 of 50 additional metaphases examined. FISH analyses using the 18q subtelomere probe, BAC clone RP11-49E14 (48,822,719-48,977,691), and BAC clone RP11-45M11 (49,370,974-49,572,264) confirmed the array CGH results: RP11-49E14 (closest to the deletion breakpoint) is deleted in all cells, while RP11-45M11 (slightly distal to RP11-49E14) and the subtelomere probes are deleted only in cells with a visible deletion [ish del(18)(q21.2q21.2)(RP11-49E-,RP11-45M11+,qter+)[80]/del(18)(q21.2q23)(RP11-49E14-,RP11-45M11-,qter-)[4/80]. The much lower level of mosaicism observed cytogenetically as compared to that detected by array analysis can possibly be explained by a decreased viability of cells with the large deletion. Parental blood specimens are being sought in order to determine if the 461 Kb microdeletion is de novo. It is not clear if sequences around the breakpoints of the 461 Kb microdeletion predisposes to further deletion of sequences distally; there are no known segmental duplications that flank this microdeletion. No similar cases are found in the literature. This case again illustrates the power of chromosome microarray analysis in detecting and characterizing chromosome abnormalities. Exclusive of it, the etiology of this patient's abnormal phenotype and the 461 Kb microdeletion in all cells would not have been established. 1277T

Duplications of the DGS region on both chromosome 22 homologues in three patients - the co-occurrence on both homologues can involve both inherited and *de novo* events. *W. Bi[1], J. Wiszniewska[1], F.J. Probst[1], B.S. Carter[2], M.D. Williams[3], P. Stankiewicz[1], A. Patel[1], J.R. Lupski[1], S.W. Cheung[1].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Division of Neonatology, Monroe Carell Jr. Children's Hospital at Vanderbilt, Nashville, TN; 3) Division of Medical Genetics and Genomic Medicine, Vanderbilt University School of Medicine, Nashville, TN.

Genomic rearrangements associated with genomic disorders usually occur as heterozygous events involving only one of the two chromosome homologues. Recently, a patient with DiGeorge syndrome (DGS) was shown to inherit a common recurrent deletion from a father who was compound heterozygous for a 22q11.2 deletion and duplication; the father had no phenotype because of genetic compensation for gene dosage of this genomic disorder [Carelle-Calmels, et al.(2009) NEJM 360:1211-6]. We identified four copies of the Velocardiofacial/ DiGeorge syndrome (VCFS/DGS) region in three unrelated patients using chromosomal microarray analysis (CMA) revealed by FISH analyses to be duplications on both chromosome 22 homologues. The first patient is a newborn with cleft palate, mild micrognathia, hypertelorism, and patent ductus arteriosus. She is homozygous for a ~2.5 Mb common 22q11.2 duplication. SNP array analysis confirmed partial tetrasomy of 22q11.2, and did not show evidence of uniparental disomy (UPD) of chromosome 22. This duplication was also identified on one chromosome 22 in the mother, whereas the father was negative for the duplication. Paternity was confirmed by highly polymorphic variants used for identity testing. Thus, one 22q11.2 duplication was inherited from the mother, whereas the duplication in the paternally derived chromosome was presumably generated by a *de novo* nonallelic homologous recombination event during gametogenesis. The second patient also has the common 22q11.2 duplication on both chromosome 22 and the study of etiology for the homozygous duplication is ongoing. The third patient carries a common 22q11.2 duplication on one chromosome 22 homologue and a smaller LCR-flanked duplication of ~1.3 Mb including the *TBX1* gene on the other homologue. The common 22q11.21 duplication was inherited from the father, and the smaller duplication was inherited from the mother. Additional clinically significant copy number changes in the first and the third patient were inherited. Genotype-phenotype correlation showed that the homozygous duplication causes more severe disease; as has been previously reported for homozygous CMT1A duplication > 20 years ago! Our studies demonstrate that both inherited and *de novo* events can result in rearrangements on both chromosome homologues for a given locus and further amplify the role that gene dosage may play in conveying clinically relevant phenotypes.

The *PRR12* gene is disrupted by a *de novo* balanced t(10;19) chromosome translocation in a girl presenting with psychomotor retardation, aggression and seizures. *C. Córdova-Fletes[1,2], V. Kalscheuer[3], R. Ullman[3], P. Barros-Núñez[4], B. Verduzco-Garza[2], M.G. Domínguez[4], R. Ortiz-López[1,2].* 1) Bioquímica, Universidad Autonoma de Nuevo Leon, Monterrey, Nuevo Leon, Mexico; 2) Unidad de Biología Molecular, Genómica y Secuenciación, Centro de Investigación y Desarrollo en Ciencias de la Salud, Universidad Autónoma de Nuevo León, 64460. Monterrey, Nuevo León, México; 3) Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, D-14195 Berlin, Germany,; 4) División de Genética, Centro de Investigación Biomédica de Occidente, CMNO-IMSS, 44340 Guadalajara, México,.

Even though most of the balanced translocations are related to a normal phenotype, the risk to develop a clinical phenotype from a de novo balanced translocation is around 6.1%, and even higher in cases of complex rearrangements. It is suggested that balanced translocations also account for a congenital disorder in about 50% of the cases. This can be due to numerous factors such as the perturbation of dosage-sensitive genes at the breakpoints or any other genes surrounding it, or the not truly balanced or cryptic rearrangements. Frequently, gene disruptions or unbalances from those rearrangements lead to a variety of mental disability forms with or without additional clinical features. In the present case, we thoroughly characterized a de novo balanced translocation present in a girl with seizures, delayed psychomotor development and aggressive behavior. The patient's G-banded karyotype was 46,XX,t(10;19)(q22;q13.1)dn. Further analysis by Genome-Wide SNP arrays 6.0 indicated that the translocation was balanced. Mapping of the breakpoints by array CGH of flow sorted translocation chromosomes showed that both breakpoints disrupted a gene. On chromosome 10 *ZMIZ1* was truncated and on chromosome 19 *PRR12* was disrupted. The function of *PRR12* is presently unknown. Its high expression in brain during human and mouse cerebral cortex development let us suggest that it is the better candidate to account for the patient's clinical phenotype . Conversely, up to date, *ZMIZ1* deficiency has been related to the pathogenesis of inflammatory bowel disease and there is no indication that it plays a role in brain development and cognition. Summarizing, the molecular analyses presented here, revealed for the first time a disruption of the *PRR12* gene, which let us propose that haploinsufficiency of this gene could be responsible for the clinical phenotype present in the patient with the t(10;19) de novo balanced translocaton. This work was partially supported by FOMIX (Convocatoria M0014-2007-2010. Reg. 068251).

SNP arrays: comparing diagnostic yields for four platforms in children with developmental delay. *G. D'Amours[1,2,5], M. Langlois[3], G. Mathonnet[1], J.L. Michaud[1,2,4,5], M.S. Phillips[3], E. Lemyre[1,2,4,5].* 1) Service de génétique, CHU Sainte-Justine, Montréal, PQ, Canada; 2) Centre de recherche, CHU Sainte-Justine, Montréal, PQ, Canada; 3) Centre de pharmacogénomique, Institut de Cardiologie de Montréal, Montréal, PQ, Canada; 4) Pédiatrie, Université de Montréal, Montréal, PQ, Canada; 5) Faculté de médecine, Université de Montréal, Montréal, PQ, Canada.

Identifying the genetic causes of mental retardation and congenital abnormalities is important, both for the medical care of the patient and for genetic counseling. Recently, array genomic hybridization replaced conventional karyotyping as the first-tier diagnostic test in these patients, as it identifies a chromosomal abnormality in more patients (10-12% vs 3%).

New high-resolution platforms, combining copy number variation (CNV) detection and SNP genotyping, have been developed. In addition to identifying unbalanced chromosome rearrangements, they also allow the detection of loss of heterozygosity (LOH), and by extension, uniparental disomy (UPD).

We tested 21 children with developmental delay, and their parents, on four high-resolution arrays that combine CNV detection and SNP genotyping (Affymetrix and Illumina). We then compared the results with those of the medium-resolution array currently used at CHU Sainte-Justine (NimbleGen), to assess their diagnostic performance.

We identified a pathogenic chromosomal abnormality in three children, and they were successfully detected by each of the studied arrays. No other clear pathogenic change was identified by these high-resolution platforms. However, a number of CNVs that were classified in the final analysis as being of unlikely or uncertain clinical significance considerably burdened the analysis. No UPD for a whole chromosome was detected. Smaller LOH analysis is ongoing, and its usefulness remains to be determined.

Currently, high-resolution SNP arrays identify many CNVs whose clinical significance is presently hard to demonstrate. Therefore, their use does not seem to provide at the present time an additional benefit in the clinical setting. Our observations suggest that LOH and UPD detection using high-resolution SNP arrays appears to be theoretically justifiable, but this remains to be demonstrated.

1280T

Subtelomeric Deletion of Chromosome 10p15: Clinical Findings and Molecular Cytogenetic Characterization. *C. DeScipio[1], L.K. Conlin[2], J. Rosenfeld[3], J. Tepperberg[4], A. Patel[5], M.T. We describe clinical findings in twenty unrelated individuals with submicroscopic deletions of 10p15.3 characterized by chromosomal microarray (CMA). Interestingly, to our knowledge, only two such cases of isolated, submicroscopic 10p15.3 deletion have been reported. Common features among these individuals include: developmental or intellectual disability (19), craniofacial dysmorphism (9), language/speech delay/disorder (8), seizures (5), brain findings (5) hypotonia (5), short stature (5), GERD (2), constipation (2), spine abnormalities (2) and abnormal nipples (2). Among these twenty individuals, the male to female ratio is 9:10 (one, unknown). Parental CMA studies were performed for six individuals; the 10p15 deletion was de novo in each of the six probands. Two known genes, ZMYND11 (OMIM# 608668) and DIP2C (OMIM# 611380), map within the commonly-deleted 10p15.3 region (UCSC Genome Browser). The ZMYND11 (zinc finger MYND domain-containing protein 11) protein, first identified by its ability to bind the adenovirus E1A protein, localizes to the nucleus and functions as a transcriptional repressor with expression of E1A inhibiting this repression. The DIP2C (disco-interacting protein 2 homolog C) expression has been detected in all adult and fetal tissues and specific adult brain regions examined except lung and pancreas, where expression was low. As little is known about these genes in the 10p deleted region, a direct genotype/phenotype correlation is not clear at this time. We suggest that ZMYND11 and/or DIP2C haploinsufficiency causes clinical features associated with 10p deletions in our patients.

Cytogenetic analysis of an additional ten cells does not improve the detection of sex chromosome mosaicism. *J.T. Mascarello[1], M. Thangavelu[2].* 1) Genzyme Genetics, Santa Fe, NM; 2) Genzyme Genetics, Orange, CA.

The guidelines for cytogenetic analysis of blood set forth by the American College of Medical Genetics1 states “Cases being studied for possible sex chromosome abnormalities, in which mosaicism is common, should include a minimum of 30 cells counted”. We have examined the value of analyzing an additional 10 cells over and beyond a standard 20-cell analysis in 1081 patients with clinical indications for which a sex chromosome abnormality might be suspected. 996 cases (92%) had a normal karyotype and 85 (8%) had an abnormal karyotype. Of the 85 cases with an abnormal karyotype, 61 had no evidence of mosaicism, 9 had mosaicism involving normal and abnormal cells and 15 had mosaicism involving multiple abnormal cell types. In all mosaic cases, mosaicism was detected in the first 20 cells examined. Moreover, evaluation of more than 20 cells had only minor impact on the estimation of the proportions of the various cell types. These results support the conclusion of Wiktor et al (2009) that “analysis of 20 metaphase cells from a PHA stimulated peripheral blood culture is sufficient to identify sex chromosome abnormalities”. 1282T

21,5 Mb Mosaic Pure Inverted Duplication of Chromosome 1q42.13qter. *M.LM. Morris[1], C.N. Medina[2], E.L. Freitas[3], C. Rosenberg[3], S.F. Oliveira[1], I. Ferrari[1], J.F. Mazzeu[1].* 1) Departamento de Genética e Morfologia, Instituto de Ciências Biológicas, Universidade de Brasilia, Brasilia, DF, Brazil; 2) Secretaria de Estado de Saúde do Distrito Federal, DF, Brazil; 3) Departamento de Genética e Biologia Evolutiva, Instituto de Biociências, Universidade de São Paulo, SP, Brazil.

Distal duplications of the long arm of chromosome 1 are rare and have been reported as pure trisomy or as unbalanced translocations and patients demonstrate a wide range of manifestations of variable severity making it difficult to define a "partial trisomy 1q syndrome". In most cases, duplication is the result of an unbalanced translocation with possible imbalance of the other participating chromosome. Cases with pure partial distal trisomy 1q provide an opportunity to better define the partial distal trisomy 1q syndrome. Here we report on a female patient who presented with mildly delayed neuropsychomotor development, facial dysmorphisms and pectus excavatum. She also presented with patent foramen ovale. GTG-banding at 700 bands resolution identified a mosaic inverted duplication defined as 46,XX, dup(1)(q43q44),inv(q43p36.3)[16]/46,XX[14]. Array-CGH and FISH were performed to characterize the duplicated segments, exclude the involvement of other chromosomes and determine the orientation of the duplication. Duplication could be refined to chromosomal region 1q42.13-1q44 to a size of 21,5 Mb (225,696,992-247,164,526 Assembly NCBI36/hg18; 2006). FISH experiments confirmed the inverted orientation of the duplication. The patient presents with a pure 1q42.13qter inverted duplication of 21,5Mb, one of the smallest distal 1q duplications ever described and in mosaic, thus contributing to a better characterization of distal 1q duplication syndrome. However, her clinical signs are consistent to the distal trisomy 1q phenotype thus pointing to a more striking contribution of terminal duplicated segments to the syndrome.

1283T

45,X (40%); 46,X der X (ter rea) (60%) mosaicism. Case report. *M. Pérez Sánchez[1], A. Gonzalez Ramírez[2], A. Enriquez de Luna[3], A. Mora Guijosa[1].* 1) Análisis Clínicos, Hospital Virgen de las Nieves, Granada, Granada, Spain; 2) FIBAO, Hospital Clínico San Cecilio, Granada, spain; 3) Servicio de Ginecología, Hosptal Virgen de las Nieves, Granada, Spain.

End-to-end translocations or terminal rearrangements (ter rea) loading to duplications of nearly the entire X chromosome are rare but well know. Two X chromosome are joined together by either short or either long arms. Theoretically, union of the two chmosome can take place only after each chromosome has been broken. It follows that the ends of both involved arms should be missing. The clinical features rane from full-blown Turner syndrome to simple ovarian dysgenesis without stunted growth or the Turner stigmata. Delections on Xp end are previously been described causing amenorrhea and infertility. On the other hand, Turner mosaicism are present in an important group of Turner syndrome with a wide clinical features ranging from full-blown Turner syndrome to normal phenotype. Here we present a case of a 24 years old woman with that was referred for genetics stuies. The clinical findings were: amenorrhea without treatment response, normal secundary sexual caracteristics, hormonal status at normal levels, and hipoplastic the right ovary and no detection of the left one when magnetic resonance studies were done. No appreciable mental retardation were detected. Chromosome culture and karyotyping were realized by standard thecnics and showed a karyotype of 45,X (40 %); 46,X, der X (ter rea) (60 %). This result was confirmed by FISH in metaphase and interphase with CEPX and CEPY VYSIS probes. To determine the Xp region deleted in the X terminal rearrangement CHG-Array 60 K (Agilent) was done, a Xp terminal delection of 6.58 Mb including 17 genes was detected, with a chromosomic formula of 46,XX,arr cgh Xp22.33-p22.31 (NVBI37:2708827-9294878)x1. Mosaicism was not detected by CGH-Array due to the genomic amount compensation between lost of X chromosome in 45,X cells and the gain in the 46, X, der X (ter rea) cells. Both alterations detected in this patient (mosaicism and X terminal rearrangements) can present (in more or less degree) clinical features of Turner syndrome, but there are no sufficient data to determine previously the phenotypic effect of both alterations in the same patient. In this case the only clinical features detected were amenorrhea and ovaric disfuntion without appreciable mental retardation, that can be in concordance with the delection of Xp end due to the der X (ter rea) chromosome, and no extra effect can be detectable due to the effect of 45, X cells mosaicism.

Elucidation of inheritance and pathogenicity of CNVs: An approach to a better understanding and clinical utility of SNP arrays. *S. Schwartz[1], C.M. Smith[1], R.D. Burnside[1], I. Gadi[1], V. Jaswaney[1], E. Keitges[2], R. Pasion[1], V.R. Potluri[3], H. Risheg[2], J. Smith[3], J.H. Tepperberg[1], B. Williford[1], P.R. Papenhausen[1].* 1) Lab Corp of America, Research Triangle Park, NC; 2) DynaCare/LabCorp, Seattle, WA; 3) DynaGene/LabCorp, Houston Tx.

Since its introduction, the effectiveness of array analysis to delineate copy number variants not detectable by standard cytogenetic analysis has become apparent and previously undetectable changes are now identifiable. What has become clear is the difficulty in interpreting what these changes actually mean. In order to better understand the significance of the abnormalities detected, we have studied over 5,000 CNVs detected by SNP array. This study has focused on the size, type of abnormality, gene content, and frequency in the general population and inheritance of the CNVs to better understand the clinical significance of the detected abnormalities. Approximately 42% of the CNVs are simple deletions, 30% are simple duplications and 28% are complex abnormalities; 50% of the deletions and 45% of the duplications were greater than 1 Mb. Based on the gene involvement, 33% of the overall changes involved known pathogenic changes, 23% involve susceptibility genes and 44% involve changes with an unknown clinical effect. Parental studies indicate that 33% of the deletions were de novo, whereas only 16% of the duplications were de novo. The vast majority (~70%) of the de novo abnormalities were 1 Mb or greater and the familial cases were less than 1 Mb. 65% of deletions involving suspected pathogenic region but only 31% of duplications were de novo; 2% of duplications and 18% of deletions involve susceptibility regions were de novo. Lastly of those changes involving regions of unknown function, 28% of deletions and 15% of duplications were de novo. These findings provide an intriguing look into the CNVs delineated by array analysis including: (1) Based on size and pathogenicity initially 44% of cases are unknown with respect to phenotypic effect; (2) A larger than expected percent of de novo cases do not involve a reported pathogenic gene. This suggests that the pathogenic gene list needs to be expanded; (3) 34% of de novo cases have genes not previously described suggests that new syndromes can be defined; (4) Deletions are twice as likely as duplications to be de novo; (5) 60 different cases have been identified in our study that have been reported several times, one third of which that are currently not in the literature; (6) Many syndromes are much more variable than originally thought; and (7) This data taken together suggests that 79% of CNVs (and 96% of all samples) can be better defined, assigning a phenotypic range for better counseling.

1285T

A new microdeletion syndrome of 5q31.3 characterized by severe developmental delays, distinctive facial features, and delayed myelination. *K. Shimojima[1], B. Isidor[2], C. Le Caignec[2,3], A. Kondo[4], S. Sakata[4], K. Ohno[4], T. Yamamoto[1].* 1) Inst Integrated Medical Sciences, Tokyo Women's Med Univ, Shinjuku Ward, Japan; 2) Service de Génétique Médicale, Centre Hospitalier Universitaire de Nantes 7, Nantes, France; 3) INSERM, UMR915, l'institut du Thorax, Nantes, France; 4) Division of Child Neurology, Institute of Neurological Sciences, Faculty of Medicine, Tottori University, Yonago, Japan.

Chromosomal deletion including 5q31 is rare and only a few patients have been reported to date. We report here the first two patients with a submicroscopic deletion of 5q31.3 identified by microarray-based comparative genomic hybridization. The common clinical features of both patients were marked hypotonia, feeding difficulty in infancy, severe developmental delay, and epileptic/nonepileptic encephalopathy associated with delayed myelination. Both patients also shared characteristic facial features, including narrow forehead, low-set and dysmorphic ears, bilateral ptosis, anteverted nares, long philtrum, tented upper vermilion, edematous cheeks, and high arched palate. The deleted region contains clustered PCDHs, including PCDHA and PCDHG, which are highly expressed in the brain where they function to guide neurons during brain development, neuronal differentiation, and synaptogenesis. The common deletion also contains Neuregulin 2 (NRG2), a major gene for neurodevelopment. We suggest that 5q31.3 deletion is responsible for severe brain developmental delay and distinctive facial features, and that the common findings in these two patients should be recognized as a new microdeletion syndrome. We need further investigations to determine which genes are really responsible for patients' characteristic features.

1286T

How to recognize a recombinant pericentric inversion at array CGH. *R.F. Suijkerbuijk, L.K. Leegte, T. Dijkhuizen, B. Sikkema-Raddatz, J.B.G.M. Verheij, R.J. Sinke, C.M.A. van Ravenswaaij-Arts.* Genetics, University Medical Centre Groningen, PO Box 30.001, 9700 RB Groningen, The Netherlands.

INTRODUCTION: Large pericentric inversions may result in unbalanced offspring due to meiotic recombination within the inserted fragment. Since nowadays array-based analysis is the first diagnostic tool to examine patients with mental retardation and congenital anomalies, one should be aware that recombinant inversions present at array-CGH as a combined gain and loss of the terminal long and short arm, or vice versa, as we will demonstrate with two illustrative cases.

CASE 1 is a 20-year-old man with severe developmental delay and autism. Array-CGH resulted in a gain of 18p11.32 (1.07 Mb) and a loss of 18q21.33q23 (16.8 Mb). The terminal deletion 18q, also known as De Grouchy syndrome, could explain the phenotype in our patient. Parental chromosome studies were offered but denied. Nine months later we received amniotic fluid of the sister-in-law of our proband, because of ultrasound abnormalities. Karyotyping showed an abnormal chromosome 18 with extra material on 18p. Chromosome analysis of the brother of our proband and of their father revealed that both were carrier of an inv(18)(p11.32q21.33). Therefore, the result of the amniocentesis was interpreted as rec(18)dup(18-q)inv(18)(p11.32q21.33)pat and the karyotype of our proband as rec(18)dup-(18p)inv(18)(p11.32q21.33)pat.

CASE 2 is a 14-year-old girl with developmental delay and short stature. Her mother had experienced learning problems and premature ovarian failure. Array-CGH in the daughter resulted in a gain of Xp22.33p21.1 (33.6 Mb) and a loss of Xq27.3q28 (10.4 Mb). Karyotyping of mother and daughter showed that both have the same abnormal X chromosome, most likely the result of an inv(X)(p21.1q27.3) in the maternal grandmother.

DISCUSSION AND CONCLUSION: The concomitant gain and loss of the terminal long and short arm of the same chromosome at array diagnostics should alert to the possibility of a recombinant pericentric inversion. Further karyotyping studies in proband and parents are highly recommended, if necessary combined with metaphase FISH.

1287T

Confirmation testing for CNVs detected by whole genome microarrays: necessary or obsolete. *J. Tepperberg[1], E. Keitges[2], H. Risheg[2], J. Smith[3], V.R. Potluri[3], R. Pasion[1], B. Rush[1], R.D. Burnside[1], J. Jaswaney[1], I.K. Gadi[1], R. Royster[1], S. Moore[1], J. Kesler[1], S. Griffin[1], S. Schwartz[1], P.R. Papenhausen[1].* 1) Dept Cytogenetics, Lab Corp America, Res Triangle Pk, North Carolina; 2) Dept Cytogenetics, DynaCare/LabCorp, Seattle, Washington; 3) Dpet Cytogenetics, DynaGene/LabCorp, Houston, Texas.

Whole genome CMA testing has become the standard diagnostic tool for children with idiopathic MR, developmental delay, autism and congenital anomalies. Confirmation by a second standard method, such as FISH, MLPA, qPCR or chromosomes, if the abnormality was large enough, was recommended for early low resolution targeted arrays. However, new arrays have high density probe coverage that provide considerable redundancy and accuracy. While parental follow-up FISH is necessary to determine origin, recurrence risk and possible mechanism, the need to confirm high resolution arrays is questionable. This is particularly true for SNP arrays which provide an allele call that is not dependent on copy number changes and thus provides a secondary confirmation of genomic aberrations. We reviewed 2439 array positive cases based on size and probe coverage, to determine what percentage of the Affymetrix 6.0 SNP array results were confirmed by targeted BAC or commercial FISH. 2423 of 2439 (99.34%) cases were confirmed by FISH and 3 cases, where FISH confirmation was not appropriate, were confirmed by MLPA. All deletions and duplications > 1 Mb confirmed. Deletions between 500 kb-1 Mb, 100-500 kb and less than 100 kb were confirmed in 98.9%, 99.3%, and 94.0% of the cases, respectively. Duplications between 500 kb-1 Mb, 100-500 kb and less than 100 kb were confirmed in 99.5%, 98.8%, and 94.0% of the cases, respectively. Of the 16 cases that were considered inconclusive by FISH, BAC probe size, alignment of the copy number change (CNC) with respect to the available BACs, structural orientation of some small duplications (inverted vs. direct), absence of a second X chromosome homologue in males for comparison, presence of LCRs and probe coverage within the CNC complicated the analyses. These 16 cases would most likely confirm by other molecular methods. Thus, it appears that the inconclusive results were mainly due to technical problems rather than array reliability. The near 100.0% confirmation emphasizes the high accuracy of microarray testing. It also demonstrates (1) the high clinical concordance between microarray testing and FISH confirmation, (2) that confirmation of high resolution microarray testing for CNCs greater than 1 Mb is not required, (3) that 98.8% of deletions and duplications between 100 kb and 1 Mb confirm, (4) that CNCs below 100kb, particularly duplications, are more difficult to confirm, but would likely confirm by an alternate molecular technology.

1288T

Study on correlation between severe preeclampsia and abnormal expression of long-chain fatty acid oxidative enzyme. *X.L. Sun[1], Z. Yang[1,2], J.L Wang[1].* 1) Department of Obstetrics and G, Peking University Third Hospital, Beijing, China,100191; 2) Corresponding author: Zi Yang, zi_yang@email.com.

Objective: To investigate correlation between severe preeclampsia and abnormal expression of Long-chain 3 hyroxyacyl CoA dehydrogense (LCHAD). Methods: Serum-free trophoblast cells cultured in vitro were divided into four groups, which were stimulated by normal pregnancy serum(NP group), early onset severe preeclampsia serum (E-PE group), late onset severe preeclampsia serum (L-PE group), HELLP syndrome serum (HELLP group) respectively. Expression of mRNA and protein of LCHAD in trophoblast cells were detected by realtime PCR and Western Blot. Results: The relative expressions of mRNA of LCHAD in NP, E-PE, L-PE and HELLP groups were 1.00±0.00, 3.08±0.22,1.62±0.23,3.36±0.18 respectively. The relative expressions of mRNA of LCHAD were significantly reduced in E-PE, L-PE and HELLP groups compared with the NP group(P<0.05). Compared with the L-PE group, gene expressions of LCHAD were significantly decreased in E-PE and HELLP groups (P <0.05)), while no significant difference was found between the E-PE and HELLP group (P> 0.05). The relative expressions of protein of LCHAD in NP, E-PE, L-PE and HELLP groups were 4.94±0.02,2.93±0.13,4.14±0.06,2.80±0.09 respectively. The protein expressions of LCHAD were remarkably reduced in E-PE, L-PE and HELLP groups compared with the NP group (P<0.05). Protein expressions of LCHAD were remarkably decreased in E-PE and HELLP groups compared with the L-PE group (P <0.05)), while no significant difference was found between the E-PE and HELLP group (P> 0.05). Conclusions: These studies demonstrate that long chain fatty acid oxidation was involved in the pathogenesis and development of preeclampsia. The expressions of gene and protein of LCHAD were remarkably affected by early onset severe preeclampsia and HELLP syndrome. The Interaction mechanism and influence between fatty acid oxidation and the development of preeclampsia are worth further explored.(This work was supported by the grant of National Natural Science Foundation of China and Beijing Municipal Natural Science Foundation).

Study on the expression of LCHAD in trophoblast cells stimulated with different chain length fatty acids. *J.Lue. Wang[1], Z. Yang[1,2], X.L. Sun[1].* 1) Department of Obstetrics and G, Peking University Third Hospital, Beijing, China 100191; 2) Corresponding author: Zi Yang, zi_yang@email.com.

Objective: To investigate the influence among different chain length fatty acids on the expression of long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) in trophoblast cells. Methods: Serum-free trophoblast cells cultured in vitro were divided into five groups, which were stimulated by DMEM/F12 medium without FFA (F-FFA group), short-chain fatty acids (SC-FFA group), medium-chain fatty acids (MC-FFA group), long-chain fatty acids (LC-FFA group), very long-chain fatty acids (VLC-FFA group) individually. Expressions of mRNA and protein of LCHAD in trophoblast cells were detected by realtime PCR and Western Blot. Results: Among F-FFA, SC-FFA, MC-FFA groups, the gene and protein expreesion of LCHAD had no difference (P>0.05).Compared with F-FFA, SC-FFA and MC-FFA groups, the expressions of gene and protein of LCHAD were significantly reduced in LC-FFA group(P<0.05). while the LCHAD gene expression was significantly increased (P<0.05), but there were no difference in protein expression (P>0.05) in VLC-FFA group. Compared with VLC-FFA group, the expressions of gene and protein of LCHAD were significantly reduced in LC-FFA group (P<0.05). Conclusions: This study showed that there were different LCHAD expression in trophoblast cells stimulated with different chain length fatty acids. The Short-chain and medium-chain fatty acids had no effect on LCHAD expression in trophoblast cells. Long-chain and Very-long-chain fatty acids influenced the LCHAD expression in trophoblast cells significantly. Study on the gene and protein expression of p38MAPK and COX-2 in trophoblast cells stimulated by different chain length fatty acids. *Z. Yang, X.L Sun, J.L Wang.* Department of Obstetrics and G, Peking University Third Hospital, Beijing, China,100191.

Objective: To investigate the oxidative stress and inflammation in trophoblast cells stimulated by different chain length fatty acids. Methods: Serum-free trophoblast cells cultured in vitro were divided into five groups which were incubated with DMEM/F12 without FFA (F-FFA), short-chain fatty acids (SC-FFA), medium-chain fatty acids (MC-FFA), long-chain fatty acids (LC-FFA), very long-chain fatty acids (VLC-FFA). Then cells in each group were stimulated by DMEM/F12 medium, NADPH oxidase inhibitor (Apocynin) and p38MAPK inhibitor (SB203580) and were subdivided as each FFA plus-DMEM group, plus-NADPHΘ and plus-p38MAPKΘ groups. Expressions of mRNA and protein of p38MAPK and COX-2 in trophoblast cells were detected by realtime PCR and Western Blot. Results: Compared with other groups, the gene and protein expressions of p38MAPK in LC-FFA + DMEM, VLC-FFA + DMEM groups were increased (P<0.05). Compared with LC-FFA + DMEM group, gene and protein expressions of p38MAPK in LC-FFA + NADPHΘ and LC-FFA + p38MAPKΘ groups were significantly decreased (P<0.05). Compared with VLC-FFA + DMEM group, gene and protein expressions of p38MAPK had no difference in VLC-FFA + NADPHΘ groups(P>0.05), gene expression of p38MAPK in VLC-FFA + p38MAPKΘ group was significantly decreased (P<0.05), but there was no difference in protein expression (P>0.05). Compared with other groups, gene and protein expressions of COX-2 in LC-FFA + DMEM and VLC-FFA + DMEM groups were significantly increased (P<0.05), Compared with LC-FFA + DMEM group, gene and protein expressions of COX-2 in LC-FFA + NADPHΘ and LC-FFA + p38MAPKΘgroups were decreased (P<0.05). Compared with VLC-FFA + DMEM group, gene and protein expressions of COX-2 in VLC-FFA + NADPHΘ and VLC-FFA + p38MAPKΘgroups were all decreased (P<0.05). The correlation analysis showed there were significantly positive correlations between the gene and protein expressions of p38MAPK and COX-2 in LC-FFA group (P<0.05). There were significantly positive correlations in protein expression (P<0.05) but no correlation in the gene expression between p38MAPK and COX-2 in the other groups (P>0.05). Conclusions: The oxidative stress and inflammation may exist in trophoblast cells which were stimulated by Long-chain and Very-long-chain fatty acids. p38MAPK signal transduction pathway may contributed in this process. The interaction mechanism and influence among them are worth further explored. (supported by grant of NNSF of China and Beijing MNSF).

Biochemical and molecular characterization of the W1327X frequent mutation in Tunisian families with Glycogen storage disease type III (GSD III). *A. MILI[1,2], A. AMARA[2], I. BEN CHARFEDDINE[2], O. MAMAI[2], L. ADALA[2], A. AYADI[3], A. SAAD[2], K. LIMEM[1], M. GRIBAA[2].* 1) Biochemistry Department, Faculty of Medicine, Sousse, Tunisia; 2) Human Cytogenetics, Molecular Genetics and Reproductive Biology Laboratory. Farhat Hached Hospital, Sousse, Tunisia; 3) Paediatric Department, Tahar Sfar Hospital, Mahdia , Tunisia.

BACKGROUND: glycogen storage disease type III (GSD-III) is an inborn error of glycogen metabolism caused by a deficiency of the glycogen debranching enzyme (AGL). Some of the mutations appear to be population specific, whereas others are found in probands from a variety of different ethnic backgrounds. In this study we report a series of patient with homozygous AGL gene nonsense mutation 3980G>A (W1327X). METHODS: sixteen unrelated Tunisian families (from the region of Mahdia in the centerest of Tunisia), including 20GSD type III patients were presented with hepatomegaly and clinically symptoms of hypoglycemia. The routine laboratory investigations showed an elevated serum aspartate aminotransferase, alanine aminotransferase, creatine kinase and triglyceride levels. The blood lactate and uric acid levels were within normal limits. RESULTS: the 20 patients showed a striking elevation of glycogen content in the erythrocytes after several hours fasting and completely loss of debranching enzyme activity in leucocytes. Genotyping study, using four polymorphic microsatellite markers around AGL gene, identified a common haplotype for all patients. Direct sequencing of this gene reveal an homozygous W1327X mutation in exon 31. CONCLUSIONS: W1327X is the most characteristic Mahdia patient's mutation with GSD III. A common haplotype confirms the existence of a founder effect in this population.

Association Of Adiponectin And Leptin Gene Polymorphisms With Hypertension In Type 2 Diabetic Patients. *O. Khabour[1], S. Wehaibi[1], S. Al-Azzam[2], K. Alzoubi[2].* 1) Medical Laboratory Sciences, Jordan Univercity of Science and Technology, Irbid, Jordan; 2) Clinical Pharmacy, Jordan Univercity of Science and Technology, Irbid, Jordan.

Leptin and adiponectin are adipokines secreted by adipose tissue that play a role in regulating body metabolism and immune response. In this study, association of adiponedtin gene (ADIPQO) polymorphisms (G276T) and leptin gene polymorphisms (-G2548A) with hypertension in type 2 diabetic patients were examined. About 449 type-II diabetic patients from both genders were recruited in the study (199 normotensive and 250 hypertensive). Serum levels of adiponectin and leptin were measured using commercially available ELISA kits. Genetic polymorphisms were genotyped using polymerase chain reaction- restriction fragment length polymorphism (PCR-RFLP) method. Adiponectin level was significantly higher in normotensive compared to hypertensive subjects (P<0.05). However, there was no difference between the genotypes and alleles frequencies of SNP G276T between the two groups. In addition, G276T SNP did not affect serum adiponectin level in the two groups. Regarding leptin, neither serum level nor SNP G2548A were different between the normotensive and hypertensive groups. However, high G allele of SNP G2548A was associated with increased leptin level (P<0.05). When gender was included in the analysis, similar results were obtained. In conclusion, ADIPQO SNP G2548A and leptin G276T were not associated with hypertension in Jordanian type 2 diabetic patients.

1293T

Deficiency in Mthfr or low dietary choline may lead to adverse reproductive outcomes by modulating ApoAI and inflammatory mediators PPAR-alpha, IFN-gamma or IL-10. *L.G. Mikael, J. Pancer, Q. Wu, R. Rozen.* Human Genetics and Pediatrics, Montreal Children's Hospital, McGill University, Montreal, Quebec, Canada.

Methylenetetrahydrofolate reductase (Mthfr) deficiency, due to a polymorphism at bp 677, is the most common genetic cause of hyperhomocysteinemia (Hhcy). Mthfr synthesizes the major source of carbon units for folate-dependent remethylation of homocysteine (Hcy) to methionine. Choline, through its metabolite betaine, can also function as a methyl donor in folate-independent Hcy remethylation. Both Hhcy and mild MTHFR deficiency have been associated with birth defects, pregnancy complications and other adverse reproductive outcomes. We have previously shown that Hcy reduces synthesis of Apolipoprotein A-I (ApoAI), the major lipoprotein in HDL-cholesterol; ApoAI is regulated by PPAR-(and has anti-inflammatory properties. We had also shown that MTHFR deficiency and low choline diets in mice are associated with Hhcy and increased risk of developmental anomalies. To further address the mechanisms by which Hhcy influences pregnancy outcomes, we fed pregnant mice, with or without a deficiency of MTHFR, either a control diet or a choline-deficient diet (ChDD) and examined ApoAI and other inflammatory mediators (PPAR-(, IFN-. and IL-10). ApoAI mRNA was reduced in livers of Mthfr+/- mice; protein levels were reduced in livers due to Mthfr deficiency as well as choline deficiency; placental ApoAI protein was also reduced, particularly in developmentally delayed embryos. Reduced expression of PPAR-(mRNA and protein was observed in livers of mice fed ChDD and was associated with increased methylation of a CpG dinucleotide in its promoter. Hepatic levels of the pro-inflammatory cytokine IFN-. were increased in Mthfr+/- dams, and placental IFN-. levels were highest in Mthfr+/- dams fed ChDD. Levels of the anti-inflammatory cytokine IL-10 were reduced in livers of mice fed ChDD. PPAR-(levels correlated positively with ApoAI and IL-l0 levels in liver, while ApoAI correlated negatively with IFN-. in maternal and placental tissues. In conclusion, we propose that Hhcy, due to genetic or nutritional disturbances in one-carbon metabolism, reduces expression of Apoa1 and Ppara; the latter effect may involve promoter hypermethylation. Hcy also decreases IL-10 and increases IFN-. levels. This disturbance of the Th1 (IFN-.):Th2 (IL-10) ratio and the increase in inflammatory mediators may contribute to Hcy-induced pregnancy complications.

Large-scale replication using "Metabochip" array identifies additional genetic loci influencing glycaemic traits. *R.A. Scott[1], V. Lagou[2], E. Wheeler[3], R. Welch[4], R. Mägi[2], J. Luan[1], T.M. Teslovich[4], C. Langenberg[1], I. Prokopenko[2], I. Barroso[3] on behalf of the MAGIC investigators.* 1) MRC Epidemiology Unit, Cambridge, United Kingdom; 2) WTCHG, University of Oxford, Oxford, UK; 3) Wellcome Trust Sanger Institute, Cambridge, UK; 4) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI, USA.

Background: The Meta-Analyses of Glucose and Insulin-related traits Consortium (MAGIC) previously published the largest meta-analysis of genome-wide association studies (GWAS) for glycaemic traits in non-diabetic individuals, demonstrating 16 genome-wide significant loci for fasting glucose (FG) and 2 for fasting insulin (FI). The "Metabochip" is a custom iSELECT array of 217,697 SNPs, developed to support large-scale follow-up of putative associations for cardio-metabolic traits and fine-mapping of established loci. It contains >65,000 top-ranked, independent SNPs selected for replication of previous stage 1 meta-analyses of metabolic traits, including ~5k/1k selected for FG/FI replication, respectively ($10^{-75}<P_{\text{stage one}}<0.02$). **Methods:** To identify additional loci associated with FG/FI, we meta-analysed FG/FI replication SNPs in Metabochip genotyped studies (24/21 studies with 53,149/42,252 individuals, respectively), non-overlapping MAGIC GWAS discovery studies, and 15/13 new GWAS studies (25,618/23,130 individuals) using fixed effects meta-analysis (including up to 120,845/99,610 individuals in total). **Results:** We identified 11 novel loci for FG ($P<5\times10^{-8}$), 6 of which were in or near genes associated with other metabolic traits: *CENTD2*/*ARAP1* (type 2 diabetes [T2D]), *FOXA2* (T2D), *GRB10* (T2D), *PDX1* (MODY), *PCSK1* (obesity) and *PPP1R3B* (HDL-cholesterol). Five novel loci were located in or near genes encoding transcriptional repressors (14q31, 20q12), tRNA synthetase (14q32), nucleotide phosphodiesterase (10q24), and proinflammatory signalling kinase (9q31). Further, we identified 4 novel loci for FI including variants in or near *FTO* (BMI), *TCF7L2* (T2D, FG, HbA1C), *PPP1R3B* (HDL-cholesterol) and at 4q24 in a gene encoding a myelopoiesis-related protein. Also, 3 loci showed suggestive evidence of association ($P<5\times10^{-7}$) with FI, including *LYPLAL1* (WHR, fat distribution, fatty liver disease) and *ARL15* (adiponectin, T2D). **Conclusions:** Metabochip replication has allowed us to extend the number of genetic loci for FG and FI to 27 and 6, respectively. Identification of FI loci associated with lipids and fat distribution suggests a potential link to hepatic insulin resistance. The overlap of the novel FG/FI loci with established loci for T2D, metabolic and anthropometric traits highlights the complex relationships between these phenotypes. The Metabochip provides an efficient opportunity to widen our knowledge about the genetics of metabolic traits.

Gene and Pathway-based Analysis of 61 Genetic Variants in the Nicotinic Acetylcholine Receptor Genes and Insulin Resistance in American Indians. *J. Yang[1], SA. Cole[2], K. Haack[2], BV. Howard[3], LG. Best[4], RB. Devereux[5], ET. Lee[1, 6], J. Zhao[1].* 1) Biostatistics & Epidemiology, University of Oklahoma, Oklahoma City, OK; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) MedStar Health Research Institute, Hyattsville, MD; 4) Missouri Breaks Industries Research Inc, Timber Lake, SD; 5) The New York Hospital-Cornell Medical Center, New York; 6) Center for American Indian Health Research, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Background: Cigarette smoking impairs insulin action and induces insulin resistance which is an independent risk factor for cardiovascular disease and type 2 diabetes. Given the strong genetic predisposition for smoking behavior and insulin resistance, and the role of nicotinic acetylcholine receptors in nicotine dependence, we hypothesize that genetic variants in the nicotinic acetylcholine receptor genes are implicated in the relationship between smoking and insulin resistance. Methods: We genotyped 61 tagSNPs in seven nicotinic acetylcholine receptor genes (CHRNA3, CHRNA4, CHRNA5, CHRNA6, CHRNB2, CHRNB3, CHRNB4) in 3,665 American Indians, residing in Oklahoma (OK), Arizona (AZ) and North/ South Dakota (DK), recruited by the Strong Heart Study. Insulin resistance was assessed using the homeostatic model assessment. Cigarette smoking was categorized as current vs. nonsmokers. We first examined the association of each SNP with insulin resistance, adjusting for age, sex, smoking status, body mass index, systolic blood pressure, lipids, physical activity, fibrinogen, and renal function (assessed by estimated glomerular filtration rate). We then performed a gene-based analysis by including the adjusted p-values of all SNPs within a gene using the truncated product method. Pathway-based analysis was done using the p-values of all seven genes based on gene-based analysis. All analyses were stratified by study center (OK, AZ, and DK). Multiple testing was adjusted using the Bonferroni correction. Results: Prevalence of current smokers was highest in participants from DK (65.9%), followed by OK (57.8%) and AZ (50.3%). Insulin resistance level was highest in participants from AZ (6.3±6.6), followed by DK (5.5±8.2) and OK (4.7±6.3). Gene-based analysis showed that five genes were significantly associated with insulin resistance in participants from AZ ($P<0.0001$ for CHRNB2 and CHRNB4) and DK ($P<0.0003$ for CHRNA3, CHRNA4, CHRNA5 and CHRNB4), but not those from OK. Pathway-based analysis indicated that the nicotinic acetylcholine receptor pathway was significantly implicated in insulin resistance among participants from AZ and DK (both $P<0.0001$), but not those from OK ($P=0.18$). Conclusion: The nicotinic acetylcholine receptor gene family may play a role in insulin resistance among American Indians. Targeting this pathway may provide novel therapeutic strategies for the prevention and treatment of insulin resistance and related metabolic disorders.

MPS BRAZIL NETWORK International Program: Helping to identify MPS patients around the world. *R. Giugliani[1,2,3,4], K. Jesuino[1], A. Brites[1], M. Burin[1], S. Leistner-Segal[1], U. Matte[1,3], M. Wilke[1], A. Federhen[1,4], I.V. Schwartz[1,2,4], MPS Brazil Network members.* 1) Med Gen Service, HCPA, Porto Alegre, RS, Brazil; 2) Dep Genetics, UFRGS, Porto Alegre, RS, Brazil; 3) INAGEMP, Porto Alegre, RS, Brazil; 4) Postgraduate Program in Medicine: Medical Sciences, UFRGS, Porto Alegre, RS, Brazil.

OBJECTIVES: The MPS BRAZIL NETWORK (MBN) was created in 2004, aiming to improve the diagnosis and management of MPS diseases in Brazil. Since then, physicians from many countries have contacted MBN to request support for the investigation of patients with suspected MPS disease. METHODS: The contact with MBN has been mainly performed through the website www.redempsbrasil.ufrgs.br or through the email redempsbrasil@ufrgs.br. Customers could download informative materials and instructions for sample collection and shipment, as well as the educational material on MPS prepared by MBN. Services from several countries sent biological samples, usually dried blood spots, to the MBN headquarters, located at the Medical Genetics Service of Hospital de Clínicas de Porto Alegre, Brazil (MGS-HCPA), where the laboratory tests needed for the diagnosis of MPS were performed. RESULTS: From April 2004 to May 2011, 216 foreign patients with MPS suspicion were investigated. The MPS diagnosis was confirmed in 177/216 (82%) patients. The most frequent type of MPS diagnosed was MPS II, confirmed in 77/177 (42.9%) of the MPS patients, followed by MPS VI (23.1%) and MPS I (15.2%). Most of these patients are from Latin American countries (133/177, or 75.1%). However, there is an increasing referral rate from other continents, with significative numbers coming from Middle East (21%). CONCLUSIONS: The MPS-BRAZIL NETWORK is improving the diagnosis of MPS not only in Brazil, but also in other countries where access to diagnosis is not easily available. These results highlight the importance of not only having the information on MPS widely available, but also providing access to diagnosis of these diseases, especially now that treatment is possible for many of these conditions.

1297T

Simple and rapid testing for Citrin deficiency. *A. Kikuchi[1], O. Sakamoto[1], T. Ohura[2], Y. Matsubara[3], T. Saheki[4], K. Kobayashi[5], S. Kure[1].* 1) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan; 2) Division of Pediatrics, Sendai City Hospital, Sendai, Japan; 3) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 4) Institute for Health Sciences, Tokushima Bunri University, Tokushima, Japan; 5) Department of Molecular Metabolism and Biochemical Genetics, Kagoshima University Graduate School of Medicine and Dental Sciences, Kagoshima, Japan.

Citrin deficiency is an autosomal recessive disorder caused by mutations of the *SLC25A13*, and has two phenotypes: adult-onset type II citrullinemia (CTLN2) and neonatal hepatitis associated with intrahepatic cholestasis (NICCD). The clinical appearance of these diseases is variable, ranging from almost no symptoms to coma, brain edema, and severe liver failure that requires liver transplantation. Mutation analysis in *SLC25A13* is indispensable because of difficulties in the chemical diagnosis of citrin deficiency. Ten prevalent *SLC25A13* mutations account for 95% of mutant alleles in Japanese patients with CTLN2 or NICCD. The presence of these prevalent mutations is therefore favorable for genetic testing. Development of a simple test for these mutations would be desired. We have established the rapid and simple detection system of these seven mutation regions in *SLC25A13* using real-time PCR followed by melting curve analysis with adjacent hybridization probes (Hybprobe). We have made seven probe sets for the mutation detection. Each of six probe sets detects one mutation site, and another detects four mutation sites, which were clustered within a 21-bp region in exon 17. In the validation of the assay by single-blind manner, 76 test samples were correctly genotyped in the closed-tube assay, within an hour. This system would facilitate the genetic diagnosis of citrin deficiency, especially in East-asian populations. Also, it can be applicable not only to rapid diagnosis in any patients with suspected citrin deficiency, even showing atypical clinical presentation, but also to newborn screening at a much lower cost per sample by more high-throughput real-time PCR system, such as 384 or 1536 well format.

Molecular Genetics of Glycogen Storage Diseases. *J. Wang, G.L. Wang, F.Y. Li, M.L. Landsverk, W. Zhang, E.S. Schmitt, L.C. Wong.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Glycogen storage diseases (GSDs) are a group of inherited genetic defects of glycogen metabolism that is categorized into types 0-XII, based on the specific enzyme deficiency. Common GSD symptoms include hypoglycemia, hepatomegaly, developmental delay and muscle cramps. The GSD types 0a, I, III, IV, VI, IXa, IXb and X mainly affect liver; types 0b, V, VII and IXd mainly affect muscle. GSD type II affects nearly all organs. GSD type 0 caused by glycogen synthase deficiency. The outcome for untreated GSDs can be devastating. Early and accurate diagnosis, followed by proper treatment can greatly improve quality of life. DNA sequencing is the most effective method to confirm clinical diagnosis of GSD since it is rapid, accurate. The results will greatly facilitate carrier testing, prenatal analysis and genetic counseling. We have developed molecular testing for GSD types 0a, 0b, Ia, Ib, III, IV, V, VI, VII, IXa, IXb, IXc, IXd and X. All coding exons and their flanking regions were PCR amplified and sequenced. A total 305 patients with suspicion of GSD were referred to Medical Genetics Laboratories at the Baylor College of Medicine for sequence analyses of specific GSD genes. Among them, 125 (41%) were for GSD type Ia testing, which is the most common type of GSD. A total of 29 different mutations were detected in the G6PC gene (Type 1a), 6 (21%) of them are novel changes. Another 33 mutations have been detected in the remaining 13 GSD genes. Among them, 20 (61%) are novel changes. We have also identified two homozygous large deletions involving single or multiple exons in the GSD genes. The deletion of exons 3-5 of the G6PC gene has been confirmed by array CGH. The targeted array CGH confirmation of exon 16 deletion of the GBE gene (GSDIV) is pending. The overall positive rate in our patient cohort is 20%. Diagnosis of GSD used to depend on invasive liver or muscle biopsy and biochemical assays. Molecular analysis allows accurate diagnosis when enzymology is uninformative and identifies the pattern of inheritance. If a patient suspected to have GSD has hepatopathy as predominant symptom, analyses of GSD types I, III, IV, VI, IXa, IXb and X may be considered. If myopathy is the major symptom, then, testing of GSD types V, VII and IXd sequentially is suggested. This study underscores the importance of comprehensive molecular analysis to include genes of rare GSD types and targeted array CGH when glycogen storage diseases are suspected.

PHENOTYPE TO GENOTYPE CORALLATION IN A MILD FORM OF ISOVALERIC ACIDEMIA WITH NOVEL G391V IN THREE PATIENTS FROM A CONSANGINEOUS SAUDI FAMILY. *A.I Al-Aqeel[1,2], D. Colak[3], B. Al-Younes[4], A. Al-Bakheet[4], S. Tulba[4], F. Al-Mutairi[1], M. Al-Amoudi[4], A. Al-Odaib[4], N. Kaya[4].* 1) Department of Pediatrics, Riyadh Military Hospital,Riyadh, Saudi Arabia; 2) Stem Cell Therapy Program, King Faisal Specialist Hospital and Research Centre,Riyadh, Saudi Arabia; 3) Department of Biostatistics and Scientific Computing, King Faisal Specialist Hospital and Research Centre,Riyadh, Saudi Arabia; 4) Department of Genetics, King Faisal Specialist Hospital and Research Centre,Riyadh, Saudi Arabia.

Isovaleric acidemia (IVA) is an autosomal recessive rare disorder caused by a deficiency of isovaleryl-CoA dehydrogenase encoded by IVD gene. Numerous mutations in IVD have been reported in the literature. Here we present first Saudi IVD patients from a consanguineous family with a novel transversion mutation, causing conversion of Glycine to Valine at 391th amino acid on Exon 12 (G391V). The region around the site of the mutation was highly conserved among seventeen different species. Bioinformatics analysis proves the deleterious effects of the mutation. The change is “most likely” to interfere with the function of the IVD protein , with likely effect on its 3-D structure. This demonstrates the necessity of integrating the metabolome with the genome and proteome to bridge ``the genotype-to-phenotype gap”.

1300T

Meta-analyses of genetic association with body mass index in over 92,000 individuals using a gene-centric genotyping array. *Y. Guo[1], M. Lanktree[2], K. Taylor[3], G. Papanicolaou[4], N. Timpson[5], K. North[3], H. Hakonarson[1], L. Lange[6], B. Keating[1] on behalf of the IBC-BMI consortium.* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania 19104, USA; 2) Department of Biochemistry, University of Western Ontario, London, Ontario, Canada; 3) Department of Epidemiology, School of Public Health, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27514, USA; 4) Division of Cardiovascular Sciences, National Heart, Lung, and Blood Institute (NHLBI), Bethesda, Maryland 20892, USA; 5) MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, Bristol, United Kingdom; 6) Department of Genetics, School of Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27514, USA.

While genome wide association (GWA) studies have to date associated common variants across 48 independent loci with body mass index (BMI) at genome-wide significance (P < 5e-8), a gene-centric approach with equivalent or better coverage than GWA arrays can provide additional insight into genetic variants underpinning this trait. Thus to evaluate the association of common and low frequency single nucleotide polymorphisms (SNPs) with BMI, we used the ITMAT-Broad-CARe (IBC) genotyping array comprising up to 53,831 SNPs across ~2,100 cardiovascular-related loci. Participants included up to 78,436 individuals of European descent, 10,160 African Americans, 2,625 Hispanics, and 1,087 East Asians, across a total of 41 studies. Of the 48 established loci, ten have equal or greater coverage on the IBC array than GWA arrays. Eight of these ten loci contained a SNP(s) significantly associated with BMI at array-wide significance (P < 2.4e-6) in individuals of European descent. We describe one novel association for BMI in the *TOMM40-APOE-APOC1* locus at genome wide significance and in a previously reported gene *MC4R* we note a novel low frequency SNP, with minor allele frequency of 0.02, associated with BMI. Additionally, we performed secondary meta-analysis where we conditioned on the most significant SNP in each region in 50,933 individual of European descent and found two loci (*BDNF* and *MC4R*) showing independent signals. We also examined array-wide significant variants in the other three populations. The result indicated that directions of effects for all nine BMI signals in African Americans were consistent with those in European Americans. Finally and importantly, we observed more significant P values in seven of the nine loci in meta-analysis inclusive of the additional multi-ethnic samples, with two extra loci attaining array wide significance: *LGR4*, which is in the proximity but with limited linkage disequilibrium to the *BDNF* gene; and *NTRK2*, a BDNF receptor.

1301T

Genotype-phenotype correlations in Pompe disease. *A. Herzog, R. Hartung, E. Mengel, P. Hermanns, H. Runz, S. Gökce, J. Pohlenz, M. Beck.* Childrens Hospital, University Medical Center Mainz, Mainz, Germany.

Background Pompe disease is an autosomal recessive lysosomal storage disorder caused by a deficiency of the acid alpha-glucosidase. There is a broad spectrum of phenotypes from infantile to late onset forms. All patients show progressive skeletal muscle weakness leading to locomotive and respiratory dysfunctions. Objective: To characterize the genotypes of 37 patients with late onset Pompe disease and correlate them with the respective phenotype. Methods We clinically evaluated the patients and determined the molecular defects in the GAA gene by direct sequencing. Results On a total of 65 alleles 28 different mutations were found. In all patients 2 mutant alleles were identified except 1 pair of siblings. 30 late onset patients were compound heterozygous and 1 patient was homozygous for c.-32-13T>G, which leads to alternative splicing of exon 2 with about 10% of normally spliced products. 4 patients showed 2 other mutations each. First complaints of the c.-32-13T>G positive patients started at a median of 22 (3/34) years, whereas the late onset patients with 2 other mutations all had first symptoms in childhood at a median age of 5 (1.5/12.0) years. A milder affection of the patients with the common splicesite mutation also was seen by means of their mobility graduated by the Walton & Gardner-Medwin scale. 31% of them were able to walk and run freely (grade 0) and 51 % were able to climb stairs without banisters (grade 0-2). This wasn't achieved by any of the 4 patients with other mutations. 2 of them could climb stairs only with banisters (grade 3) and 2 of them weren't able to walk (grade 7 and 8). Furthermore, the c.-32-13T>G compound heterozygous patients had higher forced vital capacities with a median of 72% (50/98). One of the other patients needed an invasive ventilation and wasn't able to perform spirometry. The others had forced vital capacities of 32%, 50% and 56%. Conclusions This study confirms that phenotypic expression of Pompe disease primarily depends on the genotype. The common c.-32-13T>G splicesite mutation is associated with a milder phenotype than other mutations leading to the late onset form of the disease. Yet there is a broad variability in the enzyme activities as well as in disease severity between the patients bearing this mutation. Since this variability couldn't be explained by the mutations on the second allele, it is likely that there are existing secondary disease modifying factors.

1302T

MCAD mutation spectrum in individuals identified through newborn screening. *A. Millson[1], A. Openshaw[2], E. Lyon[1,3].* 1) ARUP Institute for Clinical & Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 2) ARUP Laboratories, Inc, Salt Lake City, UT; 3) Pathology Department, University of Utah, Salt Lake City, UT.

Medium-chain acyl-CoA dehydrogenase deficiency (MCADD) is an autosomal recessive inherited disease with a frequency of 1:6,500 to 1:17,000 in the US population. MCADD limits beta-oxidation of fatty acids in mitochondria, presenting in children and infants following a period of fasting and/or stress. A single point mutation in the ACADM gene, c.985A>G; p.304K>E, is the most common mutation associated with this disorder. 80% of patients are homozygous for c.985A>G and an additional 18% are heterozygous. The carrier frequency in the general population is 1/80. Due to the prevalence, and ease and benefit of clinical management, newborn screening for MCADD using MS/MS has been widely adopted. Confirmatory tests include plasma acylcarnitine profile, plasma carnitine, urine organic acids, and molecular testing. Since ARUP began offering ACADM sequencing, 2/3 of the samples received were for follow-up of abnormal newborn screening, and the remaining 1/3 were for other reasons including symptomatic patients. In a subset of cases we receive additional clinical and laboratory information, such as acylcarnitine profile results. Based on the interpretation of the acylcarnitine profile we evaluated the clinical sensitivity and specificity of our sequencing assay. Assessment of the clinical sensitivity (% of positive test results in patients with disease) found that for cases consistent with MCADD by acylcarnitine profile, slightly less than 50% carried two well-characterized pathogenic mutations, nearly 1/3 had one mutation and one variant of unknown significance (VUS) and in 3.5% no mutations were found. The clinical specificity (% of negative test results in persons without the disease) defined as acylcarnitine profiles not consistent with MCADD, identified individuals having either a single mutation consistent with carrier status or no mutations detected. In cases with acylcarnitine profiles possibly consistent with MCADD the vast majority were carriers, although in one case, one known pathogenic and one mild mutation were detected, possibly consistent with mild disease. Evaluation of the mutation spectrum of unique mutations found 48% were classified as uncertain, 41% pathogenic, 7% suspected pathogenic and 3% pathogenic-suspected mild. Of these, 79% were missense, 15% frameshift, 3% splice site and 3% nonsense. Periodic evaluation of clinical results to assess sensitivity and specificity as well as compilation of detected variants improves patient care.

The KUVAN® Adult Maternal Paediatric European Registry (KAMPER): Interim results on mutation frequencies of PKU patients. *A.C. Muntau[1], F.K. Trefz[2], A. Bélanger-Quintana[3], J. Alm[4], F.B. Lagler[5], A. Burlina[6], B. Destenaves[7], F. Feillet[8] on behalf of the KAMPER investigators.* 1) Molec Pediatrics, Univ Munich/DVH Childrens Hosp, Munchen, Germany; 2) School of Medicine University of Tuebingen, Reutlingen, Germany; 3) Hospital Ramon y Cajal, Madrid, Spain; 4) Karolinska University Hospital, Stockholm, Sweden; 5) Paracelsus Medical University, Salzburg, Austria; 6) University Hospital, Padova, Italy; 7) Merck Serono S.A. - Geneva, Switzerland, an affiliate of Merck KGaA, Darmstadt, Germany; 8) Hôpital d'enfants Brabois, Vandoeuvre les Nancy, France.

Objectives: KAMPER aims at providing information on the long-term safety of Kuvan treated patients with hyperphenylalaninemia (HPA) due to phenylketonuria (PKU) or BH4 deficiency, over the course of 15 years. Data from approximately 625 patients on growth, neurocognitive outcomes, adherence to diet, long-term sensitivity to Kuvan and pregnancy outcomes are expected. Methods: Observational, multi-centre, drug registry, including a maternal subregistry. Results: At first year interim analysis, four countries contributed a total of 58 patients with phenylalanine hydroxylase (PAH) deficiency and 15 with BH4-deficiency. This report includes results from PAH-deficient patients only. Patients were so far recruited in Germany (n=24), France (n= 19), Spain (n=13) and Italy (n=2). All results are expressed as median (Q1-Q3). The median age of recruited PKU patients was 9.7 years (6.4-14.9). Of these, 53% were male and 47% female. Most PKU patients (93%) were identified by newborn screening. Phenylalanine (Phe) concentration at newborn screening was 483 (371-727) µmol/L. A confirmatory test was performed in 86% of patients, the Phe concentration at this time point was 793 (478-1150) µmol/L. Information on the PAH genotype was available in 34 patients resulting in a total of 27 different genotypes. The majority of the reported genotypes were compound heterozygotes (25/27), while the most frequently encountered one was p.R261Q homozygous (n=4). Further analyses using the BIOPKU database to predict expected response showed that 18 genotypes could be classified as BH4-responders, 1 as slow responder and 3 as non-responders. Five of the reported genotypes have not been previously described in BIOPKU. According to the database, most of the genotypes found in KAMPER patients are associated with mild PKU/mild HPA. Almost all patients (95%) were tested for BH4 responsiveness, with the majority (64%) following a 24-hr loading test. Phe concentrations were reduced by ⁄ 30% in 51 of 55 patients tested. The mean daily Kuvan dose was 15 (10-20) mg/kg/day. Mild/moderate adverse events were reported in 3 PKU patients, which were deemed as not drug related. Conclusions: KAMPER provides a unique opportunity to gather a large collection of long-term follow up data related to BH4-responsive HPA in about 10 European countries. Future analyses will attempt to establish a link between the mutations and the metabolic status of the patients.

1304T

Biotinidase Deficiency Genotype-Enzyme Correlation and a Novel BTD Mutation Database. *M. Procter[1], A. Openshaw[1], D. Crockett[1], B. Wolf[3], R. Mao[1, 2].* 1) ARUP Laboratories, Salt Lake City, UT; 2) Department of Pathology, University of Utah, Salt Lake City, UT; 3) Henry Ford Health System, Detroit, MI.

Background: Biotinidase deficiency (BTD) is an autosomal recessive disorder that results in improper recycling of biotin. BTD affects 1 in 60,000 newborns and falls into two classes: profound/complete (<10% enzyme activity) and partial (10-30% enzyme activity). Over 160 mutations in *BTD* cause biotinidase to be nonfunctional or to be produced at very low levels. Biotinidase deficiency is characterized by skin rashes, hypotonia, developmental delay, alopecia, hearing loss or ataxia. These phenotypes may be mild or only exhibited when the patient is ill or stressed. Clinical diagnosis is dependent on presentation and biotinidase enzyme activity. Confirmation of BTD based on serum biotinidase activity is challenging due to enzyme instability. To identify mutations causing partial and profound BTD, we developed a full gene sequencing assay and a 5-mutation panel for the *BTD* gene. **Methods:** Full *BTD* sequencing and enzyme testing was performed on 113 samples. Eighty were extracted from serum and 33 were extracted from whole blood. Samples were amplified by touchdown PCR, Exo-SAP treated, and sequenced using Big Dye Terminator chemistry. We correlated enzyme activity partial (>2.0 U/L) and profound (<2.0 U/L) BTD with genotypes obtained by *BTD* mutation analysis. **Results:** Of 74 samples with enzyme levels <2.0 U/L, 61 (82%) had two causative mutations. In 32 samples with enzyme levels 2.1-3.5 U/L, we found 12 (38%) with two mutations. The remaining seven samples with enzyme activities >3.5 U/L revealed no samples with two mutations and four with only single mutations. **Discussion:** We were likely to find two causative *BTD* mutations when a sample had a very low biotinidase enzyme activity, however we did not find two mutations in partial or profound groups 100% of the time. We believe this is due to inaccurate enzyme quantification since the enzyme degrades rapidly when not frozen. For this reason the laboratory requests a paired sample from an unrelated donor be included with patient samples to for a sample handling control. In some instances *BTD* mutation analysis testing may be necessary for diagnosis of biotinidase deficiency. In the process of evaluating *BTD* mutations, we saw that information on *BTD* mutations was difficult to find. Consequently, we consolidated published mutations and added observed mutations along with clinical data if available, and made it publicly available in the form of a database(http://www.arup.utah.edu/database/BTD/BTD_welcome.php).

ABCA1 R230C variant do not contribute to dyslipidemia during gestational diabetes. *E. ZAMARRON-LICONA[1,2], M.C. MARTINEZ-LOPEZ[1], F. DE LA CRUZ-RUIZ[1], J.L. CORTÉS-PEÑALOZA[1], P. GARCÍA-GUERRA[2], R. DIAZ-MARTINEZ[3].* 1) LABORATORIO DE DIAGNOSTICO MOLECULAR, UNIVERSIDAD JUAREZ AUTONOMA DE TABASCO, VILLAHERMOSA, TABASCO, MEXICO; 2) HOSPITAL DE LA MUJER DEL ESTADO DE TABASCO, VILLAHERMOSA, TABASCO, MEXICO; 3) UNIVERSIDAD DE GUADALAJARA, GUADALAJARA, JALISCO, MEXICO.

INTRODUCTION. ABCA1 transporter plays a key role in low-HDL concentration [1]. R230C variant have been found in 10% low-HDL individuals. [2,3]. This variant is a risk allele for low-HDL, T2D in <40 years old and obesity in Mexican population. [4,5]. Gestational diabetes [6-8] is present in women with this risk allele (R230C). Objective: To determine association between R230C variant and dyslipidaemias during gestational diabetes. Methods: 182 obese women in the 24-week gestational age were recruited from the prenatal control service from Tabasco State “Hospital de la Mujer”, average age 28 years old. Glucose screening were useful to classify patients as cases when glucose⁄ 130mg/dl and as controls when glucose ≤130mg/dl. They accepted to participate by signing an informed consent. This project was accepted by both the Hospital and university bioethics committee. Glucose screening, oral glucose tolerance test (OGTT), Lipids profile (Cholesterol Total, CHT; triglycerides, TG; High Density Lipoproteins, HDL) A1c Hb, Insulin and blood type were performed in clinical laboratory of “Hospital de la Mujer”. Genotyping was carried out in the molecular diagnose laboratory at the university by Applied Biosystems' SNP Genotyping Assay for Taqman probe rs9282541 in a EcoTM Real-Time PCR system. Genotype-phenotype correlation and the association strength was determine with directional non-parametric tools for dichotomic ordinal variables, odds ratio (OR) was calculated as well in SPSS software v. 17.0. Results. Metabolic profile in both groups was not significantly different. Dyslipidaemias frequency were as follows: 71% hypercholesterolaemia, 89% hypertriglyceridemia, 11.6% High density lipoproteins lower than 35 mg/dl and 66.7% for mixed Dyslipidaemia (CHT+TG). R230C variant frequency between groups was: 25% control y 21.5% cases. Statistics analysis comparing Genotype-diabetes mellitus phenotype had not significant difference p⁄ .592 y OR=1.158: 0.9557, IC 95%. Association between Dyslipidaemias and genotypes CHT >200 mg/dl p= 0.127, OR =0.858: 1.569; TG >150 mg/dl p⁄ 0.985, OR= 1.003: 0.990 and CHT+TG p⁄ 0.235, OR = 0.896:1.405, IC 95%. Conclusión. In spite of R230C variant appeared in a higher frequency for that described for Mexican population (22.3%), It does not contribute to simple Dyslipidaemias (CHT, low HDL or TG) during gestational diabetes, however It is associated with mixed Dyslipidaemia (CHT+TG).

1306T

Massively parallel sequencing in suspected patients with mitochondrial disorders reveals multiple gene mutations unrelated to respiratory chain subunits or assembly factors. *V. Vasta[1], RP. Saneto[2,4], JL. Merritt II[3,4], S. Hahn[1,3,4].* 1) R&D, Seattle Children's Research Institute, Seattle, WA; 2) Department of Neurology/Division of Pediatric Neurology, University of Washington, Seattle, WA; 3) Department of Pediatrics/Division of Genetic Medicine, University of Washington, Seattle, WA; 4) Seattle Children's Hospital, Seattle, WA.

Purpose: Mitochondrial disorders are characterized by multi-organ involvement and often rapidly progressive clinical course. The variability in clinical presentation and the absence of a reliable diagnostic screening make the diagnosis very challenging. We explored a next-generation sequencing (NGS) test for mitochondrial disorders targeting the exons of 910 known and candidate nuclear genes in 25 patients. Methods: Targeted genes include subunits of the mitochondrial respiratory chain (RCC), assembly, transcription and translation factors, enzymes, carrier proteins and genes causing secondary mitochondrial defects or presenting with similar phenotypes. The exons of the genes were captured by in-solution hybridization followed by sequencing on an Illumina GAIIX. Results: Variants identified in two reference controls were 91.7% concordant with previous Sanger sequencing results. A complex insertion/deletion in *SURF1* gene (c.312_321del10ins2) was identified as a deletion of 8 bases. For analytic sensitivity, 90 variants detected by NGS were sequenced by Sanger and found 98.9% concordant. In intra- and inter-assay we observed an average of 1.3% and 1.8% CV respectively in the identification of coding variants. 98% of the targets were covered by >20 reads of Q⁄ 30. None of 16 patients with various RCC enzyme deficiencies presented mutations in either catalytic units or assembly factors. In 5 patients, significant alterations in *POLG1*, *CPT2*, *FASTKD2*, *SDHD*, *UBE3A*, *VARS2* (tRNA synthase) and *MTO1* (tRNA maturation) were found. Mutations in *PDSS1* were identified in a CoQ10 deficient patient. A previously described pathological mutation in *MFN2* gene was found in 2 patients, but further family studies suggest this mutation may not be clinically significant. Some patients carried mutations in two or more genes. Conclusion: This study underscores our hypothesis that sequencing only nuclear genes for RCC enzyme subunits and assembly factors may not provide the diagnostic answers for suspected patients with mitochondrial disorders. Our findings indicate that some previously described variants may not be pathological. Oligogenic cause for complex clinical presentations could be possible in some patients. Approximately one fourth of enrolled participants carried either known pathogenic mutations or variants of potential clinical significance. Despite the limitation in detecting all the pathogenic variants, our approach underscores considerable clinical benefits.

1307T

Mechanisms of *HLA-DQ* predispositions to type 1 diabetes in European and East Asian populations. *H. Miyadera, K. Tokunaga.* Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Japan.

HLA-DQ provide the strong genetic contributions to susceptibility and resistance to type 1 diabetes (T1D). It has been well established that haplotypes carrying non-Asp57) polymorphism in *DQB1* (*DQA1*03-DQB1*03:02*, *DQA1*05-DQB1*02*) associate strongly to T1D susceptibility in European populations. NOD mice model also encode non-Asp57) (*I-A*^{g7}), and the roles of non-Asp57) in selective peptide binding and TCR contacts have been proposed. However, neither models explain the disease pathway that might be shared with T1D susceptible haplotypes in East Asian population (*DQA1*03-DQB1*03:03/*04:01*), which carry Asp57). In this study we provide a comprehensive profile of HLA-DQ protein stability for all major *HLA-DQ* haplotypes, measured by an newly devised quantitative assay. Our data indicate the implication of HLA-DQ protein stability levels in susceptibility/protection to T1D, and offer a common mechanism that may underlie the association of *HLA-DQ* to T1D.

1308T

Study of mutation spectrum in patients with gaucher disease from India. *C. ANKLESHWARIA[1], M. MISTRI[1], A. BAVDEKAR[2], M. MURANJAN[3], J. SHETH[1].* 1) BIOCHEMICAL AND MOLECULAR GENETICS, FRIGE's INSTITUTE OF HUMAN GENETICS, AHMEDABAD, GUJARAT, India.Tele: ++91-79-26921414, Fax: ++91-79-26921415; 2) K.E.M. HOSPITAL, 489, RASTA PETH, SARDAR MUDLIAR ROAD, PUNE- 411011, INDIA. TELE: 020-66037300; 3) K.E.M. HOSPITAL, DEPARTMENT OF PEDIATRICS, PEDIATRICS RESEARCH LAB, PAREL, MUMBAI-400012, INDIA. TELE: 022-24136051.

Gaucher disease (GD), the most common lysosomal storage disorder, is caused by a deficiency of the lysosomal enzyme glucocerebrosidase (EC 3.2.1.45), leading to the accumulation of glucocerebroside within the tissue macrophages in multiple organs. Atleast 200 mutations in the gene for human glucocerebrosidase have been described till date. However in most, genotype-phenotype studies have focused upon screening for a few common mutations. The variants N370S, L444P, 84GG and IVS2+1G>A account for 90% of the mutant alleles in Ashkenazi Jewish whereas 50%-60% of mutant alleles were detected in non-Jewish individuals with type 1 GD. In the present study, nineteen unrelated individuals who were clinically and biochemically confirmed to have GD were investigated for mutation identification referred from various regions of India. N370S (c.1226G), L444P (c. 1448C), R463C (c. 1504T) mutations were analyzed by restriction fragment length polymorphism (RFLP) PCR. Out of 19 subjects investigated, 10 (52.63%) have shown L444P mutation, 2(10.52%) have shown R463C mutation while N370S mutation was not detected in any of the patients. This is the first report from India demonstrating high prevalence of L444P followed by R463C mutation in GBA gene in patients with Gaucher disease.

1309T

Airway obstruction and surgery in mucopolysaccharidosis type I (MPS I). *P. Arn[1], J.E. Wraith[2], L. Underhill[3].* 1) Division of Genetics, Nemours Children's Clinic, Jacksonville, FL; 2) Genetic Medicine, St. Mary's Hospital, Manchester, United Kingdom; 3) Global Medical Affairs, Genzyme Corporation, Cambridge, MA.

Background: Patients with MPS I typically undergo multiple surgical procedures during their lifetime to address various complications of this multisystemic disease. High rates of perioperative morbidity and mortality are observed among MPS I patients due to the anatomical and functional disruption of airway passages caused by glycosaminoglycan (GAG) accumulation in tissues of the respiratory tract and musculoskeletal system. Airway obstruction may be an indication, as well as a risk factor, for surgical intervention. Therefore, we examined the surgical data reported in the MPS I Registry to determine how often surgeries were performed for an airway-related indication. Methods: The MPS I Registry collects observational data to track the clinical progression and management of MPS I among the global patient population. As of May 2011, 987 patients were enrolled and diagnosed by clinical phenotype as follows: 574 Hurler, 220 Hurler-Scheie, 114 Scheie, and 21 undetermined. Patients with surgical data were included for analysis, and the surgical indication field was searched for terms consistent with airway-related surgery, excluding procedures for nasal polyps and ear tubes. Results were summarized as percentages by procedure type and patient phenotype. Results: Overall, 82% of the 987 Registry patients reported at least one surgical procedure for any indication, with similar percentages seen for Hurler (88%), Hurler-Scheie (85%), and Scheie (85%) patients. Surgeries for airway indications were more common among Hurler (24%) and Hurler-Scheie (22%) than Scheie (3%) patients. A total of 263 airway-related surgeries were reported for 165 patients, ranging from 1 to 6 surgeries per patient. Most procedures were performed to alleviate upper airway obstruction. The 3 most common procedures were adenoidectomy/tonsillectomy (n=152); bronchoscopy (n=40), and tracheostomy (n=38). Of note, tracheostomy procedures were performed in 36 patients (23 Hurler, 12 Hurler-Scheie, 1 Scheie), representing 3.6% of all Registry patients. Conclusions: Airway obstruction requiring surgical intervention is common in MPS I, and life-threatening conditions may arise among attenuated as well as severe phenotypes, as indicated by patients requiring tracheostomy. Since surgeries are performed on MPS I patients for indications other than airway obstruction, surgeons and anesthesiologists should be aware of this high-risk population.

1310T

TRANSCRIPTIONAL REGULATION OF CELLULAR CLEARANCE. *A. Ballabio[1, 2].* 1) Fondazione Telethon, Telethon Inst Gen & Med, Naples, Italy; 2) Baylor College of Medicine, Houston, Texas, USA.

As degradative requirements of the cell may vary depending on tissue type, age and environmental conditions, we postulated the presence of a system allowing the coordination of lysosomal activity. We discovered a gene regulatory network (CLEAR: Coordinated Lysosomal Enhancement And Regulation) that controls lysosomal biogenesis and function. The transcription factor TFEB acts as a modulator of the CLEAR network and it is physiologically activated by lysosomal storage. Upon activation, TFEB translocates into the nucleus, binds to CLEAR target sites in the promoter of lysosomal genes, induces lysosomal biogenesis and increases the ability of the cell to degrade complex molecules, such as glycosaminoglycans (GAGs) (Sardiello et al. Science 2009). More recent studies in our laboratory revealed that TFEB is directly involved in the regulation of two important cellular processes mediated by the lysosome: autophagy (Settembre et al. Science, DOI: 10.1126/science.1204592) and lysosomal exocytosis (Medina et al. submitted). Nuclear localization and activity of TFEB are regulated by serine phosphorylation mediated by the Extracellular Regulated Kinase 2 (ERK2), whose activity is tuned by the levels of extracellular nutrients. Similar to starvation, pharmacological inhibition of ERK2 induces autophagy by activating TFEB. Notably, TFEB-mediated activation of lysosomal exocytosis resulted in the clearance of the pathological storage in mouse models of in four different types of lysosomal storage diseases, and to a striking rescue of the cellular morphological abnormalities. These results reveal a novel mechanism that exerts a global control on the cellular degradation machinery and provide a tool to promote cellular clearance in human disease.

1311T

Higher Paraoxonase gene polymorphism frequency among Brazilian Fabry Disease patients. *A.C. Barris-Oliveira[1], K.B. Müller[2], L.T. Turaça[3], J.B. Pesquero[3], A.M. Martins[2], V. D'Almeida[1].* 1) Psychobiology, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Pediatrics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 3) Biophysics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil.

Paraoxonase (PON1) is an antioxidant enzyme which activity was described to prevent oxidation of lipoproteins by reactive oxygen species formed during oxidative stress, and also by its protective role in atherosclerosis. Several polymorphisms had already been described in the gene of this enzyme and these modifications may cause different enzymatic activities, which are related with unbalanced redox state. Oxidative stress has been considered a putative mechanism for pathophysiologycal changes among some lysosomal storage disorders, like Gaucher disease. Fabry disease (FD) is one of these disorders and is caused by a deficiency of alpha-galactosidase A resulting in globotriaosylceramide storage in lysosomes, and due to this accumulation, is associated with cardiomyopathy, early-onset stroke, progressive renal failure, and other features. The objective of the current study is to investigate PON1 polymorphisms, Gln192Arg (switch of an adenosine for a guanine) and Leu55Met (switch of a thymine for an adenosine) in FD patients. A total of 52 subjects were selected for the study, 26 controls and 26 patients (13 men and 13 women). Both polymorphisms were accessed in blood samples DNA, by PCR-RFLP using the restriction enzymes, *BspPI* for Gln192Arg and, *NlaIII* for Leu55Met. The allele frequencies of the polymorphism Gln192Arg for FD patients and controls were respectively, 0.38 and 0.25. For the polymorphism Leu55Met, allele frequencies for FD patients and controls were, 0.27 and 0.24 respectively. Comparing FD patients vs controls from Gln192Arg polymorphism, a significant difference was observed (Chi-square: 7.95), whereas Leu55Met showed no difference between FD patients and controls. Besides these analyses, another 83 FD subjects were analyzed for the same polymorphisms; however these patients were part of 3 families. The allele frequencies of Gln192Arg and Leu55Met obtained were, respectively, 0.44 and 0.19 for the Family 1 (21 patients), 0.60 and 0.33 for Family 2 (24 patients) and 0.28 and 0.33 for Family 3 (38 patients). The higher frequency of Gln192Arg polymorphism among FD patients highlighted the possibility of a correlation between the PON1 genetic variation and the phenotypes since the disease has a wide range of symptoms which until now could not be explained only by mutations on the GLA gene. Financial support: AFIP, FAPESP, CNPq and IGEIM.

Skin ultrastructural findings in type 2 Gaucher disease: diagnostic implications. *A. Chan[1], D. Crumrine[1], T. Fergusson[2], O. Goker-Alpan[2], R. Schiffmann[3], W. Hollean[1], P. Elias[1], E. Sidransky[2].* 1) Department of Dermatology, VA Medical Center & Uni, San Francisco, CA; 2) 2Section on Molecular Neurogenetics, Medical Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) 3Baylor Research Institute, Dallas, TX.

One of the major challenges in Gaucher disease, the inherited deficiency of lysosomal glucocerebrosidase, has been to distinguish type 2 Gaucher disease from the milder forms in young infants. Type 2 Gaucher disease is the rarest and most severe subtype, marked by rapid, early-onset neurodegeneration. Neither enzyme levels nor genotype reliably predict patient outcome. Making this distinction is essential for genetic counseling and for appropriate therapeutic considerations. The enzyme glucocerebrosidase also plays an essential role in maintaining epidermal permeability function, by regulating the generation of ceramides from glucosylceramides in the stratum corneum of the skin. Previous studies in a small number of patients with type 2 Gaucher disease revealed distinctive epidermal abnormalities, resembling alterations seen in a knock-out murine model of type 2 Gaucher disease. To further assess the diagnostic utility of such evaluations, the current study examined skin ultrastructure in an expanded cohort of twenty children with type 2 and two adults with type 1 Gaucher disease with varying clinical manifestations. Epidermal samples were evaluated by electron microscopy on ruthenium tetroxide post-fixed tissue. When compared to controls and subjects with type 1 Gaucher disease, only samples from patients with type 2 Gaucher disease displayed characteristic electron dense, non-lamellar clefts and immature-lamellar membranes in the stratum corneum. These changes were observed in young neonates as well as older babies, and were present even after enzyme replacement therapy. No abnormalities in the ultrastructure of corneodesmosomes, cornified envelopes, and the corneocyte lipid envelope were observed. In conclusion, the consistent and characteristic appearance of these changes continues to suggest that alterations in epidermal ultrastructure can provide a potential early diagnostic tool to distinguish type 2 Gaucher disease from other subtypes.

Diffusion Tensor Imaging and Volumetric Studies of the Brain in Canine Mucopolysaccharidosis I. *P.I. Dickson[1], J. Provenzale[2,3], S. Chen[2], I. Nestrasil[4], N.M. Ellinwood[5], S.Q. Le[1], S. Kan[1], S. Banakar[1], H. Boutte[2], E.G. Shapiro[4,6].* 1) Dept Pediatrics, LA BioMed Harbor-UCLA Med Ctr, Torrance, CA, USA; 2) Duke University Department of Radiology, Durham, NC, USA; 3) Emory University Department of Radiology, Oncology and Biomedical Engineering, Atlanta, GA, USA; 4) University of Minnesota Department of Pediatrics, Minneapolis, MN, USA; 5) Iowa State University Department of Animal Science, Ames, IA, USA; 6) University of Minnesota Department of Neurology, Minneapolis, MN, USA.

Standard magnetic resonance brain imaging correlates poorly with clinical outcomes in mucopolysaccharidosis I (MPS I), likely because findings lag behind the neuropathology. Ongoing studies (by E.G.S. and I.N.) of MPS patients reveal reduced fractional anisotropy (FA) of the corpus callosum (CC), disorganized fiber distribution in the centrum semiovale, and altered hippocampal volumes. We performed diffusion tensor imaging (DTI) of white matter tracts and volumetric analysis of the hippocampus in the canine model of MPS I. Four normal (age 18-28 m) and four MPS I dogs (age 24-26 m) underwent T1 and T2-weighted, proton density, and DTI of the brain on a 3T GE MRI scanner using an 8-channel knee coil. A three-dimensional fast spoiled gradient echo (FSPGR) sequence was employed for collecting structural data suitable for volumetric analysis (TR/TE/TI = 8.448/3.628/800 ms, flip angle = 8°, 124 axial slices, 1 mm slice thickness without interslice gap, in-plane resolution of 0.35 mm). The hippocampi were manually traced in BRAINS2 to generate a three-dimensional model for volume measurement. For DTI analysis, regions of interest were placed on FA maps in the peripheral frontal lobe white matter, the genu of the CC, the splenium of the CC, and the corticospinal tracts. Each animal was imaged twice, and values from each scan, right and left side (when applicable) were averaged. FA was 12.3 and 13.1% lower in the genu and splenium, respectively, of the CC in MPS I dogs compared to carrier dogs. This appeared to be due to reduced radial diffusivity ($3\perp$), which was 16.3% lower in genu and 19.7% lower in splenium of MPS I dogs. Myelin basic protein evaluation of the CC is underway. Hippocampal volumes were lower in MPS I dogs, averaging 0.553 ± 0.096 cm^3 for MPS I dogs and 0.662 ± 0.035 cm^3 for carrier dogs. The difference in hippocampal volumes persisted when indexed to body weight, but disappeared when indexed to brain weight, possibly indicating a difference in overall brain volume. Advanced brain imaging of the canine model may increase our understanding of MPS brain disease and lead to better ways to assess neuropathology in MPS patients.

1314T

Mucopolysaccharidosis IVA: A multidisciplinary approach. *P. Harmatz[1], C.J. Hendriksz[2], S. Tomatsu[3], W. Mackenzie[4], G.A. Solanki[2], B. Lee[5].* 1) Dept Gastroenterology, Children's Hosp Oakland, Oakland, CA US; 2) Birmingham Children's Hospital, Steelhouse Lane, Birmingham UK; 3) St Louis University, Edward A Doisy Research Center St Louis MO USA; 4) Alfred I Dupont Hospital for Children, Wilmington DE USA; 5) Dept Moleculr and Human Genetics, Baylor College of Medicine, Houston TX USA.

Mucopolysaccharidosis IVA (MPS IVA, Morquio A syndrome)is an autosomal recessive lysosomal storage disease characterized by excess storage of keratan sulfate leading to skeletal chondrodysplasia. Incidences of MPS IVA range from 1 per 76,000 to 600,000 live births. Patients with severe MPS IVA may experience significantly limited mobility associated with impaired endurance. The pathogenesis of bone dysplasia in MPS IVA is largely unknown and there is a lack of complete understanding of all clinical symptoms. To further understand the symptoms and treatments for MPS IVA, a summit was held with multidisciplinary experts to describe and develop a clinical understanding of MPS IVA, including organ-specific phenotypes of affected patients. Participants represented fields of inherited metabolic disorders, genetics, pediatrics, orthopedics, radiology, cardiology, anesthesiology, surgery (neuro and hand), pulmonology, physiotherapy, basic sciences and laboratory diagnostics. Progression and manifestations of severe and mild forms of MPS IVA were described. Management of patients with MPS IVA, including criteria for various corrective surgical procedures, management of airway compromise and risk of anesthesia, was discussed. Atlanto-axial instability with cervical cord compression and thoraco-lumbar kyphosis indicate severe spinal involvement. Concerns related to administration of anesthesia were discussed. In a survey completed by participants, all reported severe bone dysplasia and dwarfism to be the primary clinical characteristics of MPS IVA. Other reported primary clinical characteristics of MPS IVA were abnormal gait and facial features and cervical cord compression. Mitral valve stenosis and regurgitation appear to be the most prevalent cardiac manifestations and corneal clouding is commonly observed. Cardiac function is typically evaluated by flow echocardiogram and ECG and pulmonary function assessed by pulmonary function tests and sleep studies. Ligament laxity tests are not uniformly performed among participants. Participants agreed that a severity scoring system for MPS IVA is possible to develop (83%) and would be beneficial in practice (67%). MPS IVA is a genetic disease that affects multiple organ systems, hence diagnosis and management require a coordinated, multidisciplinary approach. Disease-related surgery should be performed by surgeons having a special interest in MPS diseases and anesthesiologists should be experienced with MPS patients.

Intrathecal Hydroxy-Propyl-Beta-Cyclodextrin reverses hearing loss in identical twin girls with Niemann-Pick Type C Disease. *C.A. Hastings, J. Torkildson, R. Raphael.* Pediatric Hematology/Oncology, Children's Hospital & Research Center Oakland, Oakland, CA.

Niemann-Pick Type C (NPC) is a rare, fatal, autosomal recessive neurodegenerative disorder caused by a defect in the NPC1 protein. Biochemically, NPC is characterized by intracellular accumulation of unesterified cholesterol and glycosphingolipids. No medical intervention has received regulatory approval in the USA to treat this disorder. Hydroxyl-propyl-beta-cyclodextrin (HPBCD) is a sugar compound shown to reverse cholesterol trafficking defects in murine and feline NPC models. We administered intravenous (IV) infusions of HPBCD under the FDA's Individual IND exemptions to 5 yr, 2 mos old identical twin, white females. Our patients had lost developmental milestones (speech and communication) and increasingly ataxic, despite treatment with miglustat beginning at 4 yrs 10 mos. We initiated IV HPBCD for 96 hours, followed by twice weekly infusions, escalating dosing if no toxicity. We observed no toxicities (stable hematology and chemistry panels, no SAEs occurred, and AEs were judged to be unrelated to study drug). The parents reported transient improvements in alertness and ataxia. HPBCD does not cross the blood-brain barrier in mice. Based on promising results in mice and cats with direct delivery into the central nervous system (CNS) demonstrating complete reversal or prevention of neurodegeneration in addition to prolongation of life, we amended our protocol to include HPBCD deliver to the CNS. Intrathecal (IT) infusion began at age 6 yrs 9 mos with an initial dose of 175 mg administered every 2 weeks by lumbar puncture. The twins received 6 injections without toxicity (CSF cell counts, protein, myelin basic protein remained normal) and continued to receive weekly administration of IV HPBCD (2500 mg/kg over 8 hours). After FDA review, we have continued every 2 week IT injections at an increased dose of 350 mg. Utilizing a validated NIH NPC Clinical Severity Score, the scores decreased from 36 at baseline to 29 (20% improvement). The most dramatic improvement was in hearing, assessed by brainstem auditory evoked response, which improved from moderate loss (80-95dBHL) at low frequencies and 45-65dBHL at high frequencies to mild loss (45-60dBHL) and normal (15dBHL), respectively, following 6 months of directed CNS therapy. This combination of systemic and central nervous system HPBCD drug delivery is a promising new therapeutic approach for children with NPC.

Chemical chaperone therapy for) -galactosidase deficiency. *K. Higaki[1], K. Ohno[1], Y. Suzuki[2], E. Nanba[1].* 1) Tottori University, Yonago, Japan; 2) International University of Health and Welfare Graduate School, Otawara, Japan.

) -Galactosidase deficiency is a group of lysosomal lipid storage disorder with autosomal recessive trait, which causes two clinically different diseases, GM1-gangliosidosis and Morquio B disease. It is caused by heterogeneous mutations of the GLB1 gene coding for lysosomal acid) -galactosidase. We have reported the chaperone effect of N-octyl-4-epi-) -valienamine (NOEV) on mutant) -galactosidase proteins. In this study we performed genotype analyses in patients with) -galactosidase deficiency and identified 46 mutation alleles including 9 novel mutations. We then examined the NOEV effect on mutant) -galactosidase proteins using 6 strains of patient-derived skin fibroblasts. We also performed mutagenesis to identify) -galactosidase mutants that are responsive to NOEV and found that 22 out of 94 mutants were responsive. Computational structural analysis revealed the mode of interaction between human) -galactosidase and NOEV. Moreover NOEV reduced GM1 accumulation and corrected impaired lipid trafficking and protein degradation in) -galactosidase deficient cells. These results provided further insights to the NOEV effect as a promising chaperone compound for) -galactosidase deficiency.

Attenuated phenotype in MPS VI (Maroteaux-Lamy) patients carring the p.R152W mutation. *A. Jurecka[1,2], E. Piotrowska[2], L. Cimbalistiene[3], N. Gusina[4], A. Rozdzynska[5], B. Czartoryska[6], K. Qunap[7,8], G. Wegrzyn[2], A. Tylki-Szymanska[1].* 1) Metabolic Diseases Clinic, The Children's Memorial Health Institute, Warsaw, Poland; 2) Department of Molecular Biology, University of Gdansk, Gdansk, Poland; 3) Center for Medical Genetics, Vilnius University Hospital, Santariskiu Klinikos, Vilnius, Lithuania; 4) Institute for Hereditary Diseases, Centre for Medical Genetic Services, Minsk, Belarus; 5) Anthropometry Laboratory, The Children's Memorial Health Institute, Warsaw, Poland; 6) Department of Genetics, Institute of Psychiatry and Neurology, Warsaw, Poland; 7) Department of Genetics, United Laboratories, Tartu University Hospital, Tartu, Estonia; 8) Department of Pediatrics, University of Tartu, Tartu, Estonia.

Background. Maroteaux-Lamy syndrome or mucopolysaccharidosis type VI (MPS VI) is a rare lysosomal, autosomal recessive storage disorder caused by a deficient activity of N-acetylgalactosamine-4-sulfatase, a lysosomal enzyme involved in the degradation of dermatan sulphate. Approximately 140 ARSB gene mutations have been identified thus far. Due to a large number of mutations, which are often private or novel, genotype-phenotype correlation for most MPS VI patients has been difficult. Aim. The aim of the study was to describe the natural clinical course in patients homozygous for R152W mutation from Central and Eastern Europe. Patients and Methods. From our database of 22 patients with MPS VI, we selected those with the p.R152W mutation in the homozygous (n=7, mean age 25 years, range 17-37 years) and compound heterozygous state (n=9, mean age 18, range 9-33 years). We performed a cross-sectional observational study. Results. Patients homozygous for the p.R152W mutation (n=7, age range 17-37 years) showed a much more attenuated course of the disease characterized by a significantly slower disease progression than patients heterozygous for the mutation (n=9, age range 9-33 years). First signs of the disease, usually slight range of motion limitations and mild skeletal malformations were observed at the median age of 6 years (mean age 8, range 1-21 years). Over 57% of these patients showed first signs of the disease after the age of 5 years, but even as late as 21 years. In these patients height was only slightly decreased and MPS VI features developed later in the course of the disease. Patients heterozygous for the p.R152W mutation developed symptoms earlier in life (mean age at the onset of symptoms was less 2.8 years; range 1 month - 8 years, median 1.29 year) and presented with short stature, significant skeletal malformations and other clinical abnormalities. The mean z-scores values for group of heterozygotes for body height and body weight were deviated from the reverence chart more than the z-scores values for the group of homozygotes. The average age for the homozygous group was 25.43 years while the average age for a group of heterozygotes was 18.1 years, therefore the observed differences are not the result of worsening symptoms with age. Conclusion. The p.R152W mutation in the homozygous state is associated with a relatively attenuated phenotype of mucopolysaccharidosis type VI.

1318T

Risk Factors for Fractures and Avascular Osteonecrosis in Type 1 Gaucher Disease: Analysis from the Gaucher Registry. *A. Khan[1], T. Hangartner[2], N.J. Weinreb[3], J.A. Cole[4], A.R. Gwosdow[4], J.S. Taylor[4], P.K. Mistry[5].* 1) Med Gen & Pediatrics, Alberta ChildHosp/Univ Calgary, Calgary, AB, Canada; 2) Wright State University, Dayton, OH, USA; 3) University Foundation for Lysosomal Storage Disorders, Coral Springs, FL, USA; 4) Genzyme Corporation, Cambridge, MA; 5) Yale University School of Medicine, New Haven, CT.

Background: The most debilitating skeletal complications of type 1 Gaucher disease (GD1) are avascular osteonecrosis (AVN) and fractures. These manifestations of GD1 lead to chronic pain, loss of functional mobility, hospitalization, surgical intervention and diminished health-related quality of life. **Objective:** To determine if disease severity measured by clinical and surrogate biomarkers represent risk factors for AVN or fractures in patients with GD1. **Methods:** A matched case-control analysis using the risk-set method was conducted to identify 4 groups of GD1 patients in the International Collaborative Gaucher Group (ICGG) Gaucher Registry: those with and without AVN, and those with and without fractures. Among cases and controls, we compared hematological, visceral, and organomegaly status, chitotriosidase levels, angiotensin converting enzyme, tartrate resistant acid phosphatase, white blood cell count, and spine DXA and femur DXA Z-scores. **Results:** Anemia and higher chitotriosidase activity differentiated patients with AVN compared to the control group. Patients with AVN were 1.5 times more likely to be anemic compared to the control group (OR= 1.51, 95% CI=1.06-2.15, p<0.02). Patients with AVN had higher levels of chitotriosidase activity preceding their event (OR = 2.23, 95% CI=1.13-4.41, p<0.05) compared to the control group. Patients who suffered fractures were 5.85 times (p<0.0005) more likely to have DXA lumbar spine Z-scores ≤-1 compared to the control group. **Conclusions:** Only anemia and chitotriosidase above the 75th percentile were associated with an increased risk of AVN. Risk of fractures was markedly increased among GD1 patients exhibiting low lumbar spine bone density. These findings show disease control, measured by clinical and surrogate markers, and osteopenia are useful measures to guide clinical therapy in Gaucher disease.

A mechanistic study of Fabry heart disease using induced pluripotent stem cells. *X. Meng[1], J. Shen[1], N. McNeill[1], B. Eberendu[1], R. Brady[2], R. Schiffmann[1].* 1) Institue of Metabolic Disease, Baylor Research Institute, Dallas, TX; 2) NINDs, National Institutes of Health, Bethesda, MD.

Fabry disease is an X-linked glycosphingolipid disorder caused by an insufficient activity of (-galactosidase A ((-Gal A). Cardiac complications including cardiac hypertrophy, conduction abnormalities and congestive heart failure are the leading causes of the mortality of Fabry patients. However, the pathogenesis of these cardiac abnormalities is largely unknown. The major obstacles in the mechanistic study of Fabry heart disease are the difficulty in obtaining heart biopsy from the patients and the lack of in vitro disease model systems. The induced pluripotent stem cell (iPSC) technology provides unique opportunity to solve these problems because iPSCs can be generated from skin fibroblasts and can be differentiated into cardiomyocytes in vitro. Previously, we have reported the establishment of iPSCs from mouse model of Fabry disease. In this study we generated iPSCs from hemizygous Fabry patients and healthy controls. Fabry patient-iPSCs were differentiated into spontaneously contracting cardiomyocytes in vitro. Fabry patient-iPSCs derived cardiac cells had markedly reduced (-Gal A activity and massive accumulation of globotriaosylceramide, the major substrate of (-Gal A. Using iPSC-derived cardiomyocytes we found altered function of L-type Ca2+ channel in Fabry cardiac cells. Fabry mouse iPSC-derived cardiac cells showed a significant relative resistance to Diltiazem, a specific inhibitor of L-type Ca2+ channel, compared to those derived from wild type (Wt). The beating rates of the cardiomyocytes declined with Diltiazem treatment in a dose-dependent manner in both genotypes, but Fabry cardiomyocytes needed a much higher dose of the drug to obtain equivalent decrease of beating rate compared to Wt controls. We also found significantly increased mRNA level of L-type Ca2+ channel (Cav1.2) in Fabry mouse heart tissues compared to Wt. The relationship between (-Gal A deficiency and abnormal L-type Ca2+ channel was further studied. Treatment of Fabry patient iPSC-derived cardiac cells with recombinant (-Gal A enzyme improved the response of the cells to L-type Ca2+ channel inhibitors (measured as decrement of beating rate). In conclusion, our study showed mouse model- and patients-derived iPSCs are useful tools for study of Fabry heart disease and that abnormal L-type Ca2+ channel activity may play a role in the pathogenesis of Fabry heart disease.

Postnatal and Prenatal Diagnosis of Lysosomal Storage Diseases in China. *Y. Meng[1], W. Zhang[2], H. Shi[1].* 1) Institute of Basic Medical Sciences, Chinese Academy of Medical Sciences, School of Basic Medicine of Peking Union Medical College.Beijing 100005, P R. China; 2) Peking Union Medical College Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College.Beijing 100005, P R. China.

The enzyme assay of LSD in China could be traced back to 1984. Till now, 18 microassay methods for enzyme activity have been established using fluorimetric or colorimetric substrates and 21 kinds of LSD could be diagnosed. Molecular testing for LSDs began in 2000. Since 2000, 830 index patients were diagnosed based on the characteristic clinical manifestations and specific enzyme assay(MPS 317, Gausher Disease 202 , MLD 91, ML 57, others 163.)Prenatal diagnosis had been carried out in 252 pregnancies at risk of LSD in early pregnancy, 55 affected fetuses were detected. In 317 cases of mucopolysaccharidosis (MPS), the most common type is Hunter disease (MPSII, 46.6%). The second is MPS IVA(20.5%) and the 3rd is Hurler disease(MPSI, 18%). Since 2000, we have carried out mutation analysis on Gaucher disease, Fabry disease, MPSI, MPSII, MPSIVA & MPSVI, Niemann-Pick disease, and metachromatic leukodystrophy, etc. Many novel mutations had been detected in Chinese LSD patients. For example, 33 types of mutation have been detected in 137 cases with Gaucher disease. L444P was the most common mutation, accounting for 31.9%, and N188S accounts for 7.4%, F213I accounts for 5.9%, M416V accounts for 5.4% and V375L accounts for 4.4%. 8 mutations were novel mutations in Chinese, e.g., F37V, Y205C, P122L, Y363C, N382K, L383R, L385P and M416V. The treatment of LSD in China, only Gaucher disease patients(130 cases) receive enzyme replacement therapy.

Evaluation of the pattern of X chromosome inactivation in women with Fabry Disease. *K.B. Müller[1], A.C. Barris-Oliveira[2], E.S. Ramos[3], A.M. Martins[1], V. D'Almeida[2].* 1) Pediatrics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Psychobiology, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 3) Genetics, Universidade de São Paulo, Ribeirão Preto, São Paulo, Brazil.

Background: Fabry Disease (FD) is an X-linked lysosomal storage disorder caused by the deficiency of alpha-galactosidase A ((-galA), which results in the intralysosomal accumulation of globotriaosilceramide (Gb3). Heterozygous female FD patients demonstrate a wide spectrum of symptoms, ranging since asymptomatic until a course as severe as in male hemizygotes, but the cause of this variability is still controversial. X-chromosome inactivation (XCI) is a mechanism of dosage compensation determined randomly (50:50). Skewed XCI, that is a marked deviation in this proportion, is an important phenomenon to be considered on women carriers of X-linked disorders, since some authors believe that this process can explain the manifestation of symptoms, including FD females. The aim of this work was to investigate the pattern of XCI in heterozygous FD women patients. Methods: Eight women with biochemical and molecular diagnosis of FD were evaluated for the pattern of XCI by HUMARA assay. DNA from peripheral blood was extracted using commercial kit. After digestion and nested PCR, alleles were observed in 12% polyacrylamide gel electrophoresis stained with silver nitrate. Results: A remarkable difference in the pattern of alleles was observed in one sample, when bands with and without prior digestion with HpaII were compared. This condition indicates a possible skewed pattern of XCI. The other samples showed no visible differences in the pattern of bands when analyzed by polyacrylamide gel. However it does not exclude the possibility of involvement of skewed XCI, since a more efficient evaluation will be achieved by capillary electrophoresis. Conclusion: Although there is no consensus in the literature regarding the involvement of skewed XCI and the manifestation of symptoms in women with FD, it is clear that this mechanism contributes to the physiopathology of the disease in this group of patients. Further analyses by capillary electrophoresis will add more information to confirm the proportion of skewed XCI. Supported by: FAPESP, CNPq, AFIP and IGEIM.

Screening for Fabry Disease in Japan. *K. Nakamura, K. Hattori, S. Matsumoto, H. Mitsubuchi, F. Endo.* Dept Pediatrics, Kumamoto Univ Sch Med, Kumamoto, Japan.

Fabry disease is an X-linked disorder of alpha-galactocidase A which causes the accumulation of glycolipids in lysosomes. The incidence of the classical type of the disease is approximately 1 in 40,000 males. Recent studies have revealed the late-onset type of the disease to have a higher frequency than previously known. To determine the disease incidence in Japan, we screened newborns to measure alpha-galactosidase A activity in dried blood spots from Japanese neonates. Enzyme-deficient infants were retested, and infants who were double-screening positive were diagnostically confirmed by enzymatic activity and mutation analyses. Thirty eight neonates had a deficiency in alpha-galactosidase A activities and specific mutations, including 5 neonates with classical mutations identified previously. Based on our newborn screening in Japan, the incidence of alpha-galactosidase A deficiency was 1 in 8,000 male. These results suggest that the late-onset phenotype of Fabry disease is underdiagnosed among both males and females in Japan. The recognition of the existence of these patients suggests the need for both early diagnosis and therapeutic intervention. However, ethical issues need to be taken into consideration in terms of when and whom the screening should be performed.

Validation of chitotriosidase determination in dried blood spots on filter paper as a tool for screening and monitoring of Gaucher disease patients in Colombia. *N. Pacheco Fernandez, A. Uribe.* Centro de Investigaciones en Bioquímica (CIBI), Departamento de Ciencias Biológicas, Facultad de Ciencias, Universidad de Los Andes, Bogota, Colombia.

Gaucher disease is a lysosomal storage disorder (LSD) caused by a deficiency of the enzyme) -glucocerebrosidase. This deficiency generates an accumulation of glucocerebroside in macrophages and causes bone marrow alterations, hepatomegaly and splenomegaly. Although LSDs are rare diseases, Gaucher disease is quite frequent, however there are no specific biomarkers for detection and monitoring of patients with this disease. Chitotriosidase (CT) is the only biomarker that increases 600 to 1000 times in Gaucher patients. This is why it is widely used in disease screening. The enzymatic determination in dried blood spots on filter paper (DBS) is a tool that facilitates transport and lowers costs of sampling, making it more accessible to population at risk. The aim of this study is to validate the quantification of CT in DBS to facilitate detection and monitoring of Gaucher disease patients in Colombia. Serum and DBS samples of 32 individuals between 8 months and 45 years old were analyzed, 4 of them were Gaucher disease confirmed patients by determination of enzymatic activity of) -glucocerebrosidase and the other 28 were normal controls. Using a fluorometric method with 4-methylumbelliferyl-) -D-N,N',N”-triacetylchitotrioside as substrate, the activity of CT was determined both in serum and DBS. The observed activity values do not overlap between controls (0-52 nmol/ml/hr in serum and 0-88 nmol/ml/hr in DBS) and patients (346-373 nmol/ml/hr and 311-1004 nmol/ml/hr in serum and DBS respectively). Although there is more variation in DBS essay, values between controls and patients are discriminating. This variation can be caused by the presence of cells in filter paper samples, which have been previously eliminated in serum samples. Quantification of CT in DBS works as a cheap and practical tool in detection and monitoring of Gaucher disease patients in Colombia.

1324T

Glycogen clearance by BMN 701 and alglucosidase alfa in a mouse model of Pompe disease. *J. Peng, R. Cahayag, M. Fox, C. O'Neill.* BioMarin Pharmaceutical Inc., Novato, CA.

Pompe disease (GSD Type II) is a rare neuromuscular disorder caused by deficiency of the enzyme acid (-glucosidase, resulting in accumulation of glycogen in muscle tissues. The build-up of glycogen causes progressive muscle weakness, organ failure, and death from cardiac or respiratory failure. A mouse model ($GAA^{tm1Rabn/J}$) of Pompe disease containing a disrupted acid (-glucosidase gene emulates the human disease and has been used to evaluate the potential for efficacy of treatments for glycogen clearance. Alglucosidase alfa, a recombinant human acid (-glucosidase, has been previously demonstrated to reduce glycogen accumulation in the $GAA^{tm1-Rabn/J}$ mice. BMN 701, a novel fusion protein of insulin-like growth factor 2 and acid (-glucosidase (IGF2-GAA), is being developed as an alternative therapy for Pompe disease. The glycogen clearance effects of alglucosidase alfa and BMN 701 were compared directly. $GAA^{tm1Rabn/J}$ mice were treated with repeat intravenous bolus administrations of alglucosidase alfa or BMN 701 weekly for four weeks. One week following the final dose administration, heart (left ventricle), diaphragm, quadriceps, psoas, and soleus muscles were collected and evaluated for glycogen content using an enzymatic assay. Administration of either alglucosidase alfa or BMN 701 resulted in a dose-dependent reduction in glycogen levels; however, the glycogen clearance effect of BMN 701 was generally equivalent to a corresponding 5-fold higher dose of alglucosidase alfa. Only BMN 701 demonstrated the ability to reduce glycogen storage to levels indistinguishable from wild-types in the skeletal muscles examined. We propose that BMN 701 may present an effective new enzyme replacement therapy for Pompe disease, offering improved clinical efficacy compared to current treatment.

TFEB links autophagy to lysosomal bigenesis. *C. Settembre[1,2,3], C. Di Malta[1], V. Polito[1,2,3], M. Arencibia[4], F. Vetrini[2], S. Erdin[2], D. Medina[1], M. Sardiello[2,3], D. Rubinsztein[4], A. Ballabio[1,2,3].* 1) telethon institute of genetic and medicine; 2) baylor college of medicine; 3) neurological research institute; 4) Cambridge Institute for Medical Research.

Autophagy is a lysosomal degradation pathway with a crucial role in health and disease. Polyubiquitinated proteins, protein aggregates and dysfunctional organelles are degraded, and their components recycled, by autophagy. An important step of the autophagic pathway is the fusion between the autophagosome and the lysosome. Dysfunction of the autophagic-lysosomal system has been associated to the pathophysiology of several inherited diseases, including lysosomal storage disorders and neurodegenerative diseases. We have identified a transcriptional program that controls major steps of the autophagic pathway, including autophagosome formation, autophagosome-lysosome fusion and substrate degradation. The transcription factor EB (TFEB), a master gene for lysosomal biogenesis, coordinates this program by driving expression of autophagy and lysosomal genes. We found that TFEB activity is regulated by ERK2-mediated phosphorylation TFEB. Inhibition of ERK2 signaling results in TFEB nuclear translocation and induction of TFEB activity. Thus the identification of a novel transcriptional dependent mechanism that regulates cellular clearance and of the pharmacological approach to enhance it, opens new therapeutic perspectives for the treatment of storage-related diseases.

Fabry disease mouse model exhibits cardiac hypertrophy and arrhythmias. *J. Shen, X. Meng, B. Durant, R. Schiffmann.* Institute of Metabolic Disease, Baylor Research Institute, Dallas, TX.

Fabry disease is an X-linked glycosphingolipid disorder caused by a deficiency of (-galactosidase A. Fabry disease exhibits a variety of cardiovascular complications including cardiac hypertrophy and arrhythmias. To date, the mechanism of these manifestations is poorly understood. Due to heterogeneous clinical manifestations of Fabry patients, mouse model will be particularly useful in mechanistic studies. Although mouse model of Fabry disease has been generated, there is little information on their cardiac phenotype. In this study, we characterized Fabry mouse compared to wild-type (WT) controls and identified following cardiac abnormalities. (1) We found age-dependent cardiac hypertrophy in Fabry mice. Heart weight (normalized by body weight) in Fabry mouse was significantly increased compared to WT. The increment of heart weight was seen in 12-month old, but not 5-month old, Fabry mice. The mRNA level of atrial natriuretic peptide, a marker of cardiac hypertrophy, was significantly increased in 12-month old Fabry mouse heart. Activation of Akt signaling is known to be associated with cardiac hypertrophy. We found significantly increased phosphorylated Akt in 19-month old, but not 5-month old, Fabry mouse heart. These observations demonstrated that cardiac hypertrophy occurs in Fabry mice but its progression is relatively slow. To further determine whether young `asymptomatic' Fabry mice have higher susceptibility to inducers of cardiac hypertrophy, 5-month old Fabry and WT mice were infused with) -adrenoceptor agonist isoproterenol using osmotic pumps. Both Fabry and WT mice exhibited significant increase in heart-to-body weight ratio in response to isoproterenol infusion. However, the response in Fabry mice was more significant than WT mice. (2) We found that electrocardiogram (ECG) of Fabry mouse was significantly altered in a sex-dependent manner. Compared to controls, 11-month old male Fabry mice showed lower heart rate, increased heart rate variability, longer PR and ST intervals. However, homozygous female mice of the same age had no ECG abnormalities. In conclusion, we found cardiac hypertrophy and arrhythmias in Fabry mice. Overall, these abnormalities match with Fabry patients' cardiac manifestations, and thus, Fabry mouse would be a good model for studying Fabry heart disease. We are currently trying to elucidate underlying mechanism of Fabry cardiac complications using Fabry mouse and cultured cardiac cells.

Tissue preferential synergistic effect of saposin A and saposin B on glycosphingolipids degradation in mice. *Y. Sun[1,3], M. Zamzow[1], H. Ran[1], W. Zhang[2], B. Quinn[1], S. Barnes[1], K.D.R. Setchell[2,3], G.A. Grabowski[1,3].* 1) Division of Human Genetics, Cincinnati Children's Hospital Medical Center,; 2) Division of Pathology and Laboratory Medicine, Cincinnati Children's Hospital Medical Center,; 3) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH 45229-3039.

Saposins (A, B, C and D) are lysosomal proteins derived from the precursor, prosaposin. Saposins have specific and overlapping actions in glycosphingolipid metabolism. Individual saposin A (A-/-) and saposin B (B-/-) deficient mice were created and showed unique phenotypes caused by insufficient degradation of the myelin glycolipids: galactosylceramide/galactosylsphingosine and sulfatide, respectively. To gain insight about the interrelated functions of saposin A and B, combined saposin AB null mice (AB-/-) were created by knock-in point mutations into the saposins A and B domains of the prosaposin locus. Saposins A and B were undetectable in AB-/- mice, whereas prosaposin, saposin C, and saposin D were expressed at WT levels. AB-/- mice developed neuromotor deterioration at ~75 days, and they lost 30% of body weight by end-stage. The life span in AB-/- mice (~100 days) was longer than A-/- (~84 days) and shorter than B-/- (>1 year) mice. Large multinucleated macrophages were found in AB-/- mice livers. The ultrastructure studies showed these macrophage storage inclusions to have a twisted filamentous appearance. Glycosphingolipid analyses by LC/MS and TLC identified substantial increases of lactosylceramide and minor increases of globotriaosylceramide in AB-/- mice liver, but not in the brain. Similar to B-/- mice, activated microglial cells were uniformly distributed over the entire brain of AB-/- mice. Storage material was found in Schwann cells and oligodendrocytes indicating demyelination in AB-/- nervous systems. Sulfatide levels were increased and galactosylceramide was at WT levels in the AB-/- brain. These findings indicate that combined saposins A and B deficiencies attenuated GalCer-) -galactosylceramidase and GM1-) -galactosidase functions in degradation of lactosylceramide mainly in the liver. In the brain, blockage of sulfatide degradation diminished galactosylceramide accumulation. These analyses of AB-/- mice continue to delineate the tissue preferential interactions of saposins in glycosphingolipid metabolism and homeostasis.

KIR/HLA gene variants in patients with Gaucher disease in Southern Brazil. *F. Vairo[1, 2], P. Portela[3], P. Salim[3], T. Alegra[1,2], C. Netto[1], M.L. Saraiva-Pereira[1], M. Jobim[3], L.F. Jobim[3], I.V. Schwartz[1,2].* 1) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 2) Genetics Department, Universidade Federal do Rio Grande do Sul, Brazil; 3) Immunology Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil.

Background: Gaucher disease (GD) is caused by the reduced activity of a lysosomal enzyme, glucocerebrosidase, which leads to the accumulation of glucocerebroside in the cells and a chronic stimulation of the immune system. Natural Killer (NK) cells play an important role in the immune response, and their activity is impaired in GD. Killer immunoglobulin-like receptors (KIR) regulate the activity of NK cells through an interaction with specific human leukocyte antigen (HLA) class I molecules on target cells. Objectives: To analyze the variability of KIR genes in a Southern Brazilian sample of GD patients, to compare it with controls, and to look for associations with clinical manifestations. Results/Discussion: Using the chi-square test, 31 GD patients (25 mild, 2 moderate, and 4 severe) were analyzed and compared to 200 healthy controls. There was no significative difference in the frequencies of KIR/HLA variants between the groups. No severe patient had the KIRD2S3 variant, but 7 mild and all moderate patients had it. Patients who have the HLA C1 variant appear to have less mono/polyclonal bands in protein electrophoresis. Bone mineral density appeared to correlate with the KIR2DS2 variant since 11/17 patients with osteopenia/osteoporosis have this variant. Conclusion: There are no studies about the relationship about KIR/HLA variants and GD. Despite being a limited sample of GD patients, our data suggest a possible association of KIR/HLA variants and this condition. The KIR/HLA variants must be further studied, for they seem to be a phenotype-modifier factor for GD.

Diagnostic testing for MPS VI (Maroteaux-Lamy syndrome): Laboratory survey results and recommendations from the MPS VI Diagnostic Summit. *T. Wood[1], O. Bodamer[2], M.G. Burin[3], V. D'Almeida[4], C. Eng[5], M. Fietz[6], R. Giugliani[3,7], C. Hendriksz[8], P. Hwu[9], D. Ketteridge[6], Z. Lukacs[10], N.J. Mendelsohn[11], M. Pasquali[12], A. Schenone[13], K. Schoonderwoerd[14], B. Winchester[15], P. Harmatz[16].* 1) Biochemical Genetics Laboratory at Greenwood Genetic Center, Greenwood, SC, USA; 2) University of Miami Miller School of Medicine, Miami, FL, USA; 3) Medical Genetics Service, Hospital de Clinicas de Porto Alegre, Brazil; 4) Federal University of São Palo, São Palo, Brazil; 5) Baylor College of Medicine, Houston, TX, USA; 6) SA Pathology, Women and Children's Hospital, North Adelaide, SA, Australia; 7) Dep Genetics, UFRGS, Porto Alegre, Brazil; 8) Birmingham Children's Hospital NHS Foundation Trust, Birmingham, UK; 9) National Taiwan University Hospital, Taipei, Taiwan; 10) Hamburg University Medical Center, Hamburg, Germany; 11) Children's Hospitals and Clinics of Minnesota, Minneapolis, MN, USA; 12) Univeristy of Utah School of Medicine, Salt Lake City, UT, USA; 13) Fundación para el Estudio de las Enfermedades Neurometabólicas (FESEN), Buenos Aires, R, Argentina; 14) Erasmus Medical Center, Rotterdam, the Netherlands; 15) UCL Institute of Child Health, London, UK; 16) Children's Hospital Oakland, Oakland, CA, USA.

Maroteaux-Lamy syndrome (Mucopolysaccharidosis VI) is a lysosomal storage disease caused by a deficiency of N-acetylgalactosamine 4-sulfatase (arylsulfatase B). This enzyme is required for the degradation of dermatan sulfate which accumulates in patient's cells and is excreted in large quantities in their urine. Specific therapeutic intervention is available; however, accurate and timely diagnosis is crucial for maximal benefit. To better understand the current laboratory practices for the diagnosis of MPS VI, a survey was completed by 13 diagnostic laboratories from around the globe. The data were reviewed by an expert panel as part of a Diagnostic Summit on MPS VI. Participating laboratories were from Asia, Australia, Europe, and North and South America. The various steps in the diagnosis of MPS VI were assessed including urinary glycosaminoglycan (GAG) testing, enzymatic assays, and molecular diagnostics. For urine-based testing, the methodology for qualitative and quantitative GAG measurement, normal ranges, and common problems were assessed. There was general agreement that dilute urine samples posed a significant problem although specific collection requirements were not made by most institutions. Quantitative testing was generally felt to be insufficient for diagnosis as dermatan sulfate may not always be excreted in large quantities and qualitative testing, looking for the accumulation of dermatan sulfate, was preferred. Diagnosis is usually made by demonstrating a deficiency of arylsulfatase B, typically measured in leukocytes with a smaller number of laboratories using dried blood spots and/or fibroblasts. For leukocyte testing, nitrocatechol was the most common substrate and normal ranges were compared among different laboratories. Proficiency testing is available for both urinary GAG and enzyme studies; however participation is not universal. Molecular testing, is available to clinicians, supports enzyme activity test results, and is essential for carrier testing and subsequent genetic counseling. Overall the expert group recommended caution in the use of urine GAG studies alone to rule out or confirm the diagnosis of MPS VI and felt that arylsulfatase B enzyme testing is superior. Molecular analysis, or at least measurement of another sulphatase enzyme to exclude Multiple Sulphatase Deficiency, was also recommended prior to the initiation of therapy. A diagnostic algorithm for MPS VI including laboratory testing was developed.

1330T

The spectrum of mitochondrial DNA mutations in Iranian LHON patients. *M. Houshmand[1, 2], Z. Rezvani[1], E. Didari[1], A. Arasteh[2], V. Ghodsinejad[2].* 1) Medical Genetic, National Institute of Genetic Engineering & Biotec, Tehran, Iran; 2) Genetic diagnostic Dep., Special Medical Center, Tehran, Iran.

Leber's hereditary optic neuropathy (LHON) is a maternally inherited form of central visual loss that occurs subacutely in young adult men. Experimental support for mitochondrial inheritance was obtained when LHON was first associated conclusively with an inherited mutation in the mitochondrial genome (mtDNA). Beyond this broad agreement about the G11778A, G3460A, and T14484C mutations, it is not yet clear how many other mtDNA mutations may have an etiological or pathogenic role in LHON. These three LHON mutations account for >95% of multigenerational LHON pedigrees of northern European descent. The aim of this study was to define the prevalence of a panel of mtDNA mutations associated with LHON in Iranian patients. PCR-RFLP and sequencing methods were used to investigate these mutations and also new mutation in mitochondrial complex I subunit (ND1-6) of 42 patients. 22 patients (52%) showed one of known mutation which 12 of the patients showed G11778A (55%) (8% female and 92% male), 5 showed G3460A (22.5%) (20% female and 80% male), 5 showed T14484C A (22.5%) (40% female and 60% male). In the rest of patients (20), 5 showed 4216 (25%) (20% female and 80% male), 5 showed 12308 (25%) (All male), 2 showed 10399 (10%) (All female), 2 showed 4942 (10%) (All male), and following mutations was found in the rest of the patients (14318, 14766, 3893, 10042, 10557, 3497, 4654, 13802, 14766, 12012H, 4454, 3269, 14200, 9949, 14021, 14199, 14353). We conclude that: a) Known mutations of LHON just diagnose for 52% of patients, b) even the LHON predominant by male 3:1 but more female were detected in patients with 3460 or 14484 mutations than 11778, c) combined mutations or secondary mutations may play role for pathogenicity of the LHON.

Widely targeted metabolomics for diagnosing inborn errors of metabolism. *T. Adam[1,2], H. Krätschmerova[1], K. Hron[1], P. Wojtowicz[1], A. Baresova[1], E. Hlidkova[1,2], P. Hornik[3,4], D. Behulova[5], D. Prochazkova[6,7], H. Vinohradska[7], K. Peskova[3,4], K. Adamova[2], S. Stastna[3,4], D. Friedecky[1,2].* 1) Palacky University, Olomouc, Czech Republic; 2) University Hospital, Olomouc, Czech Republic; 3) Charles University, Prague, Czech Republic; 4) University Hospital, Prague, Czech Republic; 5) University Children's Hospital, Bratislava, Slovakia; 6) Masaryk University, Brno, Czech Republic; 7) University Hospital, Brno, Czech Republic.

Objective: Metabolomics becomes an important tool in clinical research and diagnosing human diseases. In this work we focused on diagnosing inborn errors of metabolism (IEMs) in plasma samples using a targeted metabolomic approach. **Methods:** Plasma samples were analysed using the AbsoluteIDQ p 150 Kit (BIOCRATES Life Sciences AG, Austria). The standard flow injection method of the kit comprising two subsequent 20 ul injections (one for positive and one for negative detection mode) was applied for all measurements. All experiments were performed on an QTRAP 5500 tandem mass spectrometer (AB SCIEX, USA) with electrospray ionization. Multiple reaction monitoring detection for 163 metabolites and 27 internal standards was used for quantification. **Results:** We analyzed 50 control samples and 34 samples with amino acids defects (phenylketonuria, maple syrup urine disease, tyrosinemia I, argininemia, homocystinuria, carbamoyl phosphate synthetase deficiency, ornithine transcarbamylase deficiency, non-ketotic hyperglycinemia) and with acylcarnitines defects (methylmalonic acidemia, propionic acidemia, glutaric aciduria I, 3-hydroxy-3-methylglutaric aciduria, isovaleric acidemia, medium-chain acyl-coenzyme A dehydrogenase deficiency and carnitine palmitoyltransferase II deficiency). Control samples were distinguished from patient samples by principle component analysis and hierarchical clustering. **Conclusion:** This study shows that targeted metabolomics can be applied for diagnosing broad IEMs. *This work was supported by grants MSM6198959205 and Internal grant agency of Palacky University grant No. LF_2010_013. Infrastructural part of this project (Institute of Molecular and Translational Medicine) was supported from the Operational programme Research and Development for Innovations (project CZ.1.05/2.1.00/01.0030).*.

Metabolite Pattern on *in vivo* 1H-Magnetic Resonance Spectroscopy (MRS) of the brain in children with metabolic diseases. *W. Al-Hertani[1], E. Mason[1], T. Tam[1], B. Schmitt[2], S. Blaser[3], H. Branson[3], A. Schulze[1].* 1) Department of Metabolic Genetics, The Hospital of Sick Children and University of Toronto, Toronto, Canada; 2) German Cancer Research Center, Heidelberg, Germany; 3) Department of Diagnostic Imaging, The Hospital of Sick Children, Toronto, Canada.

Introduction: Identifying MRS metabolite pattern that are diagnostic of metabolic diseases is a powerful tool in inborn errors of metabolism (IEM). Methods: We analyzed brain 1H-MRS data from 1843 children from the basal ganglia (BG) and periventricular white matter (PVW). Our study involved measurements from two voxel localizations (BG and PVW) and two echo times (35 ms and 144 ms), and compared data from the 1.5T and 3T Philips Achieva clinical MRI scanners. Point-resolved spectroscopy (PRESS) acquisitions were recorded. Post-processing of MRS data and analysis was performed LC Model software. Retrospective analysis of MR spectra and quantitative information on all detected metabolites was done in children with 21 different metabolic diseases including MMA, Citrullinemia, Arginase deficiency, SSADH deficiency and GA type I. Results: We identified a number of metabolite pattern including low total choline (tCho) in MMA, Arginase deficiency and SSADH deficiency. High Inositol (Ins) was observed in Citrullinemia. Low total creatine (tCr) was seen in Citrullinemia and Arginase deficiency. Conclusions: Our retrospective analysis revealed a number of MRS metabolite pattern in children with various metabolic diseases. Further data exploration and prospective studies will identify novel metabolite patterns that are diagnostic for IEM and elucidate the neurometabolic mechanisms of disease.

Diagnostic Program for the Detection of Niemann-Pick C disease in Brazil (NPC BRAZIL NETWORK). *F. Timm[1], H. Bock[1], S.G.R. Santos[1], S.S. Mello[1], A. Brites[1], M.G. Burin[1], M.L. Saraiva-Pereira[1,2], R. Giugliani[1,3].* 1) Med Genet Serv, HCPA, Porto Alegre, RS, Brazil; 2) Dep Biochemistry, UFRGS, Porto Alegre, RS, Brazil; 3) Dep Genetics, UFRGS, Porto Alegre, RS, Brazil.

Niemann-Pick disease type C (NPC) is an autosomal recessive condition caused by defects on cholestherol trafikking, which leads to a progressive and usually severe visceral and/or neurologic syndrome. The signs and symptoms overlap with other conditions, and diagnosis is difficult as usually requires a staining test performed on cultured fibroblasts and/or comprehensive molecular studies of the two NPC genes (NPC1 and NPC2). The possibility of treating affected patients with substrate reduction therapy (miglustat) makes more important the correct and timely identification of affected patients. With this aim we set up a comprehensive diagnostic program for NPC in Brazil, which includes: 1) providing information on diagnostic procedures, including a collection and transportation kit (for skin biopsy and blood collection); 2) assay of plasma chitotriosidase; 3) culture of skin fibroblasts and Filipin staining; 4)DNA isolation and molecular analysis of NPC1 and NPC2 gene, depending on results of the Filipin testing. This protocol was performed in 140 patients with suspected NPC, referred from physicians from all Brazilian regions. Diagnosis of NPC was confirmed in 15 cases, being abnormal but not conclusive in further 12 patients. These 27 cases were referred to molecular analysis of both genes to complete investigation (molecular analyses in progress).

1334T

Proteomic Analysis of Induced Pluripotent Stem Cells (iPSC) as a Mechanism to Study Non-Alcoholic Fatty Liver Disease (NAFLD). *S. Brown-Ford[1], A. DeLaForest[2], M. Cayo[2], M. Pellitteri-Hahn[3], M. Zelembaba[3], B. Halligan[3], S. Duncan[2], M. Olivier[1,3].* 1) Medical College of Wisconsin, Department of Physiology, Milwaukee, WI; 2) Medical College of Wisconsin, Department of Cell Biol., Milwaukee, WI; 3) Medical College of Wisconsin, BBC, Milwaukee, WI.

BACKGROUND AND AIM: iPSC provide a unique resource to study liver cell dysfunction in a human cell-based model. It is our goal to study the proteome of iPSC lines created from obese patients with Non-Alcoholic Fatty Liver Disease (NAFLD) and weight-matched controls. NAFLD is commonly attributed to risk factors associated with metabolic syndrome and obesity, but some evidence has pointed to an enhanced genetic susceptibility for the development of the disease. Fatty liver increases mortality due to cirrhosis, carcinoma and liver failure. **METHODS:** In our initial analyses of iPSC, we characterized the proteome of undifferentiated hiPSC and hESC lines using mass spectrometry. Fractions were analyzed on an ion-trap mass spectrometer (LTQ Orbitrap Velos). Two biological replicates for each cell line were analyzed using the SEQUEST algorithm. SEQUEST results from the injected replicates of each sample were pooled and analyzed using VISUALIZE 125-136 software. **RESULTS:** Few proteins were detected at significantly different levels within (1.9-3.7%) the same or between (2.7-5.3%) different cell lines. Our iPSC2a and iPSK3 lines had significantly lower levels of the transcription factor, Lin28A (68% and 48%) compared with our H1ESC line. Y-box binding protein 2 was detected at 83% higher levels in H1ESC than in our iPSK3 line. Analysis of additional cell lines will confirm these initial findings. **FUTURE STUDIES:** We will differentiate control and NAFLD-patient iPSC lines to hepatocyte-like cells to detect significant proteomic and functional differences between these cells after differentiation to gain insights into the underlying cell dysfunction.

1335T

Expression of anti-lipolytic receptors in human adipose tissues and metabolic associations. *L. Chamas, M. Neville, F. Karpe.* University of Oxford, Oxford, United Kingdom.

Background and aims: Anti-lipolytic signals in adipose tissue could be related to insulin sensitivity through the generation of systemic non-esterified fatty acids. Recently uncovered G-coupled proteins receptors GPR109A, GPR109B and GPR81 respond to ligands produced in intermediary metabolism and convey an anti-lipolytic signal in adipose tissue. The endogenous ligand for GPR109A is beta-OH butyrate whereas lactate is the endogenous ligand for GPR81. Little is known about the regulation of these receptors in human adipose tissue. We hypothesize that depot-specific expression of these receptors could help explain tissue anti-lipolytic effects. Materials and methods: Due to the high degree of sequence similarity between *GPR109A* and *GPR109B*, the existing commercially available Taqman gene expression assays were tested for specificity on in-house developed specific templates for the two genes. Both gene assays were found to be non-specific. Following this, specific expression assays were developed and validated. Expression for all three genes in human adipose tissue was determined using paired abdominal and gluteal biopsy samples from 20 healthy male and 20 healthy female subjects. The mRNA expression assays were run on an ABI7900HT system and normalized to *PPIA* and *PGK1*. To assess the relevance of possible feedback loops, the plasma concentrations of the endogenous ligands were measured in plasma. Results: *GPR109A* showed a 1.34 fold higher expression in gluteal tissue compared to abdominal tissue (p=0.012). *GPR109B* showed a 1.45 fold increase in expression in gluteal tissue compared with abdominal tissue (p=0.006). When looking for effects of obesity, abdominal expression of *GPR81* was 1.17 fold lower in obese individuals (p=0.013, n=20) driven by an 1.26 fold reduction in the male group (p= 0.041, n=10). The gluteal expression of *GPR81* was negatively correlated with lactate levels (p=0.026, r=-0.33, n=40) and more so in obese men (p=0.006, r=-0.79, n=10). Conclusion: *GPR109A* and *GPR109B* showed adipose tissue depot specific expression differences. Higher expression of the anti-lipolytic *GPR109A* was seen in the gluteal tissue, known for its lower lipolysis rate. Obesity did not affect the expression of *GPR109A* and *GPR109B* but lowered the expression of *GPR81*. Plasma lactate was negatively associated to *GPR81* gene expression suggesting a ligand-receptor auto-feedback.

1336T

Does the CPT1A p.P479L variant confer risk for unexpected infant death in Nunavut, NWT and Yukon? *S. Collins[1], G. Sinclair[2], G. Osborne[3], A. Corriveau[4], M. Santos[4], B. Hanley[5], F. Bamforth[6], C. Greenberg[7], H. Vallance[2], L. Arbour[1].* 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC Canada; 2) Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC Canada; 3) Health and Social Services, Government of Nunavut, Iqaluit, NU Canada; 4) Department of Health and Social Services, Government of Northwest Territories, Yellowknife, NT Canada; 5) Health and Social Services, Government of Yukon, Whitehorse, YK Canada; 6) Department of Laboratory Medicine and Pathology, University of Alberta Hospital, Edmonton, AB Canada; 7) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, MB Canada.

Canada's three Northern territories are home to ~100,000 people, of which nearly 50% are of Aboriginal ancestry. Infant mortality rates in the territories increase from west to east, with Nunavut having the highest at 15/1000 live births, a rate 3 times the national average. Nunavut has the largest Inuit population in Canada with ~95% of the 750 infants born each year to Inuit women. Population studies have determined that the c.1436C>T (p.P479L) variant of carnitine palmitoyltransferase 1A (CPT1A) is highly prevalent in Inuit, Alaska Native and coastal BC First Nations and has been associated with increased risk for unexpected infant death in Alaska and BC. The hepatic enzyme CPT1A is a major regulatory point for transport of long chain fatty acids into the mitochondrion for use as energy source during fasting. CPT1A deficiency confers risk for hypoketotic hypoglycaemia, hepatic encephalopathy, seizures, and sudden death. It remains controversial whether the p.P479L variant causes susceptibility to decompensation, in particular during times of fever and intercurrent illness. Risk associated with the p.P479L variant in northern Canada was assessed by comparing the frequency of p.P479L homozygosity of unexpected infant death cases (SIDS, SUDI, and death due to infection) to the estimated population p.P479L homozygosity rates for each territory (64%, 3% and 0% for Nunavut, NWT and Yukon respectively). Ethics approval was obtained from university REBs and local research institutes, with consultation with territorial Aboriginal groups. Of the total 79 unexpected infant death cases identified in all the three territories, 20 of 59 Nunavut cases, 7 of 16 NWT cases and all 4 Yukon cases were available for genotyping. In Nunavut, p.P479L homozygosity was associated with increased risk for unexpected death in (OR 5.15, 95%CI:1.22-46.1). In NWT, there was no statistically significant association between infant mortality and the variant, likely due to small sample size. In Yukon, none of the cases were p.P479L homozygous. Interpretation of risk associated with the variant should be considered with caution as population stratification within Nunavut cannot be ruled out. Potential interactions between the variant and other associated risks, including sleep position, tobacco smoke exposure and breastfeeding practices, are also possible. Prospective studies in Nunavut are planned to better explore risk associated with the variant for infant mortality and morbidity.

1337T

Maternal hyperhomocysteinemia lead to methionine cycle alteration of adult offspring. *V. D'Almeida[1], V.C. Silva[2], E.J. Haseyama[1], M.T.C. Muniz[3].* 1) Psychobiology, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 2) Pediatrics, Universidade Federal de São Paulo, São Paulo, São Paulo, Brazil; 3) Universidade de Pernambuco, Recife, Pernambuco, Brazil.

Aim: Abnormal fetal antecedents have been associated with increased offspring disease risk through maternal environment, placental changes and epigenetic programming. As alterations in the methionine-homocysteine cycle are described in some disease and could have a role on fetal programming through changes on S-adenosylmethionine (SAM) levels, the aim of this study was to investigate the effects of methionine supplementation, during gestation and lactation, on methionine-homocysteine cycle of offspring. Methods and Results: One month before pregnancy, 13 Swiss female mice were distributed into 2 groups: control (CT=6) group and methionine supplemented (MS=7) group (1% of methionine in water ad libitum). After 20 days, plasma homocysteine levels from MS group were approximately 50% higher than CT group (CT= 4.45 μmol/L, MS= 8.71 μmol/L; p=0.0001). Three months old male offspring (CT=15, MS=11) were euthanized by decapitation. The blood was collected in EDTA tubes for homocysteine, cysteine and total glutathione measurement and the liver was harvested for total glutathione quantification. Our results demonstrated that the treatment with methionine throughout the pregnancy and lactation had no significant effect on offspring plasma homocysteine levels (p=0.3). However, there was an increase on plasma levels of cysteine (CT=424.74 μmol/L, MS=471.83 μmol/L; p=0.04) and glutathione (CT=195.91 μmol/L, MS=302.34 μmol/L; p=0.0003), and hepatic levels of glutathione (CT=8.45 μmol/L, MS=11.58 μmol/L; p=0.0004). Conclusion: Considering our results, we suggest that the organism develops compensatory mechanisms during high methionine intake through increase of cysteine and glutathione formation. These compensatory mechanisms may give priority to the transsulfuration instead of remethylation pathway and prevent possible alterations in gene methylation profile, despite the dams hyperhomocysteinemia. Sources of research support: FAPESP, CNPq and AFIP.

Erythropoietic Protoporphyrias: Frequency of Mutations in the Ferrochelatase Gene Causing Autosomal Recessive Erythropoietic Protoporphyria and Mutations in the 5'-Aminolevulinate Synthase 2 Gene Causing X-Linked Protoporphyria. *D. Doheny[1], I. Nazarenko[1], M. Balwani[1], L. Liu[1], H. Naik[1], K. Anderson[2], D.M. Bissell[3], J. Bloomer[4], H. Bonkovsky[5], J. Kushner[6], J. Phillips[6], D. Bishop[1], R.J. Desnick[1], Porphyrias Consortium of the Rare Diseases Clinical Research Network.* 1) Dept Gen & Genomic Scienc, Mount Sinai Sch Med, New York, NY; 2) Department of Preventive Medicine and Community Health, University of Texas, Galveston, TX; 3) Department of Medicine, University of California, San Francisco, CA; 4) Department of Medicine, University of Alabama, Birmingham, AL; 5) Department of Medicine, Carolinas Medical Center and HealthCare System, Charlotte, NC; 6) Department of Internal Medicine, University of Utah, Salt Lake City, UT.

Erythropoietic Protoporphyria (EPP), the most common erythropoietic porphyria, is an autosomal recessive disorder, resulting from mutations in the ferrochelatase (FECH) gene that cause a deficient activity of ferrochelatase, the last enzyme in the heme biosynthetic pathway. Recently, an X-linked form of EPP, termed XLP, was described due to deletions in the terminal exon 11 of the erythroid-specific 5'-aminolevulinate synthase 2 (ALAS2) gene at Xp11.21. (Whatley et al, 2008) Both EPP and XLP are characterized clinically by acute photosensitivity and painful skin lesions and, biochemically, by elevated erythrocyte protoporphyrins (PROTO), with XLP distinguishable by having about equal amounts of free-PROTO and zinc-PROTO, whereas in EPP, zinc-PROTO is a minor constituent. To date, 126 FECH mutations have been reported (Human Gene Mutation Database, 2011), as well as the common low-expression allele, IVS3-48T>C. In XLP, three ALAS2 exon 11 deletions have been reported. To determine the frequency of FECH and ALAS2 mutations causing this phenotype, we performed mutation analysis of 97 unrelated patients with biochemical and/or clinical evidence suggestive of EPP, identifying FECH mutations in 79 patients. Among these, three patients had two mutations, 74 had one mutation and the low-expression allele, and two were homozygous for the low-expression allele. Among the FECH mutations, 23 were novel, including three deletions, two splice-site, nine nonsense, nine missense. Among FECH mutation-positive patients, 33 family members were tested, identifying 7 additional affected individuals. Of the 18 cases with no detectable FECH mutation, 10 had ALAS2 lesions, nine with c.1706_1709delAGTG (Whatley et al, 2008) and one c.1734delG (Doheny, 2009). Further testing of 16 XLP family members identified three affected males and eight heterozygous females with variable but generally milder manifestations than affected males. Current efforts are directed to identify large deletions and other variations by dosage analysis and genomic techniques. The findings to date indicate that XLP occurs in about 10% of EPP patients in the US and that ALAS2 mutation analysis should be undertaken in patients with EPP symptoms and no detectable FECH lesion. Finally, there was significant clinical variability in heterozygous XLP females.

Professional and family attitudes regarding large scale genetic information generated through next generation sequencing in research. *A. Cambon-Thomsen[1], A. Soulier[1], G. Bertier[2], S. Leonard[1], S. Julia[1], GEUVADIS consortium.* 1) Faculte de Medecine, INSERM U 1027 and University of Toulouse, Toulouse, France; 2) CRG, Center for Genomic Regulation Barcelona, Spain.

While genomic science is advancing tremendously, medical, ethical, legal, and social questions are arising regarding genetic information. Ethical aspects of genetic testing related to the use of high throughput techniques pose the problems of status of large scale genetic information regarding privacy and confidentiality, clinically useful information and the duties attached, health related information where no immediate clinical measure exists. Although most of the traditional ethical/legal frames that have developed over years for genetic research and applications continue to apply, some aspects need specific attention for research: The source of samples for sequencing; the type of consent; the scope and duration of studies; the right to withdraw; the concerns for the family; privacy issues (sensitivity of data; data access); return of results. A main feature of this accelerating technology development is a certain blurring between clinical and research contexts. Questions raised by large scale genetic technologies applications are: • Can the same type of regulation apply to targeted tests and to genome-wide sequencing? • Does sequencing require a different level or kind of consent than other genetic tests or medical assessments? • Should whole-genome sequencing method be performed for children or incompetent adults? • How to communicate results when their interpretation remains uncertain and what kind of results should be communicated? • Should participants be informed of incidental findings that unequivocally predict serious disease that can be prevented or ameliorated by early detection? What if the disease cannot be prevented or ameliorated? • How to regulate sequencing services offered directly to consumers? In order to get insights on such issues group discussions and questionnaires were conducted in the context of EU funded projects (GEUVADIS, CAGEKID, ESGI) in the professional contexts (research groups in genetics) and in family situations in 5 countries. Results show a variety of attitudes, that seem influenced by the national context; generally the importance of clear information, understanding of the aims and transparency was underlined. Results also highlight the necessity of addressing such issues at an early stage by collaborative efforts of geneticists, ethicists, social scientists, patient representatives and decision makers.

The Globalization of Reprogenetic Services: A Thematic Analysis of the Current State of Knowledge. *V. Couture, C. Bouffard.* Division of Genetics, Department of Pediatrics, Université de Sherbrooke, Sherbrooke, Quebec, Canada.

Reprogenetics which can be defined as a combination of in vitro fertilization and medical genetics techniques occupy an ever increasing place within the medical tourism market and, more specifically, in the cross-border reproductive cares movement. Cross-border reprogenetic services offer people who have the means the possibility to obtain abroad services that are not available in their country due to lack of expertise or legal or economic reasons. Within the limit of the knowledge developed on the subject, our objectives are: 1) to summarize the global situation of reprogenetic tourism and 2) initiate ethical reflection on this aspect of cross-border reprogenetic services. Methods: Collection, review and thematic analysis of the literature on cross-border transactions associated with reprogenetics; OVID (Journals@Ovid Full text), EBSCO (MEDLINE, CINHAL, etc.), SCOPUS (Elsevier) and FRANCIS. Results: If more and more articles are related to cross-border reproductive cares (112), the number of publications concerning reprogenetics remains low (61). Two main themes emerge from the literature: 1) the number of users and their destinations; 2) the legal and ethical aspects of those cross-border movements. The main legal subtopics deal with: a) the diversity of national regulations and b) the relevance of regulation which can be overcome by going abroad. The ethical aspects concern: a) the psychological burden, b) the support and remote follow-up, c) the accessibility issues and d) the social disparity. It appears that the variety of regulation of reprogenetic practices and countries where they are available have a major influence on transboundary movements of experts, biological material and users. This situation also raises the question of the limits that national, transnational and international laws and ethics have in their ability to protect users and children-to-be. It also interrogates how to ensure a fair accessibility to these services. Conclusion: Cross-border reprogenetic cares have been little studied as a distinct phenomenon. However, they raise their own ethical, legal, medical and logistical challenges that require us to develop, outside national law, original mechanisms that will ensure the respect of the integrity of the body and the person as well as the autonomy and dignity of users and children-to-be. This objective is even more important now that cross-border reprogenetic services engage populations marked by great wealth disparities.

1341T

Managing incidental findings from genomic testing: A public perspective. *S. Daack-Hirsch[1], A. Spore[1], J.K. Williams[1], M. Driessnack[1], C. Siomon[2].* 1) College of Nursing, University of Iowa, Iowa City, IA; 2) College of Medicine, University of Iowa, Iowa City, IA.

Background: The potential for genomic incidental findings (GIFs) is increasing with the use of comprehensive genotyping associated with whole gene analysis. Although the groundwork has been laid, the voice of the public needs to be incorporated to inform policy-making and establish best practice in the management of GIFs. Therefore, we explored issues and concerns about the management of GIFs in clinical and research testing with members of the public. Methods: For this exploratory descriptive study we conducted seven focus groups representing a broad cross-section of public groups, including elders, young adults, Latinos, African Americans, clergy, parents of children with hearing impairment, and an addiction recovery support group. In addition, seven parents whose children had chromosomal microarray testing were individually interviewed. Data were analyzed using qualitative content analysis. Results: Participants generally viewed incidental findings as unexpected results. Although a result may be unexpected to a patient/participant, it may not necessarily be unexpected from a health care provider/researcher perspective. As well, a result may be viewed as unexpected to one person, but not to another person. Participants generally wanted GIFs disclosed to them, regardless of the severity of the associated disease or the context for the test (clinical or research); although, they did understand that others may not want to know. Participants gave the following reasons for wanting to know about GIFs: to make life style changes; financial and life planning; seek early intervention; to inform other family members; identify causes of illness; and general management of health information. An overall theme of shared responsibility for the management of GIFs emerged in data analysis. This theme reflects that while there is an obligation for the clinician or researcher to disclose the information in a manner that gives the recipient guidance on how, when, and where to follow up on GIFs, the ultimate responsibility to act on the information resides with the recipient. Conclusion: Broad public input is needed in order to understand and incorporation the public's perspective on management of GIFs, and is essential as disclosure guidelines and policies are developed in both the clinical and research setting. Further research/policy-driven efforts are needed to explore this theme of the public's desire for shared responsibility.

The Appropriate Regulation of Genetic Discrimination at European Level: What can we learn from International Legislative Efforts? *A. de Paor.* Centre for Disability Law & Policy, National University of Ireland, Galway (NUI, Galway), Newcastle Road, Galway, Ireland.

The completion of the Human Genome Project and advancing technology have opened up a new era in genetic exploration. In light of these genetic advances, questions arise as to whether an appropriate framework exists to protect the interests of individuals and also to encourage further advances in the medical and scientific fields. With these genetic developments come new economic opportunities, together with ethical, social and legal considerations. One of the main concerns arising is the potential use of genetic testing to discriminate, especially in employment and insurance, leading to a violation of a myriad of fundamental human rights. Employers and insurance companies are using the results of genetic tests (as a powerful predictive tool) to discriminate based on perceptions of long term health risks and possible future disabilities. In 2008, the United States passed the Genetic Information Non Discrimination Act (GINA). GINA targets genetic discrimination by employers and health insurers. The legislation is revolutionary, in that it is the first pre-emptive anti-discrimination statute in American history. GINA attempts to eliminate this novel brand of discrimination before it becomes widespread. The law was enacted primarily to help ease concerns about discrimination that might discourage individuals from taking genetic tests that could benefit their health. Unlike the United States, there is currently no concrete legal position in this particular area at European Union level. The United Nations Convention on the Rights of Persons with Disabilities prohibits discrimination in a range of fields including employment (Article 25 (e)). Ireland and the EU have signed this Convention and the EU made a historic decision to ratify once a majority of Member States ratify. Once ratified by the EU there will be a responsibility on the European Commission to come forward with legislative proposals as appropriate. Genetic discrimination has already been singled out as a priority area of reform as evidenced, for example in Article 21.1 of the EU Charter of Fundamental Rights which expressly prohibits discrimination based on genetic features. This makes an EU-wide response inevitable as well as preferable to isolated solutions within the Member States. This paper will discuss the need for appropriate regulation of genetic discrimination in light of technological advances and explore what shape such a regulatory model might take at European level.

Carte blanche ou carte rouge? Willingness of U.S. adults to give broad and limited consent for genetic research. *R. Dvoskin[1], J. Murphy Bollinger[1], J. Scott[2], D. Kaufman[1].* 1) Genetics and Public Policy Center, Berman Institute of Bioethics, Johns Hopkins University, Washington, DC; 2) National Coalition for Health Professional Education in Genetics, Lutherville, MD.

Introduction: Biobanks and large cohort studies increasingly collect samples under broad consent for use in unspecified future studies. Yet there is concern that broad consent approaches will result in more refusals, and study samples that are less representative than those using narrow consent models. To compare the acceptability of two consent models, we surveyed Americans aged 18+ about a proposed national cohort study, randomizing people to view and respond to either broad or narrow hypothetical consent language. **Methods:** We administered an online survey to a random sample of 3,061 U.S. residents, including oversamples of black non-Hispanics (n= 675) and Hispanics (n=708). After being shown a description of the proposed study, participants viewed one of two excerpts from a consent form. Half were told that approved researchers would use their samples and information to study a wide range of diseases; the other half were told they would be asked for permission to use their samples for specific projects. All respondents were asked whether they would agree to share their samples and information with researchers in this manner. **Results:** Slightly more respondents would agree to the broad consent model than to the narrow consent (76% vs. 71%; adjusted p=0.005). Greater willingness to agree to broad consent was observed in nearly every category of gender, age, race and ethnic group, English-language proficiency, and education level. Black non-Hispanics and participants younger than 30 found broad and narrow consent equally acceptable. The strongest independent predictors of willingness to share data and samples, adjusting for the method of consent and other demographics, were trust in the study to protect one's privacy (OR=3.0, p<0.0001), concern that researchers will not follow privacy policies (OR= 0.5, p<0.0001), and having 16+ years of education (OR=1.7, p=0.0001). Men (as compared with women; OR=0.8, p=0.008) and black non-Hispanics (as compared with white non-Hispanics; OR 0.6, p=0.05) were less likely to consent under both models. **Conclusions:** These data suggest that broad consent language is unlikely to reduce initial participation rates compared to a model that allows participants to provide consent for specific studies. Additionally, the similar responses across demographic groups suggest that use of broad consent models is unlikely to influence initial participation rates (and resulting biases) among demographic subgroups.

Internatonal legislative and factors of influence on Preimplantation Genetic Diagnosis. *L.J. Escobar[1], J. Jimenez[1], E. Quesada[2], L. Hernandez[3], M. Jimenez[4].* 1) Hospital Rafael Mende, Lorca, Murcia, Spain; 2) CS Lorca Sur, Ágrea III de Salud del SMS, Lorca, Spain; 3) Hospital Vírgen del Castillo, Área V de Salud del SMS, Yecla, Spai; 4) Biotools B&M Labs S.A.-España, Spain.

PURPOSE: To analyze the current state of legislation on Preimplantation Genetic Diagnosis (PGD) in Canada, USA and other countries of Europe and Asia as well as the influence of different factors involved in each laws and proposal of their improvement. METHOD: Bibliographic descriptive study of the legislation of 18 countries on PGD. RESULT: PGD is one of the most spectacular advances in the detection of genes-related diseases and opens other possibilities such as the elimination of genetically transmitted diseases or the risk of suffering them, and even the genetic selection of individuals. This has led to a variety of ideological trends and to a heterogeneous international legislative framework on DGP, which has opened an interesting debate in the field of science, bioethics and law. Thus, there are countries where there is a mixed framework of state regulations and recommendations of professional societies (Canada, Australia), while in others there is no specific intervention of the legislature even if the DGP is permitted (US, Japan, UK, Netherlands). In Israel and Islamic countries, specific legislation doesn't exist, but there is a significant permissiveness, influenced by religious factors. In India DGP is forbidden with some exceptions. In Europe there is no common legislation, and the next thing closest to it is the consensus reached by the European Convention on Human Rights and Biomedicine of 1997, in which some countries implement a permissive policy (Spain, France, Denmark, Sweden, Norway), and others prohibit it (Germany, Italy, Switzerland, Austria), which is causing a movement of people within the European Union towards member states with permissive laws. As a rule of thumb, in countries where PGD is accepted, such method is allowed in case of serious genetic disease for therapeutic medical purposes; Sex selection is banned except for sex related diseases. As for the donation of human tissues to others for HAL histocompatibility, there is even less consensus. CONCLUSIONS: There is no common international law on DGP and every national legislative framework is influenced by social and religious criteria. We propose to make way for a multidisciplinary debate in order to reach an agreement on a minimum ethic basis for the development of this technique and of genomics in general. The task will involve finding the ethical limit of satisfaction between society and the protection of genetic identity and the extent of legislative action.

1345T

Public attitudes and interest in newborn genetic testing. *H. Etchegary[1], E. Dicks[2], J. Green[3], K. Hodgkinson[1], D. Pullman[4], P. Parfrey[1].* 1) Clinical Epidemiology, Memorial University, St. John's, Newfoundland, Canada; 2) Clinical Epidemiology, Eastern Health, St. John's, Newfoundland, Canada; 3) Genetics, Memorial University, St. John's, Newfoundland, Canada; 4) Community Health, Memorial University, St. John's, Newfoundland, Canada.

BACKGROUND: As newborn screening (NBS) panels continue to expand, they remain a focus of academic and policy debate. Whether or not testing in the newborn period is supported by parents or the public at large remains largely unknown. To help address this gap, we measured attitudes toward newborn genetic testing in our jurisdiction. OBJECTIVES: To measure interest in newborn genetic testing for several autosomal recessive disorders and reasons for interest. METHODS: A cross-sectional, pen and paper survey was administered to the general public and prospective parents in Eastern Canada between April - December, 2010. FINDINGS: A total of 648 individuals completed surveys. Interest in newborn testing for inherited hearing loss, vision loss and neurological disorders was high (over 80% would have their newborn tested). The attitudes of prospective parents and students were positive, but somewhat less so than members of the general public. Across all disorders, interest in testing was driven by the desire to be prepared for the birth of a child with a genetic disorder. Significantly more people would use the information from testing for fatal neurological disorders in future reproductive decisions than the information generated by newborn testing for inherited hearing or vision loss. CONCLUSIONS: Interest is high in newborn testing for a variety of conditions, including those for which no effective treatment exists. Findings lend support to the expansion of newborn screening panels to include those disorders currently lacking treatment and highlight the value of including the views of diverse stakeholders in screening policies.

1346T

Uses of ancestry in structured association mapping: a critical analysis of recent literature. *S.M. Fullerton[1], J. Yu[2], K.A. Edwards[1], J.S. Taylor[3], K.L. Edwards[4].* 1) Bioethics & Humanities, University of Washington, Seattle, WA; 2) Pediatrics, University of Washington, Seattle, WA; 3) Anthropology, University of Washington, Seattle, WA; 4) Epidemiology, University of Washington, Seattle, WA.

In research, genetic ancestry estimation and related methods to control for confounding due to population stratification are widespread and increasingly regarded as best practice. Yet, as noted in the work of the ASHG Ancestry and Ancestry Testing Taskforce (Royal et al. 2010), ancestry testing also brings with it a host of relevant ethical and social concerns, concerns which have been comparatively neglected in the focus on direct-to-consumer ancestry tests. To better understand and assess the impact of using ancestry estimation to address population stratification, we conducted a content analysis of 58 articles that use Ancestry Informative Markers (AIMs) in structured association mapping. Structured association mapping is a preferred method for addressing confounding in candidate variant studies and is expected to become more common in post-GWAS efforts to map the genes and variants contributing to susceptibility to common complex diseases. Articles were identified by a PubMed keyword search of primary research articles published between 1985 and 2009, and subsequent evaluation to retain only those articles that had employed AIMs for structured association. Articles were then reviewed to identify (1) the relation of study aims to structured association methodology, (2) the nature of AIMs use relative to published recommendations, and (3) the impact of ancestry-based correction on association findings. Overall, most of the studies in this sample provided little-to-no information on their approach to AIMs selection, ancestry estimation, or structured association. Justifications for conducting structured association analysis across the articles were also inconsistent. Whereas several studies conducted a test for stratification or described the population structure of their sample, an equal number of studies provided no explanation for why structured analysis was used. Most significant - given concerns about the ethical and social consequences of ancestry estimation - the majority of articles that corrected for population stratification by adjusting for ancestry proportions found that adjustment had little effect on association results. Taken together, these observations suggest that routine correction for population stratification, especially in the context of candidate gene investigations, may be unnecessary in many cases, and should be weighed carefully in light of attendant ethical and social concerns.

1347T

The Presentation of Risk Information by Personal Genotyping Services. *S.T.K. Garcia[1], S.S. Lee[2], M.K. Cho[2,3].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Stanford Center for Biomedical Ethics, Stanford University, Stanford, CA; 3) Department of Pediatrics, Division of Medical Genetics, Stanford University, Stanford, CA.

The accurate and effective communication of health risks is an important health policy issue as incorrect perceptions of risk may lead to healthcare under or overutilization. Personal genotyping services reporting the association of SNPs with various diseases and traits are of particular concern as they provide risk assessments of unproven clinical utility and positive predictive value. There is little research to date on users' understanding of their genetic risk information and the limitations of SNP genotyping for risk assessment. This pilot study sought to address this gap by assessing personal genotyping service adherence to the best practices for risk communication in the literature and recommendations by professional organizations to disclose the test purpose and current testing limitations. We collected data from demo accounts of three popular services: 23andMe, Navigenics, and Pathway Genomics, and a non-profit program, the Coriell Personalized Medicine Collaborative. A content analysis was performed on the summary result and disease-specific pages for five conditions reported on by all services (hemochromatosis, lupus, macular degeneration, prostate cancer, and type 2 diabetes). We abstracted data on elements relevant to the communication of risk determined by our review of the risk communication literature and relevant professional organization policy statements (NSGC, ASHG, and ACMG). Primary elements included numerical formatting, use of visual aids, strength of evidence, and disclosure of risk uncertainty. Services followed most of the literature recommendations for the communication of numerical risks including providing risks in a variety of formats and using figures to convey risk information. We found significant gaps in the disclosure of the limitations of SNP-based risk assessment as recommended by professional organizations. Limitations including the uncertainty of algorithms for risk calculation and the reported odds ratios are not universally disclosed and their effect on the precision of the risk assessment is not discussed. Additionally, results formatting does not change significantly based on the risk assessment; in-depth disease information including suggested prevention is disclosed regardless of risk status. The failure to disclose uncertainty in point estimates and the lack of risk-tailored results content may lead users to overestimate the precision and personal relevance of the information provided.

The ethical and scientific challenges of representativeness in nutrigenetics clinical research. *B. Godard, T. Hurlimann, R. Stenne, Omics-Ethics Research Group.* Department of Social and Preventive Medicine, Bioethics Programmes, University of Montreal, Montreal, Quebec, Canada.

Background*:* Nutrigenetics information is expected to be relevant for treatment, prevention of chronic diseases, as well as health promotion. As such, nutrigenetics may not only benefit patients and *at-specific risk* individuals, but all *healthy* individuals. In terms of global health, both industrialized and emerging countries are facing a growing epidemic of the same chronic diseases on which nutrigenetics research tends to focus. In this context, a selection of participants in nutrigenetics studies that is representative of all populations is crucial. Yet, the selection of participants may be a challenging task that raises both methodological and ethical issues. First, researchers may be torn between the desire to exclude individuals who could bias the study results or decrease its statistical power, on one hand, and, on the other hand, the fear of compromising the validity and usefulness of their findings for a broader and general population (external validity). Second, the definition of what constitutes appropriate representation in clinical research is further complicated by major ethical requirements, in particular by issues of justice and equity. Indeed, if results in nutrigenetics research are valid for some individuals, groups, or communities, and not for others, then questions of justice may arise. This paper aims to examine inclusion of ethnic minorities and populations of all ages worldwide in nutrigenetics clinical research and its scientific and ethical challenges. ***Methods:*** 173 publications were identified through a systematic review of clinical studies in nutrigenetics published between 1998 and 2007. Data such as participants' demographics as well as eligibility criteria were extracted. ***Results:*** There is no consistency in the way participants' origins (ancestry, ethnicity or race) and ages are described in publications. A vast majority of the studies identified was conducted in North America and Europe and focused on “white” participants. Our results show that pregnant women (and fetuses), minors and the elderly (/ 75 years old) remain underrepresented. ***Conclusion:*** Representativeness in nutrigenetics research is a challenging ethical and scientific issue. Yet, if nutrigenetics is to benefit whole populations and be used in public and global health agendas, fair representation, as well as clear and coherent descriptions of participants in publications are needed.

The Kaiser Permanente Research Program on Genes, Environment, and Health: Re-consent for Sharing Data through dbGaP and Predictors of Response. *J.N. Harris[1], S. Rowell[1], A. Altschuler[1], M. Sadler[1], M. Henderson[1], P. Liljestrand[1], D. Olberg[1], N. Risch[2,1], C. Schaefer[1], C. Somkin[1].* 1) Kaiser Permanente Division of Research 2000 Broadway Oakland, CA 94612; 2) Institute for Human Genetics University of California at San Francisco 500 Parnassus Road San Francisco, CA.

The Kaiser Permanente Research Program on Genes, Environment and Health (RPGEH) received a grant to create a genetic epidemiology resource on adult health and aging, the goal of which is to create genome-wide genotypes and telomere length measurements on 100,000 subjects and to link these data to extensive phenotypic information for research. As part of the data sharing plan, data will be deposited in NIH's Database of Genotypes and Phenotypes (dbGaP). The purpose of this study was to: 1)describe the approach and response to a re-consent campaign aimed at obtaining consent from participants to deposit data into dbGaP; 2)identify sociodemographic and clinical predictors of non-response to the campaign and describe potential barriers to participation. The RPGEH maintains biospecimens and clinical, behavioral, and environmental data on more than 180,000 KP members. When the RPGEH initially consented participants, broad permission was obtained to share de-identified data with qualified researchers outside KP. However, the consent form was developed prior to dbGaP and did not include explicit consent for depositing data into this resource. Based on feedback from multiple stakeholders we decided to use an opt-in approach to obtain consent for data sharing in dbGaP, thus requiring participants to return a new, signed consent form. We analyzed responses from the first 50,000 randomly selected individuals approached for reconsent. We received reconsent from 36,600 participants (73%). Response rates differed by race/ethnicity with higher rates in European-Americans (74%) and lower rates in Asian-Americans (66%), African-Americans (67%) and Latinos (68%). Younger individuals were harder to reach with 55% of people in their 20s vs. 77% of those in their 60s consenting. We received few calls from people concerned with data sharing or dbGaP. Overall, RPGEH's opt-in approach has been successful and can serve as a model for other biorepositories that may need additional consent for data sharing. Racial/ethnic minorities and younger individuals as well as different socioeconomic and clinical subgroups may require additional outreach, and community engagement efforts to improve enrollment. While less than 1000 individuals called in to decline consent, we are unclear why they (as well as the non-responders) declined participation. Additional research is needed to elucidate barriers to reconsent and determine the extent to which sharing data with dbGaP was a deterrent.

1350T

Does a duty of disclosure foster special treatment of genetic research participants? *R.Z. Hayeems[1], F.A. Miller[1], J.P. Bytautas[1], L. Li[2].* 1) Dept. Health Policy, Management, Evaluation, University of Toronto, Toronto, ON, Canada; 2) Dept Biostatistics, University of Toronto, Toronto, ON, Canada.

Introduction: Research ethics guidance stipulates that study participants should not receive enhanced medical care compared to non-participants. Fostering a duty to disclose genetic research results warrants consideration in the context of this guidance. **Methods:** We report on interview and survey data from international autism genetics researchers (clinical and non) regarding research result disclosure and care provision to study participants. Qualitative interviews were analyzed thematically. Survey Likert scale data were dichotomized into agree (agree or strongly agree) vs. not (neutral, disagree, strongly disagree); descriptive statistics were computed for all independent variables. The influence of specific variables on judgments about providing additional care to study participants were explored using unadjusted odds ratios (ORs) with 95% confidence intervals (CIs) as well as multivariate linear models, using $p<.05$ for significance. **Results:** Qualitatively, respondents (n=23) were aware that research participation, and the provision of research results, enables access to expertise and therapeutic resources that are otherwise difficult to obtain. Researchers' views varied regarding whether this should occur. Of 168 survey respondents (RR 44%), 52% agreed that study participants should gain access to additional knowledge and 46% agreed they should gain access to additional services that might not be as readily available to non-participants. Respondents who agreed they should report clinically significant results were twice as likely to agree they should provide additional knowledge [OR=2.04, 95% CI (1.012,4.125)]; those who agreed they should report results of uncertain significance were 7.5x more likely to agree they should provide additional knowledge [OR= 7.54, 95% CI (2.123,26.769)]. **Conclusion:** Providing research results to study participants can address needs that may otherwise be unmet. Qualitatively, we identified ambivalence about whether research should seek to ensure or avoid providing special treatment. Survey data found no consensus about providing study participants with care that may not be as available to non-participants. Feeling obliged to report research results to study participants, however, seems to heighten the disposition to ensure special treatment. This instinct runs contrary to fundamental research ethics guidance; fostering a duty to disclose genetic research results may further fuel this distortion.

1351T

Duty to warn: a case report. *K. Hodgkinson[1], R. Singleton[2], F. Curtis[3], D. Pullman[4].* 1) Medicine, Memorial Univ, St John's, NL, Canada; 2) Pastoral Care, Eastern Health, St. John's, NL, Canada; 3) Provincial Medical Genetics, Eastern Health, St. John's, NL, Canada; 4) Community Health, Memorial Univ, St John's, NL, Canada.

Arrhythmogenic Right Ventricular Cardiomyopathy genetic subtype 5 (ARVD5) caused by a p.S358L change in gene *TMEM43* is common in Newfoundland. The disease is autosomal dominant and lethal with 50% of affected males deceased by 40 years, and 80% by 50 years in the absence of treatment; compared to 5% and 20% respectively of women. Treatment with the implantable cardioverter defibrillator (ICD) increases survival significantly. A recently ascertained family via a 56-year-old female proband (subsequently determined to have the common *TMEM43* mutation)had lost a brother aged 32 to SCD many years ago. This proband was able to build some of her extended family tree but despite great effort, was unable to find their current whereabouts. The distress to this proband was obvious, as the death of her brother remained traumatic and she wanted no other families to suffer. She had the names and approximate years of birth of some of her at-risk family members so an ethics consult was convened to determine if hospital records could be broached to find these individuals. This is a `duty to warn' scenario, where the responsibility for contact is extended from the proband to the care givers. The ethics consultation discussion included health care privacy consultants, bioethicists, informatics experts, hospital lawyers, senior hospital physicians (including public health) and genetic counsellors. It was determined that the privacy consultants would broach the system, and the genetic counsellor would contact the family. This scenario is ongoing. It has lead us to consider the `circle of care' and to what diameter that extends. From the proband to the immediate family and potentially from the hospital to the extended family? Maintaining this analogy, it might be extended to public education and screening in the communities in which this gene is prevalent. Our cardiomyopathy research team has a significant ethics component, one major feature of which will be the determination of the extent of the potential issue of `duty to warn' and population screening for this lethal, yet treatable disease caused by the *TMEM43* mutation.

1352T

A qualitative analysis of European clinical geneticists' views of direct-to-consumer genetic testing. *H.C. Howard[1,2], P. Borry[2,3,4].* 1) Institute of Bio- and Medical Ethics Basel, University of Basel, Missionstrasse 24, CH-4056, Basel, Switzerland; 2) Centre for Biomedical Ethics and Law, Katholieke Universiteit Leuven, Kapucijnenvoer 35 BOX 7001, 3000 Leuven, Belgium; 3) Department of Clinical Genetics, section Community Genetics, VU University Medical Center, EMGO Institute for Health and Care Research, Van der Boechorststraat 7, 1081 BT Amsterdam, the Netherlands; 4) Department of Medical Humanities, VU University Medical Center, EMGO Institute for Health and Care Research, Van der Boechorststraat 7, 1081 BT Amsterdam, the Netherlands.

The offer of genetic testing services directly to consumers has been the subject of debate among health care professionals, researchers and policy makers for the last couple of years. There is a growing body of research regarding consumer views and attitudes on the subject but little is known about how clinical geneticists view direct-to-consumer (DTC) genetic testing. We, therefore, conducted a survey to collect information regarding the awareness, experiences and attitudes of European clinical geneticists about genetic tests and test interpretations sold directly to consumers. European clinical institutes where genetic counseling is offered to patients were contacted and 300 clinical geneticists from 28 countries were invited to participate in the survey. One hundred and thirty-one of the eligible respondents (44%) answered the survey. We previously reported the results of the quantitative aspects of the survey. Herein we discuss the results of a content analysis of the written comments made by the respondents. We focus on comments made regarding four main themes: 1) Their views and direct experiences with patients who have asked about DTC GT; 2) their attitudes about offering genetic testing without face-to-face medical supervision; 3) their views on the legal banning of certain types of genetic tests presently sold DTC; and 4) their attitudes on offering genetic counseling to patients who enquire about DTC genetic testing. These results will contribute valuable information to the debate regarding DTC genetic testing.

1353T

Ethical issues related to high throughput technologies for translation into clinical genetic testing. *S. Julia[1], A. Soulier[2], E. Rial-Sebbag[2], A. Cambon-Thomsen[2], TECHGENE consortium.* 1) Medical genetics, Inserm U 1027 and University Hospital of Toulouse, Toulouse, France; 2) Inserm u 1027 and University of Toulouse, Faculty of Medicine, Toulouse, France.

The goal of the EU funded TECHGENE project (www.techgene.eu) is to incorporate the novel massive parallel sequencing technology in routine diagnostic laboratories for the improved diagnosis of genetically heterogeneous diseases. As high throughput technologies (HTT) may reduce the cost and increase the throughput of genomic sequencing, these technologies are expected to become an essential clinical tool. Part of the project is addressing ethical aspects of HTT. Literature survey, conceptual analysis and discussion within the consortium generated a list of agreed points to consider, and corresponding positions. Complexity of individual results will increase the counselling demand and require much more elaborate and detailed informed consent procedure. Clinicians and laboratory personnel will require training to use the sequence data effectively and appropriate methods will need to be developed to deal with the incidental discovery of pathogenic mutations and variants of uncertain clinical significance. In addition the effective translation of genomic advances into better health care will inevitably require access to and integration of multiple databases, which is likely to raise logistical and ethical considerations. The pace of clinical integration will not be limited by the rate of technology development, but by the ability to accurately interpret the resulting data. HTT has the potential to transform practice of medical genetics and related fields, but the vast amount of personal genomic data produced will increase the responsibility of geneticists to ensure that the information obtained is used in a medically and socially responsible manner. There is a need for a sustained drive to collect relevant evidences about the scientific and clinical validity and utility of HTT before they become implemented and utilized. These elements include: well-functioning health systems; access to health services; an evidence-based infrastructure that evaluates, regulates, sets guidelines, and compares cost-effectiveness of interventions; and an understanding of how local contexts influence relevance, uptake and acceptance of interventions. To ensure fair and reasonable translation of sequencing technologies, the issue of prioritization needs to be addressed explicitly by collaborative efforts of geneticists, ethicists, health economists, patient representatives and decision makers. A translational infrastructure is urgently needed with adaptable governance systems.

1354T

Public views of study design features for biobanks and large-scale genetic cohorts: results of a nationally representative conjoint analysis. *D. Kaufman[1], J. Bollinger[1], J. Bridges[2], C. Buttorff[2], R. Dvoskin[1], J. Scott[3].* 1) Genetics & Public Policy Center, Berman Institute of Bioethics, Johns Hopkins University, Washington, DC; 2) Department of Health Policy & Management, Johns Hopkins University, Baltimore, MD; 3) National Coalition for Health Professional Education in Genetics, Lutherville, MD.

Background: Biobanks and large genetic studies need to minimize participant burden and maximize value of the data, while remaining affordable. To inform future research, we measured the public's preferences for design features for a proposed national cohort study. **Methods:** In April 2011, we surveyed a nationally representative sample of 1,538 US adults. Study design preferences were assessed using conjoint analysis. Participants viewed nine pairs of study designs that varied with respect to six features: study length (5, 10, or 15 years); the return of individual research results, or IRRs (none, some validated, all); whom data are shared with (US academics; US and foreign academics; US academics and industry); annual compensation (none, $50, $100), health data collection (via surveys, medical records, or exams); and possible study requirements (fitness test, diet journal, home visit). For each pair of study designs, respondents chose the study they would prefer. A random utility model was estimated using conditional logistic regression. Participants were also surveyed about other aspects of the proposed study. **Results:** After viewing an explanation of the proposed national study, 54% would definitely (13%) or probably (41%) participate. Annual bonuses were the most important design factor, followed by the return of IRRs and the length of the study (all $p<.0001$). The most attractive design features were a 5-year study length (odds of participating in a 5-year study, compared to the odds of participating across all possible study designs, OR=1.29), annual bonuses of $100 (OR=1.75) and $50 (OR= 1.10), and return of all IRRs (OR=1.32) or a few valid IRRs (OR=1.13). Respondents would also be more likely to join studies that conduct fitness tests and use physical exams to update history. The most repulsive elements were lack of an annual bonus (OR=0.52), no IRRs returned (OR=0.67), a 15-year duration (OR=0.74), sharing data with foreign academics (OR= 0.91), and a required diet journal (0.91). A separate question found that 60% preferred a 12-year study returning a small number of actionable IRRs to a 10-year study providing no results (24%) or a 20-year study returning all results (16%). **Conclusions:** Study duration and rewards for participation were the most important factors to potential participants. The importance of receiving personal health information was underscored by people's preferences for the fitness test and physical exams.

1355T

Public views of sample collection methods for biobanks. *J. L'Heureux[1], J.C. Murray[1], C.M. Simon[2,3].* 1) Department of Pediatrics, Univ Iowa, Iowa City, IA; 2) Program in Bioethics and Humanities, Univ Iowa, Iowa City, IA; 3) Department of Internal Medicine, Univ Iowa, Iowa City, IA.

Background: Biobanks often utilize one of two broad methods of collecting biological specimens: 1) collection of discarded clinical specimens or 2) collection of new specimens specifically for use in the biobank. Little has been reported regarding people's views of these two methods. This study explored public perceptions of these two sample collection methods in the context of a hospital-wide biobank that links both discarded and newly collected biological specimens to electronic medical records for research purposes. Methods: Focus groups and telephone surveys were conducted within the University of Iowa Hospitals and Clinics patient catchment area, to assess relevant public opinions and preferences for a number of biobank features including the two methods of sample collection. Results: Forty-eight individuals participated in 7 focus groups, followed by a survey of 751 randomly selected individuals from counties across Iowa and neighboring states that fall within the UIHC catchment area. Focus group participants were predominantly female (58%) and Caucasian (88%), with an average age of 52.4 years (range: 18-92 yrs). Survey participants were predominantly female (63%) and Caucasian (97%), with an average age of 58.4 years (range: 18-94 yrs). Advantages of utilizing discarded specimens identified by focus group participants were: 1) the convenience of not having to have an extra blood draw or appointment, 2) using samples instead of wasting them (like recycling), 3) cost and time savings for the biobank, and 4) the possibility of increasing accrual rates. Perceived advantages of having a blood draw specifically for biobank purposes were: 1) the ability to get more desirable samples and 2) increased participant awareness of their samples being used for research. Seventy-three percent of survey participants viewed either method as equally workable options, 17% preferred use of discarded specimens, and 6% preferred collection of specimens specifically for the biobank. Conclusion: While collection of specimens specifically for biobanking may deter some potential biobank participants, many find it no less acceptable than the collection of discarded specimens. Limiting inconvenience to potential participants by combining blood draws with already scheduled appointments may help to make this method of sample collection even more acceptable to potential participants.

1356T

Diverse Maternal Perspectives of the Return of Results in Pediatric Genetic Research: Results from Formative Research for the National Children's Study. *K.D. Lakes[1], E. Vaughan[1], A. Lemke[2], M. Jones[1], D. Baker[1], J. Swanson[1].* 1) Pediatrics, University of California, Irvine, Irvine, CA; 2) Center for Genetics Medicine, Northwestern University, Chicago, IL.

As the field of genomics rapidly advances, there is growing interest in applying these technologies to study children's health. Discoveries of associations between genetic variants and disease have increased significantly, but the utility of much of this information for any specific individual remains undetermined. Despite uncertainties, some have argued that parental discretion should be allowed regarding disclosure of individual results when research involves comprehensive genomic testing. Ethical concerns include which results to report and through what methods. Our goal was to identify how concerns, preferences, information needs, cultural values and reasoning strategies impact decisions to receive individual-level findings in order to identify potential disclosure impacts and to develop strategies that improve the conduct of genomic research with children from diverse backgrounds. We report findings from formative research conducted for the National Children's Study. We conducted 7 focus groups in English or Spanish with 53 socioeconomically and ethnically diverse women (28% Hispanic, 49% White/Non-Hispanic, 21% Asian American), and analyzed transcripts of discussions using qualitative thematic methods. Themes emerged that support the need for further research and reconsideration of assumptions that currently guide practices for return of results in genomic research. The analysis revealed that: decisions about receiving results may not be immutable and preferences may change over time; clinical utility may not be the primary determinant of a parent's desire to receive results; nondisclosure may present emotional “harms” not currently considered in bioethics discussions; cultural values play a role in the impact of and decisions about return of results; disclosure of certain findings could affect the parent-child relationship; diverse research populations may have strong expectations for the ethical process of information sharing that go beyond commonly approved protocols; the probability that certain genetic patterns are predictive of disease may not represent participants' decision models; and the timing of the return of results could affect emotional impacts of disclosure. Our results provide insights about diverse expectations, preferences and reasoning strategies for decisions regarding the return of results in pediatric genomic research and identify important gaps in scientific evidence to guide the ethical conduct of such research.

1357T

Returning Research Results: A Deliberative Engagement in Southside Chicago. *A. Lemke[1], C. Halverson[2], L. Friedman Ross[2].* 1) Northwestern University, Chicago, IL; 2) University of Chicago, Chicago, IL.

To promote broad representation and participation in biobanks, it is important that policies are developed in a way that is respectful of diverse communities. In an effort to widen knowledge and inform institutional policies, we conducted a deliberative engagement of individuals from various socioeconomic communities to consider biobank policies regarding return of research results, informed consent, and data sharing. Each group engaged in 4 sessions over 2 days, with each session preceded by an educational presentation. Pre- and post-session surveys were also administered to assess participant attitudes and beliefs. Forty-five individuals participated: two groups consisted of primary caregivers of children who receive pediatric care at a Federally Qualified Health Center (n=22), and two groups consisted of primary caregivers of children who receive pediatric care at a university clinic (n=23). All participants self-identified as African-American and 76% were women. Participants from the FQHC compared to the University clinic were more likely to have ≤ high school education (~36% vs. 9%, $p < .05$). Major themes from the focus group data included: 1) overall interest in individual research results, broad consent, and data sharing; 2) awareness of historical events and lack of education as root causes of fear and distrust; 3) the role of research recruitment and biobank strategies for establishing trust; 4) ensuring accessible benefits from biobank research to all, regardless of ability to pay; and 5) positive experience with the deliberative engagement process. Survey data revealed that approximately 90% of participants expressed interest in receiving individual research results indicating a risk for asthma, and Alzheimer's disease; and roughly 80% were interested in receiving gene findings more common in a racial group and findings with uncertain significance. The degree of interest was the same for learning results about themselves and their children, and did not differ between clinic types or over the 2 days. Level of perceived likelihood of identification from their genetic research data, and potential harm as a result of being identified, decreased over the sessions. In contrast, views regarding protection of privacy of genetic research information remained the same (85% concerned). Our findings revealed community insights that may be important in facilitating relationships and policy discussions between biobank researchers and research participants.

1358T

Exploring the ethics of incidental findings from whole genome studies: understanding what research participants, genomic researchers and genetics professionals want. *A. Middleton[1], M. Parker[2], H. Firth[1], N. Carter[1].* 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) Ethox, University of Oxford, Oxford, United Kingdom.

The Deciphering Developmental Disorders (DDD) project will use the latest whole genome technologies to investigate 12,000 children with undiagnosed developmental delay and their parents from every Regional Genetics Service in the UK. The aim of this is to identify new genetic causes for developmental disorders. However, in doing so, clinically significant `incidental findings' will be uncovered. For example, a BRCA1 mutation may be found in a two year old. Such a finding is unlikely to be related to the developmental disorder and yet could still be clinically significant to the child in later life as well as to other family members. Incidental findings could include variants of known and unknown significance, information about life-threatening and serious conditions and information about carrier status. In the DDD research project, incidental findings will not be revealed to participants until more is known about the ethical implications of reporting such results. However, pressure is mounting from policy makers and ethicists to share clinically significant incidental findings, the thinking being that it is unethical to withhold genetic information that could enable the research participant to take preventative or therapeutic action. Whilst there is often sympathy with this position, some genomic researchers are concerned that the time spent searching for, interpreting and reporting incidental findings unrelated to the research aims might jeopardise attaining those aims. As yet there are no published large-scale studies that have gathered empirical data on any of these issues; we aim to address this omission as part of the DDD project. We are ascertaining the views of research participants, genomic researchers, genetic health professionals and laboratory staff. Our questions focus on attitudes towards sharing incidental findings, how such findings could be categorized, what to do with findings of unknown significance, attitudes towards mining specifically for certain types of incidental findings as well as views on how consenting procedures in whole genome studies should be structured. We have designed a social sciences study using a mixed methods approach, utilising both quantitative and qualitative techniques. Throughout 2011 more than 20,000 people will be invited to participate in an online questionnaire and 50 invited for face-to-face interview. We aim to report the first findings from our study at the ICHG conference.

1359T

Informing the return of individual research results in biobanks and large-scale genetic studies: results from a public survey. *J. Murphy Bollinger[1], J. Bridges[2], G. Gallego[2], R. Dvoskin[1], J. Scott[3], D. Kaufman[1].* 1) Genetics and Public Policy Center, Berman Institute of Bioethics, Johns Hopkins University, Washington, DC; 2) Department of Health Policy & Management, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 3) National Coalition for Health Professional Education in Genetics, Lutherville, MD.

Researchers have reported a strong public desire for the return of individual research results (IRRs) to participants in genetic studies. As guidelines for the return of IRR emerge, questions remain as to which results to return and how to deliver them. To understand public preferences and inform researchers considering the return of IRR, we surveyed a representative sample of 3,061 US residents aged 18+. **Methods:** Experiment 1: 1,523 respondents were randomly selected for a discrete choice experiment, to measure the relative importance of eight attributes of a policy to return IRR from a proposed study. In each of 12 survey tasks, the attributes were divided into two mutually exclusive groups and respondents chose the preferred policy. Experiment 2: We measured the influence of the actionability, magnitude of risk, and disclaimers surrounding a given research result on peoples' desire for particular types of IRR. Participants (n=3,061) were randomized to view one of eight sample results and asked their opinion of the information. **Results:** Experiment 1: All eight attributes significantly influenced IRR policy preferences ($p<0.0001$). The most influential features were IRR for treatable diseases (odds ratio of selecting a policy with this feature compared to one without=1.8) and common diseases (OR=1.6), IRR indicating major change in disease risk (OR=1.6), and the provision of detailed reports (OR=1.6). Of lower priority were IRR returned at no cost (OR=1.3), IRR for serious diseases (OR=1.1), IRR confirmed in other studies (OR=1.1), and the option to discuss IRR with study staff (OR=1.1). Experiment 2: Participants who viewed a result conferring a 2x increase in risk were significantly more likely than those who saw a 1% risk increase to find the result “more useful” (29% vs. 24%) and “more worrisome” (17% vs. 10%) than they had expected. More participants would pay for IRR that show 2x risk than results showing a 1% increase (43% vs. 38%). Results shown without disclaimers were seen as “more useful than expected” more often than results with disclaimers (29% vs. 24%). Actionable results were seen as “more useful than expected” more often than inactionable data (OR=1.3). **Conclusions**: People place high value on actionable IRR and ones showing large changes in risk. Since a limited number of research results are likely to meet these criteria, returning a small number of findings, including those for common diseases, may satisfy much of the desire for IRR.

Consumer genetics in East Asia: public attitudes and policy analysis. *K. Muto, Y. Inoue, T. Arauchi, H. Hong, C. Chang, M. Sato.* Dept Pub Policy, IMS, Univ Tokyo, Tokyo, Japan.

Background: In 2010, DTC (direct-to-consumer) genetic testing for health purposes have been featured again in the US for several warnings by FDA. In contrast, several Shanghai-based companies started to advertise in Japan to sell DTC genetic tests including talent identification, such as memory, concentration, music and drawing. However, regulation of DTC genetic tests for non-health purposes have rarely been discussed before. Is this just fun or entertainment using human DNA? The JSHG didn't agree and published the statement for consumer genetics in 2010 for further discussions on genetic tests non-health purposes. Purpose and methods: To address broad ethical, legal and social implications arising from such tests, we've conducted a questionnaire survey to the Japanese general public to know their recognition and interests towards DTC tests. We've also conducted policy analysis towards consumer genetics and clinical genetic testing in East Asian countries. Results: Advertisement is commonly observed in East Asia though some of the tests have been banned in South Korea. Regarding our survey, 3,606 respondents completed (Respond rate=60.1%). 72.9% of respondents replied that they didn't know DTC genetic tests and 1.3% of them have purchased before. Multi-factorial diseases (53.4%), congenital disorders (36.6%) and aging (32%) for themselves are most attractive tests. Younger generation shows higher interests DTC tests of several purposes, including personality (26.2%), intelligence (26.1%) and physical strength (23.3%). Discussions: We confirmed that DTC genetic tests for non-health purposes are less popular than those for health purposes. Advocacy for younger generation is necessary.

Translational pathways for prenatal aneuploidy testing using cell-free fetal DNA. *L. Sayres[1], M. Allyse[1], J. King[2], S. Kelly[3], M. Nunes[4], M. Cho[1].* 1) Center for Biomedical Ethics, Stanford University, Stanford, CA; 2) Hastings College of the Law, San Francisco, CA; 3) ESRC Centre for Genomics and Society (Egenis), University of Exeter, Exeter, UK; 4) Pediatrics and Medical Genetics, San Diego Medical Center, Kaiser Permanente, San Diego, CA.

Fetal aneuploidy detection using cell-free fetal DNA (cffDNA) in maternal blood may routinize prenatal testing due to its non-invasiveness, earlier detection time, and low cost. Given recent publication of three independent studies that robustly demonstrate the accuracy of sequencing techniques to detect aneuploidy and the emergence of several companies developing these, it is likely that aneuploidy testing using cffDNA will soon be commercialized. However, translation of this technology into clinical application is not necessarily inevitable and may take divergent pathways in different settings. For instance, similar testing using cffDNA for RhD blood typing, although commercially available, has not realized widespread use in the United States whereas it is farther advanced in many European countries. CffDNA testing for aneuploidy must demonstrate analytic and clinical validity, utility, and cost-effectiveness to achieve effective translation. This technology must also surmount issues of patenting, regulation, the potential for direct-to-consumer testing, competition with existing testing regimes, third-party payment, informed consent, and moral issues around diagnosis or prediction of an expanding list of fetal traits. The priorities and perceptions of stakeholders must be integrated into the development process to ensure successful, ethical translation. Stakeholders in aneuploidy testing using cffDNA include patients and their families, practitioners, researchers, testing companies, insurers, government agencies, and members of the disability rights, pro-life, and pro-choice communities. We present an innovative framework that uses socio-technical mapping to evaluate the potential pathways of cffDNA aneuploidy testing implementation and the values underlying each. This framework seeks to align the values of researchers and technology developers with those of other stakeholders. Due to its accelerating development and commercialization, aneuploidy testing using cffDNA provides a valuable case study for the translation of novel genetic technologies into clinical practice. We anticipate that this framework can also be applied to other emerging genetic technologies and that stakeholder opinions surrounding cffDNA testing will have wider implications for the translation of these technologies from bench to bedside.

Parental reflections on choice and decisions to accept newborn blood-spot screening. *S.G. Nicholls.* PPR, Lancaster University, Lancaster, Lancashire, United Kingdom.

Introduction: Newborn screening programmes, whilst offered to individuals, resemble traditional public health programmes because (a) they are targeted at large groups of the population and (b) they are offered as preventive interventions to a population considered healthy. For many programmes this potentially presents an ethical tension between the goal of promoting high uptake of supposedly `effective' population oriented programs and the goal of promoting genuinely informed decision-making. Methods: I explore this potential tension through an exploratory sequential mixed methods approach using an initial phase of qualitative interviews with parents (n= 18) and a subsequent postal questionnaire (n=154). Qualitative data was coded using a thematic analysis approach with survey responses analysed using descriptive statistics and structural equation modelling (SEM). Results: Interviews indicated that there may be discord between the stated aims of supporting informed choice and the practice of providing a population screening programme. In particular parents referred to aspects of procedurlisation and information presentation as diminishing the perceived availability of choice. Parents also noted aspects of timing that impacted on their ability to make considered informed decisions. Survey results suggested that ability to make a choice was of less concern than the availability of choice with 80% of parents agreeing to some degree that it had been expected that their child have the heel prick and over 30% indicating that they did not feel they had a choice to decline the screening. Perhaps most disconcerting was that over 10% of parents felt that they had not made an informed choice. SEM revealed the importance of this finding with perceived choice having a significant impact on the perceived quality of decision made and a standardised coefficient almost twice as large as the parents' specific attitudes towards screening itself. Conclusions: These results suggest that parents view choice as an important factor in their decision-making. Despite an explicit mandate to gain consent and facilitate informed choice this may not be the case for some parents. The factors identified within the interviews may be appropriate avenues for development, with the provision of information prenatally being spontaneously offered by parents as a way to facilitate decision-making.

How does the genetic test report format change physician decision making for at-risk relatives of cancer patients? *S. Plon[1,2,3], B. Parks[1], H.P. Cooper[4], T. Wang[2], S.U. Dhar[2,3], S. Staggs[5], A.D. Weinberg[4], S.G. Hilsenbeck[2,4].* 1) Dept Pediatrics, Texas Children's Cancer Center, Baylor College of Medicine, Houston, TX; 2) Dan L Duncan Cancer Center, Baylor College of Medicine, Houston, TX; 3) Dept Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 4) Dept Medicine, Baylor College of Medicine, Houston, TX; 5) Texas Medical Association, Austin, TX.

Background: DNA sequence-based testing is used for prediction of cancer risk with results described as negative, deleterious mutation or variant of uncertain significance (VUS). We previously demonstrated that non-geneticist physicians chose comprehensive sequencing for healthy relatives in situations where the cancer patient carried a deleterious mutation or VUS. We now determined whether changing the genetic test report format would alter physician decision making. Methods: Practicing physicians in Texas from five specialties completed an online case-based survey which asked for genetic testing and management recommendations for the healthy relatives of cancer patients. The new survey only differed in the test report format which for each variant contained: classification, likelihood of pathogenecity and specific follow-up recommendations. Results: Surveys were obtained from an independent sample of 226 physicians. When the cancer patient carried a deleterious mutation (Class 5 variant), there was little change with a minority of physicians recommending “single site testing” of the relative (26% in new survey versus 20% in prior one, p=0.0525). When the cancer patient carried a VUS (Class 3 variant), physicians were more likely to choose “testing not appropriate” with 33% for the new versus 18% on the prior survey (p=0.007). Per physician, estimated median total testing costs for all cases fell from $10,020 to $8430 (p=0.0003) in the new survey, however, still far exceeding total costs of $950 if national guidelines were followed. Experience with BRCA1/2 testing did not impact testing decisions (p=0.0906). In the current survey there was less intense cancer risk management for at-risk relatives found to carry the VUS but only breast MRI and mastectomy recommendations met statistical significance, e.g. 5% versus 11% previously recommended mastectomy (p=0.0248). Conclusions: Using a defined classification scheme for reporting cancer susceptibility test results has only modest impact on physician decision making. For VUS carriers, physicians were less likely to pursue testing of at-risk relatives and less intense cancer risk management was recommended. Physicians overall continued to choose more comprehensive sequencing compared with national guidelines for at-risk relatives. Improving the care of family members and decreasing costs will require utilization of genetic professionals and better education of physicians. Supported by grant 5R01HG004064.

OMIM.org, A New and Improved Website for Online Mendelian Inheritance in Man. *J.S. Amberger[1], F.J.-M. Schiettecatte[2], C.A. Bocchini[1], A.F. Scott[1], A. Hamosh[1].* 1) Inst Gen Med, Johns Hopkins Hosp, Baltimore, MD; 2) FS Consulting, LLC, Salem, MA.

The advent of whole genome and exome sequencing has allowed information on gene-phenotype relationships to flourish. Online Mendelian Inheritance in Man (OMIM) brings a long, rich history and unique expertise to the challenge of curating these relationships and classifying newly recognized disorders. A new web interface, omim.org, hosted at UCSC Genome Bioinformatics now provides the research community with optimal views of the OMIM data. Gene-phenotype connections are displayed prominently at the top of both the gene and phenotype entries. Phenotypic series have been created to show the relationship of a particular phenotype across the genome. To enhance the clinical utility of OMIM, ICD and SNOMED codes are available for medical records coding, and phenotype entries have links to GeneTests, Clinical Trials, POSSUM, and Orphanet. Links to many other genetics resources are topically organized within each entry. These resources include genome browsers, protein databases (UniProt and HPRD), gene info (e.g., BioGPS, Gene Cards, PharmGKB), variation databases, model organism databases (e.g., MGI, KOMP, IKMC, ZFIN) and cellular pathway databases. OMIM's Synopsis and Morbid Gene Map is now searchable by genomic coordinates and the clinical synopsis information is available in the full view or new quick view format. OMIM terms have been mapped to SNOMED Clinical Terms, the Unified Medical Language System (UMLS), the Phenotype Ontologies, and the Disease Ontology. These terms are also available via the National Center for Biomedical Ontology (NCBO) BioPortal. Additionally, a thesaurus is an optional supplement to the standard search to allow the retrieval of similar concepts (e.g., cryptorchidism and undescended testes). Researchers interested in data mining can access the OMIM data via an API. OMIM, a data mainstay of the genetics community, continues to provide timely and authoritative accounting of the correlation between mendelian disease and the genes that cause them, and looks forward to working with the research and clinical communities to maximize the usefulness of the database.

The Human Variome Project - Collection of Variation Worldwide. *R.G.H. Cotton, collaborators of the Human Variome Project.* Human Variome Project, Melbourne, Australia.

The Human Variome Project (*Nat Genet*39(4): 423,2007)(www.humanvariomeproject.org) was initiated in June 2006 (Ring et al.*Pharmacogenomics*7(7): 969-72,2006) drawing attention to the importance of collection of variation and its phenotype and to develop programs to put this into effect. The project builds on work and concepts of the HGVS and others over many years (www.hgvs.org) to focus on all variation associated with disease. The project will include those discovering mutations and their effects and then collecting the data making it instantly available for those who need it to inform clinical decisions,therapy,and research. A high level meeting in Spain (Kaput et al.*Hum Mutat* 30(4): 496-510,2009) developed plans to implement the recommendations of the HVP Melbourne meeting (Cotton et al.*Nat Genet*39(4): 433-6, 2007). The HVP was featured recently in relation to Neurogenetic databases in Science (Cotton et al.*Science* 322(5903): 861-2,2008) and a HVP Neurogenetic Database Initiative is being formed after an HVP Neurogenetics forum in Hawaii October 2009. The Nutrigenomics community is establishing protocols in partnership with HVP. This activity culminated in the third HVP meeting hosted by and under the patronage of UNESCO in Paris(Kohonen-Corish et al.*Hum Mutat*31(12): 1374-81,2010). The HVP and InSiGHT (International Society for Gastrointestinal Hereditary Tumours) (www.insight-group.org) has developed a major pilot study to develop procedures and systems to allow effortless flow of de-identified data for the colon cancer genes from the patient/clinic/diagnostic laboratory via curated locus or gene specific databases to central databases/genome browsers such as NCBI, UCSC and EBI. The system will be easily adaptable to other genes and to multiple laboratories,states and countries worldwide. A country specific collection pilot is underway in Australia and an International Confederation of these countries has been initiated with Malaysia, Korea, China, Australia, Egypt, Belgium, Spain, Greece and Saudi Arabia in the application process. Other pilot studies developed include specific ethical studies related to mutation collection, loading of LSDB content to NCBI databases,funding of curation of LSDBs, a system of Microattribution/reward for mutation submission. Recent commitment by the Chinese Government will allow the rate of the program to be increased (Cyranoski.*Nature* 469(455),2011).

Human Resource Training in Medical Genetics in Cuba. *P. Lantigua-Cruz, N. Gonzalez-Lucas.* National Center of Medical Genetics, La Habana, La Habana, Cuba.

Developing countries face challenges in incorporating advances in genomics in heath services. In Cuba, these are accessible to the entire population as a social benefit. Information from predictive and genetic testing creates an ethical dilemma when there are insufficient numbers of health personnel with the scientific training to explain the preventive possibilities and risks implied by test results. On the other hand, the risks of occurrence and recurrence of genetic diseases become more clear on the basis of information from clinical diagnosis and the assessment and analysis of genetic susceptibility to environmental risk factors for common diseases, identified by epidemiologic research in communities. The present work describes the design and development of human resources training programs in medical genetics and their effect on prevention of genetic diseases in Cuba, focussing on Community Genetics. Cuba's strength in training human resources for genetics is in a 60-hour medical genetics course in the fourth semester of the undergraduate medicine program and related material in undergraduate nursing and health technology programs. Since 1977, there has been a postgraduate medical program in clinical genetics with several subspecialties. Since 1992, medical residents must also complete a specialty in comprehensive general medicine (MGI). There are also master's programs in medical genetics and genetic counselling, lasting two years and eighteen months, respectively. Since 1977, 149 physicians have graduated as specialists in clinical genetics, 78.5 % of them between 1992 and 2010. A further 835 professionals have earned master's degrees in clinical counselling (61.4 % MGI and 36.3 % baccalaureate nurses). Master's degrees in medical genetics have been taken by 48 professionals (25 physicians with various specialties, including neurology, pediatrics and neonatology) and 23 non-medical professionals involved in genetic research. The cornerstone of the mission for equitable distribution of the benefits of genomic research in medicine is human resource development that ensures, based on academic training, a scientific level capable of dealing with the sensitive information communicated between professionals and clients of genetic services.

Impact of Web-based Case Conferencing on Cancer Genetics Training for Community-based Clinicians. *K. Blazer[1], C. Christie[2], G. Uman[3], J. Weitzel[1].* 1) Division of Clinical Cancer Genetics, City Hope Comprehensive Cancer Center, Duarte, CA; 2) Graduate School of Education and Information Studies, University of California Los Angeles, Los Angeles, CA; 3) Vital Research, 6380 Wilshire Blvd, Los Angeles, CA.

Introduction: Technology and market forces are driving the demand for cancer risk assessment and preventive care in the community setting, where clinicians are often inadequately prepared to order and interpret predictive genetic tests. City of Hope Cancer Center conducts a three-phase training course in genetic cancer risk assessment (GCRA) for community-based clinicians across the Unites States and internationally, comprised of distance didactics, face-to-face workshops and 12 months of post-course professional development. As designed, the course cannot meet growing demands for GCRA training. Previous action research with key course stakeholders identified face-to-face case-based workshops as a barrier to increasing course access and capacity. This study compared the effectiveness of participation in an established Web-based case conference forum as a more accessible alternative to face-to-face case-based training. Methods: A quasi-experimental design compared pre-post knowledge, case-based skills and professional self-efficacy outcomes from 2009-2010 course cohorts (n=96). The intervention group (n = 52) engaged in Web-based case conferences concurrently with distance didactics; the comparison group (n = 44) participated in the course as originally designed. Results: Both groups and all practice disciplines demonstrated significant pre-to-post increases on all measures. Knowledge increases were higher for the intervention group ($p < .015$); skills and self-efficacy increases were comparable between groups ($p < .33$ and $p < .30$, respectively). Discussion: Findings support the efficacy and utility of Web-based case conferencing to support case-based GCRA training for community-based practitioners. Further studies may inform the development of tools to assess the impact of Web-based case conferencing on long-term practice change and patient outcomes, in alignment with the highest standards of continuing professional development.

Development and dissemination of a knowledge support service in genetics for primary care providers. *J.C. Carroll[1], R. Grad[2], P. Pluye[2], N. Pimlott[3], J. Allanson[4], J. Permaul[1], B. Wilson[5].* 1) Department of Family Medicine, Mount Sinai Hospital, Univ of Toronto, 60 Murray St, Box 25, Toronto, Ontario, Canada, M5T3L9; 2) McGill University, Department of Family Medicine, 517 Pine Avenue West, Montreal, Qc, Canada, H2W 1S4; 3) Department of Family and Community Medicine, Women's College Hospital University of Toronto, 60 Grosvenor Street Toronto, ON M5S 1B6; 4) Department of Genetics Children's Hospital of Eastern Ontario 401 Smyth Road Ottawa, ON, K1H 8L1; 5) University of Ottawa, Faculty of Medicine, Department of Epidemiology & Community Medicine, 451 Smyth Road (3230E), Ottawa ON K1H 8M5.

Background: Patients look to their family physicians (FPs) for credible information and guidance in making informed choices about genetic testing. FPs express a willingness to play a role in delivering genetics services but are challenged by lack of knowledge and by the rapid pace of genetic discovery. In a recent trial (GenetiKit), we demonstrated the effectiveness of a multi-component knowledge translation strategy on FPs' genetics referral decisions and confidence in core genetics competencies. We now report the findings of a follow-up project, designed to disseminate and evaluate one of the components of GenetiKit, a knowledge support service. These 2-page `Gene Messengers' review genetic tests or disorders recently featured in the media. We have combined them with the Information Assessment Method (IAM), a valid and useable evaluation tool for linking the delivery of information on email with continuing professional development of physicians. Using a theory and four constructs derived from information sciences, IAM assesses the value of clinical information: relevance, cognitive impact, use and expected health benefits associated with that information use. Aims: The project goal was to determine the value of Gene Messengers as a genetics e-learning program for FPs. Methods: An email invitation was sent to 19,000 English-speaking members of the College of Family Physicians of Canada in active practice, soliciting participation in this knowledge translation initiative. Those consenting to participate were asked to complete an on-line demographic questionnaire. They were then sent an email with a Gene Messenger on a different topic every 2 weeks for 6 months. After reading each Gene Messenger, participants could click on a link to complete one IAM questionnaire. Demographic data and frequency responses to the relevance, cognitive impact, information use and expected health benefits of Gene Messengers were collected as well as free-text comments. Results: 1400 of 19,000 (7.4%) FPs contacted are participating in this ongoing project. Conclusion: FP feedback regarding the value of Gene Messengers will be used to redesign them, to optimize this e-learning genetics program, and to assess the potential of this approach for supporting primary care providers, from the point of view of effectiveness and longer term sustainability.

Genetics Awareness Project (GAP) promotes genetics education and genomic research participation in under-represented racial-ethnic groups in South Florida. *K. Czape, C. Jean, M. Gavier, J. Lee, R. Martinez, L.D. Adams, D. Caldwell, K. Murphy, S. Hahn, K. Walz, M.L. Cuccaro, M.A. Pericak-Vance.* John P. Hussman Institute for Human Genomics, University of Miami School of Medicine.

Underrepresented groups in genomic research, especially Hispanics and African Americans, are unlikely to benefit fully from genomic medicine discoveries. In turn, this may further exacerbate these groups' existing health disparities. To remedy this, it is crucial to maximize research participation of all groups. To address barriers due to limited awareness or misconceptions about genetics and research, a novel community-based culturally sensitive educational program was developed called the Genetics Awareness Project (GAP). GAP aims to increase awareness and knowledge by providing presentations and educational materials about the current and potential impact of genetic information on health, the benefits of family health history, and the importance of genetic research participation among the ethnically diverse. Materials, a website, and presentations were developed in Spanish, English, and Haitian Creole (www.geneticsawareness.org). Since mid-2010, GAP has provided educational materials to over 700 South Floridians in community centers, churches, and fairs. Of these, 595 adults and 120 children participated in 45-minute presentations on genetics, and the benefits of one's family health history and research participation. Pre- and post-presentation surveys were administered during presentations to measure the program's effect on genetics knowledge, attitudes, and research participation. Of 405 audience members who opted to complete the demographic information on the survey, 42.5% self-identified as African American. A total of 38.8% identified as White, 47.4% of whom also indicating Hispanic/Latino ethnicity. Participants were 70.1% female with average age of 65 years. A total of 35.3% had a high school education or less and 43.7% had some form of additional education (e.g., college). Over twenty percent did not specify education, we believe due to low literacy levels of some participants. Preliminary data indicate presentations improved participants' 1) attitudes about genetic research, 2) willingness to participate in genetic research, and 3) likelihood of collecting family health histories. Participants did not indicate the importance of including all ethnic groups in research during the pretest, and this was unchanged by the presentation. Further research may identify the reasons for this and may direct future educational efforts in these communities, ultimately increasing participation in genomic research and improving health equity.

Biotech 101: An educational outreach program in genetics and biotechnology. *K.M. East[1], A.M. Hott[1], N.P. Callanan[2], N.E. Lamb[1].* 1) Education Outreach, HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Genetic Counseling Program, University of North Carolina Greensboro, Greensboro, NC.

Recent advances in research and biotechnology are making genetics and genomics increasingly relevant to the lives and health of the general public. For the public to make informed healthcare and public policy decisions relating to genetic information, there is a need for increased genetic literacy. Biotech 101 is a short-course for the public introducing participants to topics in genetics, genomics, and biotechnology, created at the HudsonAlpha Institute for Biotechnology. This study evaluated the effectiveness of Biotech 101 in increasing the genetic literacy of program participants through pre-and-post surveys. Genetic literacy was measured through increases in self-perceived knowledge for each content area covered through the course and the self-reported impact the course had on various aspects of participants' lives. Three hundred ninety-two individuals attended Biotech 101 during the first three course offerings. Participants reported a significant increase in self-perceived knowledge for each content area ($p<0.01$). Participants also reported the program had high levels of impact on their lives and decision-making, a high likelihood for continued self-learning, and overwhelming satisfaction with course content and logistics. Biotech 101 is an effective mechanism for impacting participants' lives and genetic literacy and serves as a model for other similar programs, adding to the currently limited evidence-base regarding public educational strategies in genetics and biotechnology.

From genetics to genomics: the impact on national genetics education strategies for healthcare professionals in the UK. *P. Farndon, D. Latham.* NHS National Genetics Education Centre, Birmingham Women's Hosp, Birmingham, West Midlands, United Kingdom.

The UK NHS National Genetics Education and Development Centre has developed a continuum of genetics education for healthcare by undertaking educational needs analyses and practice based surveys (www.geneticseducation.nhs.uk). Pre-registration core learning outcomes are built on in postgraduate training, and workforce competences inform clinical practice; they have been incorporated into medical school curricula, and into nationally agreed requirements for trainee medical specialists, general practitioners, nurses and dietitians. The outcomes were developed by health professionals identifying applications of genetics in their practice and identifying knowledge, skills and attitudes required by non-geneticists to provide care for patients with genetic conditions. The outcomes therefore tend to focus on identifying patients, family history and the genetics of single gene and chromosomal disorders. The Centre's educational resources also emphasise the clinical utility of genetics by using clinical scenarios to set genetic science in context. However, advances in laboratory techniques and the application of therapies developed through genomics need new specific learning outcomes about the applications and practice of genomic medicine. These have been devised but it has proved more difficult to generate resources specifically highlighting clinical applications: it has been necessary to mine primary research papers to generate completely new resources. Educational delivery methods too are changing. Until recently learners would embrace only face to face learning, but the willingness to undertake technology assisted learning is increasing, particularly as day release from clinical duties becomes more difficult. Practitioners particularly want “just in time” information in clinical practice delivered electronically. In developing resource material, it is important to identify the questions which other professionals want answered which may well be different from those a geneticist might suppose they would want to know. Genetics education at a national level needs a long term educational policy, inclusive of learners, educationalists and their institutions which is evidence based, flexible and responsive to changes in workforce structure, provision of clinical services and conceptual and financial commitments to education. Engagement of national policy, regulatory and professional bodies is vital. The UK policy is continually adapting to these changes.

Teaching Medical Genetics in Nepal: Cultural Implications and Teaching Strategies. *J. Gair[1,2].* 1) Dept Med Gen, University of British Columbia, Victoria, BC, Canada; 2) Island Medical Program, Division of Medical Sciences, UVic, Victoria, BC, Canada.

I teach medical genetics to medical students in Canada. Although there are topics and terms that are very “charged” with meaning in genetics, such as abortion, prenatal diagnosis, genetically modified organisms (GMOs), evolution and eugenics, I have been teaching these topics in the culture in which I was raised. Teaching these same topics in Kathmandu, Nepal will require a totally different approach. As I prepare to leave for Nepal to teach medical genetics in the Patan Academy of Health Sciences School of Medicine (PAHS-SOM), I wonder how different it will be. I want to explore the cultural complications that might arise for me, for the students and for the faculty involved in teaching medical genetics in Nepal - from an anthropological point of view. How will my teaching strategies be affected? My main method will be to document my thoughts, work process and experiences as I prepare my materials for Nepal and as I teach in Nepal and I will compare this to the same things in Canada by taking field notes, blogging and consulting with other professionals. I will create a culturally informed manual of terms, concepts and images for Western faculty teaching in Nepal.

Testing the Efficacy of Conceptual Change Texts in Undergraduate Students' Understanding of Genetics Concepts. *M. Glassford[1], B. Bowling[1], S. Barnes[1], S. Borgman[1], T. Beery[2], E. Reilly[3], C. Huether[4].* 1) Department of Biological Sciences, Northern Kentucky University, Highland Heights, KY; 2) College of Nursing, University of Cincinnati, Cincinnati, OH; 3) Genetic Counseling Program, University of Cincinnati, Cincinnati, OH; 4) Department of Biological Sciences, University of Cincinnati, Cincinnati, OH.

Even after formal instruction in genetics, many students continue to hold misconceptions concerning various genetics concepts. Conceptual change texts (CCTs) are written exercises that introduce a misconception, refute it with scientific evidence, and then introduce the correct concept. This study involved the development of CCTs meant to challenge three common misconceptions among undergraduate non-science majors enrolled in general biology and genetics courses including: 1) DNA is different in different types of cells within one individual, 2) the terms gene, DNA, and chromosome can be used interchangeably, and 3) all mutations have a negative effect. The goal of this research is to test the efficacy of CCTs as an intervention for use in a relatively large lecture course to address and correct genetics misconceptions. This study uses a two-group experimental design to assess students at two Midwestern universities. Students were randomly assigned into the experimental or control group. Eighty of these students will be randomly selected to participate in the one-year post-course assessment. Students in the experimental group received a CCT on the identified misconception, while students in the control group received a text that discussed a topic from the course, but one that has been found to be widely understood after instruction. Participants were assessed pre-course, at the time of intervention, and post-course. Pilot data were used to revise the assessment questions and to create rubrics to quantitatively characterize the responses. Content analysis of responses at the various time points will identify persistent misconceptions throughout the course. Transforming student answers into quantitative data will allow statistical comparisons and determination of the effectiveness of the intervention. Results and conclusions from the data obtained from 150 students will be presented.

1374T

DNA: Key to Diversity in Animals and People Festival. *M. Godfrey[1], E. Mulkerrin[2].* 1) Univ Nebraska Med Ctr, Omaha, NE; 2) Henry Doorly Zoo, Omaha, NE.

DNA Day has now been recognized since the announcement of the sequencing of the human genome in 2003. Activities in schools and communities have been sponsored by the National Human Genome Research Institute and the American Society of Human Genetics, among others. Here we describe a partnership between an academic medical center, the University of Nebraska Medical Center (UNMC), and a zoo, Omaha's Henry Doorly Zoo to commemorate DNA Day. The zoo hosted the event on their 130 acre grounds. The public's fascination with genetics and genomics was energized by the announcement of the sequencing of the human genome. Here in the American Midwest, daily advertisements regarding genetically engineered crops abound. Yet in other parts of the world fear of “Frankenfoods” have created a stir. In all instances, education is the answer to unfounded fears and inaccurate information. Genetics and education professionals have an obligation to present to the public truthful information in a manner that is interesting and understandable. DNA Day programs provide such a means. Our DNA Day program took advantage of the excellent and well respected educational resources of the Henry Doorly Zoo and UNMC to reach a large number of people in a relatively short time. Two days of programming was scheduled one primarily for visiting school groups and the other for the general public. Activities were scattered throughout the zoo, so that no matter where people wandered, an activity related to DNA Day was nearby. Visitors were provided with a map and schedule of events. The program included a tour of the zoo's Center for Conservation Research, talks by conservation or human geneticists, and a special appearance by a Gregor Mendel impersonator. Hands on activities included: creating DNA bracelets; extracting DNA from bananas; Easter egg genetics; Reebops; Fingerprinting and DNA fingerprinting; legume fitness; horse evolution; and a demonstration of Augmented Reality using the DNA double helix. In all some 14,000 visitors participated in DNA Day activities over the two days of the Festival. It is important that educational institutions partner with organizations with a large a public following to provide novel opportunities for education and outreach.

Assessment of online health information seeking behavior to inform the development of the National Newborn Screening Clearinghouse. *KM. McWalter, AK. Yu, LE. Hasegawa, S. Scollon, SM. Au.* Genetics Program, Hawaii Dept Health, Honolulu, HI.

With more than four million newborns having newborn screening (NBS) every year, there is a need for centralized, accessible, and accurate information for NBS stakeholders. This is illustrated by the NBS Saves Lives Act of 2008: a mandate to improve the ability to disseminate accurate and appropriate NBS resources by creating the nation's first NBS Clearinghouse, a “one-stop shop for newborn screening information”. The Genetic Alliance aims to fulfill this mandate with the BabysFirstTest.org website. In the late 2000s, the proportion of Americans searching for health information online was 61%, and the subsequent trend shows increased use of the internet to access health information. To aid in the development of the Genetic Alliance's NBS Clearinghouse, the Hawaii Genetics Program assessed the online health information seeking behavior of attendees at the 2011 Hawaii Baby Expo. This is a gathering of diverse consumers interested in prenatal to preschool issues, products, and information. 784 surveys were completed via two types of media - iPads (n=487) and paper (n=297). Participants of Asian (37%), Hawaiian (23%), and Pacific Islander (6%) background were well represented; and 34.6% reported being of two or more ethnicities. Over 96% of participants had previously searched online for health information. Almost 58% spend at least 1-2 hours per day online for personal use and 55% had searched online for health information in the last week (83% in the last month). 58% have a health question at least once a week. When looking for answers, participants most commonly try the internet (49%), followed by asking their doctor (31%) or family/friends (16%). Participants most commonly searched online when worried about being sick (48%) or if curious after seeing a news story (20%). They most often began their searches with search engines (89%). 74% said they were likely or very likely to start a future search for health information on the internet. Results suggest that websites with higher rankings in search engine results may generate more traffic, and that giving specific websites to providers to disseminate to patients may be an effective strategy. News stories about the NBS Clearinghouse may also generate website traffic. Overall, the internet can be a powerful tool for the dissemination of accurate NBS information, particularly if the NBS Clearinghouse website is developed in a way that maximizes visitors.

Why students don't understand meiosis: An analysis of undergraduate textbooks. *D.L. Newman, C. Catavero, L.K. Wright.* Sch Biological & Medical Sciences, Rochester Institute Technology, Rochester, NY.

Students and professors rely on textbooks to accurately and reliably convey information. However, in order for textbooks to be useful, they must meet students where they are conceptually. We hypthesize that biology textbooks routinely fail in this regard. We surveyed >50 faculty from undergraduate and graduate institutions to determine what they felt students should know about the process of meiosis. In parallel, we examined the explanations of meiosis in 12 textbooks from all major publishers, written for different levels (non-majors, majors introductory and advanced). Previous work has shown that students have significant cognitive deficits in the areas of chromosome structure and ploidy. We found that faculty and textbooks both assume that students understand these concepts better than they really do, especially at higher levels. Since students base their conceptual models on textbook diagrams, and faculty use these materials as their primary means of explaining the concepts in the classroom, we suggest that textbooks need to be redesigned to focus on the fundamentals of chromosome structure and ploidy rather than on the superficial aspects such as phase names of meiosis.

Cyanide and Phenylthiocarbamide: Correlation with Mid-Phalangeal Hair and Color Blindness in Saint Xavier Community. *T. Tatum Parker, D. Cramarosso, E. Barry.* Biological Sciences, Saint Xavier University, Chciago, IL.

The two goals of this experiment were to 1) compare the findings of Giles, et al (1968) of hydrogen cyanide (HCN) and phenylthiocarbamide (PTC) sensitivity, mid-phalangeal hair and color blindness in Yucatan Mexico with a current population at Saint Xavier University in Chicago, Illinois and 2) find a way to increase genetics education by having students actively participate in an experiment. Our preliminary test had 19 volunteer subjects, 14 female and 5 male. For HCN and PTC sensitivities, modifications were made to the protocols for safety reasons. To limit the exposure to PTC, subjects were provided taste strips of phenylthiourea-phenylthiocarbamide from precision laboratories along with plain paper strips of similar size and texture instead of the cups of liquid PTC used in the previous experiment. The modification for HCN sensitivity was using ground peach pits instead of a HCN solution. Ground peach pits contain amygdalin, which has been shown to have a NOAEL of 10.8 mg/kg bw compared with an acute lethal does of 0.5 - 3.5 mg/kg bw for HCN KCN (Montgomery, 1969; Gosselin et al., 1976; Geitler &Baine, 1983). Subjects were asked to smell three vials, one with liquid extracted from the ground peach pits, one with distilled water and one with vanilla. Color vision was tested using the Ishihara pseudoisochromatic plates, testing for red-green color blindness. For mid-phalangeal hair, all ten fingers of each volunteer were examined for the presence of hair or follicles. Presence or absence of hair for each digit was recorded. Our preliminary results for PTC tasting were similar to those in the previous experiment, with 84% of our subjects able to taste the PTC. However for the other traits, our values were lower. Forty two percent of our subjects could not smell anything in the vial with the distilled water or the vial with the peach pits. Only one female, tested for color blindness and 47% of the participants had mid-phalangeal hair compared to over 75%. Similarly to the previous experiment we found no significant genetic variation among the individuals that were tested. Our next steps will be to increase our sample size and examine single nucleotide polymorphisms associated with the ability to taste PTC. This experiment is an ongoing experiment, to increase genetics education in our majors and non-majors classes by increasing student ownership through their participation in both sample collection and being subjects.

1378T

The latent class analysis to clarify the factors associated with the structure of the public attitude toward the genome research. *Z. Yamagata[1], T. Maeda[2], K. Muto[3], A. Nagai[1], A. Tamakoshi[4], I. Ishiyama[5].* 1) Department of Health Sciences, University of Yamanashi, Yamanashi, Japan; 2) The Institute of Statistical Mathematics, Tokyo, Japan; 3) The Institute of Medical Science, The University of Tokyo, Tokyo, Japan; 4) Aichi Medical University, Aichi, Japan; 5) Teikyo-Gakuen Junior College, Yamanashi, Japan.

We clarified the factors associated with the structure of the public attitude toward the genome research by the latent class analysis. The data was derived from the national wide surveys on the attitude toward the genome research were comprised of 4,000 people (age, 20-69) in 2005 and in 2009, randomly selected from the Japanese general population. The response rate was 54% and 52% respectively. We conducted similar survey on a small scale in 2008. Five clusters (“Group of aggressive promotion”, “Group of passive support”, “Group not making judgment”, “Group making prudent judgment”, “Group not interested in genome”.)were assumed as an explanation model of six variables related to the knowledge of genome and attitudes toward genomic research promotion about three themes; basic genome research, genome research related to agriculture and medicine at the survey. These clusters were associated with academic background, socioeconomic status, donation to their blood for genome research, interest of science, consciousness to take genetic testing, behavior to go to genome lectures. These factors become the basis of genome research outreach programs. We tried to make outreach programs having public understood genome researches based on these results.

1379T

Preference for genetic testing among patients offered participation in the Additional KIF6 Risk Offers Better Adherence to Statins (AKROBATS) trial. *S.L. Charland[1], B.C. Agatep[1], V. Herrera[2], E.J. Stanek[1].* 1) Medco Research Institute, LLC, Medco Health Solutions, Inc., Bethesda, MD; 2) Medco Research Institute, LLC, Medco Health Solutions, Inc., Franklin Lakes, NJ.

Background: Utilization of genetic tests has improved personalized healthcare. However, factors that influence a subject's decision to accept or decline genetic testing are poorly defined. The objective of this study is to characterize the rationale from patients new to statin therapy to either decline or accept KIF6 genetic testing associated with participation in the AKROBATS trial. **Methods:** Subjects were contacted via telephone by study nurses. During this call, subjects were provided information on the study and KIF6 variant testing, and were offered enrollment. Based upon response, patients were queried on reasons to accept or decline study participation. Responses were categorized and collapsed for analysis. Categorical and continuous variables were analyzed using chi-squared and t-tests, respectively (significance at $p<0.05$). **Results:** A total of 773 patients declined participation and 682 subjects agreed to enroll in the AKROBATS study. Enrollees were significantly younger (60±12 vs 64±13) and more likely to be prescribed atorvastatin or lovastatin ($p<0.05$). Reasons for enrollment included: Confident that KIF6 test results would improve my disease outcomes (53.8%), help humanity (17.4%), general interest/knowledge (15%); family history of heart disease (5.9%), confident others were receiving KIF6 test (1.6%), asked to participate (0.9%), and no reason provided (5.4%). Those declining enrollment indicated no reason (43.1%), no perceived benefit of KIF6 testing (19.7%), time constraints (18.4%), not enough knowledge about KIF6 test (8.8%), privacy concerns (6.7%), anxiety associated with results or lifestyle changes (0.9%), and other (2.5%). **Conclusion:** Multiple factors, including age, therapy prescribed, logistical considerations, and health beliefs, may influence the decision to decline or accept genetic testing under trial conditions. Lack of interest, lack of perceived or potential benefit, and time concerns were primary reasons for study participation/KIF6 test declination. In contrast, belief in personal value/utility, altruism, and general interest appeared to drive study participation/KIF6 test acceptance. As genetic testing advances, information such as this is key to fully understanding patients' attitudes towards acceptance and reservations about genetic testing, and may serve as a basis to develop effective patient communication and education strategies to support individualized decision making.

1380T

Efficacy of knowledge of Genetics in the Field of Psychiatry and its impact in patient treatment plan and option. *H. Azimi.* Genetic Informatic, Psychogenome, Nepean, Ontario, Canada.

BACKGROUND: Early detection of genes that predispose individuals to behavioural, psychological and psychiatric illness can have benefits such as: to decrease healthcare cost, increase efficacy of treatment and aid health professionals in advising parents of predisposed newborns of environmental changes that can decrease the like hood of psychiatric manifestations. As the field of Clinical Genetics and metabolic is growing, many psychiatrists are interested to help their patients, from individuals with known psychiatric disorders to their potential children in preventing and predicting diseases. OBJECTIVE: To evaluate the knowledge of genetics in the field of Medical Psychiatry and Mental Health. Method: Design: Standardized Questioner Survey. Setting and Participants: 300 practising Psychiatrist in Canada and USA, 100 from Canada, 100 from USA and 100 international. Information was gathered by phone calls, emails or in person interview. Hypothesis: To identify the gaps in genetics knowledge among practising Psychiatrists. Main Outcome: Number of Bipolar, Schizophrenic, Alcoholic, Autistic, Depressed, and Mentally challenged patients which the Psychiatrist was helping to cure was asked from the Psychiatrist. The outcome was compared with the comparison to knowledge of genetics which the Psychiatrist had about the disease. Results: Mean disorder, prevalence, knowledge and core knowledge of genetics was asked from the Psychiatrist. After six month of follow up with the Physicians, the gaps in knowledge of genetics in Psychiatrist those who trained internationally was higher in the field of genetics compared to Canada and USA trained Psychiatrists. (mean (SD), 0.88(0.22) mM vs. 0.68(0.25) mM in North American Group; P=0.001) Among specialist in Canada (P =0.84). Seven psychiatrists in Canada wore involved in daily genetic literature reading and referred the patients that needed genetic counselling to appropriate centers. Over nine psychiatrists in USA wanted to obtain a fellowship in Psychiatric Genetics and thought of this field to be very interesting and stated “the knowledge genetics needs to be more open to us psychiatrist”. 143 psychiatrists did not want to be involved in any further studying and wanted to just retire, but stated “If we had a Psychiatric genetic round during residency at least for 4-week then maybe we be in different shape”.

1381T

Developing a national competence framework in the UK to support the delivery of non-invasive prenatal diagnosis. *M. Bishop, J. Haydon, D. Latham, P. Farndon.* NHS National Genetics Education Centre, Edgbaston, Birmingham, United Kingdom.

The integration of new genetic technologies into clinical practice impacts not only on clinical genetics but also on the wider health service that may be called upon to offer these tests to their patient groups. One such development is non-invasive prenatal diagnoses (NIPD) where the ability to detect and test fetal cell free DNA and RNA circulating in maternal blood has the capacity to transform prenatal diagnosis for single gene disorders and chromosomal anomalies. For effective integration into standard clinical care health professionals providing the service must be knowledgeable about the test in question. To understand how health professionals in the UK National Health Service (NHS) see NIPD impacting on clinical care and their educational needs to provide this service, the NHS National Genetics Education and Development Centre carried out an explorative study leading to the development of a competence framework. A mix of interviews and focus groups with participants from three clinical areas including fetal medicine (n=7), clinical genetics (n=12) and midwives (n=46) were conducted. Participants were provided with a number of clinical scenarios demonstrating how NIPD could be used in clinical practice to initiate discussion. Interviews and focus groups were audio taped and transcribed, with thematic analysis employed to elicit common views regarding the integration of this technology into clinical practice and the education needs of the workforce who will deliver this service. While all three groups of participants recognised that NIPD will impact on the clinical service they provide, they believed the introduction of this new technology should be viewed as supplementing current roles as opposed to changing practice. As such, the identified educational needs focused more on the procedural issues associated with NIPD, such as understanding the clinical reason for offering the test, knowing the laboratory process and appreciating the implications of test results. In addition to identifying the educational needs, participants stated that any educational package developed needed to reflect the service model for delivering NIPD to ensure education was relevant to the health professional's role. These findings have informed the development of a competence framework which provides the basis for educational packages to support the implementation of NIPD into clinical practice.

1382T

A Comprehensive Analysis of High School Genetics Standards: Are States Failing to Keep Pace with Modern Genetics? *M. Dougherty[1], C. Pleasants[2], L. Solow[3], A. Wong[1], H. Zhang[1].* 1) Education, ASHG, Bethesda, MD; 2) 5 Crystal Springs Rd., Greenville, SC; 3) Wesleyan University, Middletown, CT.

Science education in the United States is driven by the testing and accountability requirements of the No Child Left Behind Act (NCLB). Implementation of NCLB relies heavily on learning outcomes, or “standards,” which are currently developed on a state-by-state basis. Standards, in turn, drive curriculum and instruction, yet they have never been evaluated for scientific accuracy and completeness. We investigated the quality of the standards in genetics for all 50 U.S. states and the District of Columbia and found them to be poor, with more than 85 percent of states receiving overall grades of `inadequate'. Individual genetics concepts are covered poorly as well, with particular weakness in areas related to complex traits—an area that is increasingly important in genomics research. The deficiencies we identified may adversely affect genetics instruction and learning, the preparation of students for college and careers in genetics, and the genetic literacy of the U.S. citizenry.

1383T

Usability Testing in the CFTR2 Web Site. *M.H. Lewis[1], P. Sosnay[2], F. VanGoor[3], H. Yu[3], R. Dorfman[4], J. Rommens[4], M. Corey[4], C. Castellani[5], C.M. Penland[6], R. Karchin[7], G. Cutting[2].* 1) Genetics and Public Policy Center, Berman Insitute of Bioethics, Johns Hopkins University, Washington, DC; 2) Departments of Medicine, Pediatrics, Johns Hopkins University, Baltimore, MD; 3) Vertex Pharmaceuticals, San Diego, CA; 4) Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 5) Ospedale Civile Maggiore, Verona, Italy; 6) U.S. Cystic Fibrosis Foundation, Bethesda, MD; 7) Department of Biomedical Engineering, Center for Computational Medicine, Johns Hopkins University, Baltimore, MD.

Background: The Clinical and Functional Translation of CFTR (CFTR2) project is an international effort to link 1800+ CFTR mutations with expert-reviewed clinical parameters. A Web site was developed to communicate this information to the Cystic Fibrosis research and patient communities. Since genetic information may be confusing to the lay public, prior to the public launch of the Web site, usability testing was conducted. Usability testing is a technique for ensuring that the intended users of a system can carry out the intended tasks effectively. Usability testing is carried out pre-release so that any significant issues identified can be addressed. Methods: In this qualitative study, multiple iterations of usability testing were conducted. Participants were members of the general public and the Cystic Fibrosis patient community. In each iteration, three participants were each asked to view the Web site, complete a series of tasks, and answer questions based upon the information they obtained. Improvements to the Web site design were implemented after each iteration. Testing was completed in-person and over the telephone. Participants were asked to think out loud as they attempted to complete the assigned tasks. Results: Problems identified were related to content rather than technical issues. One participant noted, “I don't understand what a sweat test is. I need education first.” In some cases, participants answered questions correctly but based upon incorrect interpretation of information. For example, one participant answered correctly that a particular mutation would cause pancreatic insufficiency but was unclear whether pancreatic insufficiency meant that the pancreas was not affected or whether the pancreas did not “sufficiently produce what it is supposed to.” Additional content was added to the Web site to address these issues. During early iterations, participants thought the language was “too textbooky,” and commented, “I don't understand this.” As a result, the Web site was divided into 2 parts, one designed for the general public and another designed for researchers. Conclusions: Usability testing identified problems with a Web site designed to provide information about the genotype-phenotype relationship of specific CFTR mutations. This information was used to improve the Web site content, structure, and design. Usability testing has been a crucial element in the Web site development process.

Automated generation of diseases classification supported by Orphanet Ontology of Rare Diseases. *F. Dhombres[1,2,4,5,6], S. Aymé[1], A. Rath[1], A. Olry[1], PY. Vandenbussche[2,3,5], J. Charlet[2,5,6,7].* 1) Orphanet, INSERM, Paris, France; 2) UMRS872 Eq.20, INSERM, Paris, France; 3) Mondeca, Paris, France; 4) Service de Gynécologie-Obstétrique et Centre de Diagnostic Prénatal de l'Est Parisien, Hôpital Armand Trousseau, AP-HP, Paris, France; 5) UPMC, Paris Sorbonne Universités, Paris, France; 6) Université Paris Descartes, Paris, France; 7) Assistance Publique Hôpitaux de Paris, Paris, France.

Background. Orphanet is evolving towards an integration of semantic technologies in its editorial workflow and representation of data. This evolution aims to improve edition and maintenance of rare diseases classifications and allow cross referencing with other ontologies. An ontology of rare diseases, including all genetic diseases, has been build from (1) Orphanet Knowledge base stored in a standard relational database and (2) Orphanet core ontology consistent with a meta model of the domain (alpha version available on Bioportal). The full Orphanet nomenclature of phenoma (groups of diseases, disorders, subtypes and clinical signs and symptoms), genes, hierarchies and textual resources were used in this design process.

Objectives. Assessment of an automated generation of Orphanet Classification of Genetic Diseases supported by a semantic editorial workflow.

Methods. Using the rare diseases ontology with its meta-model, a unique query allows automated building of Orphanet Classification of Genetic Diseases. This process involve semantic web technologies (Sparql request on RDF Triplestore). Assessment of the generated classification is performed by a strict automated comparison with the original Orphanet Classification of Genetic Diseases.

Result. An automatically generated classification of 4,997 genetic diseases was built. There is an exact match between the original and the generated classification of genetic diseases.

Discussion. This approach simplifies the editorial process, which is then limited to the maintenance of the ontology itself. The process used for the whole genetic classification is reproducible. Therefore, automated generation of classifications may be extended to produce any other classification based on the semantics defined in the ontology (classification of genetic developmental anomalies during embryogenesis, classification of dominant skeletal diseases, ...). Moreover, once the ongoing gene-disease relationships characterization is achieved, new automatically generated classifications based on the contribution of genes to the etiology of diseases will be conceivable.

1385T

Comparisons of Disease Risk Assessment of Direct Consumer Genetic Services for Japanese Individuals. *T. Kido[1], M. Kawashima[2], S. Nishino[3], G. Sherlock[3], A. Butte[3].* 1) Rikengenesis/JST, Tokyo, Japan; 2) The University of Tokyo, Tokyo, Japan; 3) Stanford University, CA, U.S.

Background: Several companies offer direct-to-consumer (DTC) genetic tests to evaluate individual's disease risks. However, Craig Venter et.al. reported that only 50% or less of the predictions of two DTC companies agreed across five individuals for seven diseases. It is important to examine why such a large discrepancy occurs. In addition, most of the disease risk predictions by DTC companies are based on the GWAS researches in Caucasian population; we need to adapt these predictions to other ethnicities. Methods: First, we compared the risk assessment for each disease used in 23andMe, Navigenics, Pathway Genomics and DeCODEme in detail for one healthy Japanese individual. Then we also compared the risk assessments of 23andMe, Navigenics across three healthy Japanese for 23 diseases, using same methodologies as Craig Venter. Next, we investigated where the discrepancies come from past researches have reported that variance in multigenic risk interpretation can be explained by differences in (1) the average lifetime risk, (2) the SNPs selected for the assessment, and (3) the risk assignment methodologies. We evaluated each of these factors for four DTC companies for Japanese individual, and classified the reasons for their discrepancies. Results: 23andMe, deCODEme, Navigenics, Pathwaygenomics provide 95, 42, 25, and 17 risk assessment reports respectively, and 10 reports were shared for same diseases across the four companies. 23 reports were shared for the same diseases between 23andMe and Navigenics. In total, there were 27 mismatches in predicted risk for three Japanese individuals (approximately 9 mismatches per individual in 23 diseases) between 23andMe's and Navigenics's predictions. For seven diseases, a third or less of the predictions of two companies agreed across three individuals. These mismatches owe to differences in the SNPs used in the calculation, the reference population used, and different risk assignment methodologies. Navigenics does not provide the reports specifically for Asian individuals, while 23andMe provides only three reports (for type2 diabetes, rheumatoid arthritis, and prostate cancer) specifically tailored for Asian individuals. Conclusions: Greater consistency is needed for the risk assessment among different DTC genomic tests. The risk assessments in each ethnicity is important, but only limited data is available. Establishments of reliable risk assessment methods for all ethnicities are required.

Traditional Bone Setting and Healing: Bane or Blessing. *P. SINGH, PANKAJPREET SINGH.* SPORTS SCIENCES, PUNJABI UNIVERSITY, PATIALA, PUNJAB, India.

Traditional Bone setting (TBS) is a practice of healing bones and related injuries .It contributes largely to the alternative medicine in the Asian continent and especially in India. TBS is easily accessible, cheaper and is believed to give quick results. On the other hand, non union, malunion, traumatic osteomyelitis and limb gangrene are some of the major complications of TBS treatment. In spite of these complications, there is a great demand for TBS, that patients leave orthodox hospitals in favour of treatment by a TBS. The possible reasons for this include cultural beliefs, ignorance, third party advice, and the short supply of trained orthodox man power in rural areas and the fear of amputation at an orthodox hospital. If properly educated about the therapy, radiological diagnosis , duration of healing , complications of mismanagement and rehabilitation exercises , the Traditional bonesetter's can be of immense help in sharing the burden of public health service providers in the developing countries.

The influence of a positive family history of prostate cancer on the initial screening age, screening interval, and biopsy decisions in a population of PSA screened males. *D. Cross[1], D. Reding[2], G. Aryal[2], K. Sparks[1], C. McCarty[1].* 1) Marshfield Clinic Research Foundation, Marshfield, Wi; 2) Marshfield Clinic, Marshfield, Wi.

Purpose: We examined the PSA screening practices in a multispecialty primary care clinic, including the initial age at screening (with and without a family history of prostate cancer), the interval between PSA screenings, the PSA values and elapsed time between PSA testing and biopsy. Materials and Methods: We used a population based cohort consisting of 4632 men within the Personalized Medicine Research Project with at least one recorded PSA test, 935 individuals underwent a prostate biopsy with 466 diagnosed with prostate cancer. Univariate chi squared analyses were performed to determine if family history was used to determine screening frequency and biopsy decisions in the cohort. Results: Within the population the average age of the cohort was 67.2 years with an average age of initial PSA test of 55.7 years and an average of 6.8 PSA tests with a screening interval of 465 days. Individuals who self reported a family history of prostate cancer were older (73.6 years versus 66.8 years $p<0.01$). The average interval between screenings was not different for individuals with or without a family history of prostate cancer (437 days versus 479 days). However, the time between a PSA test and initial biopsy was significantly different (73.3 days for individuals with a family history of prostate cancer versus 201.5 days for those without a positive family history $p<0.01$.) Individuals who reported a family history of prostate cancer were more likely to have a biopsy (50% versus 20%) $p<0.0001$ and were significantly more likely to have a positive biopsy $p<0.0001$ (81% versus 25%). Discussion: Despite a number of recommendations suggesting men with a family history of prostate cancer begin screening early, we did not observe early or more frequent screening in men with a self reported family history of prostate cancer. This may be because individuals do not know their family history early enough to influence the initial screening date. However, knowledge of a positive family history of cancer does appear to be used by physicians and patients for making biopsy decisions and is associated with a quicker time between PSA testing and biopsy, referral for a prostate biopsy, and a positive biopsy.

FGF8 mutation screening in patients with VCFS-like phenotype. *I.C. Sgardioli, T.P. Vieira, M. Simioni, L.C. Souza, V.L. Gil-da-Silva-Lopes.* Department of Medical Genetics, Faculty of Medical Sciences University of Campinas, Campinas , São Paulo, Brazil.

INTRODUCTION: Velocardiofacial Syndrome (VCFS) is the most common chromosomal microdeletion syndrome in human, with an incidence of 1/ 4.000 to 1/6.000 births. The main clinical features are congenital heart disorders, typical facial appearance, palatal abnormalities, hypocalcemia, immunodeficiency, learning disabilities and developmental delay. A microdeletion in 22q11.2 is the main cause of the syndrome. However, it is not detected in about 10 to 20% of patients with this clinical suspicious. Some of them have other chromosomal aberrations or TBX1 gene mutations. Based on animal models, VCFS phenotype could also be related to mutations in FGF8 gene. AIM: To investigate the clinical suspicion of SVCF by different laboriatorial techniques and To investigate FGF8 mutations in patients with VCFS suspicion without 22q11 deletion or TBX1 mutations. METHODS: Karyopyte with GTG banding, MLPA (kit P250-A1 DiGeorge - MRC-Holland®), FISH (TUPLE1 probe - Kreatech Diagnostics) and direct sequencing (ABI Prism BigDye Terminator kit). RESULTS: Among 102 individuals, seven had chromosomal aberrations (only one related to 22q11.2 deletion); 31 had deletion in 22q11.2 and 69 had normal karyotypes and no deletion in 22q11. These patients were clinically re-evaluated and those with congenital heart disease were screened for TBX1 and FGF8 gene mutations. To date, among 31 individuals selected, the analysis of TBX1 gene identified just polymorphisms previously known and no sequence changes were found in the 3, 4, 5 and 6 exons of the FGF8 gene. CONCLUSION: This study reinforces the clinical and etiological heterogenity of VCFS spectrum. This is the first report in humans of FGF8 gene investigation in this condition; these results could bring new informations about (the etiology) genetic pathway of the VCFS phenotype. Financial support: FAPESP and CNPq.

Quantitative and qualitative analysis of DNA from human blood samples stored at different temperature for different time intervals. *S. Goyal[1,3], I. Bhadu[1], M. Rajpurohit[3], A. Raina[2], T.D. Dogra[2], A. Agarwal[1], R.P. Agrawal[1], S. Jain[1], D. Goyal[1].* 1) Diabetes Care & Research Centre, S.P.Medical college, Bikaner, Rajasthan, India; 2) All India Institute of Medical Sciences, New Delhi, India; 3) Tanveer Malawat College of Bioscience, MGS University, Bikaner, Rajasthan, India.

Introduction:-DNA is a genetic material which is used in forensic laboratories like blood, semen, blood stain, bones, semen stain, etc. Mainly white blood cells are used as the major source of DNA due to presence of high quantity of genomic DNA. Quality and quantity traces obtained after isolation of DNA from biological samples, have an important role in forensic science. To investigate qualitative and quantitative estimation of DNA extract from human blood samples analysis better DNA yielding. Method: - All protocols used in this research were standard protocol according to the DNA finger printing lab. Standard protocols were used for collection of blood samples, extraction of DNA, qualitative and quantitative analysis. Result:- Blood was collected from unknown (6) dead bodies and divided into 6 tubes containing 1ml in each tube and kept for different temperature (room temperature(37ºc), cooled at 4ºc and freezed at -20ºc) and for different time periods (2, 4, 6, 9 days). It was observed that though DNA was isolated from same amount of blood in all the samples, a variation was seen, as yield of DNA was obtained at sample freeze at -20ºc i.e. 578.50 ng/µl of DNA, 4ºc and 37ºc(Room Temperature) was 429 ng/µl and 390 ng/µl of genomic DNA respectively. According to qualitification of DNA best quality was observed in 4ºc i.e. 1.692 µg/ml, comparison to another temperature-20ºc and 37ºc i.e. 1.610 µg/ml and 1.645 µg/ml. Discussion: -From all the results it was concluded that quality wise 4ºc was best and -20ºc was best for maximum yield of genomic DNA. For long time storage, the quality of DNA was maintained on 4ºc as it prevents the denaturation of DNA.

Inauguration of a programme for Disorders of Sex Development (DSDs) in Cameroon (sub-Saharan Africa). *A. Wonkam[1,2], W.Y. Joko[1], F. Mouafo[3], S. Dahoun[4], C. Ngongang[1], C. Lecoultre[5], J. Birreaux[5], B. Paturel[6], P.Y. Mure[6].* 1) Service of Medical Genetics, Gyneco-Obstetric and Pediatric Hospital Yaoundé, Cameroon; 2) Division of Human Genetics, Faculty of health Sciences University of Cape Town, Cape Town , South Africa; 3) Service of Pediatric Surgery, Gyneco-Obstetric and Pediatric Hospital Yaoundé, Cameroon; 4) Service of Genetic Medicine, Geneva University Hospitals, Geneva, Switzerland; 5) Service of Pediatric surgery Geneva University Hospitals, Geneva, Switzerland; 6) Service of Pediatric Surgery, CHU of Lyon, France.

BACKGROUND: Practice of genetic medicine was recently introduced in Cameroon. The increasing number of patients with DSDs reveals the lack of local technical and human resources to face the multiples management challenges. A specific national program for DSDs was launched, with the collaboration of the Ministry of Public Health and a Swiss charity organization. OBJECTIVE: 1-To identify patients with DSDs; 2- to describe the genetic diagnosis; 3- to offer treatment options; 4- to address ethical, legal and social issues. METHODS: 1-Inaugural media campaign to call for patients' participation (16-20th November 2009). 2-Multidisciplinary consultations with local and international professionals (geneticist, endocrinologists, paediatric surgeons, gynaecologist, psychiatrist) 3-Cytogenetic and molecular genetics analyses (locally and abroad) 4-Medical and local surgical management RESULTS: 179 patients were consulted; 122 (66.1 %) were diagnosed with various external and internal genitalia anomalies: 1-Hypospadias (44.3%) 2-46, XX DSD (18%): CAH (8 Cases); 46, XX ovotesticular DSD SRY negative (4 cases); mullerian abnormalities (5 cases); cloacal extrophies (5 cases). 3-Sex chromosomes DSD (12.3%): Turner's syndrome (13 cases), Klinefelter's syndrome (2 cases). 4-46, XY DSD (11.5%): Disorders in androgen synthesis or action (9 cases); 46, XY ovotesticular DSD (2 cases); Kallmann' syndrome (3 cases). 19 patients have been operated. 3 cases needed legal gender reassignment. CONCLUSION: The programme evidences universal need of medical genetics services and provide a model for international collaboration to bridge the technical and human recourses gap in the management of DSDs in a Sub-Saharan Africa country.

1391T

Improving quality of clinical services for patients with genetic susceptibility to breast cancer: An evidence-based approach. *J. Jbilou[1, 2], R. Landry[3], N. Amara[3], J. Simard[4, 5].* 1) Public administratio, Université de Moncton, Moncton, Canada; 2) Department of community health, Université de Sherbrooke, QC, Canada; 3) Department of management, Université Laval, QC, Canada; 4) Department of molecular biology, Université Laval, QC, Canada; 5) Canada Research Chair in Oncogenetics.

Background Female with a BRCA1 or BRCA2 mutation carrier have a lifetime risk of breast cancer of between 50% and 80%. To guide health professionals to decide whether or not personalized medical services are indicated and to ensure that women with genetic susceptibility to breast cancer have access to effective and relevant genetic services, effective strategies are to be put into place to help health professionals to adequately predict breast cancer genetic susceptibility and better communicate it to individuals and their families. Nevertheless, there is a lack of knowledge on stressing factors of this process. Objective Identify key steps of evidence-based genetic services Identify the drivers and challenges that impact on the quality and efficiency of genetic services. Method A qualitative study based on a systematic review of the literature (prior to 2010), using an inductive analysis and content analysis approach. We adopted the perspective of health professionals. We assumed that genetic services are based on a combination of a clinical behaviour and a knowledge transfer process and adopted an integrative framework based on: social cognitive theories and Knowledge value creation framework. Results We retrieved 147 articles that encounter the inclusion criteria. We have identified 5 steps that broadly illustrate degree of variation in the content and process of genetic encounters: assessing risk, informing about risk, confirming risk, announcing risk and supporting women at high or moderate risk. We extracted 327 indicators that have been identified in the literature as confirmed (quantitative articles) or potential (qualitative articles) determinants of genetic services. We abstracted them into 4 major conceptual categories: professional's factors, organizational factors, patient's factors and ethical, legal and social factors. We derived a questionnaire and validate through a Delphi technique with a panel of experts representing all professional categories involved. A second validation of the questionnaire is undergone in a clinical setting. Conclusion Our results are easy to transfer in other clinical setting and our framework may be also used in empirical research of assessing healthcare services delivery and performance. The questionnaire will be administrated in a cross-sectional survey among a sample of Canadian health professionals involved in genetic services for patients with genetic susceptibility to breast cancer.

A working model for developing countries towards fulfilling the promise of molecular medicine in the rare lethal genetic disorder, Duchenne muscular dystrophy. *B.R. Lakshmi.* MDCRC, Coimbatore, Tamil Nadu, India.

The benefits of genomics and biotechnology are concentrated primarily in the developed countries, while their potential to combat neglected/orphan disorders in the developing countries has been largely untapped. Capacity building in developing countries like India becomes crucial to address disorders like Duchenne muscular Dystrophy. In India, with its population over a billion, the anticipated number of DMD affected patients should be high and there is an urgent need to incorporate genetic approaches into their health care services. The challenges in developing countries involve the limited or even absent regulatory infrastructure and limited capacity to offer diagnostics and treatments and strategies adopted pertains to the country specific needs. The centre's accomplishments in capacity building with time and the establishment of a working model to holistically address DMD are elaborated here. Precise molecular diagnosis enables prevention of the disease through carrier and prenatal diagnosis and also is essential to understand the numbers who could probably benefit from emerging therapeutic strategies like exon skipping and PTC 124. With our systematic and passionate efforts in the past 5 years we have close to 1100 cases of which we have offered precise molecular diagnostics to close to 800 cases as per International guidelines, with strict quality and ethical protocols. Networking of Clinicians has been established, informing them on the benefits of genetic testing and the various services offered at our facility. We are the only Government recognized referral centre for the State, where samples are streamlined through nodal centres involving hospitals, physiotherapy centres and private practitioners across the state and other neighboring southern states of India. A DNA bank is maintained for every patient sample received at the lab. Follow up of genetic diagnosis is done by providing genetic, psychosocial and reproductive counseling, strengthened by carrier analysis offered at the centre. Quarterly parents meeting are held to update them on the recent progresses in the field. Recently we have initiated the Multidisciplinary clinical evaluation as per International guidelines to monitor disease progression and offer appropriate and timely interventions to ensure good quality of life. We believe that the above initiatives have set the platform towards a DMD registry database in the country that contributes to global efforts to combat the disorder.

The Philippine Birth Defects Surveillance Project: a 3 Year Experience. *C. Padilla[1,2], E. de la Paz[1,2], B. Cavan[3], C. Abarquez[4], R. Sales[1], A. Sur[1], J. Posecion[5], L. Orbillo[6], J. Basilio[6] for the Philippine Birth Defects Surveillance Study Group.* 1) Institute of Human Genetics, NIH Philippines,; 2) Department of Pediatrics, College of Medicine, University of the Philippines Manila; 3) The Children's Genetic Center, Cebu City,; 4) Southern Philippines Medical Center, Davao City; 5) West Visayas State University Medical Center, Iloilo City; 6) Department of Health.

The burden of birth defects is not well-established in the Philippines because of constrained diagnostic capabilities, poor health-related statistics, and the absence of any systematic birth surveillance and registries. Causes are unknown and risk factors and preventive strategies are not yet established. Information on birth defects can be used to facilitate clinical services to affected children and families, improve programming and prevention strategies, and enhance community links. An effective surveillance is needed to allow for the ready use of data for implementation of population-based planning for public health programs. Currently, there is no formal national birth defects surveillance system in the country, and no organized efforts to establish the burden of birth defects. In 2008, the Philippines became part of the March of Dimes Global Network on Maternal and Infant Health. One of the objectives of the project was to establish hospital- and community-based surveillance systems to capture data on adverse birth outcomes. This led to the establishment of the Philippine Birth Defects Surveillance Project, a joint project of the National Institutes of Health Philippines and the Department of Health. To cover all newborns including the home delivered (62% of all births) and to facilitate referral of diagnosed cases among health facilities and communities, the surveillance was implemented in sentinel sites, geographically selected. A sentinel site has at least 1 tertiary private hospital, at least 1 tertiary government hospital, local government hospitals, and communities. From Sept 2008 to March 2011 a total of 82 health facilities and communities from 18 sentinel sites distributed in the 3 major island groups (Luzon, Visayas, Mindanao) have participated. A total of 2949 patients were reported. The top ten birth defects were oral and facial cleft, limb deformities/limb reduction, ankyloglossia, skin tags, multiple congenital anomalies, neural tube defects, Down Syndrome, hydrocephalus, hemangioma, and hypospadia. The biggest challenge of this project is the completeness of the submitted forms and the difficulty in accurate description of the patients. This problem is being solved with the introduction of a telegenetic service. The other challenge is increasing coverage in the community setting, considering that 62 percent are home delivered. The project is now expanding to cover more hospitals and more communities.

1394T

Microbial and genomic studies of A.Indica (Neem) for medicinal purpose. *I. Bhadu[1], S. Goyal[1,2], P.K. Ranga[2], D. Gupta[2], R.P. Agrawal[1], A. Agarwal[1], P.R. Jatkhar[2], V. Agarwal[1], H. Bhadu[1].* 1) Diabetes Care & Research Centre, S.P.Medical college, Bikaner, Rajasthan, India; 2) Tanveer Malawat College of Bioscience, MGS University, Bikaner, Rajasthan, India.

Introduction: - A.Indica (Neem) tree can be labelled as wonder tree for its multipurpose uses in real sense. The word Azadirachta is derived from the Persian azaddhirakht meaning “Noble tree”. Compounds of A.Indica have several types of biological activities like antifungal, antibacterial, hypoglycemic, antitumour, anti-inflammatory etc. Method: -The present study was carried out to check the efficacy of aqueous and ethanolic leaves extracts of A.Indica on different strains of S. aureus Discs (5 mm) soaked and dried in different concentrations viz. 30%, 20 %, 10 % of alcoholic and aqueous solution of leaves were prepared and the antimicrobial efficacy was studied. CTAB method was utilized for quantitative analysis of genomic DNA while qualitative analysis was performed by using gel elcetrophoresis. Result: - A zone of inhibition 12 mm, 10 mm and 9mm in alcoholic and 9mm, 8 mm and 7 mm in aqueous solution were formed by 30 %, 20 % and 10 % for both solutions, respectively. It was observed that A.Indica has a good amount of genomic DNA that is 4.55 µg/ml with high purity was analysed i.e. 2,419 bps. Discussion: - Antimicrobial and genomic analysis of A.Indica was carried out to observe all characteristics of plant parts which is useful in governing the valuable medicinal property for its medicinal and therapeutic purpose.

What genetic competencies are realistic and achievable for US primary care providers? Qualitative study with key informants. *N. Qureshi[1], K. Szegda[2], J. Kai[1].* 1) University of Nottingham, Nottingham, United Kingdom; 2) Pioneer Valley Asthma Coalition, Baystate High Street Health Center Pediatrics, Springfield, USA.

Purpose: Genetic medicine is increasingly being incorporated into clinical practice, but poses challenges for primary care. Further, this may amplify existing disparities in health service provision for ethnic minority populations in the US and other developed countries. This might be counteracted by improving the genetic competency of primary care providers. In the US, these include family doctors, general internists and paediatricians. The purpose of this study was to critically appraise the skills, attitudes and knowledge of primary care providers currently providing genetic provision for underserved populations. Methods: Key informants were identified through academic residency-training primary care practices and through US family practice conferences (Society of Teachers of Family Medicine and American Academy of Family Physicians). A series of 12 semi-structured interviews were completed with key informants from different settings throughout the US. These interviews were transcribed. The quality of transcription were confirmed by one of the researcher or a second transcriber reviewing transcripts against audio files. Data were thematically coded by two independent researchers and analyzed according to agreed emergent themes. Results: Core attributes were identified which are required for primary care providers to develop genetic competency. These included adapting communication skills, working with families and appreciating disease prevalence in local communities. These attributes could be enhanced by primary care providers' keeping up to date, using standard procedures such as genetic-related checklists produced by American Medical Colleges and presence of genetic literacy in consulting patients. However genetic competency is hindered by lack of time and resources, poor awareness of patients' beliefs, and clinicians displaying unsubstantiated confidence in their own competency. Conclusion: Primary care providers' genetic competency can be improved by incorporating transferable skills and concentrating on genetic conditions with higher prevalence in local areas. This can also be enhanced by improving communties' genetic literacy.

The distribution of telomere length in buccal cells of healthy volunteers. *Y. Shidoji, S. Yabuta, C. Sakane, M. Masaki.* Graduate School of Human Health, University of Nagasaki, Nagayo, Nagasaki 851-2195, Japan.

Telomere length has been implicated as an indicator of physical aging and other health conditions. In considering widely use of this indicator to various biological fields, it is indispensable to establish a method to measure the telomere length with promptness, handiness and high sensitivity by using a buccal swab that is a low-invasive sample. In order to measure the telomere length of the buccal cells, we decided to apply a monochrome multiplex PCR method that was developed and has recently been improved (Cawthon, 2009). The officerss of Nagayo town (89 men and women with age from 20s to 50s) were voluntarily recruited with a written informed consent, and the buccal cells were harvested by using the swab and the resultant genome DNAs were prepared with Qiagen DNA blood-mini kit. Single-copy gene (A: albumin) was assumed to be an internal standardization and the number of relative copies of telomeres (T: telomere) was calculated as ratio (T/A) of respective threshold cycles (Ct) in monochrome multiplex real-time PCR. As a result, typical amplification curves of both albumin gene and telomere were presented in one tube, and each Ct was obtained separately. T/As of the samples analyzed in the present study were 213 ± 205 (13 twenties), 97 ± 126 (21 thirties), 182 ± 200 (21 forties), and 191 ± 185 (34 fifties), in other words, the telomere length resulted in the shortest in thirties. However, because the sample size was too small, and the variations of the data were also large, the re-examination in the future is certainly required why the thirties showed the shortest telomere length. Alternatively, when the correlation analysis with the result of the food-intake frequency investigation done at the same time was conducted, it was interesting to find a negative correlation between the amount of alcohol drinking and the telomere length in man. However, such a correlation was not seen in heavy drinkers. On the other hand, the telomere length has significantly decreased in women who usually take a massive amount of vitamin C. Any association of the telomere length with whichever blood biochemistry test, food frequency questionaire, daily-life activity investigation, or other single nucleotide polymorphisms will be explored. The correlation of the telomere length of the buccal cell and its length of a peripheral-blood lymphocyte is now under investigation.

Peculiarities of growth hormone and insulin-like growth factor (IGF-1, IGFBP-3) secretion in genetically determined types of short stature in Uzbek population. *N.Sh. Ibragimova, S.I. Ismailov.* Endocrine diseases, Research Institute of Endocrinology, Tashkent, Uzbekistan.

Stunting is a heterogeneous state accompanied by many genetic diseases. Ethnic Uzbeks often marry to close relatives being a risk factor of giving birth to a child with genetic pathology. Medical sources do not have detailed data on studying a hormonal spectrum and pathogenesis of stunting as well as issues of effective utilization of growth hormone in genetically determined types of stunting (GDTS). Goal. To study secretion of GH and insulin-like growth factor (IGF-1, IGFBP-3) in GDTS in the Uzbek population. Materials and methods: 92 patients with GDTS (11 patients with Russell-Silver, 16 ones with Noonan, 10 with Sekkel, 9 with Prader-Willi, 8 with Cornelius de Lange syndromes, 38 girls with TS) at the age of 7 to 18 were examined. Blood serum was tested for the level of GH, IGF-1, IGFBP-3. Anthropometry (SDS) and past history were studied. The control group included 21 healthy children and adolescents of relevant age. Results: According to the past history, parents of 45.6% of patients examined were married to close relatives. Stunting of a various degree was seen in all patients with GDTS but it was most expressed in patients with Russell-Silver (-5.16±1.18 SDS), Sekkel (-4.18±1.12 SDS) and Cornelius de Lange syndromes (-6.10±1.14 SDS). A reliably low level of GH against the control was found in patients with Cornelius de Lange (0.64±0.05 ng/ml, $p<0.05$), Russell-Silver (0.7±0.04 ng/ml, $p<0.05$), Sekkel syndromes (1.02±0.07 ng/ml, $p<0.05$) on the background of a low level of IGF-1 and IGFBP-3. Patients with Noonan syndrome, TS and Prader-Willi syndromes had a GH level within the low limits except for 12 girls of the pubertal age (14 to 16) with TS who had a low level of GH (0.04±0.05 ng/ml, $p<0.05$), the IGF-1 and IGFBP-3 rates corresponded to the low age limits. Conclusions: The results obtained suggest that patients with GDTS of the Uzbek population had stunting of a various degree but the most expressed stunting was found in patients with Russell-Silver, Sekkel and Cornelius de Lange syndromes due to disturbances in the feed-forward and feedback in the GR- IGF-IGFBP-3 system. Girls with TS of the pubertal age had a low GH level and relative deficiency of IGF-1 and IGFBP-3 due to disturbances in the hypophyseal -ovarian system.

The NINDS Human Genetic Resource Center: A Resource for the Discovery of Genetic Risk Factors for Neurological Disorders. *C. Tarn[1], M. Self[1], E. Londin[1], E. Janeczko[1], A. Scutti[1], K. Reeve[1], K. Gwinn[2], R. Corriveau[2], M. D'Andrea[1].* 1) Coriell Institute for Medical Research, Camden, NJ; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD, USA.

The burden of neurological disorders is a serious public health concern and presents a massive challenge to healthcare systems globally. In most cases, the causes of neurological disorders are multifactorial, involving the interactions of many genetic and environmental factors. However, many neurodegenerative disorders such as Parkinsonism and Amyotrophic Lateral Sclerosis (ALS) still lack reliable disease biomarkers. Many studies aimed at identifying novel mechanisms of disease onset require large numbers of biomaterials from both affected and unaffected individuals. The National Institute of Neurological Disorders and Stroke (NINDS) Human Genetics Resource Center (NINDS Repository) is a public resource established to provide a centralized and open resource of biological samples (DNA and cell lines) and corresponding phenotypic data. Many researchers involved in neurodegenerative disease research have integrated into their study protocols the submission of biological samples and associated clinical data to the Repository for processing, storage, and distribution. Since its inception in 2002, biomaterials from more than 30,000 individuals have been banked, with more than 18,000 samples from individuals with cerebrovascular diseases (5,648), Parkinsonism (4,165), motor neuron diseases (2,255), epilepsy (1,043), Tourette syndrome (436), Huntington's disease (15), neurologically-normal controls (5,019) and unaffected primary blood relatives (1,965) publicly available through the Coriell Cell Repositories' web catalog (ccr.coriell.org). To aid high-throughput gene discovery, the Repository offers disease-focused panels of genomic DNA samples in 96-well plate formats as well as custom plate design services. Additionally, genotype data from over 4,000 NINDS Repository samples are available on dbGaP. More than 50,000 samples have been distributed to researchers by the Repository since inception. Analyses of NINDS Repository samples have been published in more than 200 peer-reviewed scientific articles. Furthermore, the Repository has begun to establish and bank fibroblast cell cultures from individuals with neurodegenerative disorders for purposes of cellular reprogramming to generate induced pluripotent stem cells. By establishing a centralized, publicly accessible resource of biospecimens and associated clinical data, the NINDS Repository facilitates discovery of new genetic and molecular signatures that lead to neurological disorders.

Family history systems in primary care: a public engagement study. *B. Wilson[1], S.M. Craigie[1], D. Castle[2], H. Etchegary[3], J. Allanson[4], D. Avard[5], J.C. Carroll[6], T. Caulfield[7], P. Chakraborty[4], L. Lemyre[8], J. Little[1], K. Morin[9], F.A. Miller[10], B.K. Potter[1], G.A. Wells[1].* 1) Department of Epidemiology & Community Medicine, University of Ottawa, Ottawa, ON, Canada; 2) ESRC Innogen Centre, University of Edinburgh, Edinburgh, United Kingdom; 3) Faculty of Medicine, Memorial University, St. John's, NL,Canada; 4) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada; 5) Centre of Genomics and Policy, McGill University, Montreal, QC, Canada; 6) Department of Family & Community Medicine Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada; 7) Health Law Institute, University of Alberta, Edmonton, AB, Canada; 8) School of Psychology, University of Ottawa, Ottawa, ON, Canada; 9) Genome Canada, Ottawa, ON, Canada; 10) Department of Health Policy, Management and Evaluation, University of Toronto, Toronto, ON, Canada.

Background Family history (FH) is associated with the risk of many complex diseases, and there are many tools and systems to store FH information and facilitate its use in primary care. There is also a much literature exploring family perspectives on genetic information, particularly around issues of disclosure and communication. Some of these issues might influence individuals' views on FH information. If so, then a health care provider's request to a patient to gather extensive FH information might raise concerns and potential resistance. In addition, given that collecting this information essentially depends on patient self-report, family relationships and dynamics may have a direct effect on the accuracy of the FH data which make their way into the medical chart. **Aims** We developed this study to complement work on developing evidence-based FH tools for implementation in Canadian health care settings. We wished to identify important issues around the systematic (a) collection and (b) storage and use of FH information in primary care populations. **Methods** This study used a qualitative approach supplemented by a structured survey. Issues salient to the general topic (finding out about FH, and using systems to store this information) were identified through literature review and extensive discussion. These were developed into `information sets' which presented the issues in a logical sequence, using lay language. Within a workshop setting, the information sets were presented incrementally, with pauses for facilitated discussion. Individual responses to two key questions were tracked after each information set, using instant voting technology. These questions were: *Do you think [the province] should invest in setting up family health history systems for family doctors?* and *If your own family doctor asked you to, would you be prepared to find out your family health history information and share it with him or her?* At the end of the workshop, participants completed a structured survey with more extensive question sets on attitudes and demographics. This general approach can be adapted for different participant groups, where different issues may be salient according to life stage or other population attributes. We will present findings from workshops involving two groups: (1) otherwise unselected adults aged 50+, and (2) parents of young children, asked to consider FH systems specifically from a parental context.

The beta-thalassaemia carrier screening process in Australia- Is it acceptable? *N.E. Cousens[1,2], C.L. Gaff[1,2], S.A. Metcalfe[1,2], M.B. Delatycki[1,2,3].* 1) Murdoch Childrens Research Institute, Royal Children's Hospital, Parkville, Victoria, Australia; 2) Department of Paediatrics, Faculty of Medicine, Dentistry and Health Sciences, The University of Melbourne, Victoria, Australia; 3) Department of Clinical Genetics, Austin Health, Heidelberg, Victoria, Australia.

Background: There is currently no structured) -thalassaemia carrier screening program in Victoria, Australia. Instead it has been incorporated into routine healthcare practice. Many women are screened through a full blood examination (FBE) at their initial prenatal visit, with a low MCV triggering further) -thalassaemia diagnostic testing. The experiences of and attitudes of women found to be carriers through this ad hoc approach to screening are not known. The views of health professionals also have not been ascertained. Aim: To explore carriers' and health professionals' experiences of and attitudes towards the) -thalassaemia carrier screening process in Victoria. Method: Semi-structured interviews were conducted with 26 female carriers and 10 carrier couples of) -thalassaemia who had been pregnant within the last 12 months as well as 23 health professionals. Interviews were analysed using inductive content analysis. Results: Women were identified as carriers at different times of their lives, either before or during pregnancy, with many being screened incidentally as part of routine antenatal testing or testing to diagnose medical symptoms. Most did not recall being told about thalassaemia before being notified of their carrier status. Most did not make a decision about whether or not to be screened, as they reported being unaware screening was taking place, and therefore did not provide informed consent. Most women were happy for their doctors to decide what tests are conducted, however preferred to have been told that they were being screened for thalassaemia before being tested. Health professionals' views of informed consent varied, with some believing that patients should be informed before they are specifically tested for thalassaemia. Women placed a great importance on the information provided after receiving their test results, believing it to be inadequate with this lack of information leading to misconceptions and confusion. Conclusion: Most women in Victoria are not providing informed consent for thalassaemia screening, and do not recall being told about screening being performed. However there was a greater value placed on awareness of testing and information rather than choice and decision-making by both carriers and health professionals. These results suggest that routine screening as part of clinical care is acceptable, but more emphasis should be placed on awareness of the screening process and post-test education of carriers.

1401T

Establishing a Theoretical Financial Framework for Biobanks for the Purpose of Returning Individual Clinically Significant Genetic Information to Research Participants. *A.M. Peterson[1], M.E. Smith[1, 2], S. Aufox[2, 4], D. Dranove[3].* 1) Clinical and Translational Sciences Institute -Northwestern University, Chicago, IL; 2) The NUgene Project - Center for Genetic Medicine - Northwestern University, Chicago, IL; 3) Kellogg school of management - Northwestern University, Evanston, IL; 4) Center for Genetic Medicine - Northwestern University, Chicago, IL.

Background: Disclosing genetic research results to participants is controversial, particularly when clinical utility or validity has not been established. This debate is founded in ethical, legal, and practical concerns. While ethical and legal concerns have been addressed previously, the practical concerns, including the financial ramifications, have yet to be addressed through scientific analysis. This is especially relevant to large-scale biobanks, which are increasingly accessed for genetic research. The objective of this study is to explore potential avenues where costs may arise throughout the process of returning research results to biobank participants. Methods: Semi-structured interviews were utilized with purposefully selected biobanking professionals. Participants were asked: 1) Their initial impressions surrounding the return process, 2) The methodology they would use to determine clinical significance of a research finding, 3) How they would return results and, 4) What, if any, follow-up would be implemented post-disclosure. Interviewees' responses were analyzed for themes and were used to develop a theoretical model for returning results. The model was assessed for anticipated costs. Results: The seven interviewees had a range of industry experience (0.8-10 years), biobank size (1,400 - 20,000) and consenting processes. Interview data illustrated a lack of consensus on method for returning results. All participants felt their respective IRBs should be consulted and results need to be clinically useful to warrant return. The majority felt there were circumstances where they could consider returning results, would consult advisory groups, utilize multiple attempts and mechanisms for contact, and confirm results in a CLIA lab. Five of 7 would offer genetic counseling for follow-up. The return model illustrates potential costs, ranging from $52.83 - $2,054.65 per participant. Conclusions: Returning research results is not commonly practiced among biobanks. Clearly, biobanking professionals are thinking about the issue. Returning genetic information to research participants could be both time consuming and costly.

1402T

The MiSeq DNA sequencing platform and its application to Public Health. *G.P. Smith[1], W. Meuleman[1], J. Betley[1], J. Becq[1], O. Schultz-Trieglaff[1], L. Murray[1], M. Bauer[1], F. Oaks[2], J. Yeager[2], MiSeq program team.* 1) Illumina Cambridge Ltd, Saffron Walden, United Kingdom; 2) Illumina Inc., Hayward and San Diego, CA. USA.

Next generation sequencing has enabled the routine sequencing of whole human genomes at a scale of many thousands per year. Over the last few years technology advances with the Illumina platform has increased throughput to over 1Tb of high quality data per run, and reduced the costs of sequencing a human genome to less than $10,000. Although these DNA sequencing systems provide an optimised platform for the sequencing of large genomes, there are many projects that require much smaller amounts of data, and faster turnaround times from sample to answer. We have developed a new sequencing system, called MiSeq, that generates over 1Gb of data from 2x150 base reads in just over a single day. Miseq integrates all the steps of the Illumina sequencing process from cluster generation, to paired end sequencing reads, into a fully automated `hands-off' workflow that involves 20 minutes of set up time, and includes the steps of primary and secondary data analysis, including variant calling and de novo assembly. At its core, Miseq runs the same reversible terminator SBS chemistry as the high throughput Hiseq and GAIIx systems, and benefits from the knowledge and understanding that has been acquired in over 1000 peer-reviewed publications. To simplify the upstream library preparation process, we have developed a transposon-based method called Nextera, that generates Illumina-compatible libraries from amplicons or genomic DNA within 1.5 hours and makes possible a complete workflow on MiSeq from sample-to-answer within 8hours, or a single working day, including analysis time. In this study we demonstrate that a single run of the MiSeq instrument is capable of highly accurate and deep sequencing of a range of human pathogens, including E. coli, MRSA and Pseudomonas aeruginosa. In addition, the data is well suited to the de novo assembly of these bacteria, rivalling performance of the higher throughput (and more expensive) machines. The rapid turnaround of the system, coupled with the simple operation of the instrument, makes possible the deployment of Next Generation sequencing in the clinical setting, revealing details of strain identification, antibiotic sensitivity and epidemiology of human pathogens at base-pair resolution. Examples of the integration of the technology into the workflow of MRSA strain characterisation will be provided.

1403T

Candidate gene variants and susceptibility to infection by hepatitis A and E viruses in the US population: analysis using the Third National Health and Nutrition Examination Survey (NHANES III), 1991-1994. *L. Zhang[1], M.H. Chang[2], D.J. Hu[1], E. Teshale[1], N.F. Dowling[2], C.G. Teo[1].* 1) Division of Vrial Hepatitis, Centers for Disease Control and Prevention, Atlanta, GA; 2) Office of Public Health Genomics, Centers for Disease Control and Prevention, Atlanta, GA.

The 2 main causes of enterically-transmitted hepatitis are hepatitis A virus (HAV) or hepatitis E virus (HEV). These viruses are widely prevalent and cause significant public health problems in many countries. Prior to the introduction of hepatitis A vaccine in the US in 1995, HAV periodically caused large, nationwide epidemics, leading to substantial morbidity and economic losses. HEV is not associated with substantial morbidity and mortality in the US, but appears highly prevalent. Human genetic variation is a determinant of viral hepatitis but to date studies of human genetic variation for hepatitis A are few and there are none for hepatitis E. We evaluated associations between 510 single-nucleotide polymorphisms (SNPs) in 200 candidate genes and seropositivity for HAV and HEV among 7159 participants from the second phase (1991-1994) of the Third National Health and Nutrition Examination Survey (NHANES III), a population-based and nationally representative survey of the US. Individuals aged 12 years and older who self-reported as non-Hispanic white (n = 2434), non-Hispanic black (n = 1919), and Mexican American (n = 1919) were included in analysis. Among non-Hispanic whites, non-Hispanic blacks, and Mexican Americans, respectively, the number (weighted frequency) of seropositivity was as follows: 958 (24.9%), 802 (39.2%), and 1540 (71.5%) for HAV; 628 (22.3%), 279 (15.3%), and 449 (21.8%) for HEV; and 304 (32.3%), 156 (21.9%), and 415 (27.3%) for both HAV and HEV. No significant associations between seropositivity for HAV or HEV infection and any of the 510 SNPs were observed among non-Hispanic whites or non-Hispanic blacks. Among Mexican Americans, 3 SNPs located in *ABCB1*, *APOA4*, and *VLDLR* associated with HAV-seropositivity and 1 SNP in GSDML associated with HEV-seropositivity were identified (p-value adjusted for false discovery rate < 0.05). Seropositivity for both HAV and HEV was associated with SNPs in *CDKAL1*, *IL10*, *IL7R*, and *ILF* among non-Hispanic whites, *AFF1* among non-Hispanic blacks, and *TMEM18* among Mexican Americans. **Conclusions**: Susceptibility to infection by HAV and HEV may be genetically associated, and the nature of associations varies across the three racial/ethnic groups. Replication studies involving larger population samples are warranted.

Evaluation of cystine in urine samples for a diagnostic approach in Colombian cystinuria. *L. Buitrago Alvarado, J. Benavides Sanchez, A. Uribe Ardila.* Centro de Investigaciones en Bioquimica(CIBI), Departamento de Ciencias Biologicas, Facultad de Ciencias, University of the Andes, Bogota, D.C., Colombia.

INTRODUCTION Cystinuria is an autosomal recessive metabolic disorder, with an estimated incidence of 1:7.000 births. It is caused by the defect in intestinal and renal transport of dibasic amino acids cysteine, ornithine, lysine and arginine, causing predisposition for the formation of stones in the urinary system. Early detection improves disease prognosis and prevents further complications, hence the importance of developing screening protocols that do not involve prolonged urine collections, a key objective of this study. METHODOLOGY We performed high-risk screening by qualitative tests (sodium nitroprusside) and semiqualitative (chromatography). Spectrophotometric quantification is performed by a modification of the Brand test for cystine. For the data analysis we used the statistical program SPSS 18, the Kolmogorov-Smirnov normality test, and Ln was used for homogeneity of variance. RESULTS AND ANALYSIS We evaluated samples from 148 individuals, ranging in age from newborns to 63 years, this involves 69 normal controls, 79 patients followed for nephrolithiasis in which five were related to Cystinuria biochemical findings such as positive nitroprusside, chromatographic patterns of cystine, ornithine, and lysine and increased levels of cystine in voided urine samples. We established that the normal value of cystine was 11.9± 11.5 mg/g creatinine. Cystines values of affected individuals were higher than 37.2 mg/g creatinine. Was established as a cutoff 30.3 mg/g creatinine. There is a correlation between the concentration of cystine and creatinine of an individual ($p<0.01$), according to an ANCOVA analysis, and there is a correlation between the concentration of cystine and the age of individuals, men and women ($p<0.02$). These results are highly significant because they suggest age and sex should be taken into account as a parameter for quantification of metabolite creatinuria, and the collection of urine for 24 hours as currently used is not sufficient. CONCLUSION There is a marked difference between affected and healthy individuals in relation to concentrations of cystine in urine. This allows for a preliminary reference value for the Colombian population and improves the differential diagnosis.

Background: Newborn screening (NBS) in Ontario and many other juris-dictions is delivered as standard care: parents may opt out but it is not explicitly presented as a choice for most. Issues around education and consent have recently come to the fore in the context of debate about expansion of NBS programs and attention to policies related to the storage and secondary use of NBS bloodspots. There is some evidence that parents currently receive limited education about NBS and that what they do receive focuses mainly on the purpose, benefits, and process of screening. Previous work suggests that mothers may prefer more comprehensive information, but NBS programs may be concerned about potential for decreased uptake of the service with provision of additional information, particularly that which emphasizes possible harms. Concerns have also been expressed that pro-viding parents with too much information may compromise understanding or foster anxiety. **Objectives:** The goal of this study is to measure and compare expecting mothers' responses to different educational messages about NBS. By identifying the messages that appear most salient to mothers with respect to their intentions/decision-making about participating in NBS, this work will contribute to ongoing discussions about appropriate educa-tional content and the links between education and parental involvement in decision-making. **Methods and Findings:** We are conducting a self-com-plete survey with pregnant women attending routine 16-20 week ultrasounds at two clinics in Ottawa, ON, Canada. The survey has a factorial design: expecting mothers receive differing messages about newborn screening including those related to the possibility of false positive/negative results; pain from the heel-prick; potential for overdiagnosis of infants not at serious risk of illness; storage and secondary use of bloodspots; and parental choice/consent. Participants respond to questions measuring intention to screen their baby, level of decisional conflict about this decision, and understanding of the messages. Data collection is underway. **Implications:** The findings will have implications for the design and delivery of parental education about NBS in Ontario and other jurisdictions; and will also inform a broader debate about the roles of parents, providers and policy makers in decisions about NBS.

Haptoglobin phenotypes in Saudi Arabia. *S. Sayeeduddin.* Laboratory Medicine, AlJouf University, Sakaka, AlJouf, Saudi Arabia.

Objective: To find out frequencies of different phenotypes of haptoglobin among Saudi population. Materials and Methods: Eighty one (81) randomly selected people visiting clinics at King Faisal Hospital, Qurayat town, volun-teered to be the subject of this study. Sera collected were analyzed for haptoglobin phenotypes. Haptoglobin phenotypes were determined by verti-cal polyacrylamide gel electrophoresis, and the bands were visualized by staining with benzedine solution (Awadallah and Hamad, 2000). Results: It was observed that maximum number of subjects, 38 (46.9 %) out of 81, belonged to HP 2-2. The HP 2-1 were 29 (35.8 %) and remaining 14 (17.5 %) were of HP 1-1 type. Conclusions: The present work is the preliminary report being reported from the Northern region (Al-Qurayat population in the AlJouf region). Future plans are to extend the study to include the population from other regions of the kingdom and also increase the sam-ple size.

1407T

Access to genetic health care: qualitative study of new universal screening for sickle cell and thalassaemia disorders in England. *J. Kai[1], F. Ulph[2], T. Cullinan[1], N. Qureshi[1].* 1) Division of Primary Care, University of Nottingham, Nottingham, United Kingdom; 2) University of Manchester, UK.

Background: Universal antenatal and newborn population screening for haemoglobin disorders has recently been implemented across the National Health Service in England. This provides an important testing ground for the expansion of genetic health care, and appropriate access to its potential benefits by those diverse minority ethnic communities with highest preva-lence of these disorders in the UK. **Aim:** This study aimed to explore experi-ences of access to new genetic screening for sickle cell and thalassaemia disorders in England. **Methods:** The research was conducted within screen-ing services across 13 hospital provider units and primary care localities in two regions of England with ethnically diverse populations. This involved analysis of service processes and communications to patients; key informant interviews with 19 health professionals and user groups; and substantive qualitative interview study with a purposeful sample of 37 parents with experience of sickle cell or thalassaemia carrier identification following screening, with grounded approach to data analysis; and respondent valida-tion and discussion of findings with parents, health professionals and user groups. **Results:** Users articulated those components of services and out-comes they had valued or would value. However there was wide variation in the quality and accessibility of information for patients. Experience of communication within critical screening interactions with professionals could be poor, with, for example, incomplete exchange or reception of the benefits of screening or diagnostic tests, or the problematic use of family members as interpreters in this context. This compromised access across the screening pathway, generating anxiety and misunderstanding, and lowering opportuni-ties for users to be fully informed. Desire to avoid anxiety or risk during pregnancy could also lead some users to decline services or not pursue information or testing as part of antenatal screening. While service influences and organisation appeared dominant, low community awareness of disor-ders also shaped misperceptions and stigma about screening. **Conclu-sions:** Many factors that may compromise access to haemoglobin disorder screening and the promotion of fully informed choices reflect the way ser-vices are provided rather than patient-specific influences or choice. These factors are likely to be salient to other areas of genetic service development and delivery.

1408T

Familial breast cancer: Risk communication, predictive testing and management in four European countries. *I. Nippert[1], H. Harris[2], C. Julian-Reynier[3], J. Schmidtke[4], C. van Asperen[5], A. Tibben[5,6], D.G. Evans[7,8].* 1) Women's Health Research, Westfälische Wilhelms-Universität, Münster Medical School, Münster, Germany; 2) GenEd Coordinating Centre, Univer-sity of Manchester, Manchester, UK; 3) U912, INSERM, IRD, Aix-Marseille Université, Institut Paoli-Calmettes, Marseille, France; 4) Institute of Human Genetics, Hannover Medical School, Hannover, Germany; 5) Centre for Human and Clinical Genetics, Department of Clinical Genetics, Leiden Uni-versity Medical Centre (LUMC), Leiden, The Netherlands; 6) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 7) Genetic Medicine MAHSC, Central Manchester University Hospitals NHS Founda-tion Trust, St Mary's Hospital, Manchester UK; 8) Genesis Prevention Cen-tre, University Hospital South Manchester, Wythenshawe Hospital, Man-chester, UK.

Background: Genetic testing has its greatest public health value when it identifies individuals who will benefit from specific interventions based upon their risk. This paradigm is the basis for the use of predictive tests, such as BRCA1/2 testing, which has become part of clinical practice for more than a decade. Currently in Western European countries predictive BRCA1/2 testing is offered to women using low, moderate and high risk based upon family history as cut-off levels. Non-genetic health professionals, such as general practitioners (GPs) are seen as gate keepers to manage demand and/or facilitate access for high risk women to adequate services.

Methods: Assess current practice of GP's cancer risk communication and management of familial breast cancer in Germany (DE), France (F), The Netherlands (NL) and the United Kingdom (UK).

Results: 1197 GPs completed a 70 item questionnaire. The majority of GPs report that when an unaffected person presents with cancer concerns they will take a family history (DE 95.7%, F 93.8%, NL 83.7%, UK 80.2%) and provide risk assessment based upon the family history (DE 61.5%, F 67.9%, NL 53.9%, UK 51.7%). However, less than half of the respondents in NL (47.7%) and UK (46.1%) would ask about cancer history of the extended family. Only 44.8% (DE), 26.5% (F) and 43.5% (NL) agreed that inheritance patterns of familial breast cancer should be explained by a genetic specialist whereas 30.1% (DE), 63.6% (F), 49.7% (NL) and 33.8% (UK) state that this should be better done by themselves.

Discussion: There is a critical disconnect between GPs and genetic spe-cialists. The observed tendency in the four countries is that GPs prefer to assess and communicate genetic risks themselves and are unaware that they may not perform adequate risk assessment and risk communication.

1409T

Developing and validating clinical genetics-specific patient reported outcome measures: Are we finally at the end of a long and winding road? *M. McAllister[1], A.M. Wood[2], G. Dunn[3], K. Payne[3], L. Davies[3], S. Shiloh[4], C. Todd[5].* 1) Genetic Medicine, School of Biomedicine, The University of Manchester, Manchester, UK; 2) School of Psychological Sciences, The University of Manchester, Manchester, UK; 3) School of Community-Based Medicine, The University of Manchester, Manchester, UK; 4) Department of Psychology, Univerity of Tel Aviv, Israel; 5) School of Nursing, Midwifery & Social Work, The University of Manchester, Manchester, UK.

An enduring challenge in clinical genetics is how best to measure patient benefits. PROMs offer a possible solution. PROMs are short self-completion questionnaires that can capture aspects of health and health-related quality of life that come directly from the patient. PROMs are used in research to generate evidence of patient benefit from new interventions, for example as the primary outcome in a randomised controlled trial. PROMS are also be used to collect data on patient outcomes in routine clinical practice to enable patient choice and control. US and UK health policy encourages use of PROMs data. However in clinical genetics, there is no consensus about the best PROMs to use. This talk will present findings from a UK programme of research (2003-2011), involving some 450 patients and 130 clinicians, to address the problem of PROMs use in clinical genetics. Mixed-methods were used to identify patient benefits from using clinical genetics: (a) systematic literature review of validated outcome measures used in the field (b) Delphi survey to identify consensus amongst UK clinicians and patients about appropriate outcome domains and (c) qualitative focus groups and interviews. The next stage involved validating two clinical genetics specific PROMs with potential to capture patient benefits: the Genetic Counseling Outcome Scale (GCOS-24) and the Perceived Personal Control (PPC) Scale. The 24-item GCOS-24 was developed to capture a construct, empowerment, summarising patient benefits identified in the qualitative research. Both internal consistency of the GCOS-24 ((=0.87) and test-retest reliability (r = 0.86) are good. Concurrent validity and sensitivity to change over time (Cohens d=0.70) were also demonstrated. The first psychometric validation of the English translation of the Perceived Personal Control scale (PPC-E) was also conducted. The PPC-E was demonstrated to have (a) a one factor structure (b) concurrent validity (c) high internal consistency ((=0.83) (d) sensitivity to change and able to identify moderate changes in PPC (Cohens d=0.40) following clinic attendance. These properties suggest that both the GCOS-24 and the PPC-E are appropriate validated PROMS to (1) evaluate the impact of introducing new interventions in clinical genetics research and (2) collect data on patient outcomes in routine clinical genetics practice. Both PROMs would benefit from further psychometric validation such as testing for known groups and discriminant validity.

1410T

Impact of family history information on accuracy of cardiovascular disease prediction in middle aged women. *Q. Hasanaj[1], BJ. Wilson[1], J. Little[1], Z. Montazeri[1], GJ. Prescott[2] on behalf of CIHR Emerging Team in Genomics in Screening.* 1) Epidemiology, University of Ottawa, Ottawa, ON, Canada; 2) Department of Public Health, University of Aberdeen, Aberdeen, UK.

Background: Positive family history (FH) is associated with risk of many common complex diseases. Most clinical guidelines mention FH as important in assessing disease risks. However, the evidence base to inform the routine use of FH in primary care is largely lacking. The 2009 NIH State-of-the-Science Panel on Family History and Improving Health concluded that, for FH to be established as an evidence-based tool, there is a need to evaluate its predictive ability and prognostic value in combination with traditional risk factors. The limited research published to date suggests that FH might offer statistically significant improvements to disease risk classification, but clinical utility still needs to be adequately evaluated. We report the findings of a study of cardiovascular disease risk prediction in women, in which the impact on clinical decisions of adding FH information to guideline-based risk factor information is provisionally evaluated. **Objectives:** To assess the incremental improvement in individual risk prediction which is gained by adding FH to other clinical information recommended in guidelines, and its potential impact on patient classification and management. **Methods:** This is a secondary cross-sectional analysis of data from the Aberdeen Study of Cardiovascular Health in Women, a retrospective cohort study. The dataset contains information on a range of risk factors as well as FH. Cardiovascular disease outcomes defined according to the Rose Angina Questionnaire and/or Minnesota EKG coding. We used a specific guideline applicable to this British study population (`JBS2') to select variables for univariate and logistic regression analyses. We developed three models: Model 1 included only the covariates in JBS 2; Model 2 added FH to Model 1; and Model 3, which we developed using a fuller range of risk factors available in the dataset, including FH. For each model, the predictive/discriminatory ability was evaluated using ROC curves. **Results:** We will present: the three models, their accompanying ROC curves, and relevant statistics; details of the original classification and reclassification of participants between risk groups resulting from the different models; and comments on the likely effects of reclassification on guideline-based clinical management recommendations, i.e. the changes in specific recommended preventive interventions which follow when participants shift from lower to higher risk strata and vice versa.

1411T

Weighted Metrics for Assessing Quality of Regional Public Health and Clinical Genetics Services. *J. Mulvihill, S. Whitehead, A. Chou, Genetics Systems Assessment Working Group.* Dept Pediatrics & Genetics, OU Medical Ctr, Children's, Oklahoma City, OK.

As health care costs increase, emphasis is being placed on assessing, reporting, monitoring, and improving quality. Using metrics to assure quality has been implemented for management of common chronic diseases, but there is a growing recognition that public health and clinical and laboratory genetics should likewise develop and apply measurements of quality. The objective of this project is to identify and pilot test a set of metrics as a tool for assessing the quality of genetics services within a geographic region of the US. A systematic review of literature (Amer J Med Genet 2009;151C:214-234), prior guidelines, and professional statements yielded 61 measures for further review and selection. A panel drawn from a US pool of experts and stakeholders was assembled and conducted a modified Delphi Technique to rank the measures on a five point Likert scale, according to criteria of relevance, feasibility for evaluation, and strength of scientific evidence. Ratings were computed to generate a score for each measure. Three iterations of the Delphi process and consensus discussion among the panel identified 25 measures for pilot testing. The Departments of Health of Hawaii and of Washington were pilot sites since both have been perceived as “high-performers” in public health and clinical genetics programs. The states' genetics coordinators completed the tool, with input from their databases, local geneticists, genetic counselors, and others. The current metrics tool has five domains (Capacity of Services, Access, Clinical Processes and Quality Improvement, Performance Reporting, and Workforce) with a total of 18 measures. The measures are being weighted for importance in final scoring. After review and clarifications and documentation to guide implementation, the eight states in the Heartland Genetics and Newborn Screening Collaborative (AR, IA, KS, MO, ND, NE, OK, SD) have volunteered to use the Genetics Systems Assessment Tool. The hope is results will facilitate mutual assistance among states and regions and sustain funding to assure the public has access to high quality public health and clinical genetics and genomic services. (US DHHS, Health Services and Resource Administration, Bureau of Maternal and Child Health, Genetics Services Branch, Cooperative Agreement to University of Oklahoma Health Sciences Center, U22MC03962).

Predictive genetic tests of alcohol intolerance for moderate and responsible drinking; Actions for reducing harmful drinking. *Y. Ohta[1], S. Suzuki[2], F. Kato[1], M. Sami[1], T. Kanda[1], I. Kobayashi[3].* 1) Res Lab for Fundamental Tech, Asahi Breweries, LTD., Ibaraki, Japan; 2) Shonan Kamakura General Hospital, Kanagawa, Japan; 3) Central Hospital, National Cancer Center, Tokyo, Japan.

Health hazards from inappropriate alcohol intakes are increasing year by year(1). To reduce this world-wide public health problems, efforts for eradicate harmful drinking from the society are strongly required. We established a convenient genetic test for the SNP rs671 on Aldehyde Dehydrogenase 2 gene, which uses saliva samples. Additionally, that system does not collect any personal genetic information. With the educational seminars on moderate and responsible drinking and drinking rules, we have provided this DNA test free of charge. (1); World Health Organization, “Global strategy to reduce the harmful use of alcohol”.

Medical Genetics in Southeast Asia: Status and Current Drivers. *J.K. Thompson[1], M. Laurino[2], D.L. Sternen[3], K. Leppig[4].* 1) Provincial Medical Genetics Program, Children's and Women's Health Centre of British Columbia, Vancouver, BC; 2) Institute for Public Health Genetics, University of Washington, Seattle WA; 3) Division of Genetic Medicine, Seattle Children's Hospital, Seattle, WA; 4) Genetic Services, Group Health Cooperative, Seattle, WA.

There is a broad range of genetic services and testing currently available for the 593 million individuals residing in Southeast Asia (SEA). Some countries have nascent newborn screening while others have a broad spectrum of specialized genetic services. It is foreseeable that the cost of genetic testing will continually decrease with its increasing utilization (e.g., clinical testing, direct to consumer testing, pharmacogenetics, etc.). Thus, we propose possible strategies for infrastructure development of genetic programs in SEA to meet these demands. Through literature review using PubMed, Medline, World Wide Web searches, and personal correspondence, we assessed the current status of newborn screening programs, genetic counseling training programs, and the utilization of clinical genetic technology for diagnoses and carrier screening for each country in SEA. Using the United Nations classification of geographical regions, countries in SEA include: Brunei Darussalam, Cambodia, Indonesia, Lao People's Democratic Republic, Malaysia, Burma (Myanmar), Philippines, Singapore, Thailand, Timor-Leste, and Viet Nam. National newborn screening programs have been implemented in Indonesia, the Philippines, Singapore, and Thailand. Other countries are conducting pilot newborn screening projects and anticipate program implementation in the near future. Clinical genetic services, including diagnostic testing and screening, are available in Indonesia, the Philippines, Singapore, Thailand and Viet Nam, albeit with varying degrees of access, resources, and specialization. The newly implemented genetic counseling program in the Philippines could serve as a potential model for developing an educated work force in SEA that can meet consumer demands for genetic services. Training health professionals to offer genetic counseling services is a cost-effective public health strategy. It provides the opportunity to improve the identification, diagnosis and support of management care of individuals with congenital and genetic conditions. Given the variability of available genetic services in SEA, the development of sustainable and comprehensive genetic services to disseminate accurate genetic information is now of utmost importance. Cultural competency in acknowledging the various cultural and spiritual perceptions on genetic attribution towards disease development and self-sustainability is imperative for success.

Cystic Fibrosis carrier screening: customer satisfaction study. *L. Ditta, S. Egiziano, C. Salbe, M. Mattiuzzo, L. Tognetto, A. Brugnoli, G. Romagnosi, M. Gion, L. Bartoloni.* Clinical Pathology, ULSS12 Veneziana, Venezia, Italy.

We have been performing pre-conceptional identification of Cystic Fibrosis (CF) heterozygotes since 2001. 13168 subjects were analyzed and 400 carriers found. We refined the distribution of the different CFTR mutations in our population, defining a more sensitive and less expensive mutation panel. To assess the impact of this test on the carriers, we performed more than 100 phone interviews. Even if the couples were followed by gynecologists and family doctors and received an informative leaflet and a written report, the majority of the carriers didn't know what CF was and what a carrier status meant when they received the written report. They asked for information the gynecologist, the family doctor and they searched the internet (three options that often gave wrong information). Talking to a geneticist was the fourth choice, just before asking friends. The majority of the women were prescribed the test during the pregnancy and not before, and there isn't an agreed protocol for testing (both members at the same time or one member first). Only 39% of the carriers decided to have a second level test(DHPLC or sequencing of the entire gene) for their partner, and 12% of them got a positive response too. This five couples were not influenced in their reproductive choices by the positive test, and asked for a CF pre-natal test for all their pregnancies, with no double heterozygote babies to date. The carriers that did not screen the partner with a second level test (61%) did not report the birth of CF babies. Even if the interviewed carriers were happy with the test and suggest to their friends and family to be tested, the results of the questionnaire forced us to change the way we deliver the report and to improve the dissemination of informations among the physicians and the public.

Recognizing health care needs of orofacial clefts individuals during genetics evaluation in Alagoas, Brazil. *M.I.B. Fontes[1], K.M. Santos[1], J.I. Vieira Filho[1], A.K.M. Andrade[2], F.S. Anjos[1], T.P. Vieira[3], I.C. Sgardioli[3], N.L.V Campos[3], I.L. Monlleó M.D.; PhD.[1], V.L. Gil-da-Silva-Lopes M.D.; PhD.[3].* 1) Department of Pediatrics, State University of Alagoas, Maceió, Alagoas, Brazil; 2) Medical Genetics Sector, Federal University of Alagoas, Maceio, Alagoas, Brazil; 3) Department of Medical Genetics, University of Campinas, Campinas, Sao Paulo, Brazil.

Introduction: Orofacial clefts (OC) occur in approximately 1/600 newborns babies worldwide and are among the most common birth defects. Multidisciplinary, team-based, coordinated and family-centered healthcare is accepted as the state of the art in this field. Public healthcare for patients with orofacial clefts was structured in 1998 in Brazil through 21 units arranged as a network unevenly distributed. Alagoas is a poor state located in the Northeast region of the country in which there is not specialized center for care of patients with OC. Aim: to describe demographic and clinical-genetic characteristics as a subside to structure healthcare for patients with OC in Alagoas. Methods: All patients were systematically seen by two clinical geneticists using a pre-tested protocol from September 2009 to February 2011. Conventional and molecular cytogenetic analyses were performed in selected patients. Fisher Test was used for statistics with p-value<0.05.Results: majority of patients were males, country side residents, with isolated cleft lip with cleft palate. Ages ranged between 0-37 years. Thirty six percent had never undergone surgery while 100% had never attended to genetic evaluation. Isolated cleft was diagnosed in 75%, syndromes in 14.4%, multiple congenital defects in 9.6% cases and additive randomic defects in 1.0%. Recurrence and parental consanguinity were, respectively, 28.7% and 9.7%. Twenty-three individuals without cleft surgery were registered for multidisciplinary treatment. Conclusions: Clinical-genetic characteristics corroborate the literature. Findings revealed high levels of unmet medical needs and provided an evidence base for health care planning. Support: Fapeal, Fapesp, CNPq.

Novel mouse models for hearing loss associated with proximal 1p36 deletions. *H. Zaveri[1], B.J. Kim[1], O.A. Shchelochkov[2], F.A. Pereira[3], A.K. Groves[1], J.S. Oghalai[4], M. Justice[1], B. Lee[1], D.A. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Dept of Pediatrics, University of Iowa, Iowa City, IA; 3) Cell & Molecular Biology, Baylor College Med, Houston, TX; 4) Otolaryngology, Stanford School of Medicine, Palo Alto, CA.

Terminal and interstitial deletions of 1p36 are a common cause of cognitive and developmental delay with an incidence of 1 in 5000 newborns. Although 28% of individuals with 1p36 deletions also have sensorineural hearing loss, the gene(s) responsible for this phenotype have yet to be identified. The arginine-glutamic acid dipeptide repeats gene (*RERE*), located in the proximal region of 1p36, encodes a nuclear receptor coregulator that is required for normal embryogenesis, and is highly conserved from *Drosophila* to humans. In zebrafish, reduced expression of the *RERE* homolog *Rerea* leads to inner ear anomalies—fused otoliths and abnormal semicircular canals—and diminished microphonic potentials. We hypothesized that *RERE* plays a similar role in the development of the inner ear in mammals. To test this hypothesis, we used immunohistochemistry to show that RERE is expressed in critical regions of the mouse inner ear including the inner and outer hair cells and the marginal and basal cell layers of the stria vascularis. However, further studies of the function of RERE in the inner ear were hampered by the early lethality seen in *Rere* null mice (*Rere*$^{-/-}$), which die in utero at E9.5 due to cardiac failure. To overcome this, we generated an allelic series of RERE-deficient mice bearing different combinations of a *Rere* null allele and a hypomorphic allele (V193A) we identified in an ENU mutagenesis screen. *Rere*$^{-/\ V193A}$ mice have diminished startle responses to a 108 dB burst at 19.9 kHz emitted from a click box—a common preliminary test for severe hearing loss. Distortion product otoacoustic emission (DPOAE) and auditory brainstem evoked response (ABER) testing at p21 revealed that *Rere*$^{-/\ V193A}$ and *Rere*$^{V193A\ /\ V193A}$ mice have early onset hearing loss. *Rere*$^{-/\ V193A}$ mice also fared poorly in the dowel test which requires normal balance and coordination. Histological analyses and 3D micro-CT reconstructions of the inner ear showed that *Rere*$^{-/\ V193A}$ mice have normal cochlear morphology at p21 but have increased cross-sectional diameter of their semi-circular canals when compared to their wild type littermates. We conclude that RERE is required for normal hearing and vestibular function and that *Rere*$^{-/\ V193A}$ and *Rere*$^{V193A\ /\ V193A}$ mice represent useful models for studying the molecular mechanisms by which RERE-deficiency contributes to the hearing loss in individuals with 1p36 proximal deletions.

1417T

Alternative polyadenylation: gene mechanism to avoid miRNA regulation. *C. Barbacioru[1], F. Tang[3], E. Nordman[1], E. Heard[4], K. Lao[1], A. Surani[2].* 1) Life Technologies, Foster City, CA; 2) Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QN, UK; 3) BIOPIC, School of Life Sciences, Peking University, Beijing, 100871, China; 4) CNRS UMR3215, INSERM U934, Institut Curie, Paris F-75248, France.

Many protein-coding genes have more than one polyadenylation site, so a gene can code for several mRNAs that differ in their 3' end. The single cell RNA-Seq analysis uses poly(T) primer for reverse transcription, which is biased towards a better coverage of the 3' end of mRNAs and therefore enhances detection of alternative polyadenylation identified as coverage peaks of the 3'UTRs. Here we performed single cell RNA-Seq analysis of single blastomeres of mouse embryos, which revealed significant changes in the transcriptome. We found that 1,718 genes have two transcript isoforms with the same coding region but different lengths of 3'UTR, suggesting that approximately 13% of expressed genes exhibit at least two isoforms with long (distal) and short (proximal) 3'UTR in the same cell at the same time. Prediction of polyadenylation sites are searched for the presence of CPSF binding motif site located at -20 nt upstream of their 3'end and we found 40% of short (proximal) and 70% of long (distal) 3'UTRs, respectively, suggesting that the stop of majority of these 3'UTRs are at the canonical polyadenylation recognition sites. We propose that in individual blastomeres, the majority of transcripts from a gene have a short 3'UTR, which will be translated constantly, whereas for a small number of transcripts from the same gene with long 3'UTR, their translation will be dynamically regulated by microRNAs or RNA-binding proteins. This would allow relatively stable translation of a large set of genes, while permitting subtle adjustment in protein levels. The abundance of transcript isoforms with short 3'UTR is about 5 - 6 fold higher compared with those from the same gene with a long 3'UTR in two-cell embryos. Thus, the impact of miRNA regulation of mRNA translation for these mRNAs with two different lengths of 3'UTRs in early blastomeres is probably negligible. Interestingly, whereas the ratio of long to short 3'UTR is maintained at four- and eight-cell stages, it changes in postimplantation epiblast cells, where mRNAs with the longer 3'UTR isoforms increase from 16% to 33%. This suggests that later in development, transcripts with long 3'UTR might provide greater flexibility for translational regulation, at a time when cells respond to more complex signaling conditions for diverse cell fate decisions.

Understanding the anomalies in the development of the skull and craniovertebral junction in achondroplasia. *F. Di Rocco[1,2], N. Kaci[1], E. Mugniery[1], C. Benoist-Lasselin[1], N. Litim[1], A. Munnich[1], L. Legeai-Mallet[1].* 1) INSERM U781, Laboratoire de Génétique et Epigénétique des maladies métaboliques, neurosensorielles et du développement, Paris, France; 2) Craniofacial Unit, Pediatric Neurosurgery, Hôpital Necker Enfants Malades, Paris, France.

FGFR3 is a regulator of bone formation. Several pathologies involving this gene in which the skull growth and craniovertebral junction are affected (achondroplasia, Muenke syndrome) have been described. We have used three *fgfr3Y367C/+* mouse models expressing the Y367C mutation ubiquitously (*CMV -fgfr3Y367C/+*), only in the osteoblasts (*Col I-fgfr3Y367C/+*) or only in the chondrocytes (*Col II-fgfr3Y367C/+*) to understand the impact of FGFR3 mutations on the development of the skull and determine the role played by each of these cell types.The three mouse models have been studied at 3 weeks of age using macroscopic, histology, radiology and microCT analysis. The *CMV-fgfr3Y367C/+* mice display severe morphological changes affecting the long bones but also the cranial vault and skull base. The length of the skull was reduced (66%, p<0,001) and the high increased (103%, p<0,05). The size of nasal, frontal, interparietal and occipital bones was significantly altered (55%, 82%, 125%, and 46%, respectively). The posterior fossa was hypoplasic with a small foramen magnum. In all mice, a prognathism was found with an absence of basal synchondrosis. All these features of *CMV-fgfr3Y367C/+* mice closely mimic the human chondrodysplasia. Conversely, *Col I-fgfr3Y367C/+* model results in mild morphological changes. An increase in length of the skull (106%, p<0.01) and alteration in the anterior and occipital foramen angles was found (97%, p<0.05 and 110%, p<0,01, respectively). No anomalies of the calvarial sutures and no prognathism were observed. *Col II-fgfr3Y367C/+* mouse model shows also some severe morphological alterations. Skull length was reduced (75%, p<0.0001), and high increased (103%, p<0.05), with a modification of anterior and posterior angles (76%, p<0.001 and 107%, p<0.05, respectively) and a reduction of the size of the occipital foramen and atlas vertebra. Skull base anomalies were also observed with a complete absence of the synchodrosis and a prognatism. However, no defect in calvaria bones was found. This study allows a better understanding of cranial and craniovertebral abnormalities in achondroplasia. The comparative analysis of our three models confirms the importance of endochondral ossification in the growth of the skull and craniovertebral junction. The differences in phenotypes observed between the three mouse models show that FGFR3 plays a role also in membranous ossification and highlight the impact of encephalic anomalies on calvarial growth.

1419T

Loss of prolyl-3-hydroxylation at position 986 of type I collagen in transgenic mice has a negative effect on bone mass and structure. *I. Grafe[1], D. Baldridge[1], E. Homan[1], T. Bertin[1], Y. Chen[1], M-A. Weis[2], D. Napierala[1], T. Yang[1], B. Dawson[1], C. Lietman[1], E. Munivez[1], S. Chen[1], M. Grover[1], M-M. Jiang[1], D. Eyre[2], B. Lee[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Orthopaedics and Sports Medicine, University of Washington, Seattle, Washington.

Purpose Cartilage associated protein (CRTAP) is required for prolyl-3-hydroxylation (3-Hyp) at position 986 of the triple helical domain of fibrillar collagens in vivo. It has been shown that loss of CRTAP results in recessive Osteogenesis Imperfecta (OI), but it is unclear if the concomitant loss of 3-Hyp directly contributes to the bone phenotype. Therefore, this study investigates if loss of 3-Hyp at position 986 of the (1(I) collagen chain has a negative impact on bone tissue through use of a transgenic mouse model. Methods Transgenic mice with overexpression of mutated Col1a1 gene in bone have been generated. Specifically, a point mutation was introduced in the Col1a1 DNA, resulting in a proline to alanine change at position 986. Alanine cannot be 3-hydroxylated and as it is the second most common amino acid in the X-position of the collagen Gly-X-Y triplet, the P986A substitution is predicted not to disrupt folding or stability of the collagen triple helix. The P986A Col1a1 gene is expressed in transgenic mice (P986A-Tg) under control of the osteoblast specific 2.3kb Col1a1 promoter. Similarly, transgenic mice with overexpression of the wildtype col1a1 gene were generated as controls (Control-Tg). Expression levels of Col1a1 mRNA were quantified by RT-PCR and 6 week old female P986A-Tg and Control-Tg mice with similar expression were chosen for further studies. Results In bone of P986A-Tg mice, mass spectroscopy confirmed a 20% expression of the alanine form of total (1(I) collagen chains. As compared to non-transgenic littermates the P986-Tg mice had a 8% reduced weight (p<0.05). MicroCT analysis of vertebral body L4 demonstrated a reduced BV/TV (-11.1%;p<0.05), reduced trabecular number (-9.6%;p<0.05), increased trabecular separation (+14.2%;p<0.05) and a slightly reduced BMD (-8.3%;p= 0.054). No significant differences regarding these parameters were observed in Control-Tg mice compared to non-transgenic littermates. Conclusion Our results indicate that bone specific expression of (1(I) collagen chains lacking 3-Hyp at position 986 affects bone mass and structure in a dominant negative manner. This suggests that 3-Hyp is required for the formation of normal bone and that loss of 3-Hyp, at least in part, may contribute to the OI phenotype related to loss of function of Crtap.

1420T

Consequences of gain-of-function mutations of ALK on central nervous system development. *C. Gordon[1], L. de Pontual[1,2], D. Kettaneh[1], M. Oufadem[1], N. Boddaert[3], M. Lees[4], J. Mollet[5], A. Munnich[1,6], L. Brugière[7], O. Delattre[5], M. Vekemans[1,6], S. Lyonnet[1,6], I. Janoueix-Lerosey[5], J. Amiel[1,6].* 1) Université Paris Descartes, INSERM U-781, Paris, France; 2) Service de Pédiatrie, Hôpital Jean Verdier, AP-HP, Bondy, France; 3) Service de Radiologie Pédiatrique, INSERM U-1000, Hôpital Necker-Enfants Malades, AP-HP, Paris, France; 4) Department of Clinical Genetics, Great-Ormond Street Hospital for Children, London, UK; 5) INSERM U-830, Institut Curie, Paris, France; 6) Département de Génétique, Faculté de Médecine ; AP-HP, Hôpital Necker-Enfants Malades, Paris, France; 7) Service d'Oncologie Pédiatrique, Institut Gustave Roussy, Villejuif, France.

Neuroblastoma (NB) is a frequent embryonal tumour of sympathetic ganglia and adrenals with extremely variable outcome. Recently, somatic amplification and gain-of-function mutations of the anaplastic lymphoma receptor tyrosine kinase (ALK, MIM 105590) gene, either somatic or germline, were identified in a significant proportion of NB cases. We have identified a novel syndromic presentation associating congenital NB with severe encephalopathy and abnormal shape of the brainstem on brain MRI in two unrelated sporadic patients harbouring de novo, germline, heterozygous ALK gene mutations. Both mutations are gain-of-function mutations that have been reported in NB and NB cell lines only. Electroporation of the neural tube of embryonic day 1.5 chicken embryos with a mutant ALK construction results in spreading of neural progenitors beyond the ventricular zone at two days post-electroporation; this phenotype is not observed when wild-type ALK is over-expressed. This supports the hypothesis that activating mutations in ALK disrupt neurogenesis in the central nervous system. These observations further illustrate the role of oncogenes in both tumour predisposition and normal development, and shed light on the pleiotropic and activity-dependent role of ALK in humans. More generally, missing germline mutations relative to the spectrum of somatic mutations reported for a given oncogene may be a reflection of severe effects during embryonic development, and may have to be looked for in patients with extreme phenotypes.

1421T

The Nuclear Receptor Co-Regulator, RERE Regulates the Development of the Cerebellum. *B. Kim[1], H. Zaveri[1], Z. Yu[1], O.A. Shchelochkov[2], M. Justice[1], B. Lee[1], D.A. Scott[1].* 1) Department of Molecular and Human Genetics, Baylor College Med, Houston, TX; 2) Department of Pediatrics, University of Iowa, Iowa, IA.

Cerebellar malformations have been documented in association with over 280 genetic syndromes and account for 3% of all CNS malformations identified in perinatal/neonatal autopsies. Although the cerebellum has been recognized for its importance in motor control and coordination, there is increasing evidence that it also plays an important role in higher cognitive functions. Despite these important roles, little is known about the genes that influence cerebellar development. The arginine-glutamic acid dipeptide repeats gene (*Rere*) is expressed in the developing mouse cerebellum, cerebral cortex, and hippocampus and encodes a nuclear receptor co-regulator that has been shown to interact with several nuclear orphan receptors including NR2F2 (COUP-TFII). Ablation of *Nr2f2* in the mouse cerebellum causes abnormal patterning and cerebellar hypoplasia. This prompted us to hypothesize that RERE interacts with NR2F2 to control cerebellar development. Mice that are homozygous for a *Rere* null allele have open neural tube and structural defects in the developing brain. However, early prenatal lethality precludes their use in studies of cerebellar development, which occurs during the later stages of prenatal period and continues postnatally. To overcome this problem, we created an allelic series of RERE-deficient mice bearing combinations of the previously described *Rere* null allele and a hypomorphic allele (V193A) we identified in an ENU mutagenesis screen. During the prenatal period, the cerebellums of $Rere^{-/V193A}$ mice are hypoplastic and show delayed formation of the principle fissures. Purkinje cell development is also delayed. Although the number of LHX-1 positive Purkinje cell precursors is normal, the expression of calbindin—a marker of mature Purkinje cells is limited to the posterior part of the cerebellum at E18.5 and Purkinje cell dendrite branching in the postnatal period is also attenuated. While the levels of granule cell proliferation and apoptosis are unaffected in $Rere^{-/V193A}$ mice at E18.5, granule cell migration is delayed during the postnatal period. $Rere^{-/V193A}$ mice also fare poorly in the dowel test which requires normal balance and coordination. These results suggest that RERE deficiency causes delayed cerebellar development which, in turn, causes functional deficits in motor coordination. We are presently working to determine if the defects seen in the cerebellum of $Rere^{-/V193A}$ mice are due to interactions between RERE and NR2F2.

Intellectual disability-associated synaptic protein KIRREL3 interacts with MAP1B and Myr8. *Y.F. Liu[1], S.M. Sowell[1], Y. Luo[1, 3], A.K. Srivastava[1,2].* 1) J.C. Self Research Institute of Human Genetics, Greenwood Genetic Center, Greenwood, SC; 2) Department of Genetics and Biochemistry, Clemson University, Clemson, SC; 3) Present address: Department of Pediatrics, Emory University School of Medicine, Atlanta, GA.

Cell-adhesion molecules of the immunoglobulin (Ig) superfamily play critical roles in brain development, as well as maintaining synaptic plasticity, the dysfunction of which is known to cause cognitive impairment. Recently, we have identified a potential role for KIRREL3, a synaptic molecule of the Ig superfamily, in intellectual disability (ID). We have functionally characterized the human KIRREL3 and determined that the protein is primarily located on the neuronal cell membrane and interacts with the X-linked ID-associated synaptic scaffolding protein CASK through its cytoplasmic domain. Furthermore, its extracellular domain (ECD) contains five Ig-like domains that are post-translationally modified by N-glycosylation and cleaved after expression in neuronal cells. To further elucidate the physiological function of the KIRREL3 ECD, we used yeast two-hybrid screening and found that the domain interacts with MAP1BLC, the microtubule associated protein light chain, and Myr 8, an unconventional myosin protein. The interactions were confirmed by reciprocal co-immunoprecipitation analysis of proteins expressed in transfected HEK293H cells. MAP1B has been previously implicated in synaptogenesis and is involved in the development of the actin-based membrane skeleton. Myr8 is expressed in hippocampal neurons, interacts with Neurexin 1, and was recently found to be deleted in a patient with ID. Together, these findings point to a possibility that the function of KIRREL3 at the synapse is carried out by a cytoplasmic domain-dependent pathway through its interaction with CASK and a pathway through its ECD interactions with other synaptic proteins such as MAP1B and Myr8. The latter function is considered critical as ECD of *syg-1*, a *C. elegans* ortholog of human KIRREL3 that localizes at the site of future synapses and has been shown to be involved in the clustering of synaptic vesicles, is capable of rescuing the terminal phenotype of a syg-1 mutant. Further studies will help define the molecular mechanisms underlying the physiological action of KIRREL3 at the synapse and its role in cognitive function.

1423T

Aristaless brain diseases: a class of pathologies associated with an altered GABAergic homeostasis? *L. Poeta[1,2], D. Drongitis[1], F. Fusco[1], M. Paciolla[1,2], S. Filosa[1], P. Collombat[3], M.B. Lioi[2], M.V. Ursini[1], M.G. Miano[1].* 1) Institute of Genetics and Biophysics, CNR, Naples, Italy; 2) University of Basilicata, Potenza, Italy; 3) INSERM U636 Diabetes Genetics, Nice, France.

ARX is one of the most important X-linked brain disease genes encoding the homeo-Transcription Factor Aristaless with a crucial role in the development of cerebral cortex, thalamus, hippocampus, and striatum. Mutations in humans cause a large spectrum of neurological disorders including lissencephaly, severe epilepsy and mental retardation. Male embryonic Arx null mice shows aberrant migration and differentiation of gamma-aminobutyric acid (GABA)-ergic interneurons, characteristics recapitulating some of the clinical features of lissencephaly and epilepsy in humans. In this report, we present molecular and morphological signatures that appear altered during the transition from neuronal precursors to fully committed Arx deficient GABA cells. In ES and neurosphere cells from wt and Arx-/Y embryonic brains, we analysed specific proliferative and neuronal hallmarks, during in vitro GABAergic maturation. They were investigated in critical transition stages: proliferation, intermediate differentiation and full differentiation. In the absence of Aristaless, we established by real time PCR robust transcriptional changes of a number of critical determinants of proliferating precursor cells and of early neuronal fate. Subsequent analysis performed by immunofluorescence confirms a parallel deregulation of the corresponding proteins. In addition, in full differentiation condition, confocal microscopic study puts in evidence abnormality in neuronal morphology and the high percentage of immature GABAergic neurons. In light of these results, we investigated whether impaired induction of neuronal differentiation was accompanied by generation of cells derived from the other germ layers. Transcript levels of mesoderm/endoderm specific genes revealed abnormal expression during neuronal differentiation. We are currently producing Arx deficient ES cell lines stably transfected with normal Arx to evaluate molecular and morphological rescue effects. In summary, we reveal the existence of changes in critical neuronal markers compatible with an impaired Arx-dependent synaptic function, which impacts on GABA homeostasis. One of the altered markers was suspected to be a direct transcriptional target of Aristaless, even if further work is required to define their functional connection. These findings emphasize the “interneuronopathy” hypothesis and will hopefully lead to the identification of a novel entry point to study ARX physiopathology in epilepsy and mental retardation.

1424T

Candidate Gene Effects on Human Craniofacial Variation in Males and Females. *S.F. Miller[1], D. Defay[1], S. Weinberg[2], C. Kummet[3], J.C. Murray[4], M.L. Marazita[2], G.L. Wehby[5], L.M. Moreno[1].* 1) Department of Orthodontics, University of Iowa, Iowa City, IA; 2) University of Pittsburgh, Pittsburgh, PA; 3) Dows Institute, University of Iowa, Iowa City, IA; 4) Department of Pediatrics, University of Iowa, Iowa City, IA; 5) College of Public Health, University of Iowa, Iowa City, IA.

Purpose: Identifying genetic factors that give rise to human craniofacial variation are of a primary interest within the field of craniofacial biology. This study seeks to further our understanding of this interface between genes and facial morphology. Methods: Thirteen SNPs within candidate genes/ loci for craniofacial development (IRF6, FOXE1, 8q24, and 20q12) and left-to-right asymmetry (LEFTY1, LEFTY2, ISL1, and SNAI1) were analyzed along with facial phenotypes including linear distances, three dimensional geometric morphometric (3D GM) phenotypes via relative warps analysis (RWA) from coordinate data and scores indicating facial shape asymmetry utilizing a multivariate regression model and Spearman correlations. Facial phenotypes were regressed on the genotypes separately for males and females. The facial coordinate data were obtained from 3dMD images of normal adults (62 males and118 females). Results: Suggestive associations ($p<0.05$) were observed between genes and the facial phenotypes. In males, SNPs in IRF6 were associated with nose width and lower face protrusion, SNPs in 8q24 were associated with a principal component (PC) summarizing variation in facial width, SNPs in FOXE1 were associated with philtrum height and a PC summarizing facial width, SNPs in LEFTY1 were associated with nasal base width, maxillary protrusion and overall facial size and finally a SNP in 20q12 was associated with a PC summarizing facial convexity. Interestingly SNPs in 8q24, FOXE1 and LEFTY1 together explained up to 17% of the variation in the PC summarizing facial width ($p=0.01$). In females SNPs in IRF6 were associated with upper facial height and philtrum width, SNPs in 8q24 were associated with a PC summarizing facial convexity, SNPs in FOXE1 were associated with facial height, a SNP in 20q12 explained 20% of the variation in facial shape asymmetry scores ($p=0.03$). Finally LEFT1 SNPs were associated with nasal base width, facial protrusion, cranial base width and overall facial size. Conclusions: These results are among the first to show multiple suggestive correlations between facial phenotypes and candidate genes for left-to-right asymmetry and facial development. This study highlights the importance of identifying genetic factors influencing human craniofacial variation in order to understand abnormal craniofacial development requiring surgical interventions and reducing quality of life.Support:DE016148, CDC5R01DD000295, AAOF 2008 OFDFA.

The ciliary kinase *Nek8* is required for Polycystin2-mediated signaling. *D.R. Beier[1], D.K. Manning[1], R.G.H.P. van Heesbeen[2,3], M. Sergeev[2,3], I.A Drummond[4], J.V. Shah[2,3].* 1) Genetics Division, Medicine Dept., Brigham & Women's Hospital/Harvard Medical School, Boston, MA; 2) Harvard Medical School, Systems Biology, Boston MA; 3) Renal Division, Medicine Dept., Brigham & Women's Hospital/Harvard Medical School, Boston, MA; 4) Renal Division, Medicine Dept. Massachusetts General Hospital/Harvard Medical School, Boston MA.

The *Nek8* gene encodes a serine/threonine kinase that localizes to the axoneme of primary cilia and is mutated in the juvenile cystic kidneys (*jck*) mouse model of polycystic kidney disease. The *jck* allele harbors a missense mutation that affects an RCC repeat in the C-terminus of NEK8 and full-length mutant protein is expressed in *jck* homozygotes. To elucidate the function of *Nek8* we generated a null allele, and found that *Nek8-/-* embryos exhibit randomization of left-right asymmetry and die shortly after birth. Mutants with abnormal laterality either display situs inversus totalis or right pulmonary isomerism (RPI) coupled with severe structural cardiac anomalies. Whole-mount in situ hybridization of the laterality marker genes *nodal* and *Pitx2* reveal aberrant nodal signaling in *Nek8-/-* embryos. Mutant embryonic nodal cilia appear normal, suggesting there is a defect in signaling rather than an overt cilial structural abnormality. The requirement for *Nek8* in left-right patterning is conserved as knockdown of the zebrafish orthologue causes randomized heart looping. Independent of laterality status, renal function is impaired in all *Nek8-/-* embryos as late-gestation and P0 kidneys have glomerular cysts and proximal tubule abnormalities. Interestingly, PKD-like tubular cysts are not present in mutant kidneys nor can they be induced in renal explant culture cyst formation assays. In addition, *jck/Nek8-* compound heterozygotes develop PKD but cystic disease is much less severe than in *jck* homozygotes, suggesting the *jck* allele is a gain of function allele of *Nek8*. The laterality, cardiac and kidney phenotypes in *Nek8-/-* embryos are strikingly similar to those identified in Pkd2-/- mice. Polycystin2 protein is present and properly localized in *Nek8* mutants but its function is likely perturbed in null embryos and cells, as *Nek8-/-* cells are resistant to triptolide. Together, the data demonstrate a requirement for *Nek8* in proper embryogenesis and suggest the protein is a critical mediator of polycystin2-dependant signaling.

Exploiting the Mid1 null mouse line to understand cerebellar development. *G. Meroni[1], F. Petrera[1], D. Licastro[1], A. Lancioni[2], R. Ferrentino[3], C. Migliore[1], M. Zanchetta[1].* 1) Functional Genomics, Cluster in Biomedicine (CBM), Trieste, Italy; 2) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy; 3) Institute of Genetics and Biophysics, CNR, Naples, Italy.

Opitz G/BBB Syndrome (OS) is a genetic disorder characterized by midline developmental defects. Male patients with the X-linked form of OS, caused by loss-of-function mutations in the MID1 gene, show high variability of the clinical signs. MID1 encodes a ubiquitin ligase that controls Phosphatase 2A (PP2A) but its role in the pathogenesis of the disease is still unclear. Recently, we reported the generation and characterization of a mouse line carrying a non-functional ortholog of the human MID1 gene, Mid1. Mid1 null mice show the brain anatomical defect observed in patients, i.e. hypoplasia of the medial cerebellum, the vermis and the presence of motor coordination and procedural learning impairments. The defect is limited to the most anterior lobes of the vermis, the region of the developing cerebellum adjacent to the dorsal midbrain. We reported that lack of Mid1 causes a mis-specification of the midbrain/cerebellar boundary that results in abnormal development of the most anterior cerebellar lobes. To unravel the early events triggered by the lack of Mid1 in the developing cerebellum, we applied a genome-wide approach. We used laser capture microdissection to select the developing posterior dorsal midbrain and cerebellum, i.e. the entire region around the midbrain/cerebellum boundary, from sagittal sections of E12.5 and E13.5 Mid1 null and WT littermate embryos. We extracted RNA from the dissected tissues and perform microarray-based expression profiling. Bioinformatic analysis revealed the presence of several genes differentially expressed between Mid1 null and WT embryos. Gene enrichment analysis of the differentially expressed transcripts shows GO terms statistically significant over-represented in classes defined as `muscle contraction' and `spinal cord neuron specification'. Noteworthy, among the differentially expressed genes in our system the former class is represented by genes coding for proteins of the cytoskeleton and the second by several homeodomain-containing transcription factors. Considering that Mid1 is a microtubular protein involved in cytoskeleton stabilization and that homeodomain containing proteins are important for antero-posterior neural tube determination, these results represent promising bases to understand the origin of the defects observed in Mid1 null mice and in Opitz Syndrome patients.

Analysis of time-series embryonic diaphragm transcriptomes identifies *Pbx1* as a candidate gene for diaphragmatic defects. *M. Russell[1], M. Longoni[1], J. Wells[2], F. Maalouf[1], A. Tracey[1], K. Ackerman[3], B. Pober[1,4,5], K. Lage[1,6,7,8,9], C. Bult[2], P. Donahoe[1,6,7].* 1) Pediatric Surgical Research Laboratories, Massachusetts General Hospital, Boston, MA 02114 USA; 2) The Jackson Laboratory, Bar Harbor, ME 04609 USA; 3) The University of Rochester, School of Medicine and Dentistry, Rochester, NY 14642 USA; 4) Children's Hospital Boston, Boston, MA 02115 USA; 5) Department of Pediatrics, Harvard Medical School, Boston, MA 02115 USA; 6) Department of Surgery, Harvard Medical School, Boston, MA 02115 USA; 7) Broad Institute, Cambridge, MA 02142; 8) Center for Biological Sequence Analysis, Technical University of Denmark, Lyngby, Denmark; 9) Center for Protein Research, University of Copenhagen, Copenhagen, Denmark.

Congenital Diaphragmatic Hernia (CDH) is a birth defect with significant morbidity and mortality that occurs in 1 in 2,500 live births. Classic genetic studies are in most cases statistically underpowered to identify genes responsible for CDH due to its genetic heterogeneity, polygenic inheritance, and small kindred sizes. To overcome these challenges, time-series whole-genome expression profiles generated from laser capture microdissected embryonic C57BL/6J mouse diaphragms (at E11.5, E12.5, and E16.5) were analyzed. Specifically, gene sets defining biologically relevant pathways (obtained by Gene Set Enrichment Analysis) and temporal expression patterns in the diaphragm (obtained by Short Time-series Expression Miner) were assessed for enrichment of a curated list of “bait” genes known to be associated with diaphragm defects in humans and/or in mutant mice. Genes belonging to the intersecting subset of these two independent algorithms were considered the highest priority CDH candidates. This data filtering approach revealed 31 candidate genes, among which 4 were bait genes, providing positive proof of principle. Each of a dozen candidates tested to date, demonstrate expression in the primordial mouse diaphragm by either immunohistochemistry and/or RT-q-PCR. Among the 28 novel candidates, pre-B cell leukemia transcription factor 1 (*Pbx1*), a known facilitator of muscle differentiation and mesodermal patterning during embryogenesis, was selected to assess further the validity of the enrichment strategy. Ex vivo examination of 3/3 *Pbx1*^{tm1mlc} knock out mouse embryos at E15.5 revealed a range of diaphragmatic defects. Thus, the validity of the computational approach is supported by the discovery of *Pbx1* as a new CDH-associated gene. Sequencing of PBX1 in 150 human subjects with CDH is underway. Finally, we anticipate that our novel expression dataset and the narrowed list of candidates will continue to reveal new CDH-associated genes and provide insight into the developmental biology of this malformation.

1428T

Deletion of *PAX6* entire gene in a patient with aniridia. *E.S.S. França[1], M.S. Guaragna[1], A.T. Maciel-Guerra[2,3], G. Guerra-Júnior[3,4], M.P. de Mello[1].* 1) Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade de Campinas (UNICAMP), Campinas, SP, Brasil; 2) Departamento de Genética Médica, Universidade de Campinas (UNICAMP), Campinas, SP, Brasil; 3) 3Grupo Interdisciplinar de Estudos da Determinação e Diferenciação do Sexo (GIEDDS), Universidade de Campinas (UNICAMP), Campinas, SP, Brasil; 4) 4Departamento de Pediatria, Faculdade de Ciências Médicas, Universidade de Campinas (UNICAMP), Campinas, SP, Brasil.

Aniridia is a congenital eye condition characterized by the iris underdevelopment that usually occurs in both eyes. It is inherited as autosomal dominant trait with high penetrance. WAGR syndrome (Wilms'tumor - Aniridia - Genitourinary Anomalies - Mental Retardation Syndrome) is caused by large deletion in 11p13. Normally, this deletion encompasses several genes, including *PAX6* and *WT1*, resulting in both aniridia and increased risk for Wilms' tumor. Heterozygosis for *PAX6* gene mutations are also found in cases of isolated aniridia, suggesting that *PAX6* haploinsufficiency causes this condition. However, not all cases of aniridia are due to mutations. This study was conducted to identify *PAX6* mutations in a Brazilian patient with isolated aniridia. The patient was a girl showing bilateral aniridia, cataract in the left eye and nystagmus. There was no other case in the family. She had no neurological disorders and no other physical problem such as Wilms' tumor, which was monitored periodically by kidney ultrasound scanning. The exons of *PAX6* and *WT1* genes were amplified by polymerase chain reaction and direct sequenced. Copy number variations were investigated by multiplex ligation-dependent probe amplification (MLPA). MLPA was performed with SALSA Kit P219-B1 from MRC Holland (Amsterdam, Netherlands). Molecular analyses for *WT1* and *PAX6* gene did not revealed any mutation in the patient with aniridia. However MLPA demonstrated the heterozygous deletion of every *PAX6* exons. Other probes, including those from *PAX6* 5' and 3' flanking regions and WT1 gene did not show copy number variations. These results discarded deletion and/or mutation on the *WT1* gene. In this study we show the heterozygous deletion of *PAX6* gene in one isolated case of aniridia. This deletion probably occurred de novo, which corresponds to a rare case. Our results indicate that MLPA technique might be included in the molecular diagnosis of *PAX6* gene, mainly to confirm or rule out deleted genes mapping to 11p13 as causes of isolated aniridia or Wilms' tumor. The molecular diagnosis of aniridia in the case described here was only achieved when MLPA technique was used to identify the *PAX6* gene deletion. However, the exact deletion breakpoint was not determined yet. Additional studies such as genotyping with microsatellite markers will be further conducted to delimitate deletion boundaries.

1429T

Knock-down of Zic2 in embryonic stem cells blocks neural differentiation through its effects on miRNA expression. *L. Brown, S. Brown.* University of Vermont Burlington VT.

Heterozygous mutations in the transcription factor ZIC2 result in holoprosencephaly (HPE) in humans and mice, leaving no doubt that ZIC2 plays an important role in early forebrain patterning. Despite this knowledge, there is currently very limited insight into how ZIC2 normally functions in brain development. Our lab has shown that Zic2 is expressed in the preimplantation mouse embryo as well as in embryonic stem (ES) cells and in adult neural stem cells. This observation led us to hypothesize that Zic2 plays a role in regulating early neural differentiation events. To test this hypothesis, we used lentiviral-mediated shRNA to knock down the expression of Zic2 in mouse ES cells by about 90%. ES cells with reduced Zic2 expression ("Zic2-kd-ES") continue to grow with typical ES cell morphology and continue to express markers of pluripotency, such as Oct3/4, Sox2 and Nanog. However, when Zic2-kd-ES cells are allowed to differentiate in culture, they no longer differentiate into neurons or neural precursor cells. Thus, loss of Zic2 appears to block an entire differentiation pathway without affecting known regulators of pluripotency. We used Affymetrix arrays to assess miRNA expression in Zic2-kd-ES cells and show that diminished Zic2 expression major changes in a discreet group of miRNAs. In particular, we show that diminished Zic2 expression results in the 5-60 fold decrease in the expression of the miRNA-302 family. This result is paradoxical, since published data indicate that diminished miRNA-302 expression is associated with loss of expression of standard markers of pluripotency. Current efforts in our lab are aimed at understanding the overall effects of Zic2 on gene expression, as well as understanding how Zic2 regulates miRNA expression. Taken as a whole, our data indicate that Zic2 specifically modulates neural differentiation in pluripotent stem cells and that, by exploring the role of Zic2 in ES cell biology, we will gain insight into the molecular details of neurogenesis. This will be critical for efforts to reprogram adult cells into neural stem cells.

Asymmetric expression of Claudin-10 is required for correct patterning of the left-right axis. *M.M. Collins[1], A. Simard[2], A.K. Ryan[1,2].* 1) Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Pediatrics, Research Institute of the Montreal Children's Hospital, MUHC, Montreal, Quebec, Canada.

In vertebrates, the asymmetric positioning of internal organs relative to the midline is evolutionarily conserved, and required for normal physiological function. The genetic cascade that defines asymmetric organ positioning initiates during gastrulation, during which several ions including calcium, have been implicated in the initial symmetry breaking event. The mechanisms by which these events are translated into asymmetric gene expression remain unknown. We previously examined the role of the integral tight junction protein, Claudin-1, in patterning the left-right axis in the chick, and showed that overexpression of Claudin-1 on the right side of the embryo randomized the direction of heart looping. To identify other claudins expressed during gastrulation, we performed expression analyses of the claudin family. We identified that 15 claudins exhibit unique and/or overlapping expression patterns during gastrulation. Interestingly, we discovered that Claudin-10 was asymmetrically expressed at Hensen's node, the site where asymmetric gene expression is first observed in the chick embryo and where the initial symmetry breaking events required for left-right patterning occur. Overexpression of Claudin-10 on the left side of the node, or knockdown of endogenous Claudin-10 on the right side of the node, caused a significant increase in abnormal leftward heart looping, indicative of abnormal left-right patterning. We also observed alterations in the expression of the classic left-right morphogenesis gene, Pitx2c, in these embryos. We are currently examining the effects of manipulating Claudin-10 expression on other classic left-right patterning genes, and identifying the functional domains necessary for the role that Claudin-10 plays during left-right patterning. These data suggest that asymmetric expression of Claudin-10 is required for normal left-right patterning, perhaps through regulation of the permeability of the ions that have been proposed to be involved in the initial symmetry-breaking event that occurs at Hensen's node.

NOTCH signaling pathway and Holoprosencephaly: A transcriptomic approach using chick model. *V. David[1 2], L. Ratié[1], I. Gicquel[1], S. Mercier[1 3], C. Dubourg[1 2], S. Odent[1 3], V. Dupé[1].* 1) Faculté de Médecine, UMR 6061 CNRS/Université Rennes1, Rennes, France; 2) Laboratoire de Génétique Moléculaire, CHU Pontchaillou, Rennes, France; 3) Service de Génétique Clinique, CHU Pontchaillou, Rennes, France.

Holoprosencephaly (HPE) is a congenital malformation of the human brain due to an imperfect division of forebrain during early development. Multiple genetics defects have been identified as involved in this process. It is now currently admitted that HPE is a multihit pathology caused by at least two or more dysfunctional events involving genes from more than one signaling pathway. The SHH and NODAL pathways have been presented to be the main signaling pathways involved in human HPE. To a lesser extend, FGF has also been found to be implicated. Importantly, by CGH array we have recently found several recurrent rearrangements in 6qter in our cohort of HPE patients and identified a component of the NOTCH pathway, DLL1, as a new HPE candidate gene. We described a mutation in *DLL1* in HPE patients and showed that Dll1 was expressed in the chick developing forebrain and notably co-expressed in the anterior neuropore with Fgf8, one of the major genes implicated in ventral forebrain patterning. These results strongly suggest that a disturbance of Notch pathway may well confer a susceptibility to HPE. However, if previous studies have showed the importance of Notch throughout the neurogenic phase of forebrain development, no link with HPE has ever been described. To assess this question, we have implemented an ex ovo chick embryos culture system with a pharmacological inhibitor known to block specifically Notch pathway. Subsequently, the molecular reprogramming of the treated brain has been tested using expression microarray and in situ hybridization approaches. These analyses provide functional data about the NOTCH signaling pathway during HPE appearance as well as throughout normal forebrain development.

Assisting research into human embryonic and fetal development. *D. Gerrelli[1], S. Suren[1], V. Morrison[1], Y. Cheng[2], L. Overman[2], M. Crosier[2], S. Lisgo[2], S. Lindsay[2], A.J. Copp[1].* 1) Institute of Child Health, University College London, London, United Kingdom; 2) Institute of Genetic Medicine, Newcastle University, Newcastle. United Kingdom.

The Human Developmental Biology Resource (HDBR) is funded by the MRC and Wellcome Trust to provide human embryonic and fetal tissue for gene expression studies related to congenital disease. This research is essential if we are to understand the developmental origin of these conditions, including both malformations and inherited metabolic disorders, and to produce new methods for primary prevention. Use of the HDBR material should also illuminate developmental gene expression underlying aspects of functioning that characterise humans as opposed to lower animals (e.g. higher brain function, language), since such studies are challenging using rodent and other animal models. The HDBR has ethics committee approval for the collection, storage and distribution of human embryonic and fetal material between 4 and 16 weeks of gestation. In addition the HDBR administers a previously collected fetal tissue bank, with specimens available between 8 and 19 weeks of gestation. A significant proportion of the HDBR material is karyotyped and chromosomally normal material is provided for research. Karyotypically abnormal material can also be provided on request. Freshly collected material from the HDBR can be used to generate cell lines (e.g. stem cells), protein, RNA and DNA. cDNA is also available from embryonic tissue for gene expression analysis. In addition, paraffin wax and frozen sections of embryos and early fetuses are available for in situ hybridisation and immunohistochemistry. The HDBR offers an in-house gene expression service (IHGES) using in situ hybridisation and/or immunohistochemistry. The service includes: • Initial testing of in situ cRNA probes or antibodies. A report showing initial results with sense and antisense probes together with positive controls on the human fetal tissue will be provided. • Once good quality results have been generated, a full project can be performed on a number of different developmental stages. High quality images of gene expression patterns suitable for publication will be produced and the HDBR will provide advice on interpretation of results. Recent completed and published IHGES projects have included analysis of gene expression in the limb, eye, liver, kidney, central and peripheral nervous system at a range of human developmental stages. Information on all aspects of the HDBR, can be found on www.HDBR.org or by contacting the centre manager at Hdbr@newcastle.ac.uk or Hdbr@ich.ucl.ac.uk.

1433T

Is TMED2 essential in the chorion for normal interaction between the allantois and the chorion in mice? *W. Hou[1], D. Sarikaya[1,3], L. Jerome-Majewska[1,2].* 1) Department of Human Genetics, McGill University, Montreal, QC, Canada; 2) Montreal Children Hospital Research Institute, Montreal, QC, Canada; 3) Organismic and Evolutionary Biology Department, Harvard University, Cambridge, Massachusetts, USA.

During vesicular transport between the endoplasmic reticulum and the Golgi, members of the transmembrane emp24 domain (TMED) protein family form hetero-oligomeric complexes that facilitate protein cargo secretion and transportation. In our laboratory, we are investigating the function of one member of the TMED protein family, TMED2, in mouse placental labyrinth development. Formation of the mouse labyrinth layer requires proper interactions between two extraembryonic tissues, the allantois and the chorion; and is essential for nutrition, waste, as well as hormone exchange between the fetus and mother. We have shown that Tmed2 is expressed in the allantois and chorion and is required for normal labyrinth layer formation. We hypothesized that TMED2 is essential in the chorion or allantois for normal interaction between the allantois and chorion- a critical step in placental labyrinth layer development. To test this hypothesis, we have generated an ex-vivo allantois and chorion recombination model. We show that the early events of labyrinth layer development: chorioallantoic attachment, fusion of the mesothelium and allantois, and chorionic trophoblast differentiation are recapitulated in this model. We used in situ hybridization and immunohistochemistry to confirm the chorioallantoic attachment event and to monitor development of labyrinth layer in the chimeric explants.We will then use combinations of wild type and Tmed2 null chorion and allantois in these ex-vivo cultures to follow branching morphogenesis in the chorion. Our work will provide insight into the contribution of placental-specific vesicular transport by TMED2 to labyrinth layer morphogenesis. Ultimately we will identify novel mechanisms that may be implicated in the prediction and treatment of placental diseases such as EPL and IUGR.

Genome wide screening of mesenchymal signalling molecules involved in epithelial differentiation during mice palatogenesis. *K. Kwon, W. Sohn, H. Kim, M. Choi, Z. Ryoo, S. Lee, J. Kim.* IHBR, Kyungpook National University, Daegu, Korea.

In mice palatogenesis, along with the palatal fusion, dorsal and ventral epithelia of palatal shelves are differentiated into the nasal and oral mucosa respectively. Based on the key concept of epithelial-mesenchymal interactions during epithelial morphogenesis, we hypothesized that differentiation of palatal epithelium would be regulated by palatal mesenchymal factors. At E14, prior to palatal fusion, palatal shelves were fronally cryo-sectioned and dorsal and ventral region specific palatal mesenchymal tissues were collected using Laser Micro-Dissection (LMD) method respectively. After the collection of palatal tissue using LMD, total RNAs were harvested and analyzed by the genome wide screening method. We selected the genes which showed the over 2-fold alterations genes then examined RT-qPCR and in situ hybridizations. Tissue specific expression patterns of candidate molecules would suggest that they would play important roles in epithelial differentiation with the region specific manner. Moreover, these region specific expression patterns of mesenchymal factors would be a plausible answer for understanding the pathogenesis of cleft palate.

1435T

Epithelial splicing regulatory proteins 1 and 2 (ESRP1/2) regulate alternative splicing events during mouse embryogenesis. *T. Revil[1], L.A. Jerome-Majewska[1,2].* 1) Dept of Human Genetics, McGill University, Montreal, Quebec , Canada; 2) Department of Pediatrics, Montreal Children's Hospital, Montreal, Quebec, Canada.

The development of a fetus from a single cell requires highly coordinated cell movement and differentiation for proper morphogenesis. We hypothesized that coordinated alternative splicing of mRNAs is a regulatory mechanism via which large groups of genes can change their state and location during embryogenesis. In previously published work, we used a Systems approach to show that a large number of genes are alternatively spliced during embryogenesis. More recently, using the same dataset, we have found that expression levels of two splicing factors, epithelial splicing regulatory proteins 1 and 2, (ESRP1 and 2) are upregulated during differentiation. ESRP1 and 2 are major regulators of epithelial to mesenchymal transition (EMT) in human cancer cells. EMT, the process via which polarized epithelial cells change their states to a mesenchymal cell type, and MET, the reverse process, are the driving forces of morphogenesis. We found that expression of ESRP1 and 2 was increased in the placenta, which represent the more “differentiated” cell types in our dataset when compared to staged match embryos. We also found that alternative splicing of several validated targets of ESRP1 and ESRP2, that were previously shown to be required for embryogenesis, correlated with the expression levels of these genes in our dataset. We have validated our microarray data set and further show that ESRP1 and ESRP2 are expressed throughout embryogenesis. We hypothesize that Esrp1 and 2 are required for the normal morphogenesis of developing embryos and that abnormal alternative splicing of their targets, will result in arrested development as a consequence of abnormal EMT. We are currently performing *in situ* hybridizations, using RNA and LNA probes, to determine the expression of Esrp1 and 2, as well as their putative target exons. Furthermore, we are developing a technique by which to knockdown gene expression of these genes in embryos directly in the uterine horns of mice using morpholinos. Finally, we are creating a conditional knockout mouse for these two genes. These results will allow us to assess the importance of the splicing factors ESRP1 and 2 during mouse embryogenesis.

1436T

Signaling modulations of Rgs19 in palatal EMT process. *W. Sohn[1], Y. Ji[1], H. Kim[1], K. Kwon[1], C. An[1], H. Park[2], H. Jung[3], Z. Ryoo[1], S. Lee[1], J. Kim[1].* 1) IHBR, Kyungpook National University, Daegu, Korea; 2) Forensic Science, Busan Metropolitan Police Agency, Busan, Korea; 3) Yonsei University, Seoul, Korea.

Palatal development is one of the crucial events in craniofacial morphogenesis, according to the significant signaling pathway including the out growth, elevation, and fusion of palatal shelves. In the fusion of palatal shelves, epithelial to mesenchymal transition (EMT) is a fundamental process to achieve the proper morphogenesis of palate. Mechanisms of EMT have been reported as the processes of migration, apoptosis or general EMT through the modulations through various signalling molecules. Rgs19, known as a regulator of G protein signaling (RGS) family through GTPase activity, showed the interesting epithelial expression patterns in various organogeneses including palatal development. To evaluate the precise developmental function of Rgs19 in palatogenesis, we employed the loss of function study using AS-ODN treatments while in vitro palate organ cultivations. Three dimensional reconstructions with the immunostaining of pan-Cytokeratins showed the much decreased number of apoptotic cells in medial edge epithelium (MEE) after the knocking down of Rgs19. These retarded patterns of palatal fusion would be resulted from the altered expression patterns of candidate genes including Axin2, CyclinD1, Lef1, Twist, Snail, Slug and TGFb3. Overall, Rgs19 modulates the palatal EMT process through the apoptotic pathway and signaling interactions among Wnt responsive and EMT related genes.

1437T

Reprogramming Senescent Fibroblasts from Werner Syndrome for Studying Premature Aging. *H. Cheung, X. Liu, O.M. Rennert.* Section on Clinical & Developmental Genomics, NICHD, NIH, Bethesda, MD. USA.

Werner syndrome (WS) is a progeroid-like disease characterized by premature aging features such as loss of hair, osteoporosis, cataracts, myocardial infarction and cancer. These phenotypes become apparent in adolescence. Mutation of the DNA helicase WRN is identified in patients with WS. Deficiency of WRN protein results in genomic instability and telomere erosion, and its clinical manifestations result in phenotypes of accelerated aging. Intriguingly the major affected organs in WS are of mesenchymal origin. Previous studies of WS focused on patient-derived fibroblasts to study the pathology of affected tissues. It remains unresolved as to whether this is reflective of the sequence of events that define the developmental pathology of cells such as cardiomyocytes and osteocytes. Patient specific embryonic stem cells (ESCs) from WS are currently unavailable, making it difficult to study the pathological differentiation in this disease. We have been deriving patient-specific iPSCs (induced pluripotent stem cells) from human skin fibroblasts for studying the pathogenesis of genetic diseases including WS. Unlike normal cells, skin fibroblasts from WS demonstrate slow growth rate, shortened telomere and susceptibility to genotoxic stress. We reprogrammed WS cells to pluripotent state with Yamanaka's transcriptional factors KLF4, OCT4, SOX2, c-MYC. To overcome the accelerated senescence occurring in WS, patient fibroblasts were immortalized with telomerase (hTERT), and/or treated with small molecules targeting the p38/MAPK pathway to revert the aged morphology. The derived iPSCs will be differentiated into mesenchymal stem cells (MSCs) and non-mesenchymal lineages. We will compare cellular senescence and susceptibility to genotoxic stress between WS-iPSC and normal iPSC, as well as their differentiated derivatives. We will establish the consequences of WRN mutation on the ability to reprogram to pluripotency, and their capacity for differentiation into different cell lineages. These studies help establish a cell model for studying human premature aging, using WS as an example.

1438T

Molecular genetic studies of planar polarity gene SCRIBBLE1 in neural tube defects. *K.KH. Fares[1], A.Ra Radouane[1], P.Ma De Marco[2], E.Me Merello[2], V.Ca Capra[2], K.Zo Zoha[1].* 1) biochemistry, university of Montreal, Montreal, Québec, Canada; 2) pathologiy, university of montreal, montreal, québec, Canada.

The neural tube defects (NTDs) including anencephaly and spina bifida, represent a very common birth defect in humans. These anomalies are caused by partial or complete failure of neural tube closure during embryogenesis. Their etiology is quite complex involving environmental and genetic factors and their underlying molecular and cellular pathogenic mechanisms remain poorly understood. Studies in animal models showed an important role of the non-canonical Frizzled (Fz) / Dishevelled (Dvl) signalling pathway in NTDs. This pathway controls planar cell polarity (PCP) in Drosophila and the process of convergent extension (CE) during gastrulation and neurulation in vertebrates. Our study involves the genetic and molecular analysis of the PCP gene SCRIBBLE1 (SCRB1) in human NTDs. The open reading frame and exon-intron junctions of SCRB1 were sequenced in a cohort of 479 NTD patients. We identified 11 novel and rare missense heterozygous mutations in NTDs. Genetic analysis of 7 of these mutations in a cohort of 467 ethnically-matched controls revealed the absence of 3 mutations in all controls analyzed. We are currently finishing the genetic validation of SCRB1 variants in controls and other family members. We will also validate the potential pathogenic effect of these variants by testing their effect on the interaction of SCRB1 with other PCP proteins using the Yeast-two-hybrid system and on CE in a zebrafish model. Our study will help us better understand the role of the PCP pathway, and more specifically of SCRB1, in the complex etiology of the NTDs in humans.

Dysregulation of DNA damage repair and cell cycle checkpoint control pathways as a mechanism for cleft lip/palate. *G.S. Kobayashi[1], L.A. Cruz[1], D.Y. Sunaga[1], D.F. Bueno[1], S.G. Ferreira[1], M. Aguena[1], L.A. Andrade-Lima[2], C.F. Menck[2], M.R. Passos-Bueno[1].* 1) Human Genome Research Center, Institute for Biosciences, University of São Paulo, Brazil; 2) Institute for Biomedical Sciences, University of São Paulo, Brazil.

Purpose: Non-syndromic cleft lip/palate (NSCL/P) is a multifactorial disease that arises from errors during embryonic development. Although much effort has been put into identifying genetic and environmental factors underlying disease susceptibility, the aetiology of this complex malformation remains obscure. Since a tight regulation of ontogenetic mechanisms is required to ensure appropriate orofacial morphogenesis, our objective was to identify dysregulated pathways that may be accountable for disease manifestation, thus providing more information on the pathogenesis of NSCL/P. **Methods:** We performed a global transcriptome profiling of 7 dental pulp mesenchymal stem cell cultures from NSCL/P patients by comparison to 6 controls, using the Affymetrix platform (HuGene 1.0 ST). Differentially expressed genes (DEGs) were obtained using SAM and RankProd algorithms (MeV TM4 software, $p<0.05$ and $p<0.01$, respectively), followed by validation with qRT-PCR assays (t-test, $p<0.05$). Functional annotation and gene network analysis were performed with Ingenuity Pathways Analysis, while gene clustering, functional pathways/categories, and transcription factor (TF) enrichment procedures were carried out on EXPANDER, using K-means and supervised clustering, KEGG/Gene Ontology and PRIMA, respectively. Finally, TF enrichment was confirmed using the FANTOM 4 database. Quantification of H_2O_2-induced DNA damage was assessed through flow cytometry for anti-. H2AX. **Results/Conclusion:** Among the 228 DEGs obtained by comparing NSCL/P and control cells, we identified a cluster of co-expressed genes that was associated with a general dysregulation of cell cycle checkpoint and DNA repair pathways. We encountered abnormal expression of key molecules that orchestrate these mechanisms, some of which are involved in the aetiology of sporadic forms of cancer, and include *BRCA1*, *BRIP1*, *MSH2*, *RAD51* and *BLM*. TF enrichment analysis on the aforementioned gene cluster pointed *E2F1* as a putative regulator driving the observed expression signature. Moreover, preliminary . H2AX assays confirmed deficiency of DNA repair in NSCL/P cells. Our results suggest that disarrangement of these mechanisms could be related to impairment of embryonic lip and palate morphogenesis, and also provide a link between dysregulation of these pathways and the documented increased occurrence of sporadic cancer in NSCL/P families. Allele Specific Expression Single cell RNA-Seq Analysis. *K. Lao[1], F. Tang[2], C. Barbacioru[1], E. Nordman[1], S. Bao[2], C. Lee[2], X. Wang[1], B. Tuch[1], E. Heard[3], M. Surani[2].* 1) Molec Cell Biol, Applied Biosystems, part of Life Technology, Foster City, CA; 2) 2Wellcome Trust/Cancer Research UK Gurdon Institute of Cancer and Developmental Biology, University of Cambridge, Tennis Court Road, Cambridge, CB2 1QN, UK; 3) 3CNRS UMR3215, INSERM U934, Institut Curie, Paris F-75248, France.

Dissecting the relationship between genotype and phenotype is one of the central goals in biology and medicine. Cell development is driven and controlled by temporal and spatial changes in gene transcription, followed by translation of the resulting messenger RNAs into proteins. Recent advances in high throughput sequencing technology make it possible to obtain information on single cell transcriptomes at high resolution by RNA-Seq analysis, which can be instructive concerning how individual cells respond to signals and other environmental cues at critical stages of cell fate determination, or when they acquire aberrant phenotype. Essentially all cells within an individual organism share a virtually identical genotype, but the individual transcriptomes reflect expression of a subset of genes, which is determined by their epigenetic state, including DNA methylation and histone modifications. If these two copies of a gene are expressed at different levels, the quantities of messenger (mRNA) from individual alleles will differ. This phenomenon is called allele specific gene expression (ASE). ASE is potentially important for development, and during evolution when a new allele emerges from mutation, which might immediately affect development through changes in expression levels in a heterozygous cell. However, the extent of ASE in individual mammalian cells and, especially during early embryonic development has not so far been examined. Here, we took advantage of recent technical and methodological advances concerning single cell RNA-Seq, to analyze allele specific gene expression within individual early mouse blastomeres. We found that around 50% of distinguishable expressed alleles of individual genes showed differential allele specific expression. This shows that ASE is widespread at the earliest stages of mammalian development. ASE is likely to occur as a result of sequence polymorphisms of cis regulatory elements, or this might occur in response to different local chromatin structures mediated by epigenetic modifications.

Genomic and Genetic Analyses Define Causative Elements of Two Developmental Defects in an Avian Biomedical Model. *E.A. Robb, M.E. Delany*. Animal Science Department, University of California, Davis, Davis, CA.

Advances in genomics can be applied to the study of unique phenotypes in biomedical models to generate new knowledge on pathways involved in human congenital malformations. The chicken has long been a premier research model in the field of vertebrate developmental biology due to the advantages of access and ease of manipulation. The power of the chicken as a model organism has been further improved given the release of its genome sequence and progress in creation of tools and reagents (e.g., SNP arrays, ESTs, gene expression and cDNA databases, microarrays) and availability of unique genetic resources and cell lines. Two single gene mutations in the chicken, *coloboma* (*co*) and *diplopodia-1* (*dp-1*), were studied for the purpose of identifying the element responsible for each developmental syndrome. These mutant models provide an invaluable means of studying craniofacial morphogenesis as well as limb and organ development. In the recessive condition both *co* and *dp-1* produce syndrome phenotypes shared in common with human congenital malformations including cleft palate, facial-tissue defects, polydactyly, and dwarfism. A 60K SNP array study paired with fine-mapping techniques led to the discovery of a specific chromosomal region associated with each syndrome (*co*: 240 kb, 5 genes; *dp-1*: 260 kb, 11 genes). The expression patterns of sixteen genes found within the regions were studied by *in situ* hybridization during early embryogenesis. Examination of the results allowed further prioritization of candidate genes, suggesting that several genes be emphasized in future studies. In addition, next-generation technologies including a targeted-capture array with deep-sequencing were employed to investigate the regions linked to each mutation. Bioinformatic analyses identified unique genetic features (e.g., SNPs, short INDELs, large deletions) associating with each mutation region. These genetic elements are being evaluated for their contribution to the mutant phenotypes using a variety of genetic and genomic techniques. The results of this study will increase our understanding of the mechanisms underlying similar human disorders and will promote insights into the molecular mechanisms of normal development. Ultimately, this new knowledge could lead to screening tools for preventative medicine applications. [USDA NIFA -NRSP8, -NC1170; Fiddyment Endowment].

1442T

Craniofacial abnormalities result from knock down of nonsyndromic clefting gene, crispld2, in zebrafish. *Q. Yuan[1], B.T. Chiquet[1,2], L. Devault[1], M.L. Warman[3], Y. Nakamura[4], E.C. Swindell[1,2], J.T. Hecht[1,2].* 1) Department of Pediatrics, University of Texas Medical School at Houston, Houston, TX; 2) Graduate School of Biological Sciences, University of Texas Health Sciences Center, Houston, Houston, TX; 3) Howard Hughes Medical Institute, Department of Genetics, Boston Children's Hospital, Boston, MA; 4) National Hospital Organization, Clinical Research Center, Murayama Medical Center, Tokyo, Japan.

We have previously found that variation in the CRISPLD2 (cysteine-rich secretory protein LCCL domain containing 2) gene is associated with non-syndromic cleft lip and palate (NSCLP). Crispld2 was first identified in mice and designated Lgl1 (late gestation lung 1). LGL1 plays a role in early branching morphogenesis of the developing lung and kidney and in the epithelial to mesenchymal transition in lung tissue. Defects in the epithelial to mesenchymal transition in craniofacial tissue are thought to underlie nonsyndromic orofacial clefting. Moreover, we found that Crispld2 is expressed in the developing murine craniofacies suggesting that CRISPLD2 may play a role in craniofacial morphogenesis. To define the role of CRISPLD2 in zebrafish craniofacial development, antisense morpholinos (MO) directed against the ATG start site (MO3) and exon/intron boundaries for exons 3 and 4 (MO1 and MO2, respectively) of zcrispld2 were injected into early embryos. We observed a wide range of phenotypic abnormalities including early embryonic death, severe reduction in head size and shortening of the body. All of the resulting offspring showed a range of craniofacial phenotypic abnormalities involving both the jaw and palate with the most severe phenotypes resulting from injection of MO3. Jaw abnormalities included fewer ceratobranchial cartilages (three/four pairs in MO embryos compared to five in uninjected controls) and malformations in Meckel and palatoquadrate cartilages. A variety of palatal malformations included short palate, absent cartilage and abnormal ossification. DLX2, a marker for neural crest cells (NCC), shows abnormal expression in MO injected embryos suggesting that loss of zcrispld2 is specifically affecting these cells. These results show that zcrispld2 is involved in palate and jaw morphogenesis. Moreover, these results demonstrate that genes involved in complex birth defects, such as nonsyndromic cleft lip and palate, can be identified in candidate gene studies and functionally assessed in animal models to define the biological processes that are the basis for these complex birth defects.

Identification of the Danforth's short tail mouse mutation using next generation sequencing. *C.N. Vlangos[1], A.N. Siuniak[1], D. Robinson[3], A.M. Chinnaiyan[3], J.D. Cavalcoli[4], R.H. Lyons[5], C.E. Keegan[1,2].* 1) Department of Pediatrics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Center for Translational Pathology, University of Michigan, Ann Arbor, MI; 4) Center for Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 5) Biological Chemistry Department, University of Michigan, Ann Arbor, MI.

The Danforth's short tail (Sd^{Sd}) mouse first appeared as a semi-dominant spontaneous mutation in an inbred colony at Stanford University in the 1920s. The phenotype of heterozygous ($Sd^{Sd/+}$) animals includes unilateral kidney agenesis, vertebral anomalies, and a shortened and kinked tail. Homozygous ($Sd^{Sd/Sd}$) mice are more severely affected with bilateral renal agenesis, lack of tail, vertebral anomalies, spina bifida, imperforate anus, and persistence of the cloaca. Homozygous mice are born live but die within 24 hours of birth. The phenotypic characteristics of the *Sd* mouse parallel those of the human malformation syndromes limb-body wall complex, OEIS complex, and VACTERL association. We hypothesize that identification of the *Sd* mutation will provide a model for understanding the etiology behind these human syndromes. Previous work by others genetically mapped the *Sd* mutation to a 1.0cM (1.5Mb) region of mouse chromosome 2qA3. Using bioinformatic analysis of the mouse DNA physical map we identified 9 annotated genes with a total of 86 coding exons spanning the corresponding 1.5Mb critical region. Direct sequencing of the exonic DNA and intron/exon boundaries did not reveal any mutations. Since direct sequencing of the exonic DNA only provided _1% coverage of the *Sd* critical region we performed next generation sequencing (NGS) of the entire 1.5Mb. Prior to NGS we performed an enrichment capture using an Agilent oligo DNA chip designed to cover all unique (non-repeat masked) DNA of the *Sd* critical region. After successful locus specific DNA enrichment, 36bp paired end NGS on an Illumina Genome Analyzer IIx was completed, generating 1.85Gb of sequence. Standard bioinformatics analysis of our NGS data did not reveal any causative mutations. We then turned to interrogation of reads where only a single end of the paired end sequencing mapped correctly to the *Sd* locus. By using this novel technique, we were able to identify the presence of an early transposon (ETn) retroviral like insertion at the *Sd* locus. The ETn insertion was confirmed via Southern analysis, and is not present in additional inbred mouse lines tested. Further, expression studies revealed that the ETn causes mis-expression of the adjacent *Ptf1a* gene. Currently, work is underway to determine the role of *Ptf1a* in proper caudal development in mice and humans.

Direct or indirect stimulation of an epigenetic change in bladder urothelial cells (UC) in response to uropathogenic *E.coli* (UPEC) infection. *A. Kapila[1,2], C. Tolg[1], B. Weber[1,2], N. Sabha[1], R. Cortese[3], T. Panchal[1], A. Petronis[2,3], K.J. Aitken[1,2], D.J. Bägli[1,2].* 1) Developmental & Stem Cell Bio, Research Institute and Urology Division, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) The Krembil Family Epigenetics Laboratory, Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada.

Introduction: Urinary tract infection (UTI) and UTI recurrence can seriously compromise patients with dilated urinary tract pathologies or other preexisting medical conditions. However the inability to predict which of these patients are at such risk for UTI or its recurrence forces pre-emptive surgical correction of dilating uropathies or widespread indiscriminate antibiotic use. Identification of UPEC-induced DNA methylation marks for UTI recurrence may eventually make it possible to provide a valuable diagnostic tool for refining medical and surgical therapy for such patients, thereby curbing antibiotic use and reducing prophylactic surgery.

Methods: We established an in vitro model of chronic infection using low moi of UPEC and non-UPEC (FimH-) bacteria in the urothelial cell line HTB-9, for 6 days. After the chronic infection, cells were fixed and examined for intracellular bacteria (anti-E.coli antibody) and DNMT1 by confocal microscopy. DNMT1 activity was also assessed in UPEC and non-UPEC inoculated cultures (by Epiquik DNMT activity kit). DNMT1 expression was assessed by real-time PCR. Conditioned media (CM) from UPEC and non- UPEC infected cells was isolated and filtered twice through 0.22 micron filters and was placed on urothelial cell lines for six days and DNMT1 expression was examined by confocal microscopy. Also urothelial cell lines were treated with LPS and examined for DNMT1/3a/3b by confocal microscopy.

Results and Conclusions: Persistent infection of UC with FimH[+] UPEC results in DNMT1 upregulation and decreased cell proliferation. Infection with FimH[-] E.coli had no effect on DNMT1 or UC growth. These results show that FimH adhesin plays an important role in the epigenetic reprogramming of host cell gene expression by E.coli. DNMT1 expression was associated with UC in inoculated cultures; though even neighbouring cells without intracellular UPEC showed an increase in DNMT1 staining. The increase in DNMT1 was replicated in CM from UPEC inoculated cultures, suggesting that the infected UC release paracrine factors which are similarly able to increase DNMT1 expression. Exposure to LPS increased nuclear DNMT 3a and 3b levels but had only minor effects on DNMT1 signifying that the endotoxin may lead to distinct effects from the pathogen itself.

1445T

Evidence of *NFIA* as a dosage-sensitive gene involved in central nervous system development and neurobehavioral functioning. *K. Hovanes[1], M.N. Strecker[1], M. Dasouki[2], E. Youngs[2], D. Superneau[3], S. Hunkapillar[3], P. Miner[4], C. Munn[4], G. Hoganson[4], S. Gunn[1].* 1) CombiMatrix Diagnostics, Irvine, CA; 2) Kansas University medical Center, Kansas City, KS; 3) Our Lady of the Lake Regional Medical Center, Baton Rouge, LA; 4) Rockford Memorial Hospital, Rockford, IL.

We report on four individuals with copy number changes in *NFIA* as the result of non-recurrent microdeletions/duplications at 1p31.3. Six cases of haploinsufficiency (HI) of *NFIA* due to gene disruption or deletion have been reported in association with structural central nervous system (CNS) and urinary tract abnormalities. Previous microdeletions that include *NFIA* have been relatively large: 12Mb (48 genes), 7.9Mb (16 genes), and 2.2Mb (9 genes). To our knowledge, this is the first report of patients with deletions/duplications <1Mb and encompassing fewer than two genes in addition to *NFIA*. All patients were evaluated on a 180K oligonucleotide platform. **Patient 1** is an 8 y/o male with macrocephaly, advanced bone age, attention deficit-hyperactivity disorder (ADHD) and mild dysmorphic features. A non-contrast head CT at 2 years of age demonstrated relative atrophy with a prominent septum pellucidum cavum and prominent ventricles. Chromosomal microarray analysis (CMA) revealed: arr 1p31.3(61,656,200-62,245,026)x1, encompassing *NFIA* (partial), *TM2D1* and *INADL* (partial). **Patient 2** is a 16 y/o female with agenesis of the corpus callosum, developmental delays, cognitive impairment, ADHD and mild dysmorphic features. CMA demonstrated: arr 1p32.1p31.3(60,890,159-61,833,408)x1 mat,2q13(110,186,668-111,127,490)x1. The 1p deletion encompasses only *NFIA*. The 2q deletion includes six genes of uncertain function and one (*NPHP1*) which is associated with autosomal recessive nephronophthisis and Joubert syndrome. **Patient 3** is a 36 y/o female with a Dandy Walker malformation, a history of hydrocephalus requiring shunting, and a history of vesicoureteral reflux. Patient 3 is the mother of Patient 2, and was found to have the same copy number loss as her daughter. **Patient 4** is a 5 y/o male with a history of infantile tremors, autism spectrum disorder, ADHD, anxiety and verbal apraxia. CMA revealed: arr 1p31.3(61,475,400-61,916,101)x3, with a partial gain of *NFIA*. His brain MRI was normal. This report strengthens the evidence suggesting that HI of *NFIA* alone is sufficient to cause CNS malformations. In our patient series, it also was associated with ADHD. Unlike previous reports, only Patient 3 had urinary tract abnormalities. Patient 4, who has a partial gain of *NFIA*, has significant neurobehavioral differences, but no CNS structural abnormalities, suggesting that *NFIA* may be dosage sensitive, but that HI alone is implicated in structural CNS malformations.

Small RNA deep sequencing reveals co-ordinate expression of microRNAs and argonaute-2 during mammalian embryogenesis. *P.N. Valdmanis, H. Kim, B. Roy-Chaudhuri, Y. Pouliot, M.A. Kay.* Pediatrics, Stanford University, Stanford, CA.

RNA interference occurs by two broad processes: mRNA site-specific cleavage and non-cleavage mRNA degradation and/or translational repression. Mammals have four argonaute genes; however, only argonaute-2 (Ago-2) is able to perform site-specific cleavage, while all four mammalian argonaute proteins (Ago-1 to Ago-4) can carry out non-cleavage-mediated inhibition. The role of Ago-2 in mediating site-specific mRNA cleavage is essential in mammals, in particular during embryonic development, as Ago2 -/- mice suffer severe developmental abnormalities after embryonic day 10.5 (E10.5) and are lethal soon thereafter. To identify the cause of this Ago2-dependent embryonic event, we performed small RNA high throughput sequencing of mouse embryonic fibroblast (MEF) cell lines both before (E10.5) and after (E13.5) this critical time point as well as Ago2 -/- E10.5 MEF cells. MirVana-extracted small RNAs were cloned in a 5'phosphate dependent manner, aligned to linkers and sequenced on an Illumina GAII machine. Reads (17-28bp) were aligned to the mouse genome and to mirBase (release 15) using the Bowtie alignment program. Normalization of microRNA reads revealed a cluster of ~50 microRNAs in a ~800 kilobase pair region on mouse chromosome 12 that are dramatically upregulated in E13.5-derived MEFs relative to E10.5 wildtype and Ago2-/- MEFs. This imprinted region is implicated in uniparental disomy on human chromosome 14. The expression of representative microRNAs in the locus including mir-127 and mir-376 were validated by northern blot analysis. Interestingly, mir-127 is expressed from a transcript antisense to the Rtl1 gene and has been shown to cleave Rtl1 in an Ago-2 dependent manner. Taqman quantitative RT-PCR analysis revealed that the expression of nearby coding and non-coding RNAs including Gtl2, Dlk1 and Rtl1as transcripts are activated after embryonic day 10.5 and are dramatically up-regulated though the remainder of mouse embryo development. Notably, Ago-2 is the only mammalian argonaute that exhibits a similar increase in expression later in embryo development, while Ago-1, Ago-3 and Ago-4 transcripts remain unchanged. This contemporaneous upregulation of these mouse chromosome 12qF1 non-coding RNAs and microRNAs is one that we believe is critically dependent on Ago2 for development.

1447T

Identification and characterisation of endogenous LXR ligands in ventral midbrain development. *S. Theofilopoulos[1], K. Karu[2], S. Kitambi[1], P. Sacchetti[1], K. Sousa[1], J. Sjovall[1], W. Griffiths[3], E. Arenas[1].* 1) Molecular Neurobiology, Medical Biochemistry and Biophysics Department, Karolinska Institute, Stockholm, 17177, Sweden; 2) The School of Pharmacy, 29-39 Brunswick Square, London, WCN 1AX, U.K; 3) Institute of Mass Spectrometry, School of Medicine, Swansea University, Singleton Park, Swansea SA2 8PP, U.K.

The liver X receptors (Lxr(and Lxr)) are ligand-dependent nuclear receptors activated by oxidized derivatives of cholesterol (oxysterols). Our laboratory has recently shown that Lxr(and Lxr) promote ventral midbrain (VM) neurogenesis in vivo and in human embryonic stem cells (Sacchetti et al., Cell Stem Cell 5,409-19, 2009). Our current study focused in identifying and characterizing the endogenous LXR ligands in the embryonic mouse VM. Using LC-MSn and LXR-activation reporter assays, we identified two distinct molecules that are present in the E11.5 mouse VM and are potent activators of LXR(and LXR) . Employing several types of rodent primary cultures, embryonic stem cells, organotypic `open-book'cultures, and zebrafish models, we showed that the two identified LXR ligands have a different mechanism of action and effect in the embryonic VM. We demonstrate that recruitment of specific transcriptional co-activators (such as SRC-1 and ASC-2) and/or transcriptional repressors (such as N-CoR and SMRT) to the transcriptional machinery complex is regulated by the presence of distinct LXR ligands and this leads to different responses in survival versus neurogenesis in the developing VM. We believe that these LXR ligands may lead to improvements in dopaminergic differentiation of human ESCs and their application in drug development and cell replacement therapy for Parkinson's disease.

1448T

Spga-lncRNA3, a novel lncRNA that regulates developmental programs of spermatogonial stem cells. *T. Lee[1,2], W. Chan[2], O. Rennert[2].* 1) School of Biomedical Sciences, The Chinese University of Hong Kong, Shatin, Hong Kong, China; 2) Laboratory of Clinical and Developmental Genomics, National Institutes of Child Health and Human Development, National Institutes of Health, Bethesda, MD, U.S.A.

Spermatogonial stem cells (SSCs) are male germ line stem cells that control spermatogenesis by their ability to both self-renew and generate subsequent germ cell types into spermatozoa through rounds of differentiation. Although factor like Glial cell line-Derived Neurotrophic Factor (GDNF) is known to be important in self-renewal of SSCs, the exact mechanisms that govern SSCs differentiation and pluripotency remain largely unknown. To identify the differentiation and self-renwal mechanisms, we performed large-scale transcriptome studies on male germ cells by whole-genome tiling microarrays and sequencing approaches. The findings suggested majority of SSC genome is transcribed and is far more than current gene annotations. We found a huge number of transcript species are known as long non-coding RNAs (lncRNAs). By applying various bioinformatics pipelines, we have identified a number of SSC-specific lncRNA candidates and examined their effects on cellular differentiation using C18-4 SSC in vitro differentiation model. We found a potential candidate, code-named as Spga-lncRNA3, demonstrated significant differentiation inhibition, suggesting it may be important in maintaining stem cell state of SSCs. Our contribution in this study is expected to provide detailed understanding of how lncRNAs regulate cell differentiation and proliferation in spermatogenesis. Dysregulation of these developmental programs is known to associate with gametogenesis defects and disease states such as cancer. The findings are expected to substantially change the concepts in developmental and cancer biology, which could lead to the development of novel therapeutic strategies.

1449T

Notch signaling during chondrogenesis. *S. Chen, J. Tao, M. Jiang, T. Bertin, B. Lee.* Howard Hughes Medical Institute and Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Notch signaling is critical during development directing binary cell fate between progenitors and differentiated cells. Aberrant Notch function causes several human skeletal diseases such as Spondylocostal dysostosis (SCDO) and Alagille syndrome. Recently, cartilage specific gain- or loss-of-function of Notch mouse models have been made in our and other laboratories. Although detailed phenotypic studies of these mice have been conducted, a full knowledge of the mechanisms of the pathway is still lacking. The canonical Notch pathway involves Rbpj as a co-factor to induce target gene expression. However several findings suggest Rbpj-independent mechanisms exist to promote Notch signaling transduction. Our goal is to unravel the molecular mechanisms by which Notch signaling controls cartilage development. We hypothesize that the function of Notch signaling is mediated by both the canonical and non-canonical pathways. To study the gain-of-function of Notch in cartilage, we crossed a Col2a1-cre line with a line having a conditionally activated allele of Notch1 intracellular domain (N1ICD). Resulting mutant mice have shortened limbs, undersized ribs, and virtual absence of the spine and tail. Decreased Alcian blue staining highlights the general defects of chondrogenesis. The decreased expression of Sox9, Col2, Col10 in the mutant suggests the inhibition of chondrocyte differentiation by Notch signaling. On the other hand, complete loss-of-function of Notch (achieved by deleting Presenilin 1/2 in cartilage) causes undersized and underdeveloped skeletal elements. The limbs and spine are about 40% shorter in the mutants at 3 weeks of age. Interestingly, cartilage specific deletion of Rbpj causes only a mild phenotype. The body weight and histology of cartilage appear to be normal at 3 weeks of age. To test whether Notch signal transduction depends on Rbpj, we made mice with deficient Rbpj on the Notch gain-of-function background. These mice have nearly normal limb structure but demonstrate irregular curvature of the spine with a shortened tail, suggestive of incomplete rescue. To completely map the Notch signaling pathway, we are identifying Notch targets by a CHIP-seq approach in the ATDC5 cells, a chondrocyte cell line. We have achieved high specificity and enrichment of the occupancy of the Notch targets using a tagged system. We hope to identify differential targets of canonical vs. noncanonical Notch signaling using this approach.

1450T

WT1 suppresses EZH2 during early nephrogenesis. *M.M. Akpa[1,2], L.L. Chu[1,2], D.M. Iglesias[1,2], P.R. Goodyer[1,2,3].* 1) Human Genetics, McGill University, Montreal, Canada; 2) Montreal Children's Hospital Research Institute, Montreal, Canada; 3) Montreal Children's Hospital, Montreal, Canada.

During development, progenitor cells are induced to form nephron in the embryonic kidney. The exact mechanism involved in this process remains unexplained. The metanephric mesenchyme is known to receive a signal inductive from the ureteric bud, which triggers the differentiation cascade. Wilms tumor suppressor 1 (WT1), a zinc finger transcription factor, is believed to play a key role in this process. Moreover, stem cells retain their pluripotency during embryogenesis by suppressing key differentiation genes through epigenetic modifications, involving Polycomb group protein among others. How this repression is lifted during differentiation is still unclear. We hypothesize that WT1 is crucial to the de-repression of differentiation genes. We further hypothesize that WT1 modulates EZH2, the key catalytic unit of the Polycomb Repressor Complex 2 (PRC2). We showed that WT1 has a direct transcriptional effect on EZH2 through promoter and expression experiments. Using Western immunoblotting, we observed a repression of EZH2 at the protein level in the presence of WT1 compared to the baseline. Using an EZH2 promoter-reporter construct, we also observed a repression of the luciferase activity in the presence of WT1 as compared to the baseline. We confirmed that the effect is mediated through binding of WT1 to a WT1 recognition motif on the EZH2 promoter sequence using Electrophoretic Mobility Shift Assay (EMSA), and that this interaction is specific using an antibody against WT1 that would interfere with the binding ability of WT1 to the motif. Using real-time PCR, we investigated the role of miR-101 and miR-26a in repressing EZH2, mediated through WT1. We showed that WT1 did increase the expression of the two miRNAs and thus also showing an indirect repressive effect of WT1 on EZH2 at the post-transcriptional level. During nephrogenesis, WT1 plays a key role in the differentiation process, achieved in part through the modulation of EZH2's expression, thus lifting the repression exerted on key differentiation genes. The effect of WT1 on EZH2 expression seems to be at the transcriptional level through direct interaction with the promoter region, as well as at the post-transcriptional level indirectly through increased expression of miRNAs. They will bind the 3'UTR and degrade the EZH2 RNA transcript.

EnSpm-N6_DR DNA transposons shape the repertoire of p53 target genes in zebrafish. *M. Loviglio, L. Micale, C. Fusco, A. Calcagni, B. Augello, G. Cotugno, E.V. D'Addetta, G. Merla.* Medical genetics Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy.

Transposable elements (TEs) represent the largest genomic component of most eukaryotic organisms. In spite of and, to some extent, because of their selfish and parasitic nature, TEs have exerted a strong influence in the structural organization and plasticity of genomes. Recent discoveries support the hypothesis that TEs can directly regulate the expression of nearby genes both transcriptionally and post-transcriptionally. For instance, TEs are known to supply functional elements to their host genomes, as transcription factors binding sites, transcription start sites and enhancer elements. Here we describe the role of zebrafish (Danio rerio) En-SpmN6_DR non-autonomous DNA transposon in shaping the repertoire of a transcription factor, the pleiotropic master regulator p53. Multiple copies of En-SpmN6_DR transposon, which present as single element or clusters, are mapping throughout the genome of zebrafish, the vast majority of which in the upstream or in the introns (less frequently just downstream) of zebrafish coding genes. By luciferase assay, we assessed whether the p53 transcription regulator was able to bind two predicted p53 responsive elements (REs) mapping within the EnSpm-N6_DR transposon, which was found to be proximal (<500 bp) to predicted promoter regions. Notably, we demonstrated that these well conserved p53 binding sites are functionally responsive to Drp53, resulting in the transactivation of several zebrafish genes, including cell cycle regulators and neuron morphogenesis-related factors. Remarkably, a large fraction of orthologs of the genes harboring the EnSpm-N6_DR element in zebrafish are annotated as putative or validated p53 targets in human, and functional annotations evidence a partecipation to diverse neural developmental pathways, such as neurogenesis, synaptic transmission and axonogenesis. Furthermore, predominant expression is found in brain and brain-related structures. Our experimental evidences demonstrate that EnSpm-N6_DR transposon identifies a class of functionally related zebrafish genes, transcriptionally controlled by p53 protein, providing further indication that p53-dependent molecular pathways affect multiple developmental processes, including neuronal maturation and differentiation.

Modeling Developmental Eye Defects using Zebrafish. *L.A. Schimmenti[1], J. Hatler[1], E. Speltz[1,2], A. Spahn[1], S. Lerach[1].* 1) Dept Pediatrics, Ophthalmology, Genetics, Cell Biology and Development/Inst Human Gen, Univ Minnesota, Minneapolis, MN; 2) Current Address: Yale University, Molecular Biophysics and Biochemistry.

Proper eye development during embryogenesis is critical for normal visual function. Clinically significant ophthalmologic disorders, anophthalmia, microphthalmia and coloboma, result from defective developmental processes and are observed at a rate of 3 per 10,000 live births accounting for approximately ten percent of childhood blindness. The breadth of genetic and cellular mechanisms leading to defective eye development is still not well understood. Dominant mutations in *PAX2*, a member of the paired box transcription factor family, have been identified in patients with renal coloboma syndrome, and *pax2a* mutations in animal models recapitulate this phenotype. The overall goals of this research are to identify and study the network of gene products that function under the control of pax2 and are required for normal eye development. Previous studies in Drosophila identified sparkling (spa) as a pax2 ortholog (Fu & Noll, 1997). Spa mutants have abnormal eye development and reduced expression of cut, a DNA binding protein. These observations led us to hypothesize that cutl1 functions downstream of pax2a during zebrafish eye morphogenesis. The zebrafish embryo is a useful model in which to study eye morphogenesis because its eyes have many similarities with mammalian eyes, particularly in terms of retinal layering. Additionally, eye development in zebrafish is a rapid process with retinal differentiation beginning at ~30 hours post fertilization (hpf) and functional vision occurring at 72 hpf following the formation of photoreceptor outer segments. Moreover, zebrafish embryos are optically clear and develop externally allowing for ease of experimental manipulation and observation. Here, we find that morpholino (MO) antisense oligonucleotide knockdown of the DNA binding protein, cutl1, significantly reduces eye and pupil sizes in zebrafish embryos. Histologically, retinal lamination appears to be partially intact, although some disorganization is observed at higher MO doses. Importantly, the reduced eye size phenotype is likely due to a defect in photoreceptor outer segment (OS) development and/or reduced retinal ganglion cell (RGC) dendrite growth within the inner plexiform layer (IPL). Our findings implicate a novel DNA binding protein, cutl1, in eye development and may represent an avenue by which *PAX2* mutations cause human eye disorders.

1453T

Ofd1 controls dorso-ventral patterning in the brain and plays a developmental stage dependent role in ciliogenesis. *B. Franco[1,4], A. D'Angelo[1], A. De Angelis[1], B. Avallone[2], I. Piscopo[1], M. Studer[3], R. Tammaro[1].* 1) TIGEM, Fondazione Telethon, Naples, ItalyTelethon Institute of Genetics and Medicine, Naples, Italy; 2) Department of Biological Science, Federico II University, Naples, Italy; 3) INSERM U636 University of Nice Sophia Antipolis Nice, France; 4) Medical Genetics Services, Department of Pediatrics, Federico II University, Naples, Italy.

Oral-facial-digital type I syndrome (OFDI) is a human X-linked dominant-male-lethal developmental disorder caused by mutations in the OFD1 transcript. Similar to other inherited disorders associated to ciliary dysfunction OFDI patients display neurological abnormalities. We therefore characterized the neuronal phenotype resulting from Ofd1 inactivation in early phases of mouse embryonic development and at post-natal stages. We determined that Ofd1 plays a crucial role in forebrain development, and in particular in the control of dorso-ventral patterning and early corticogenesis. Interestingly, we observed abnormal activation of the Sonic hedgehog (Shh) and Planar Cell Polarity (PCP) signalling, two major pathways modulating brain development. Ultrastructural studies demonstrated that early Ofd1 inactivation results in the absence of ciliary axonemes despite the presence of mature basal bodies that are correctly orientated and docked. On the contrary, Ofd1 inducible-mediated inactivation at birth does not affect ciliogenesis in the cortex demonstrating for the first time a developmental stage-dependent role for a basal body protein in ciliogenesis. Moreover, we showed a defective cytoskeletal organization in Ofd1 null embryos, most likely due to lack of ciliary axonemes. Thus, the present study identifies Ofd1 as a developmental disease gene that is critical for forebrain development by regulating proper axoneme formation during ciliogenesis in embryonic life, and elucidates the precise step of ciliogenesis in which Ofd1 plays a crucial role in vivo.

1454T

Novel intergenic trans-splicing generating double fusion transcripts in a case of chronic myeloid leukemia in blast phase with the t(7;17) translocation. *S. Hazourli, J. Hébert.* Quebec Leukemia Cell Bank, Maisonneuve-Rosemont Hospital Research Center, Montreal, Quebec, Canada.

Alternative pre-mRNA splicing contributes to protein diversity and plays a crucial role in different cellular mechanisms. Splicing defects have been associated with many human genetic diseases, as well as cancer. We present a novel aberrant intergenic splicing detected in the leukemic cells of a patient with the t(7;17)(p15;q22) chromosomal translocation, associated with chronic myeloid leukemia in blast phase (CML-BP). Using fluorescence in situ hybridization analyses, we studied the breakpoints in the *HOXA* cluster and the RNA-binding protein Musashi 2 gene (*MSI2*), located on chromosomes 7 and 17, respectively. Two different in-frame fusion transcripts, which contain exons 1 to 5 of *MSI2* fused to exon 2 of either the *HOXA9* or the *HOXA11* gene, were identified by RT-PCR and sequencing. The predicted chimeric proteins contain the RNA Recognition Motif domain of MSI2 and the homeodomain of HOXA9 or HOXA11. The presence of fusion transcripts involving two different *HOXA* genes in the same case has already been described in two patients with the t(7;11)(p15;p15)/*NUP98-HOXA* fusion, including one CML-BP case. Only one other case of CML-BP with the t(7;17) has been reported, in which a different translocation breakpoint, fusing exon 9 of *MSI2* to exon 2 of *HOXA9* was detected. A rearrangement of the *MSI2* gene has also been found in nine cases of myeloid malignancies (myelodysplastic syndrome, acute myeloid leukemia and CML-PB) with the t(3;17)(q26;q22). However, *EVI1-MSI2* fusion transcripts have not been detected in these cases. Recently, *MSI2* has been identified as a positive regulator of both mouse and human hematopoietic stem cells. Moreover, *MSI2* overexpression has been associated with advanced CML and with a poor survival in acute myeloid leukemia. This case provides additional evidence that aberrant alternative splicing and the deregulated expression of the genes involved in chromosomal translocations are relevant mechanisms in the pathogenesis of the progression of CML into a more aggressive phenotype.

Treatment outcome with sequential radiotherapy and chemotherapy based on loss of heterozygosity in both chromosomes 1p and 19 q in anaplastic oligodendroglioma. *HO. Shah[1], A. Yuil[2], A. Pigal[2], M-L. Desormeaux[2], W. Gebre[2], L. Freedman[2].* 1) Dept Pathology, Cytogenetics, Nassau Univ Med Ctr, East Meadow, NY; 2) Dept Pathology, Nassau Univ Med Ctr, East Meadow, NY.

A 46 years old male, who presented to the hospital with symptoms of headaches over the past three years and visual changes during last visit. A CAT scan and MRI of the head were done and both demonstrated a large right frontal mass with significant mass effect. The clinical laboratories were unremarkable. Craniotomy was performed and the specimen of frontal lobe tumor was submitted to Pathology. Anaplastic oligodendrioglioma was diagnosed by the neuropathologist. PCR - based microsatellite analysis that was performed in the paraffin-embedded tissue, revealed a combined loss of chromosome number 1p and 19q, and confirmed the final diagnosis. The patient started treatment with radiotherapy and temozolomide, with good response and no tumor recurrence in the last 6 months. It has been described that patients who have tumors that showed combined 1p and 19q loss in chromoses, had significantly improved outcomes compared with patients who had tumors that lacked 1p/19q loss, hence, clinically testing oligodendroglial tumors for 1p/19q status has become increasingly common, in addition to patient outcomes, 1p/19q status has been associated with tumor location (frontal, parietal, and occipital lobe and bilateral growth). Patients with oligodendrogliomas with the combined loss of 1p and 19q not only have a better response to chemotherapy, they also have a more indolent clinical course and a longer lasting response to radiotherapy. Several studies have found the presence or absence of combined loss of 1p and 19q to be the most important prognostic factor for overall survival in anaplastic oligodendroglial tumors. The median survival duration was 6 -7 years in the presence of the 1p/19q codeletion, and 2-3 years in the absence of the codeletion. The overall picture that emerges from this is that 1p/19q codeleted tumors tend to have slower growth rates and to be more responsive to treatment than tumors without this codeletion. Currently, sequential treatment with radiotherapy and chemotherapy, depending on the expected side effects and treatment efficacy, seems to be the optimal approach.

Identification of genetics alterations in colorectal cancer patients in Tamil Nadu population, India. *V. Balachandar[1,2], M. Arun[1], P. Manikantan[1], K. Sasikala[1], P. Varsha[3], S.N. Dharwadkar[4], P. Singaravelu[2].* 1) Human Molecular Genetics lab, Bharathiar University, Coimbatore, India; 2) Thiruvalluvar University, Vellore, India; 3) Molecular Biology and Human Genetics, Department of Zoology,Bharathiar University, Coimbatore, India; 4) KLE Medical University, Bangalore,India.

Colorectal cancer (CRC) is the most common inherited cancer syndromes, in which cells in colon or rectum become abnormal and divide without any order forming a tumor. CRC is the second leading cause of malignant mortality in humans in developed countries, accounting for more than 10% of all cancer-related deaths. About 96% of CRC are adenocarcinomas, which evolve from glandular tissue. CRC incidence and mortality rate are 35% higher in men than in women. It is believed that chromosomal anomalies play a major role in tumorigenesis by increasing the rate of chromosome mutations, including deletion and amplification of genes involved in cellular proliferation and/or survival. The main objective of the present study was to identify the chromosomal alternations of CRC patients in Tamil Nadu population, South India. Carcinoembryonic antigen (CEA) has been investigated extensively to test its clinical value in the management of CRC. The aim of CEA monitoring after curative resection of colorectal cancer is to detect recurrent disease at an early and treatable stage. In our study, totally 62 patients were recruited and divided in to 2 groups based on their serum CEA level. In this study chromosomes mainly affected in CRC patients were 1,2, 8, 17, 18 and 22. The major CA was deletions and translocations. The serum CEA level was found to be higher in CRC patients compared to their controls. More number of CA was observed in group II patients who were of higher serum CEA level in comparison to other groups. The present study has been useful in identifying molecular targets for controlling onset of the disease. A good understanding of the genetic changes underlying colorectal carcinogenesis may provide new perspective for prognosis and screening of high risk individuals. Early detection, accurate diagnosis and intensive surveillance are important for best improving a patient's diagnosis and response to therapy.

CGH+SNP microarrays for copy-neutral aberration detection in cancer research. *P. Costa[1], B. Curry[2], B. Peter[2], P. Anderson[2], N. Sampas[2], S. Giles[1], A. Ashutosh[1], A. Vadapalli[1], A. Ijpma[1], J. Ghosh[1], S. Fulmer-Smentek[1], A. De Witte[1].* 1) Agilent Technologies Genomics, Santa Clara, CA; 2) Agilent Technologies Laboratories, Santa Clara, CA.

Advances in cancer research have greatly benefited from high resolution copy number (CN) measurements provided by oligo array Comparative Genomic Hybridization (aCGH). The addition of single nucleotide polymorphism (SNP) measurements to CGH microarrays enables the detection of copy-neutral loss of heterozygosity (cnLOH) events and allelic imbalances arising from genomic instability during cancer development and progression. Nonetheless, cancer studies face challenges associated with genomes' aneuploidy, polyclonality and mosaicism due to the admixtures of tumor and normal cells. In the quest to decipher tumor complexity, the power and sensitivity of Agilent's CGH+SNP platform has been expanded with new computational methods capable of determining clonal fraction, total CN and allele-specific CN in aneuploid samples. Genomic DNA from hematology-oncology samples, cell lines and HapMap control samples was digested with AluI and RsaI restriction endonucleases to allow for SNP profiling at the enzymes' restriction sites. Experimental samples and a reference HapMap sample of known genotype were differentially labeled and hybridized to the Agilent CGH+SNP array, containing ~120K CGH probes and ~60K SNP probes. The data were analyzed using algorithms with extended capability to determine aneuploid fraction, total and allele-specific CN of the aberrant clone. As expected, significant diversity was found in different chronic lymphocytic leukemia (CLL) tumors. In one CLL sample a small heterozygous deletion and cnLOH were identified on chromosome 13. In another CLL case a trisomy of the entire chromosome 12 was observed, together with a small heterozygous deletion and cnLOH on chromosome 18. An Acute Lymphoblastic Leukemia (ALL) tumor sample was found to harbor an amplification on chromosome 6, as well as two small amplifications on chromosome X. To assess the ability of detecting low level mosaicism, we conducted a mixed sample experiment whereby a sample with a known aberration was mixed at known ratios with a matched sample not containing the aberration. The computed aneuploid fraction, total and allele-specific CN matched the expected values. We have shown that the new algorithms developed for cancer sample analysis determined the genotypes, total copy numbers and clonal fractions in aneuploid samples highly mixed with normal cell populations.

Analysis of cytogenetic aberration in children with acute lymphoblastic leukemia in relation to other prognostic factors. *E. Maly[1], M. Przyborska[1], K. Derwich[3], O. Spychaka[3], D. Januszkiewicz[1,2,3].* 1) Department of Medical Diagnostics, Poznan, Poland; 2) Institute of Human Genetics Polish Academy of Sciences, Poznań, Strzeszyńska Street 32; 3) Department of Pediatric Oncology, Hematology and Bone Marrow Transplantation of Medical University, Poznań, Szpitalna Street 27/33.

Acute lymphoblastic leukemia (ALL) is the most common malignancy in childhood and accounts for 30% of all cases of cancer. Chromosomal aberrations have a major role in the risk assessment of acute lymphoblastic leukemia. Detection of chromosomal abnormalities is used to determine the risk group, treatment and prognosis of outcome. Karyotypes of 85 ALL patients were analyzed along with immunophenotype and other clinical factors important in assessing the prognosis of ALL. Normal karyotype was encountered in 41 cases (48,2%), translocation t(12;21) - in 12 (14,1%), tetrasomy 21 - in 7 (8,2%), hiperdiploidy - in 5 (5,9%). One case carried translocation t(9;22) (1,2%), two cases- MLL rearrangement (2,3%). Three patients had a complex karyotype (3,5%). Due to lack of metaphases or bad quality of chromosomes karyotype wasn't perform in 14 patients. Girls predominated in common B-ALL, in the rest of subtypes the majority were boys. The highest leukocytosis was observed in the T-ALL subtype, also the L2 morphology was predominated in the T-ALL. Cytogenetic abnormalities with poor prognosis were documented in pro-B ALL and T-ALL. Patients with common B-ALL have had the highest rate of remission on the 15 day of treatment. The highest poor prednisolone response was observed in T-ALL and pro-B ALL patients. Determination of chromosome changes in the karyotype of the patient is an individual and independent prognostic factor in acute lymphoblastic leukemia. Today cytogenetics is a standard in the hematological diagnostics and without it, it is difficult to identify and stratify patients into appropriate treatment groups and to determine the risk of leukemia recurrence.

1459T

Blastic plasmacytoid dendritic cell neoplasm caused by loss of genomic DNA copy numbers in the p18, p16, p27 and RB loci. *N. Oiso[1], Y. Tatsumi[2], T. Arao[3], S. Rai[2], M. Kimura[4], S. Nakamura[5], K. Nishio[3], I. Matsumura[2], A. Kawada[1].* 1) Dept Dermatology, Kinki Univ Faculty Med, Osaka-Sayama, Osaka, Japan; 2) Dept Hematology, Kinki Univ Faculty Med, Osaka-Sayama, Osaka, Japan; 3) Dept Genome Biology, Kinki Univ Faculty Med, Osaka-Sayama, Osaka, Japan; 4) Dept Pathology, Kinki Univ Faculty Med, Osaka-Sayama, Osaka, Japan; 5) Dept Pathology, Nagoya Univ Grad Sch Med, Nagoya, Japan.

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a rare plasmacytoid dendritic cell precursor-derived aggressive neoplasm with a poor prognosis. Recent studies show that two-thirds of BPDCNs have an abnormal tumor cell karyotype with an average of six to eight abnormalities. We show a 74-year-old Japanese male with BPDCN. The patient's genomic DNA copy numbers were analyzed using array-comparative genomic hybridization (CGH) to identify the chromosomal and genetic features of the malignant cells. The array-CGH analysis revealed the loss of the chromosomes1p31.3-33, 9p/q, 12p13.1-13.2 and 13p/q, and the gain of chromosome 16p/q. These lost regions included the loci of the tumor suppressor genes of CDKN2C/p18, CDKN2A/p16, CDKN1B/p27 and RB1, which are well-known cell-cycle inhibitors. We identified a novel loss of a chromosome 1p31.3-33 region including CDKN2C/p18, which may be involved in the pathogenesis of BPDCN.

1460T

Detection of chromosome alteration and RB1 gene polymorphisms in retinoblastoma patients, India. *P. Varsha[1], V. Balachandar[2,3], S. Mohana Devi[2], K. Sasikala[1,2].* 1) Molecular Biology and Human Ge, Bharathiar University, Coimbatore, India; 2) Human Molecular Genetics Lab, Bharathiar University, Coimbatore, India; 3) Thiruvalluvar University, Vellore, India.

Retinoblastoma is a rare childhood eye cancer initiated by the loss of function of both alleles of the RB1 tumor suppressor gene, mapping to 13q14 chromosomal band. The hereditary form develops at an earlier age than the sporadic one and usually appears as bilateral or multi-centric tumors or both. Approximately 80% of the unilateral cases are a result of a somatic, nonhereditary mutation. The aim of the present study was to assess the risk of retinoblastoma developing in children with chromosomal alterations with mosaic deletions and RB1 gene mutation. Chromosomal alteration and RB1 gene were examined in 42 retinoblastomas (RB) patients (28 with unilateral and 14 with bilateral retinoblastoma) who were treated in Tamil Nadu population, India. We studied 14 patients with bilateral retinoblastoma with or without familial history and 28 patients with unilateral retinoblastoma. Three of the unilateral patients had a positive familial history at diagnosis. All identifiable reported cases of unilateral and bilateral retinoblastoma, which included CA and the RB gene, were analysed in the present study. In the present study, 14 patients, interstitial deletion in chromosome 13 covered region q13~q22. In two URB patient with, a constitutional del 46, XX, del (13) (q14-q21) were observed and four of the patient (2 URB and 2 BRB), a 22- days-old male with BRB, a constitutional 46, XY, 13q14-q22 was transmitted from his asymptomatic mother. In summary, more accurate and reliable genetic testing would provide an important advance in treating patients with retinoblastoma and their families. The molecular techniques used to identify RB gene mutations have improved dramatically in recent years. Conclusive identification of RB1 mutations in retinoblastoma is predicted to improve the clinical management of affected children and relatives.

1461T

Abnormal Signal Patterns Involved in t(12;21) TEL-AML1 in Childhood Acute Lymphoblastic Leukemia Patients. *O. Altiok Clark[1], CF. Sargin Özkaya[2], S. Yakut[2], Z. Cetin[2], A. Kupesiz[3], G. Tezcan[3], V. Hazar[3], G. Luleci[2], S. Berker Karauzum[2].* 1) Department of Medical Genetics, Akdeniz University Medical Faculty, Antalya, Turkey; 2) Department of Medical Biology and Genetics, Akdeniz University Medical Faculty, Antalya, Turkey; 3) Department of Pediatrics, Akdeniz University Medical Faculty, Antalya, Turkey.

The TEL (ETV6)-AML1 (RUNX1) chimeric gene fusion which results from the translocation t(12;21)(p13;q22) is the most common genetic abnormality in childhood B-cell precursor Acute Lymphoblastic Leukemia (ALL). While this translocation is associated with a good prognosis, it is thought that the deletion of the second TEL allele, a gain of the second AML1 allele, and the duplication of the derivative chromosome 21 can each have a negative effect on the clinical outcome. In this study, bone marrow samples from 18 B-cell precursor ALL patients (ages ranging from 6 months to 16 years) were analyzed. Using conventional cytogenetic analysis, it was found that 5 patients had normal karyotypes, 5 patients had numerical and structural abnormalities on chromosome 12 and, no metaphases were observed in eight of the patients. Fluorescence In Situ Hybridization (FISH) was used to determine the translocation between chromosomes 12p13 and 21q22. FISH analysis showed the classical TEL (ETV6)-AML1 (RUNX1) chimeric gene fusion in two cases, whereas double chimeric gene fusion was observed in two other cases, one of which had a wild-type TEL allele deletion while the other had a wild-type AML1 allele deletion. In addition, one t(12;21) positive patient had both a wild-type TEL allele deletion and a wild-type AML1 allele deletion. Four of the patients were found to have the TEL allele deletion without the t(12;21) translocation. Also, the loss of 12p, monosomy 12, and t(6;12)(q16;p12.3) and t(6;9;12)(q13;p22;p13) translocations were observed in these four cases using cytogenetic analysis. In two of patients an extra signal was observed at the AML1 gene locus. One of these two patients had Down Syndrome while the other had a normal karyotype. In the patient with the normal karyotype it is thought that this extra signal was due to amplification of the AML1 gene. During the study, two patients died, one due to an infection which occured during remission and the other because of a relapse. The remaining 16 patients are all still in remission and continuing with their treatment. Our data shows that a deletion of the wild-type 12p13 locus (with or without the t(12;21) translocation) in childhood patients more likely indicates a good prognosis rather than exerting a negative effect on the clinical outcome. Furthermore, the deletion of the TEL allele in patients who do not have the t(12;21) translocation may be used to help identify new ETV6 partner chromosomes.

Ten years experience of Cytogenetic Investigation in Tunisian Leukemic Patients. *W. AYED[1], O. Kilani[1,2], N. Ben Romdhane[4], S. Ladab[3], L. Torjmane[3], A. Lakhal[3], H. Guermani[1,2], N. Abidli[1,2], F. Talmoudi[1,2], T. Ben Othmen[3], S. Abdelhak[2], A. AMOURI[1,2].* 1) Cytogenetics, Pasteur Institute of Tunis, Tunis, Tunisia; 2) Unité de recherche EMGOOD : Etude des Maladies Orphelines d'Origine Génétique, Institut Pasteur de Tunis, Tunisie; 3) CNGMO of Tunis; 4) La Rabta Hematology.

We analyzed bone marrow and peripheral blood samples of more than 750 Tunisian patients referred from hematology-oncology centers at Tunis. They were either suspected of leukemia at presentation or being monitored for their response to medication. Bone marrow or/and blood cells were cultured, harvested and R-banded according to the standard protocols. Chromosome analysis was performed following ISCN guidelines. The patients were divided into six major groupings as far as the leukemia subtypes were concerned: CML, AML, ALL, MIDS, myeloma and others. Most cases had bone marrow aspiration whereas peripheral blood was utilized only in fraction of cases. The common typical chromosomal abnormalities as well as rare and complex forms were observed. The overall chromosomal abnormality rate obtained was around 30%. The breakdown figures for different categories were roughly as follows: 90% in CML, 25% in AML, 25% in ALL, 30% in MDS and 20% in other types. Compared to published data, the observed chromosomal abnormality rate in the present study is considered average.

1463T

High-resolution confirmation of balanced *RARA* gene rearrangements in acute promyelocytic leukemia by using array CGH. *B.C. Ballif[1], A. Gruver[2], R.R. Tubbs[2], J.R. Cook[2], J.H. Rogers[2], J.R. Batanian[3], A. Furrow[1], L.G. Shaffer[1], R.A. Schultz[1].* 1) Signature Genomic Laboratories, PerkinElmer Inc., Spokane, WA; 2) Clinical Pathology, Cleveland Clinic, Cleveland, OH; 3) Molecular Cytogenetics, SSM Cardinal Glennon Children's Medical Center, St. Louis, MO.

Acute promyelocytic leukemia (APL) is typically characterized cytogenetically by a *PML-RARA* fusion [t(15;17)(q22q12)]. APL cases lacking clear evidence for *PML-RARA* may exhibit alternative chromosomal abnormalities including fusion of *RARA* to other genes (e.g., *ZBTB16*, *NPM*, *NUMA1*, and *STAT5B*), submicroscopic insertions, or complex translocations involving multiple chromosomes. When cryptic, such cases pose a challenge for this critical diagnosis. *ZBTB16* and *STAT5B* fusions are important to recognize as these are resistant to ATRA therapy. Additionally, although it would require a higher resolution test, defining the *PML* breakpoint (bcr1, bcr2 or bcr3) may offer prognostic value. The importance of the genetic lesion in APL has recently been highlighted by the costly use of next generation sequencing technologies to resolve the molecular basis of a cryptic event. As an alternative, we developed a high-resolution microarray-based technology coupled with linear DNA amplification [translocation-CGH (t-CGH)], which can identify balanced translocations and map the breakpoints within ±200 base pairs. We used such a single disease-specific multiplexed assay designed to examine multiple translocations including those aforementioned that are associated with APL to evaluate two cases with a tentative diagnosis of APL. The first case involved a 57-year-old male presenting with classic clinical features and numerous blasts including promyelocytes with Auer rods and high expression of CD13, CD33, and CD117. Although RT-PCR was positive, both karyotype and FISH showed normal results. We performed t-CGH and detected a *PML-RARA* fusion (breakpoints: chr15:72113684-72113889; chr17:35749732-35749887). Both genes showed small copy gains <50 kb presumably resulting from a cryptic fusion. The second patient presented with classic APL symptoms and pathology, with a three-way translocation involving *PML* and *RARA*. The clinician desired additional confirmation with no specimen available for RT-PCR. We performed t-CGH and detected a *PML-RARA* fusion (breakpoints: chr15:72103712-72103789; chr17:35746843-35746876) as well as a 311.6 kb deletion at the breakpoint in *PML*. t-CGH results also provided high-resolution mapping of the *PML* breakpoints (case 1 = bcr1; case 2 = bcr3). Our results illustrate that t-CGH technology applied in a clinical setting provides unambiguous confirmation of APL translocations with additional potentially relevant details not otherwise readily available.

1464T

Evaluation of chromosomal instability in patients with Langerhans cell Histiocytosis. *L. Bobadilla-Morales[1-2], E. Franco-Perez[1], R. Silva-Cruz[1], J.L. De León-Rendón[1], C. Barba-Barba[2], V. Soto-Chavez[2], F. Sánchez-Zubieta[2], A. Corona-Rivera[1-2].* 1) Biol Molecular Genomica, Univ Guadalajara, CUCS, Instituto de Genética Humana ECR, Laboratorio de Citogenetica, Guadalajara, Jalisco, Mexico; 2) Unidad de citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Hospital Civil “Dr Juan I Menchaca” , Guadalajara.

Introduction: Langerhans cell histiocytosis (LCH) is a clonal proliferative disease of Langerhans cells with local organic or diffuse infiltration of tissues. It has not been possible to establish the physiopathological mechanisms of LCH. Objectives: To evaluate the presence of Chromosomal Instability (CI) in cultured lymphocytes in the presence of mytomicin C (myt C) as a factor for follow-up and response to treatment. Material and methods: We included 8 patients with LCH; lymphocyte cultures were evaluated in the presence of myt C, 100 metaphases per patient, and their respective matched control. We evaluated the presence of CI and performed routine karyotype. Were grouped the patients into 4 stages according to disease course, and in those with localized or multiorgan disease. Results: It was observed statistically significant increase of CI in 78 patients with LCH with respect to the controls. The percentage of aberrations in patients with active and multiorgan disease was the highest observed and the damage more frequently found was chromatid gaps. Conclusions: It was noted the presence of CI in patient`s lymphocytes with LCH respect to the controls, the difference was significant when the disease is multiorganic, and active stage was present, so the CI could be inherent to LCH and the evaluation of CI could reflect the evolution of the disease.

A simple technique significantly improves the success rate of chromosome analysis from solid tumors. *H. Chaker, D. Turmel, R. Fetni.* Ste Justine, Montreal, Quebec, Canada.

Conventional studies provides valuable information for solid tumors diagnosis and prognostic stratification. However solid tumors cytogenetic is challenging and successful chromosome preparation depends in tumour types, tissue culture and harvesting techniques. We have optimized our laboratory tumors cytogenetic analysis by making a small change in our cytogenetic preparation procedure. We perform in situ culture method for tumor tissue samples and we have combined analysis of metaphases obtained from in situ culture slides and metaphases obtained from harvesting hypotonic solution used for cells swell. Surprisingly the hypotonic solution that is usually discarded contains a considerable number of well spread mitotic cells. A method has been elaborated for obtaining chromosome preparations from different histologic types of human solid tumors and applied to 51 cases. Both quality and quantity of analysed metaphases are significantly improved by this strategy. Use of this technique significantly improves the success rate of chromosome analyses from solid tumors.

1466T

Cytogenetic studies in 84 pediatric neuroepithelial central nervous system tumors in a single institution in Argentina. *M.C. Coccé[1], F. Lubieniecki[2], D. Alderete[3], M.S. Gallego[1].* 1) Genetics Department, Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina; 2) Pathology Department, Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina; 3) Hemato-Oncology Department, Hospital de Pediatría Prof. Dr. Juan P. Garrahan. Buenos Aires, Argentina.

Primary central nervous system (CNS) neoplasms are the most frequent solid tumor in childhood and include a heterogeneous group showing different histological subtypes, stages of malignancy and varying biological behavior. The pathogenic mechanisms leading to the development and progression of these tumors are still unclear. The aim of the present study was to identify genomic imbalances in samples of pediatric brain tumors and to correlate the findings with the degree of malignancy and clinical outcome. Surgical specimens from 84 institutionally diagnosed neuroepithelial CNS tumors (32 embryonal, 15 astrocytic, 14 ependymal, 14 mixed glioneuronal, 2 choroid plexus and 7 miscellaneous) were referred to our laboratory for cytogenetic studies from September 2005 to January 2011. Of them, 11 were recurrent tumors (2 embryonal, 6 ependymal, 2 mixed glioneuronal and 1 miscellaneous). Combined conventional and molecular cytogenetic techniques, including fluorescence in situ hybridization and comparative genomic hybridization, have been performed. Forty-two primary neuroepithelial CNS tumors (58%) had chromosomal abnormalities (CA): 24 embryonal, 5 astrocytic, 2 ependymal, 6 mixed glioneuronal, 2 choroid plexus and 3 miscellaneous. Nine recurrent tumors (82%) showed CA. The most frequent CA included unbalanced translocations, complex rearrangements and changes of ploidy. Among the medulloblastomas the chromosomes 1, 11 and 17 were the most frequently involved in gains, losses or in structural rearrangements. Most of the WHO grade I astrocytomas and primary WHO grade III ependymomas had normal karyotypes. In contrast, all WHO grade III and IV astrocytomas had complex karyotypes. The highest proportion of CA was found in WHO grade IV and recurrent tumors. We point out the findings of "novel translocation" such as t(1;3)(q21;q21) and t(2;7)(p25;q11.2) in medulloblastoma and t(6;12)(q21;q24.3) in glioblastoma as a sole structural CA. In conclusion, our results demonstrate a significant association between karyotypic complexity and aggressive tumor biology. The finding of novel CA may help to identify specific genes involved in the initiation and progression of these neoplasms. Finally, we would like to emphasize the importance of performing conventional and molecular cytogenetic studies to improve the detection of genomic imbalances and contribute in the understanding of the pathogenesis of these tumors.

t(X;1) and 5q- from a mediastinal teratoma in a Klinefelter syndrome patient. *A. Corona-Rivera[1,2], C. Barba-Barba[2], M.D. Martinez-Albarran[2], E. Corona-Bobadilla[1], H.J. Pimentel-Gutierrez[1,2], C. Ortega-de-la-Torre[1,2], F. Sanchez-Zubieta[2], L. Bobadilla-Morales[1,1].* 1) Laboratorio de citogenética genotoxicidad y biomonitoreo, Instituto de genética humana "Dr E Corona Rivera", Dpto. de Biología Molecular y Genómica, CUCS, UdeG; 2) Unidad de Citogenética, Servicio de Hematología Oncología Pediátrica, División de Pediatría, Hospital Civil "Dr Juan I Menchaca".

Introduction: Teratomas correspond to 40% of germ cell tumors (GCT), 4.4% of this group are mediastinal type. Chromosome abnormalities found in infants are: 1p-, 6q-, 1p + or 20p +. Interestingly, 10% of the GCT cases behave Klinefelter syndrome (KS). Objectives: To present a previously unreported chromosomal complement observed in a mediastinal teratoma from a patient with Klinefelter syndrome. Clinical report: A 17 years old male. He began his condition at 14 years old with chest pain, dyspnea and cough, ultrasound test reported a mediastinal mass, the biopsy showed mature teratoma, tumor resection was performed, weight 2.350gr, hairy with calcifications. The postoperative pathology report showed: 97% of mature teratoma. 3 cycles of chemotherapy were applied. He completed 2 years and 5 months in control with TAC, Rx, alpha-fetoprotein (AFP) and human chorionic gonadotropin (HCG) values which were normal. At 16 years old he relapsed, presenting high levels of AFP and HCG, bone marrow involvement, then karyotype was done with the following result: 47,XXY[1]/47,XY,+der(X)t(X;1)(q12;q13),del(5)(q23)[1]/48,XY,+der(X)t(X;1)(q12;q13)X2,del(5)(q23)[14], Constitutional alteration was suspected, so XY FISH was performed in oral mucosa to exclude Klinefelter, signals were compatible with XXY complement, After, karyotype was performed in peripheral blood and it was reported chromosome complement of 47,XXY. Conclusions: The presence of mature teratoma in a male patient should always lead to the suspicion of Klinefelter syndrome, as in our case. The discovery of the 5q-may be due to effects of chemotherapy in particular cisplatin, but the finding of the translocation (X;1) found has not been reported previously, and further studies are needed to assess its prognostic utility. Search Klinefeter syndrome is justified in all patients with teratoma and in particular those from the mediastinum.

Evaluation of MLPA and SISH as two alternative methods for assessing ERBB2 gene amplification status in breast cancer patients. *C. Durajczyk, L. Carson, S. Tennant, P. Batstone, D. Stevenson.* National Health Service, Aberdeen, Scotland, United Kingdom.

The proto-oncogene ERBB2 (HER2/neu) encodes a tyrosine kinase growth factor receptor involved in controlling cell growth, survival and proliferation. ERBB2 amplification in breast cancer is associated with faster relapse times and an unfavourable overall survival. However, the advent of the chemotherapeutic agent Trastuzumab, an anti-ERBB2 monoclonal antibody, has improved the prognosis of these patients, and is now approved as a first-line treatment for ERBB2 positive breast cancer. ERBB2 amplification status is tested in the Aberdeen Cytogenetics laboratory for equivocal 2+ IHC immunohistochemistry referrals. Currently the laboratory employs Vysis HER2/neu fluorescent in situ hybridisation (FISH) as the gold standard test, however other techniques are available as potential alternatives. The aim of this project was to evaluate multiplex ligation-dependent probe amplification (MLPA) and silver enhanced in situ hybridisation (SISH) for use in assessing the ERBB2 amplification status of 22 breast cancer patients. The sensitivity and specificity of these results were compared to FISH. Results showed that SISH was a promising alternative assay, with a high success rate (95.5%) and overall concordance with FISH (95.2%). However, despite the high concordance in determining overall gene amplification status, the equivalent ratios between SISH and FISH varied greatly, particularly in the highly amplified cases. MLPA was the most economical test of the three investigated; however it yielded substandard success (81.8%) and concordance rates (83.3%). Data from each technique will be presented, along with a discussion of the advantages and disadvantages of each assay.

1469T

Detection of telomerase genes (hTERC and hTERT) amplification by FISH in patients with acute myeloid leukemia. *M.M. Eid[1], N.A. Helmy[1], I.M. Omar[2], A.A. Mohamed[2], D. El Sewefy[2], I.M. Fadel[1], R. Helal[1].* 1) Human Cytogenetics, National research center, Cairo, Egypt; 2) Faculty of Medicine - Ain Shams University- Clinical pathology dept.

Acute myeloid leukemia (AML) describes a heterogenous group of hematological disorders. Cytogenetic and molecular assays have allowed patients' follow up aiming for detection of minimal residual disease, prediction of patients' outcome, in addition to providing the rationale for designing novel molecular-targeted therapeutic strategies. Human telomerase reverse transcriptase (hTERT), encoded by the hTERT gene and the telomerase RNA component (hTERC) genes are frequently amplified in human tumors, which may indicate that the hTERT and the hTERC genes may be target for amplification during the transformation of human malignancies including hematological malignancies. This genetic event has implications in diagnosis, prognosis and therapeutics of cancer. To evaluate the hTERC and hTERT genes as a prognostic marker in patients with AML, hTERC and hTERT gene amplification was studied in 20 adult AML patients using a commercial FISH probes (Kreatech) designated to detect the copy numbers of the genes. They were 12 males and 8 females. Their ages ranged from 16 to 67 years. The patients were further divided into two groups; group I (12 patients) containing newly diagnosed AML patients and group II (8 patients) containing patients taken at 28th day of chemotherapy. The hTERC amplification was detected in 19/21 cases (90.5%) The percent of amplification ranged from 2% to 69%. The copy number of the gene ranged from 2-5 copies per interphase cell. For the hTERT gene, the amplification was found in the same percent of the patients. The percent of amplification ranged from 3% to 76%. The copy number of the gene ranged from 2-9 copies per interphase cell. On comparing the de novo group with 28th days chemotherapy group there was a highly statistical significant difference regarding the percent of both genes amplification. The percent of amplification of hTERT gene was found to be higher among patients with poor outcome of the disease than in patients with good outcome. On the contrary the hTERC gene amplification did not exhibit such a correlation. In conclusion, hTERT and hTERC genes amplification were detected in patients with AML; therefore telomerase can be a good cancer marker which may be involved in carcinogenesis of leukemia. Higher amplification was found in de novo cases than cases in remission which emphasize its role in clinical analysis, disease monitoring and detection of minimal residual disease.

Detection of cytogenetics abnormalities in chronic lymphocytic leukemia using FISH technique and their prognostic impact. *o.m. Eid, M.M Eid, H.F Kayed, W.M Ahmed.* Human Cytogenetics, National research center, Cairo, Dokki, Egypt.

Maha M Eid, Hesham F Kayed, Ola M Eid, Wael Mahmoud Human Cytogenetics Dept., National Research Center Cairo-Egypt Introduction: Chronic lymphocytic leukemia (CLL) is a clonal lymphoproliferative disorder characterized by progressive accumulation of morphologically and immunophenotypically mature lymphocytes. Characterization of genomic aberrations may help to understand the pathogenesis of CLL and may give prognostic information independent from conventional clinical markers for a risk-adapted management of CLL patients. Aim: The aim of the present study is to determine the most common cytogenetics abnormalities between patients with CLL and its prognostic impact. Patients and methods: The present study was carried out on 20 adult patients presented with chronic lymphocytic leukemia. The patients were diagnosed on the basis of standard clinical (lymph node involvement and / or hepatosplenomegaly), hematological and immunophenotypic criteria for diagnosis of B-CLL. All cases were studied at the time of their diagnosis. FISH technique was successfully performed on PB samples using CLL LSI probes for ATM (11q22) / GLI (12q13) and 13q14/ p53 (17p13). Results: For comparative statistical studies, the patients were divided into group I (patients with favorable outcome) and group II (patients with unfavorable outcome). All patients showed one or more cytogenetic abnormality with the prevalent of the p53 in 16 patients out of 20 that perfectly correlated with the poor out come of the patients. This is followed by deletion in the 13q14 and to a lesser extend deletion in ATM gene, but no one has exhibited amplification in the 12q13 locus. Conclusion: p53 deletion as a sole abnormality has a higher prognostic power than the other cytogenetics abnormalities. The cytogenetics study using FISH panel for CLL patients in a complementary fashion to the other clinical and laboratory findings may overcome the pitfalls in the diagnosis also it may assess the assignment of therapeutic protocols for CLL patients according to the results of their cytogenetic analysis at the time of diagnosis.

Coexistence of t(12;21)(p13;q22)/ETV6-RUNX1 and MLL Rearrangement in a Pediatric Patient with B-Lymphoblastic Leukemia. *M. Hiemenz[1], W. Chen[2], N. Winick[3], C. Tirado[1].* 1) UT Southwestern, Dallas, TX; 2) AmeriPath North Texas, Dallas, TX; 3) Children's Medical Center, Dallas, TX.

The t(12;21)(p13;q22)/*ETV6/RUNX1* is the most common abnormality occurring in approximately 25% of cases of childhood B lymphoblastic leukemia (B-ALL) and is usually associated with a good prognosis. *MLL* aberrations have been described in childhood B-ALL and are considered a poor prognostic marker. Coexistence of *ETV6/RUNX1* translocation with *MLL* (11q23) rearrangements is a rare event as there are only a few reported cases in the literature. Most of these cases harbored an *MLL* deletion. Herein, we report a 3-year-old patient who presented with three days of fever, pallor, and lymphadenopathy. Laboratory examination revealed anemia (hemoglogin 7.7 g/L), thrombocytopenia (platelet count of 60,000×109/L), and a normal white blood cell count (10,700×109/L) but with 41% blasts. Flow cytometry on bone marrow specimen revealed B lymphoblasts [CD10(+), CD13(dim+), CD15(dim +), CD19(+), CD20(-), CD22(+), CD33(dim +), CD34(+), CD38(+), CD45(dim +), CD79a(+), HLA-DR(+), surface Ig(-), TdT(+), and MPO(-)]. Cytogenetic analysis showed a normal male karyotype. Fluorescence in situ hybridization (FISH) studies showed evidence of *ETV6/RUNX1* translocation in 58% of the interphase nuclei examined. One hundred one of those cells showed no normal *ETV6* signal, indicating the loss of the untranslocated *ETV6* allele. There was also a small clonal population (3% of the cells) with an *MLL* rearrangement. The patient was treated with Children's Oncology Group's protocol (AALL0331) for induction chemotherapy. Bone marrow on day 8 showed residual B-ALL (2.6% lymphoblasts by flow cytometry). Bone marrow on day 29 was negative for residual disease. Consolidation chemotherapy was delayed due to low white blood cell counts. The molecular cytogenetic and clinicopathologic features of this case are discussed along with a review of the literature regarding this uncommon subtype of B-ALL. To the best of our knowledge, this is one of the few B-ALL cases with coexistence of *ETV6/RUNX1* translocation [t(12;21)] and a small population with *MLL* rearrangement.

Juvenile xanthogranuloma with clonal proliferation in the bone marrow. *D. Januszkiewicz[1,2,3], E. Maly[2], M. Przyborska[2], A. Rybczynska[3], B. Konatkowska[3], J. Nowak[1].* 1) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 2) Department of Medical Diagnostics, Poznań, Dobra Street 38a; 3) Department of Pediatric Oncology, Hematology and Bone Marrow Transplantation of Medical University, Poznań, Szpitalna Street 27/33.

Juvenile xanthogranuloma is a common benign tumor in children occurring as a solitary or multiple yellowish-red nodules on skin, but sometimes involving internal organs. Patients with both JXG and NF1 have a 20-32 times higher risk of developing JMML. Triple association between juvenile xanthogranuloma (JXG), juvenile myelomonocytic leukemia (JMML) and neurofibromatosis (NF1) has been also known. The case of an 11-month-old infant boy with a disseminated juvenile xanthogranuloma (JXG) with unusual cytogenetic abnormality in the bone marrow is reported. NF1 and JMML, as well as other leukemias were excluded. Bone marrow and peripheral blood cytogenetic analysis revealed a karyotype with many rearrangements 46,XY,-6,der(12)t(6;12)(p21;p13),del(7)(p13p22),+9. This aberration has been only ones described in the literature in B- acute lymphoblastic leukemia case. On the contrary in our patient a bone marrow immunologic examination revealed a dominant population (61%) of mature T lymphocytes with about 10% of double-positive CD4+/CD8+ cells. Viral infections (CMV, EBV, HPV, HSV, HIV), as a possible T-cell stimulation, were excluded. To the best of our knowledge this is the first described case of systemic juvenile xanthogranuloma with determined karyotype representing unusual clonal chromosomal aberrations.

1473T

***FOXO1-FGFR1* fusion and amplification in a solid variant of alveolar rhabdomyosarcoma.** *J. Liu[1], M. Guzman[1], D. Pezanowski[1], D. Patel[1], J. Hauptman[1], M. Keisling[2], J. Hou[2], P. Papenhausen[3], J. Pascasio[1], H. Punnett[1], G. Halligan[4], J-P. de Chadarévian[1].* 1) Dept Path & Lab Med., St Chris Hosp for Children, Philadelphia, PA. Drexel University College of Medicine, Philadelphia, PA 19129; 2) Department of Pathology and Laboratory Medicine, Hahnneman University Hospital, Philadelphia, PA 19102. Drexel University College of Medicine, Philadelphia, PA 19129; 3) Laboratory Corporation of America, 1912 Alexander Drive, RTP, NC 27709; 4) Department of Pediatrics, Section of Oncology, St. Christopher's Hospital for Children, Philadelphia, PA 19134. Drexel University College of Medicine, Philadelphia, PA 19129.

Rhabdomyosarcoma is the most common pediatric soft tissue malignancy. Two major subtypes, alveolar rhabdomyosarcoma and embryonal rhabdomyosarcoma, constitute 20% and 60% of all cases, respectively. Approximately 80% of alveolar rhabdomyosarcoma carry two signature chromosomal translocations, t(2;13)(q35;q14) resulting in *PAX3-FOXO1* fusion, and t(1;13)(p36;q14) resulting in *PAX7-FOXO1* fusion. Whether the remaining cases are truly negative for gene fusion has been questioned. We are reporting the case of a nine-month old girl with a metastatic neck mass diagnosed histologically as solid variant alveolar rhabdomyosarcoma. Chromosome analysis showed a t(8;13;9)(p11.2;q14;9q32) three-way translocation as the sole clonal aberration. FISH demonstrated a rearrangement at the *FOXO1* locus and an amplification of its centromeric region. Single nucleotide polymorphism based microarray analysis illustrated a co-amplification of the *FOXO1* gene at 13q14 and the *FGFR1* gene at 8p12p11.2, suggesting formation and amplification of a chimerical *FOXO1-FGFR1* gene. This is the first report to identify a novel fusion partner *FGFR1* for the known anchor gene *FOXO1* in alveolar rhabdomyosarcoma.

1474T

Recurrent Cytogenetic Aberrations Predict MYC Breakpoints in Diffuse Large B-cell Lymphoma and Help Define Burkitt Lymphoma versus Diffuse Large B-cell Lymphoma with MYC Rearrangement. *D. Martinez[1], R. Garcia[2], P. Koduru[2], CA. Tirado[2].* 1) University of Texas Health Science Center at San A, San Antonio, USA; 2) Clinical Cytogenetics - UT Southwestern Medical Center, Department of Pathology, Dallas, Tx.

Cryptic MYC rearrangements in lymphomas are not always detected by current cytogenetic methods or Fluorescence In-Situ Hybridization (FISH). It is crucial to properly diagnose diffuse large B-cell lymphoma (DLBCL) from Burkitt lymphoma (BL) with MYC breakpoints since clinical management for each lymphoma differs greatly. In the present study, we are trying (1) to identify recurrent cytogenetic aberrations (RCA) that may predict MYC breakpoints in DLBCL and (2) to generate cytogenetic profiles to differentiate diffuse large B-cell lymphoma (DLBCL) from BL with MYC rearrangements. Two groups of MYC+ and MYC- lymphoma cases were retrieved from the Mitelman database. Karyotypes were assessed to detect associated RCA using bivariate correlations. Results were further analyzed using the Fisher Exact test in order to measure the significance of each association. A $p < .05$ was considered significant. Single hit DLBCL and BL cases were also obtained and analyzed to generate genomic profiles using the same methods. Our results revealed two recurrent associations and a deletion constantly present in our MYC+ group; concurrent gains of chromosomes 11 and 21 (+11/+21), concurrent gain of chromosome 11 and loss of chromosome 15 (+11/-15) and a deletion on the long arm of chromosome 6, del(6)(q15). When comparing DLBCL and BL, we found the following RCA significantly associated with DLBCL: -3/-4, -10/-15, -10/-22, +11/+21, +X, -2, -4, +7, +12, -15, +16, +18, +21, -22, losses of 1p36, 6p13q27 and 17p. In summary, our findings indicate that RCA may be used to predict MYC+ breakpoints that are otherwise not detected by conventional or FISH methods in DLBCL, and may also be used to define BL from DLBCL.

1475T

Proposed FISH panel with diagnostic and prognostic significance for prostate cancer. *N. Mitter[1], J. Belanger[1], J. Blackson[1], A. Singh[2], A. Lindia[2], J. Amberson[3].* 1) Dept Cytogenetics, Dianon Systems (Lab Corp), Shelton, CT; 2) Dept Histology, Dianon Systems (Lab Corp), Shelton, CT; 3) Dept Pathology, Dianon Systems (Lab Corp), Shelton, CT.

Background: Prostate cancer is mostly staged on the basis of Gleason scores on paraffin-embedded needle biopsies. FISH analysis has shown at least four genes to play major role in prostate tumorigenesis - loss of LPL gene (8p22), amplification of MYC gene (8q24.1), loss of PTEN gene (10q23.3)), and a fusion gene created from ERG (21q22.2) and TMPRSS2 (21q22.3) genes. **Statement of Purpose**: To test the prognostic and diagnostic potential of combining these probes to detect different stages of prostate cancer in a blind pilot study on 25 randomly selected patients already analyzed for Gleason scores. **Methods Used**: Four cross sections of paraffin-embedded needle biopsies were cut at 4μm thickness. An additional H&E stained slide was used to identify malignant and benign areas. A study-specific numbering system was used to conduct the study in a blind fashion, with the pathologist's information accessed only after FISH analysis. Standardized and properly validated FISH protocol was used with Abbott probes for MYC, LPL and PTEN genes and Poseidon break-apart probe for TMPRSS-ERG genes. Fifty cells were analyzed for each probe. A case was deemed abnormal if at least five (10%) cells had the same abnormal FISH signal pattern. Loss of LPL and/or PTEN gene(s) is seen in early tumorigenesis and associated with relatively favorable prognosis, while amplification of MYC gene and/or presence of TMPRSS2-ERG fusion is seen in later stages of prostate cancer and associated with a poor prognosis, even if seen in combination with loss of LPL and/or PTEN gene(s). An expected prognosis based on FISH results was then compared to the actual pathologic findings. **Summary of Results**: For 9/25 cases with normal signal pattern for all FISH probes, five had no cancer and four had benign problems. There was a complete correlation between FISH results and Gleason scores for 10/16 cases with prostate adenocarcinomas. Results were inconsistent for the remaining six cases, with three being negative by FISH but positive by Gleason scores for prostate cancer. The other three had abnormal FISH patterns but only benign pathologic abnormalities. The abnormal FISH pattern for these three cases suggests early manifestation of abnormal FISH patterns and possible prognostic significance for later development of prostate cancer. **Conclusion**: A combination of these four FISH probes has a high diagnostic value and prognostic significance for the development of prostate cancer.

ALK rearrangements in non-small cell lung cancer. *J.J.D. Morrissette, V. Aikawa, J.P. Segal, C. Deshpande.* Dept Pathology, University of Pennsylvania, Philadelphia, PA.

Lung cancer is the leading cause of cancer-related deaths and one of the most common cancers (excepting skin cancer). Non-small cell lung cancer (NSCLC) represents 85% of cases. Identification of the genetic basis of an individual's NSCLC is important for prognosis and treatment, with mutations in KRAS in ~25% of NSCLC, with an increased frequency in smokers. Mutations in EGFR are seen in ~ 20% of NSCLC and are treatable using targeted inhibitors. More recently rearrangements involving the anaplastic lymphoma kinase (ALK) gene, located on 2p23, have been shown to occur in 3% to 5% of NSCLC. These patients are more likely to be younger at presentation, never-smokers, female, and Asian. The most common ALK rearrangement involves the EML4 gene, located 13 Mb away on 2p21, and leads to a novel fusion oncogene, joining the coiled-coil domain of EML4 with the tyrosine kinase domain of ALK, leading to constitutive activation. The rearrangement results from either a small inversion of chromosome 2p23-p21 or an inversion/deletion event leading to the EML4-ALK fusion, with deletion of the reciprocal partner. Importantly, there is a specific inhibitor of ALK, Crizotinib, which has been very effective in reduction of tumor burden. We present our laboratory's experience with ALK analysis of NSCLC. Our validation consisted of 12 triple-negative cases, 6 KRAS positive cases, and 7 EGFR positive cases. We identified ALK rearrangements in 7 validation samples, which included the well-described inversion in 2 cases, the inversion-deletion in 4 cases and 1 case with both the inversion and inversion-deletion. We have subsequently performed ALK FISH on 63 cases, of which there were 3 positive cases, 57 negative cases and 3 cases which had no tumor cells in the submitted specimen. Our 3 positive cases were in a 29 year old Indian female non-smoker, a 46 year old white female non-smoker, and a 65 year old white female with minimal distant smoking history. We have also found an increased number of ALK signals (3~8 copies) in many of the negative samples. Although we have yet to identify a true amplification of ALK, these extra signals appear to represent multiple extra signals of ALK, as opposed to increased copy number of chromosome 2. Identification of this subset of patients is critical for targeted treatment and has altered their clinical course dramatically.

1477T

An unusual myeloid case involving hyperdiploidy. *C. Murray[1], L. Hendry[1], H. Roddie[2], R. Bauld[1], G. Bakirtzis[1], J. Fleming[1], J. Iremonger[1], E. Maher[1].* 1) S. E. Scotland Cytogenetics Department, Western General Hospital, Edinburgh, United Kingdom; 2) Department of Haematology, Western General Hospital, Edinburgh, United Kingdom.

We report a case of a 66 year old male patient who was admitted as an emergency with pyrexia and general malaise, and had a short history of progressive fatigue and shortness of breath. He had no past medical history of note. A full blood count revealed pancytopenia. A bone marrow aspirate demonstrated trilineage dysplasia with an increase in myeloblasts at 8% of total nucleated cells and with 30% ring sideroblasts. Based on these findings a diagnosis of myelodysplasia, WHO subtype RAEB, was made. A specimen of bone marrow was received by our laboratory for cytogenetic analysis. Four clones were identified, including one that showed hyperdiploidy with gains of one extra copy of chromosomes 1, 8, 10, 11, 13, 14 and Y, and two extra copies of chromosome 22. An unidentified marker chromosome was present in some hyperdiploid cells. Whilst hyperdiploidy is well-recognised as an abnormality in lymphoid disorders, it has been rarely reported in myeloid disease. We will present further details of this case, including full cytogenetic results and a literature review.

1478T

GENE EXPRESSION PROFILE OF AURKA AND AURKB IN CHRONIC LYMPHOCYTIC LEUKEMIA (CLL): CORRELATION WITH CLASSICAL CYTOGENETIC (GTG) AND HEMATOLOGICAL PARAMETERS. *F. Oliveira, AR. Lucena de Araújo, F. Saldanha-Araújo, E. Magalhães Rego, R. Passetto Falcão.* Internal Medicine - Hematology, Faculty of Medicine of Ribeirão Preto, Riberão Preto, São Paulo, Brazil.

Aurora kinase (AURKA/B) overexpression leads to genetic instability and trigger the tumor development. The majority of the studies involving aurora kinase genes are addressed to cancer immunotherapy and no study has comprehensively examined the role of these genes in leukemogenesis. We have evaluated AURKA and AURKB gene expression in CD19+ cells from peripheral blood (PB) of CLL patients, by real time quantitative PCR and correlate the findings with hematological parameters and classical cytogenetics. 62 CLL patients (23 female and 39 male) and 10 age-matched hematologically healthy donors were selected for investigation. AURKA/B gene expression from leukemic samples was calculated as relative quantification to normal CD19+; cells from healthy donors and expressed as 2-ΔΔCt. Metaphase induction in CLL was performed by using the immunostimulatory method that employs the combination of DSP30 and IL-2. All cytogenetic and gene expression data were validated by FISH analysis by using a specific set of probes. According to median value of AURKA/B expression, patients were divided into two groups (≤ 3.4, considered as AURKA+; and > 2.3, considered as AURKB+) and their clinical and biological characteristics were correlated. Higher AURKA/B expression were observed in CLL samples compared with PB normal samples (AURKA [mean value of ΔCt ± SD]: 0.093±0.003 vs 0.071±0.001, p=0.02; AURKB: 0.166±0.01 vs 0.09±0.002, p=0.02). Moreover, AURKA/B+ patients presented a significantly high leukocyte count compared with AURKA/B- patients (AURKA [WBC countx103 ± SD]: 37.8±5.5 vs 68.8±5.8, p=0.0003; AURKB: 40±5.5 vs 66.6±6.2, p= 0.0023, respectively). In addition, Pearson correlation showed that there is a significant association between high expression of AURKA/B and complex karyotype (relative risk: 2.4 [95%CI: 1.46-3.93], p < 0.001). Among the classical cytogenetic profile obtained, normal karyotype was found in 15 patients (24%) and metaphases with abnormal karyotype were seen in 47 subjects (76%). We demonstrated a significant correlation among high expression levels of AURKA/B genes in CLL with chromosomal abnormalities and other hematological parameters. Overexpression of aurora kinase genes have been extensively studied in solid tumors. In CLL this observation may be associated to the genesis of chromosomal abnormalities and possible be used to predict the course of genomic instability in CLL patients. Financial support: FAPESP (Proc. 07/52462-7).

Frequent cytogenetic alterations in a series of Myelodysplastic Syndrome cases. *S.P. PERDOMO[1,2], L.C. PARDO[1], Y. GUEVARA[1], C. FAJARDO[1], T.I. RONCANCIO[1].* 1) BIOGENETICA DIAGNOSTICA SAS, BOGOTA, Colombia; 2) INSTITUTO DE INVESTIGACION EN NUTRICION GENETICA Y METABOLISMO IINGM. UNIVERSIDAD EL BOSQUE,BOGOTA, COLOMBIA.

During the last decades patients diagnosed with MDS have a better survival rate due to an early diagnosis and management. Cytogenetic analysis are an especial tool in diagnosis, prognosis and classification of MDS, because they are able to detect up to 50% of acquired chromosomal alterations in dysplasic cells from bone marrow. Cytogenetic studies have been focused in some frequent alterations such as del(5q),-7,del(7q),+8,+21,+15 since they represent a valuable tool in clinical evaluation, prognosis and now treatment. In this study we made a retrospective revision of 74 cases diagnosed as MDS in a period of 18 months, using cytogenetic analysis in bone marrow by standard banding procedures and correlated results with biopsy and flow cytometry studies. 59.5% of the cases showed chromosomal alterations, a percentage higher than the reported data in literature. From these cases only 24,3% reported the most frequent and better studied cytogenetic alterations del(5q),-7,del(7q),+8,+21,+15 as the only abnormality. The most frequent alterations are represented by les common abnormalities such as complex karyotypes and balanced translocations, cited below: 46,XX,t(3;5)(p13;p14)[10]/46,sl,der(1)t(1;16),-16,+20[15] 46,XX,t(3;8)(p22;q24.1)[2]/46,XX[28] 46,XY,inv(9)(p21q21),der(1),-7,+mar[12]/46,XY,inv(9)(p21q21)[8] 46,XY,del(1)(p31→pter),+i(1)(q10),-5,-7,13,der(17),18,+r(?),+2mar[16]/45,XY,der(1)t(1;7)(p31:q22),-5,-7,-13,der(17),-18,+r(?),+2mar[14] 46,XX,del(4)(q21→qter)[2]/46,XX[18] 46,XX,i(17)(q10)[20] 50,XY,+1,-5,+8,+9,der(11),+14,+17, -18,-21,t(18;21)(q11.2;p11.2),+r,+mar [18]/46,XY[2] 44,XX,der(2)t(2;11)(p11.2,-p11.2),del(5)(pter->q15),-11,-15,-17,-19,der(20),+2mar[17]/45,sl,+8[3] 45~47,XY,del(1)(P31→pter),+i(1)(q10),del(4)(p15.2),-5,-7,-13,der(17),-18,+r(?),+3mar[6]/46,XY,del(1)(P31→pter),t(1;3)(p13;q21),-4,-5,der(1)t(1;7)(p31;q22),-13,der(17),-18,+r(?),+3mar[12]/46,XY[2] 46,XXt(3;19)(q24;p13)[15]/47,XX,del(3)(q24;q29),+8[10] 47,XX,t(1;3)(p32;q27),+5,i(9)(q10),der(17)(p12)?[12]/46,XX[8] 49,XY,add(3)(q27),-7,-17,-22,-22,+r(?),+6mar[1]/46,XY[29] 46,XY,t(1;11)(p33;p15)[2]/46,XY[23] Our results, show a higher frequency of less common reported and studied cytogenetic alterations in MDS according to scientific reports, with not well known or unknown clinical and/or prognostic value. Follow up studies must be done in order to gain a better understanding of the clinical significance of these abnormalities and reevaluate their frequency in MDS patients.

Evaluation of AURKB gene amplification status in breast cancer samples. *R.M. Rodrigues-Peres[1], J.K. Heinrich[1], R.G. Paleari[1], J. Vassallo[3], L.O. Sarian[2].* 1) CAISM - Women's Hospital, University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Department of Obstetrics and Gynecology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, Brazil; 3) Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas, SP, Brazil.

Introduction: The Aurora kinase B (AURKB) gene is involved in cell division and mitosis, playing a relevant role in chromosomal segregation and condensation, mitotic checkpoint and cytokinesis. The AURKB protein was shown to be overexpressed in many types of cancer cells, including the increase of a complex formed by Aurkb, Incenp and survivin, which is in turn related to aneuploidy. Thus, AURKB amplification might be associated with other defective genes in cancer such as p53 and BRCA-2. A connection between AURKB amplification and familial breast cancer has also been suggested. Although several authors have described the importance of the AURKB in carcinogenesis, there is still much to understand about its mechanisms in breast cancer cells. Objective: 1) To evaluate gene amplification status of AURKB gene in breast cancer samples; 2) To access genomic instability status of these samples through the correlation of AURKB gene amplification status and ERBB2, C-MYC and CCND1 status; 3) To verify the correlation of AURKB gene with familial breast cancer cases. Materials and Methods: For this study, 48 cases were obtained from mastectomies. A central tumor area and a normal tissue area of the same breast, for each case, were pair-compared. A TMA slide containing these samples was set and used in FISH assays. Homebrew probes were specifically designed for the AURKB gene and applied onto samples with a commercial probe for the chromosome 17 centromere (CEP17, Kreatech), as an internal control. Clinicopathological data were obtained from patients' records. Results: Approximately 23% of the cases presented AURKB amplification and 92% showed genomic instability, i.e., concomitant amplification in other genes. Forty-six percent of the AURKB amplified patients presented positive familiar history. Discussion: Our results corroborate previous findings of AURKB amplification in breast cancer samples. As a high frequency of amplified cases was positive for familial history, further studies should provide new issues regarding the role of this gene in hereditary cancers as well as its association with other genes. The massive correspondence of gene amplification among AURKB, ERBB2, C-MYC and CCND1 genes might suggest an important genetic component involved in the carcinogenesis and tumor development process in the central area of the tumor.

Strategy using SNP array and interphase FISH for the detection of genetic prognosis factors in neuroblastoma. *M. Roy-Tourangeau[1,2,4], M.-P. Arsenault[1,2,4], C. Nyalendo[1,2,4], S. Cournoyer[1,2,4], P. Teira[3], M. Duval[3,4], H. Sartelet[1,2,4], R. Fetni[1,2,4].* 1) Pathology and Cell Biology, University of Montreal (Quebec), Canada; 2) Pathology; 3) Hemato-oncology; 4) Research Center, CHU Sainte-Justine, Montreal (Quebec), Canada.

Neuroblastoma (NB) is the most common childhood solid tumor and is characterized by its biological and clinical heterogeneity. Some cases have a spontaneous regression, while others are very aggressive, making risk stratification of patients essential. Several genetic markers are currently used to evaluate NB prognosis, such as *MYCN* oncogene amplification, DNA ploidy, 17q gain, 11q23 LOH and 1p36 LOH. Aim of our study is to establish an optimal strategy to detect genetic prognosis factors in NB using Genome Wide analysis, fluorescent *in situ* hybridization (FISH) and DNA index. First, for whole genome screening, we used Affymetrix Genome-Wide Human SNP Array 6.0 platform, enable to detect both single nucleotide polymorphisms (SNP) and copy number variations (CNV). Ploidy was evaluated by flow cytometry and recurrent chromosomal abnormalities were also assessed by a FISH panel, including probes specific for *MYCN*, 17q, 11q23 and 1p36. Among 36 primary NB analyzed, 89 % present one or more genomic abnormalities (by SNP array and/or by FISH), while 4 cases are diploid. Moreover, 22 % are triploid (confirmed by flow cytometry and by SNP); therefore, FISH results were analyzed considering the appropriate ploidy of each sample. The most common CNV/LOH in our cohort are 11q23 deletion (43 %), 17p gain (33%), *MYCN* amplification (17 %) and 1p36 deletion (14 %). When the ploidy status is taking into account for interphase FISH results interpretation, the two techniques show comparable sensitivity. In conclusion, our analysis show that the ploidy changes and highly rearranged genome of NB tumors lead to inaccurate results interpretation for both interphase FISH and SNP microarrays. The integration of DNA index during results analysis is essential for a genetic prognosis factors assessment of NB.

Chromosomal alterations detected by conventional cytogenetic and FISH in leukemias. *F.J. Sheth[1], M.J. Desai[1], A.P. Patel[2], S.B. Mehta[1], J.J. Sheth[1].* 1) Department of Cytogenetics, FRIGE's Institute of Human Genetics, Ahemadabad, Gujarat, India; 2) Gujarat Research & Medical Institute, Shahibaug, Ahmedabad-380004.

With the increasing global attention to the newly immerging concept of genomic disease management, molecular pathway is gaining a centre stage especially in the management of leukemia and various other cancers. This has become possible due to increasing resolution power and sensitivity offered by various molecular techniques such as FISH. In the present study, 321 individuals were investigated for cytogenetic study due to clinical suspicion of CML [n=175], AML [n= 24], ALL [n= 41], CLL [n=02], MPD [n=24], MM [n=6] and MDS [n=49]. Primary alterations were detected in 158 cases, secondary rearrangements in addition to primary alteration were seen in 10% cases and 163 were found to be cytogenetically normal. Fluorescence *in situ* hybridization [FISH] study has facilitated to recognize not only genomic alteration detected in 33 and 125 cytogenetically normal/abnormal cases respectively. Moreover, dual colour dual fusion specific BAC clones have additionally helped in identifying gene amplification/loss which was missed in 17 cases by routine conventional cytogenetic [CC] analysis. Similarly multiple minor cell lines were identified in one case of AML-M3. Translocations involving more than two chromosomes were observed in 16 cases and of these, two cases showed apparently balanced genome and were responding well to supportive therapy. Together, the combination of CC and FISH analysis incorporates the screening potential of cytogenetics with accuracy of molecular genetics technique, which will lead to better understanding of neoplastic disease, more accurate diagnosis, stratification of patients in to genetic subgroups and eventually improvements in prognostification. This study is supported in parts by DBT, India.

Acute Promyelocytic Leukemia with a Novel Variant (15;17) Rearrangement. *A. Zaslav[1], M. Bellone[2], B. Kiner-Strachan[3], M. Golightly[4], T. Mercado[1], Y. Hu[2].* 1) Cytogenetics, Dept of Clinical Pathology, Stony Brook Univ Hosp, Stony Brook, NY; 2) Department of Anatomic Pathology, Stony Brook University Medical Center, Stony Brook, NY 11794; 3) Department of Medicine, Bone Marrow Transplant Unit, Stony Brook University Medical Center, Stony Brook, NY 11794; 4) Flow Cytometry, Department of Clinical Pathology, Stony Brook University Medical Center, Stony Brook, NY 11794.

Acute promyelocytic leukemia (APL) is associated with a reciprocal translocation of chromosomes (15;17)(q22;q21), resulting in the fusion of the PML and RARA genes. We describe a patient of 67-year-old with APL carrying a novel variant of (15;17) translocation. The marrow showed typical APL morphology except for absence of Auer-rods. Flow cytometry analysis was consistent with APL. RT-PCR confirmed the PML/RARA transcripts. Standard G-banding analysis on bone marrow cells demonstrated a karyotype of 46,XY,del(17)(q12q21.1),ins(15;17)(q22;q21.2q25.3)[18]/46,XY[2]. Fluorescence in situ hybridization (FISH) using the dual-color, dual-fusion PML(15q22-orange)/RARA(17q21-green) probe also showed a variant abnormal pattern (figure 1): Typical APL patients have 1O (orange):1G (green):2F (fusion) signals. Our patient had 1.5% of cells with the typical abnormal pattern, however, 85% of the cells had 2O:1G:1F. The results demonstrated that the RARA/PML fusion was absent from chromosome 17. PML remained on the der(15) and PML/RARA was inserted into or translocated to the der(15). To our knowledge this abnormality has not been described before. The patient was treated following the Cancer and Leukemia Group B (CALGB) protocol 9710 regimen. His response to ATRA has been slow. Three follow up cytogenetic and FISH analyses demonstrated the absence of the RARA/PML rearrangements in all cells. The patient will be closely monitored. His clinical progress should add to our knowledge of the prognostic significance of this novel variant rearrangement.

Increased molecular cytogenetic (FISH) abnormality detection rate using plasma cell enriched cell sorting for plasma cell disorders. *S. Zneimer, M. Sasaki.* Cytogenetics, US Labs, Irvine, CA.

The detection of cytogenetic abnormalities in plasma cell disorders (PCD's) are difficult due to the low viability of actively dividing cells in culture. Fluorescence in situ hybridization (FISH) offers a better abnormal detection rate since the cells are analyzed in interphase without the need for actively dividing cells. However, both techniques, when performed on whole bone marrow or peripheral blood samples, do not offer the most reliable means for observing the most common abnormalities seen in PCD's due to the small number of plasma cells in the whole bone marrow or blood specimen. Sorting of plasma cells by various methods have been reported in the literature, and using the autoMACS Pro magnetic cell separator by Milteny Biotech since May 2010, we have been able to increase our abnormal detection rate using FISH analysis of specific recurrent abnormalities. Abnormality rates were compared before and after cell sorting of plasma cells using DNA probes consisting of centromere probes of chromosomes 3, 7, 9 and 11 to detect hyperdiploidy; chromosome 13q14.3 for del(13q) and monosomy 13; IGH/CCND1 for t(11;14); IGH/MAF for t(14;18); FGFR3/IGH for t(4;14); and TP53 gene for del(17p). The abnormality detection rate of 1103 samples using DNA probes of these regions increased from 40.0% before cell sorting to 71.7% after cell sorting and analyzing only plasma cells. The method for plasma cell enrichment had a zero percent failure rate when enough material was received, with a 0.6% insufficient quantity received. These results strongly support the need for cytogenetic labs to use some method for isolating plasma cells to perform FISH analysis for optimum abnormal detection rates of the typical, highly observed abnormalities detected in PCD's for increased sensitivity of abnormal molecular cytogenetic results.

Gene Expression and SNP Array Analyses of Spindle Cell Lipomas and Conventional Lipomas with 13q14 Deletion. *H. Bartuma.* Department of Clinical Genetics, Lund, Sweden.

Spindle cell lipomas (SCL) are circumscribed, usually subcutaneous tumors that typically occur on the posterior neck, shoulder and back of middle aged men. Cytogenetically, almost all SCL are characterized by deletions of chromosome arm 13q, often in combination with loss of 16q. Deletions of 13q are seen also in approximately 15 % of conventional lipomas. Through single nucleotide polymorphism (SNP) array analyses we identified two minimal deleted regions (MDR) in 13q14 in SCL. In MDR1, four genes were located, including the tumor suppressor gene RB1. MDR1 in SCL overlapped with the MDR detected in conventional lipomas with 13q14 deletion. In MDR2 in SCL there were 34 genes and the two miRNA genes miR-15a and miR-16-1. Global gene expression analysis was used to study the impact of the deletions on genes mapping to the two SCL-associated MDR. Five genes (C13orf1, DHRS12, ATP7B, ALG11, and VPS36) in SCL and one gene C13orf1) in conventional lipomas with 13q-deletions were found to be significantly underexpressed compared to control tissues. Quantitative real-time PCR showed that miR-16-1 was expressed at lower levels in SCL than in the control samples. No mutations were found at sequencing of RB1, miR-15a, and miR-16-1. Our findings further delineate the target region for the 13q deletion in SCL and conventional lipomas and show that the deletions are associated with down-regulated expression of several genes, notably C13orf1, which was the only gene to be significantly down-regulated in both tumor types.

1486T

Aberrant translocations t(3;17)(q22;p13) and t(5;21) (q13;q22) in a case of Ph-positive chronic myeloid leukemia during blastic transformation. *A. Bennour[1], M. Zaier[2], I. Azzouz[1], I. Ouahchi[1], Y. Ben Youssef[2], A. Khelif[2], A. Saad[1], H. Sennana[1].* 1) Cytogenetics Department, CHU Farhat Hached Hospital, Sousse,Tunisia; 2) Department of clinical hematology, CHU farhat Hached Hospital, Sousse, Tunisia.

Secondary chromosome changes are frequently observed during the blastic phase of chronic myeloid leukemia (CML) owing to clonal evolution. We report a patient with Philadelphia (Ph)-positive CML who developed abnormal clones with translocations t(3;17)(q22;p13) and t(5;21)(q13;q22) during the blastic phase. A 44 year old man was diagnosed with CML, he was treated with imatinib during 3 months and a serial chromosome and molecular study was performed over the clinical course of the disease. The patient remained in complete cytogenetic remission after imatinib treatment, when a conventional cytogenetic study performed on the bone marrow was negative for the Ph chromosome. The treatment was discontinued during 11 months, subsequently, the patient developed acute transformation of the disease and cytogenetic examination showed the development of two clones, consisting of the translocations t(3;17)(q22;p13) and t(5;21)(q13;q22) in addition to the standard Ph rearrangement. Whole chromosome paintings with chromosomes 3, 5, 17 and 21 confirmed these translocations. The patient was chemotherapy resistant; he received a second tyrosine kinase inhibitor (dasatinib) for one month. He was then discharged home in a markedly improved clinical condition. Unfortunately, he died. The association of a Ph with abnormalities unusually observed in CML raises the question of whether these aberrant translocations are part of the disease process and casually related to the acute transformation. In our knowledge, t(3;17)(q22;p13) has never been reported previously in the literature, the breakpoint in 17p13 clusters a transcriptional regulator gene PER1 which may play a potential role in the transformation process of the CML. T(5;21)(q13;q22) was rarely described in myelodysplastic syndrome (MDS) and acute non lymphocytic leukemia (ANLL). The gene in 5q13 is yet unknown, and it is therefore uncertain whether this translocation involve a new AML1 (21q22) partner. In conclusion, we find that the combined use of fluorescence in situ hybridization, chromosome painting, and classic cytogenetic analysis allows a better evaluation of the genomic aberration involved in CML blastic transformation, and offers new directions for its further molecular investigations.

1487T

The first case of Philadelphia-negative acute promyelocytic leukemia following imatinib for chronic myeloid leukemia. *J.J.W. WAKIM[1], C.A.T TIRADO[2], W.C CHEN[3].* 1) HEMATOLOGY-ONCOLOGY, UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL CENTER, DALLAS, TX; 2) PATHOLOGY, UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL CENTER, DALLAS, TX; 3) AMERIPATH NORTH TEXAS, DALLAS, TX.

In chronic myeloid leukemia (CML), chromosomal abnormalities (CA) in Ph-negative cells are scarce and transient, but rarely associated with the development of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). We present the first case of Ph-negative acute promyelocytic leukemia (APL) in a patient in complete cytogenetic response (CCR) following 7 years of treatment with imatinib for CML. A 81 year-old male was diagnosed with t(9;22)(q34;q11.2)/BCR-ABL1 CML in 1999. He received interferon for 9 months then imatinib 400mg daily and achieved CCR. Imatinib was discontinued in November 2007 because of gastrointestinal intolerance. The patient remained in CCR, but in April 2010 presented with APL. FISH showed PML-RARA, but no evidence of BCR-ABL in 1000 interphase nuclei examined which gives the sensitivity of PCR studies. Karyotype revealed: 46,XY,t(15;17)(q24;q21.1)[19]/46,XY[1]. He developed subdural hematomas and died. CA in Ph-negative cells have been observed in 2-21% of CML patients following interferon or imatinib. They are usually transient but 2% of affected patients develop MDS and/or AML. We are the first to report the emergence of t(15;17)/PML-RARA APL in Ph-negative metaphases. Promyelocytic blast crisis of CML was ruled out when FISH showed no evidence of BCR-ABL in 1000 interphase nuclei examined. t(15;17)/PML-RARA was a new event in Ph-negative cells rather than clonal evolution of CML into accelerated phase. Several theories can be advanced to explain this rare event. The first proposition entails a two-step pathogenesis of CML where the Ph-negative stem cell accumulates CA and the Ph chromosome represents a “second hit”. The selective suppression of the Ph-positive clone by imatinib allows the Ph-negative clones expressing the “first hit” to emerge. The second explanation describes a genetically damaged hematopoiesis that produces multiple abnormal clones which remain masked until the eradication of the dominant Ph-positive clone by imatinib. The third proposition implicates imatinib in the appearance of CA since its target, ABL, is involved in DNA repair. The hematopoiesis of a patient with imatinib-induced CCR would be relying on a restricted group of Ph-negative stem cells riddled with genetic instability and prone to the emergence of new CA. In conclusion, CML patients in CCR should be monitored by classical cytogenetics in addition to BM aspirations, as they risk developing additional CA which can rarely be fatal.

Detection of exonic copy-number changes by high resolution array-CGH of human cancer genes. *H. Chong, A. Elliott, A. Kammesheidt.* Ambry Genetics, Aliso Viejo, CA.

Alterations in genomic copy numbers may lead to changes in gene expression and function and are known to underlay various disease states including congenital anomalies, developmental disorders and numerous cancer syndromes. Array-based comparative genomic hybridization (aCGH) provides a powerful tool to study diseases resulting from genomic copy number variations (CNV). aCGH can identify which chromosomal regions harbor large gains and losses on a genome wide level, with a resolution typically greater than 100Kb on a standard microarray. In the effort to identify smaller CNVs in genes implicated in cancer, we designed and validated an exon focused 180K whole-genome human CGH microarray using the Agilent platform (Santa Clara, CA). The Ambry CancerArrayTM covers the majority of exons in cancer-related genes based on the Sanger Cancer Gene Census at high resolution. The array has coverage of 5024 exons in over 400 cancer-related genes, with an average of 5.1 probes per exon (25,381 probes in 5024 exons) and backbone tiling of about 20 Kb. More than 98% of the exons are covered with at least 3 probes. The array can be used to identify duplications or deletions throughout the genome involving at least one exon. We demonstrate the ability of the custom-designed exon-targeted array to detect clinically relevant intragenic CNVs with subkilobase resolution in patients with various clinical phenotypes. This exon-targeted array enables detection of intragenic copy number changes in situations that would be missed by traditional aCGH and would not be detected by gene-specific DNA sequencing.

Automating the Dropping Process to Generate Quality Metaphase Spreads in Preparation for Fluorescence In Situ Hybridization (FISH). *B. Kirk[1], A. Avila[1], T. Tisone[1], K. Sundin[2], D. Buller[2], C. Glotzbach[2], C. Kashork[2].* 1) BioDot, Inc., Irvine, CA; 2) Signature Genomic Laboratories, PerkinElmer Inc., Spokane, WA.

Cell `dropping' refers to the process of applying cell samples to a microscope slide in preparation for fluorescence in situ hybridization (FISH). Harvested cells, suspended in a 3:1 (methanol: acetic acid) fix solution, are applied to glass microscope substrate. When applied to the slide, the objective is to have the `dropped' cells spread in such a way that cellular DNA is presented properly for further analysis using FISH. In the case of Interphase FISH, spreading requirements are not as stringent. In the case of Metaphase FISH, however, condensed chromosomes need to be distinct, the proper size, and separated form neighboring metaphase cells. Historically, the dropping process has been done manually in cytogenetic laboratories and while the definition of a quality metaphase is widely accepted, laboratories often differ greatly with respect to the dropping conditions. The process to date is still inherently manual, and is often viewed as an art, rather than a science. Using the BioJet Plus™ dispensing technology from BioDot Inc. (Irvine, CA), a quantitative, non-contact, liquid dispensing system with drop volumes in the range of 10-4,000 nL, we demonstrated the transition to a consistent automated method, thus eliminating the “art” in the process. The BioDot AD1500 configured with the BioJet Plus technology was used to evaluate the automation of the dropping process and produce consistent, quality, metaphase spreads. Control slides were prepared with the standard manual process (protocol supplied by Signature Genomics) and were used to establish quality standards for the BioJet Plus technology. All slides were evaluated using a phase microscope. Experimentally, we have explored the effect of dispense volume (350 nl to 2 ul), surface temperature (30°C to 70°C), surface angle deposition (0° to 60°), surface pre-treatment and local relative humidity (45% to 70%RH) on the quality of metaphase spread preparations. In doing so, an automated protocol was developed that produced metaphase spreads that are sufficient for FISH analysis. In addition to automating the dropping process, drop volumes have been reduced to the point where multiple cell spots can be applied to a single glass slide allowing for high throughput multiplexing. Multiplexing allows for replicate spots of any given sample or multiple samples to be spotted on a single slide.

1490T

Comprehensive Genetic Diagnosis of B-Cell Chronic Lymphocytic Leukemia. *Y.Y. Wen, X.F. Hu, M.M. Li.* Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

B-cell chronic lymphocytic leukemia (CLL) is the most common leukemia in the United States, predominantly occurring in older males. Some patients with CLL show slow progression of the disease with minimal therapy while others progress aggressively regardless of treatments. Great efforts have been expended on studying the genetic alterations in CLL, leading to the identification of prognostic markers for patients with CLL. Five cytogenetic prognostic categories have been proposed: deletion in the short arm of chromosome 17 is associated with the worst outcome, and deletion of chromosome 13q as the sole aberration appears to have the best outcome. In addition, mutation status of IgVH has also been suggested to correlate with the prognosis of CLL. While many individual prognostic markers have been identified, several open questions remain. First, large-scale study of genes associated with common cytogenetic alternations in CLL was absent. Second, the correlation of cytogenetic aberrations and hypermutation of IgVH is currently unknown. In order to answer these two questions, we performed cytogenetic study, FISH with a panel of probes, IgVH hypermutation study, and chromosome microarray analysis (CMA) using a 400K Cancer-specific CGH/SNP array on ten patients with CLL. Our results demonstrated that CMA not only detected all FISH aberrations, but also helped to define the size and the genes involved in these aberrations. Furthermore, CMA data revealed many previously unknown genomic abnormalities, including copy numbers neutral loss of heterozygosity, which cannot be detected by FISH or cytogenetic study. Based on these results, we suggest that CMA study can replace FISH as a first tier test for CLL. When comparing cytogenetic and FISH results with hypermutation of IgVH, we found that FISH results were not always consistent with IgVH mutation status; however, no conclusion can be drawn due to the small sample size. We believe that cytogenetic, CMA, and IgVH mutation studies provide comprehensive genetic diagnosis and prognosis for CLL. The CGH/SNP array study may uncover the etiology of CLL, and lead to the development of targeted therapies.

Retrospective microarray analysis in diagnostic acute myeloid leukemia. *C.M. Higgins, D.L. Pickering, J.M. Stevens, W.G. Sanger, B.J. Dave.* Human Genetics Laboratories, Munroe Meyer Institute, University of Nebraska Medical Center, Omaha, NE.

Acute myeloid leukemia (AML) occurs mostly in adults and accounts for 70% of all acute leukemias. Cytogenetics is an important diagnostic and prognostic determinant in AML, however, approximately 30% of cytogenetic studies in diagnostic AML are uninformative due to normal fluorescence in situ hybridization (FISH) studies and/or karyotype. To investigate for the presence of chromosome imbalances not observed by either of the analyses, we examined 10 diagnostic AML cases with normal findings using genomic microarray developed by the Cytogenomic Cancer Microarray Consortium. For validation, we also included a cytogenetically abnormal AML case containing double minutes and ring chromosomes. DNA was extracted from available fresh bone marrow, refrigerated bone marrow, or fixed cell pellets from the cytogenetic cultures. These specimens were hybridized to a customized oligonucleotide array (4x180K) designed to target over 500 selected cancer genes and 130 cancer-associated chromosome regions. To distinguish between disease-associated and other possibly non-pathogenic copy number changes, a select group of controls was utilized. These included cytogenetically normal bone marrows from other hematologic disorders and peripheral blood from clinically normal individuals. Nine of the 10 cases analyzed by microarray did not show any additional clinically relevant genomic imbalances. One case revealed a small copy number gain at 17q25.2 which included the AML specific *SEPT9* (Septin 9) gene. Since this gain is contained within a known copy number variation observed in normal population, the clinical implications of this finding remain uncertain. Microarray revealed a range of 6-20 aberrations, some of which were known benign copy number variants and others were categorized as non-pathogenic based on the findings of our control subset. Additionally, microarray analysis of the cytogenetically abnormal AML case was consistent with the abnormalities defined by conventional cytogenetics and resolved all unidentified abnormalities including the origin of double minutes and ring chromosomes, thus completely characterizing the karyotype. Further investigations utilizing more recent versions of cancer microarrays including a combination of oligonucleotide probes and single nucleotide polymorphism (SNP) content are necessary to determine the benefit of microarray analysis in hematologic disorders.

1492T

Cytogenetic monitoring by use the micronucleus assay (MNs) and the chromosomal aberrations test (CAs) among Tunisian hospital staff exposed to low dose of ionizing radiation (IR). *S. BOURAOUI[1], A. DRIRA[2], H. BEN KHELIFA[1], M. GRIBAA[1], N. BOUALI[1], R. BERGUIGA[1], I. BEN ABDALLAH[1], S. BRAHEM[1], A. BENNOUR[1], O. MAMAI[1], N. MRIZEK[2], F. TABKA[2], H. ELGHEZAL[1], A. SAAD[1].* 1) Department of Cytogenetic and Reproductive Biology ,Farhat Hached University Teaching Hospital, Sousse, Tunisia; 2) Department of occupational and environmental medicine, Farhat Hached University Teaching Hospital, Sousse, Tunisia.

Of all workers exposed worldwide to man-wide sources of radiation, medical personnel represent the group most consistently exposed to low dose of (IR). The high doses of IR are clearly known to produce deleterious consequences in human, including cancer induction. However, the effect of such radiations at lower doses, as in occupational work setting, is less clear. Human cytogenetic biomonitoring studies using somatic cells have been proposed as pertinent tools to assess the possible genotoxic effects of (IR). CAs and MNs have been widely accepted as reliable biomarkers for evaluating damage induced by IR. Our study reports the finding of these genotoxicity tests for Tunisian hospital staff exposed to low dose of IR. Assessment of chromosomal damage was carried out in peripheral lymphocytes of 45 exposed to IR from radiology, radiotherapy, cardiology and nuclear medicine departments of Frahat Hached hospital of Sousse (Tunisia). We used 34 controls from administrative department of the same hospital matched for gender, age, smoking and life style. Heparized venous blood samples were collected and were processed for different cytogenetic methodologies used in this study. MNs frequency was evaluated after cytokinesis block by use the cytochalasine B. Mitomycin C was used for detection of CAs. The frequency of binucleated micronucleated cells was significantly higher ($p < 0.05$) in the exposed groups (15.8‰ ± 4.66) when compared with controls (6.91‰ ± 4.44). The highest frequency of MN was seen in exposed from nuclear medicine department. MN frequency was significantly positively correlated with time of exposure to IR (Spearman's test, $\delta = 0.046$, $p < 0.05$). CAs frequency was significantly higher ($p<0.05$) in the exposed groups (4.85 % ± 2.35) when compared with controls (1.85 % ± 1.84). Our results points to the necessity to develop procedure that allow the occupationally exposed hospital staff to be biomonitored and protected from IR.

eQTL analysis to identify candidate loci influencing cellular response to simvastatin exposure. *L.M. Mangravite[1], B.E. Engelhardt[2], M.W. Medina[3], J.D. Smith[4], M.J. Rieder[4], D.A. Nickerson[4], M. Stephens[5], R.M. Krauss[3].* 1) Sage Bionetworks, Seattle, WA; 2) Department of Computer Science, University of Chicago, Chicago, IL; 3) Children's Hospital Oakland Research Institute, Oakland, CA; 4) Department of Genome Sciences, University of Washington, Seattle, WA; 5) Department of Statistics and Department of Human Genetics, University of Chicago, Chicago, IL.

Statins are prescribed to lower cardiovascular disease (CVD) risk by reducing plasma LDL. This response is variable and, although it has been hypothesized to have a genetic component, identification of genotypes associated with plasma LDL change has met with limited success. We have, however, demonstrated associations of candidate gene loci with cellular response traits in statin-treated lymphoblastoid cell lines (LCL). We sought to extend these analyses by using a genome-wide approach to identify novel loci for statin response. Specifically, we aimed to identify cis-eQTLs, classifying each as interacting or not interacting with statin treatment, and to test for relationships of these loci with change in cell surface expression of LDL receptor (LDLR), the protein that mediates increased LDL plasma clearance in response to statins. Methods: Gene expression profiles and surface LDLR protein were measured following simvastatin or control buffer exposure in 480 LCLs. Measured genotypes were imputed to 7.8 million SNPs and tested for associations with treated and untreated expression profiles. Gene by treatment effects, or differential cis-eQTLs, were identified through the application of a novel multivariate Bayesian regression method designed to explicitly test for five possible models of association with treated or untreated gene expression. Summary: Simvastatin exposure significantly altered expression of 5509 probed transcripts (±1.09±0.08 fold change, 54.0% response rate, q<0.0001) and increased surface LDLR expression (2.22±5.16 fold change, P<0.0001). Univariate analyses identified 2145 and 2032 cis-eQTLs within the untreated and treated datasets respectively (log10BF > 8.0). For 24 genes associated with treatment-stable cis-eQTLs, expression was correlated with change in LDLR (q=0.10). Few differential cis-eQTL were observed, although the multivariate approach was more effective than standard methods for differential eQTL detection. However, statin-mediated changes in expression of genes at these loci were not strongly correlated with change in LDLR. These findings suggest that genetic regulation of LDLR, and hence plasma LDL, manifests through variation in underlying physiology rather than through statin-specific effects. In contrast, treatment-dependent differential cis-eQTLs may influence variation in statin response of non-cholesterol pathways, possibly contributing to the known pleiotropic effects of statins that influence CVD risk.

CRP predicting locus at 6q22 modulates risk of ventricular fibrillation in acute myocardial infarction. *R. Pazoki[1], M.W.T. Tanck[1], D. Dalal[2], J.S.S.G de Jong[3], A.A.M. Wilde[3], C.R. Bezzina[3].* 1) Department of Clinical Epidemiology, Biostatistics and Bioinformatics, Academic Medical Center, Amsterdam, the Netherlands; 2) of Cardiology, Johns Hopkins University, Baltimore, Maryland, USA; 3) Heart Failure Research Center, Department of Clinical and Experimental Cardiology, Academic Medical Center, Amsterdam, the Netherlands.

Introduction: Sudden cardiac death is a leading mode of death in adults in the Western world and is largely caused by ventricular fibrillation (VF) during acute myocardial ischemia-infarction (MI). A genetic component in risk of VF in the setting of MI is recognized. However, the underlying genetic factors remain largely unknown. Plasma concentration of C-reactive protein (CRP) is a predictor of sudden cardiac death. In recent genome-wide association studies (GWAS), several single nucleotide polymorphisms (SNPs) have been associated with CRP levels. In this study we investigated the effect of CRP-predicting SNPs in modulation of risk of VF in acute MI.

Methods: Patients studied were from the Arrhythmia Genetics in the NEtherlands Study (AGNES), consisting of patients with a first acute MI, with those suffering VF classified as cases (n=515) and those not suffering VF classified as controls (n=457). Twenty independent SNPs (r^2<0.75) previously found to be associated with CRP levels at genome-wide significant p-values ($P<5\times10^{-08}$) in previous GWAS were identified. Genotypes were obtained by direct genotyping (Illumina 610) or were imputed using HapMap. A Bonferroni-corrected threshold of P<0.002 was used to define statistical significance in testing of individual SNPs. We also generated a genetic risk score based on the number of CRP-increasing alleles. Logistic regression modeling was used to test for association with VF.

Results: SNP rs6901250 in GPRC6A was strongly associated with VF in acute MI (OR:1.39;95%CI:1.14,1.69;$P=9.6\times10^{-04}$), with the CRP-increasing allele being associated with increased risk for VF. Analysis of SNPs in a 50 Kb region around rs6901250 identified a stronger signal at SNP rs633420 ($P=9.7\times10^{-05}$) which was in high linkage disequilibrium (r^2=0.73) with rs6901250. The CRP genetic risk score generated based on the number of CRP-increasing alleles was associated with risk of VF after MI (OR: 1.07; 95%CI: 1.01,1.12; P=0.01).

Conclusions: CRP-predicting loci in aggregate and rs6901250 individually are associated with risk of VF in MI. Our study highlights the role of inflammatory loci on risk of VF after acute MI.

A prescription for personalized wellness: Identification of genomic signatures of VO2max responsiveness among individuals undergoing combined aerobic and resistance training. *E. Rampersaud[1,4,5], L. Nathanson[1,4], T. Musto[2], A. Mendez[3,4], R.L. Belton[1,4], K. Meshbane[1,4], A. Dressen[1,4], N. Hudson[1,4], M. Cuccaro[1,4,5], J.M. Vance[1,4,5], D. Seo[1,4], M.A. Pericak-Vance[1,4,5], P.J. Goldschmidt-Clermont[1,4].* 1) John P. Hussman Inst Human Genomic, Univ Miami, Miami, FL; 2) Department of Kinesiology and Sports Science, University of Miami, Miami, FL, USA; 3) Diabetes Research Institute, University of Miami, Miami, FL, USA; 4) Miller School of Medicine, University of Miami, Miami, FL, USA; 5) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL, USA.

Exercise is a proven method for reducing cardiovascular disease (CVD) risk but not all individuals experience equal cardiovascular benefits from exercise and some may be at risk for injury. Thus, while exercise prescription remains a primary clinical prevention tool, a one-size-fits-all approach is not universally effective. Understanding the genomic causes of variation in exercise responsiveness, will enable “personalized health” programs for exercise to be individually tailored. We performed gene expression analysis on 101 individuals from the Genetics, Exercise And Research (GEAR) study to identify a genetic profile for fitness response. Participants completed a 12 week combined aerobic and resistance training program, 3 days/ week, for 45 to 60 minutes at 60% to 80% of their age and gender predicted maximum heart rate capacity. Baseline and post-training measures were collected on VO2max and other fitness variables. Total RNA was analyzed using the Affymetrix GeneChip Human Gene ST array. Analyses were performed separately in men and women. “High responders” had a ⁄ 15% improvement in VO2max and “low responders” had <15% improvement. A set of 16 genes (fold changes of⁄ 1.5;FDR≤5%) were differentially expressed between high and low male responders. We also identified 437 genes whose baseline expression levels differed significantly among men who were subsequently classified as “high responders” compared to those who were classified as “low responders” (FDR<5%). Gene set analysis showed enrichment in oxidative phosphorylation and cardiac muscle contraction pathways (FDR<0.01). Differentially expressed genes among “high” compared to “low” responders in both pre (n=53) and post-menopausal women (25) mapped to inflammatory and immune gene networks. Comparison of our results with those from two independent exercise intervention studies revealed overlap in inflammatory and muscle contraction pathways. In summary, we identified genes that both predict and differentiate VO2max responsiveness to exercise and which map to similar biological pathways as demonstrated by two independent studies. Our findings support the application of genomic approaches for identifying the molecular signature of exercise-induced fitness.

Genotyping of Heat Shock protein-70 Polymorphisms in Hypertrophic Cardiomyopathy. *A. Rangaraju[1], M.L Satyanarayana[1], N. Calambur[2], P. Nallari[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Cardiologist, CARE Hospitals, Hyderabad, Andhra Pradesh, India.

Statement of Purpose: Hypertrophic Cardiomyopathy (HCM) is a disease of the heart muscle characterized by hypertrophy of the left/right ventricle with a predominant involvemnent of the interventricluar septum. It has a varied clinical course ranging from being asymptomatic to heart failure to even sudden cardiac death. Of late, the role of Heat shock proteins has been implicated in diseases like coronary artery disease, schizophrenia, Parkinson's disease, High altitude illness etc. Heat shock proteins (HSP) are a group of proteins expressed when the cells are exposed to elevated temperature, stress stimuli including oxidative free radicals and toxic metal ions and act as molecular chaperones, under both stressed and normal conditions, to assist polypeptide chain folding and assembly into its secondary and higher-order structures, apart from playing a role in the repair of damaged proteins and ubiqutination. Recently, three heat-shock protein 70 (HSP70) genes have been mapped within the major histocompatibility complex (MHC) class III region of chromosome 6: **HSP70-1, HSP70-2 and HSP70- Hom***Italic Text*. In the present study, the analysis of heat shock protein 70 gene polymorphisms: +190G/C-(*HSP 70-1*), +1267A/G - (*HSP 70-2*) was carried out to understand its implication in HCM. Methodology: Blood samples from 100 healthy subjects and 100 HCM cases were collected from Osmania and CARE Hospitals respectively.The genotyping of *Hsp 70* gene for the polymorphisms was carried out by PCR based RFLP analysis. Results: The `CC' genotype of +190G/C polymorphism in *Hsp 70-1* gene was found to be 23% in HCM and 7% in controls with the Odds Ratio being 3.8157 (CI:1.4423 - 10.094) and `GG' of +1267A/G in *Hsp 70-2* gene was found to be 36% in HCM and 16% in controls with Odds Ratio estimate being 3.5357 (CI;1.5826 - 7.899). +1267A/G polymorphism is in the coding region of the gene, the GG genotype may play a role in the increased transcriptional activity after receiving a stimulus. The +190G/C polymorphism is a silent polymorphism which lies 26 bp upstream of the 5'UTR region which may act synergistically in relation to other polymorphisms present in the vicinity.

329F

Genetic heterozygosity in Cardiomyopathy. *M.L. Satyanarayana[1], R. Advithi[1], S. Deepa[2], C. Narsimhan[3], N. Pratibha[1].* 1) Department of Genetics, Osmania University, Hyderabad, Andhra Pradesh, India; 2) Centre for Cellular & Molecular Biology, Hubsiguda, Hyderabad, Andhra Pradesh, India; 3) Care Hospital, Banjarahills, Hyderabad, Andhra Pradesh, India.

Cardiomyopathy is the disease of heart muscle which is caused by abnormalities in cardiac wall thickness, chamber size, contraction and relaxation. HCM is a primary cardiac disease characterized by an increase in the thickness (hypertrophy) of left ventricle walls in the absence of secondary causes, while Dilated cardiomyopathy (DCM) is associated with dilation and impaired contraction of the left or both ventricles. Hypertrophic cardiomyopathy (HCM) is known to be manifested by mutations in 12 sarcomeric genes and dilated cardiomyopathy (DCM) by sarcomeric as well as cytoskeletal gene mutations. It is well established that mutations in sarcomeric and cytoskeletal genes account to both HCM and DCM phenotypes. Hence the present study is envisaged to screen for the genetic variations of sarcomeric genes viz., beta-myosin heavy chain gene () -MYH7), Troponin T2 (TNNT2), Troponin I3 (TNNT3), Alpha -Tropomyosin (TPM1), Alpha- Actin (ACTC), Myosin Regulatory Light Chain (MYL2), Myosin Essential Light Chain (MYL3) by SSCP & sequencing in 179 controls, 309 patients (HCM & DCM). Less than 10% of the mutations accounted for the cardiomyopathy but surprisingly 40-50% of the cases harbored genetic compounds in these mutations, which may play a role in the etiopathogenesity of the condition. This can be explained on the basis of dose effect of the mutant protein, or environmental factors wherein the HCM and DCM phenotype affecting both right and left ventricles, leading to heart failure. Further the synonymous SNP and genetic compounds may effect in a dominant negative fashion and insilico analysis may highlight the significance of these variations/ mutations in cardiomyopathy which will be discussed.

A novel haplotype within CRP gene augments the risk of coronary heart disease in Indian Asians. *P.P. Singh[1], M. Singh[1], H.S. Nagpal[2], T.P. Kaur[3], M.D. Napoli[4].* 1) Molecular Genetics Laboratory, Department of Human Biology, Punjabi University, Patiala, Punjab, India; 2) Nova Heart Institute and Research Centre, Bathinda, India; 3) Amrit Poly Clinic, Ferozepur, India; 4) Neurological Section, SMDN - Center for Cardiovascular Medicine and Cerebrovascular Disease Prevention,Sulmona(AQ), Italy.

Background —Blood concentrations of C-reactive protein (CRP) have been associated with coronary heart disease (CHD) risk in epidemiological studies. However, doubts remain whether this association is causal or reflects residual confounding. The influence of CRP gene polymorphisms on elevated CRP levels as genetic mediators of the CRP-CHD link, need to be explored in Indian Asians, where this disease is rising rampantly. Methods and Results —The present study investigated three pertinent CRP single nucleotide polymorphisms (SNPs): -717A>G (rs2794521), +1059 G>C (rs1800947) and +1444C>T(rs1130864) in 180 angiographically diagnosed coronary heart disease cases and 175 control subjects of Punjab, India. Rare allele frequencies (G, C and T) of -717A>G +1059G>C and +1444C>T are found to be 11.4%, 11.7%, 17.8% and 16.9%, 10.0%, 19.7% in cases and controls respectively. Disease association analysis reveals that AGT (in order of -717A>G, +1059G>C and +1444C>T) is a susceptible haplotype for risk of CHD (OR 2.4, 95%CI: 1.23-4.84, P=0.006) which exacerbates after adjusting for the confounding effects of age, sex, BMI, SBP, DBP, lipid lowering drugs, aspirin use, arterial hypertension (OR 2.5, 95%CI: 1.27-4.99, P=0.004).The possession of each unit of this haplotype increases the risk of CHD by a factor of 2.41±0.439 () ±SE) in its recessive mode. Conclusions —In the present study, a novel susceptible haplotype within CRP gene (AGT) is found to be associated with CHD risk and higher CRP levels in Indian Asians.

Association of sequence variants in the USF1, ROS1 and ABCA genes with glycohemoglobin levels in the ClinSeq Study. *H. Sung[1], M. Krishnan[1], D. Ng[2], S. Gonsalves[2], P. Cruz[3], J. Mullikin[3,4], L. Biesecker[2], A. Wilson[1], NISC Comparative Sequencing Prgram.* 1) Genometric Section, NIH/NHGRI/IDRB, Baltimore, MD; 2) Genetic Disease Research Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Comparative Genomics Unit, Genome Technology Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 4) National Institutes of Health Intramural Sequencing Center (NISC), National Human Genome Research Branch, Bethesda, MD.

ClinSeq is a large scale medical sequencing study designed to investigate associations of rare sequence variants to traits related to the risk of developing coronary heart disease (CHD). In this study, the samples are comprised of non-smoking patients, ages 45 to 65 with normal to severe coronary artery calcification. Forty-three phenotypes related to CHD, including glycohemoglobin level, were measured at the NIH Clinical Research Center in Bethesda, MD. Sanger-based sequencing of selected coding regions across 250 genes was performed at the NIH Intramural Sequencing Center. Each genotype was converted to missing if its call was ambiguous, if the Polyphred score was less than 99 or if either forward or reverse reads were missing. After removing sequence variants with a location-specific calling rate of less than 60% and individuals with a genotyping rate of less than 60%, a total of 8,837 sequence variants (SVs) were analyzed in 436 Caucasians. Of 8,837 SVs, 5,035 SVs were not observed in either dbSNP or the 1000 Genomes databases and were considered to be novel SVs. Tests of association of glycohemoglobin level (adjusted for age, sex and abdominal circumference) and each sequence variant were performed with simple univariate linear regression assuming additive allelic effects using PLINK v1.07. Thirty-four SVs, of which 27 were novel, with estimated minor allele frequencies of less than 0.003, were associated with both untransformed and transformed glycohemoglobin level at a significance level of less than 1e-08. In most cases the minor allele of these significant variants occurred only once in the entire sample. These findings will be investigated further by collapsing rare variants by position and by functional domain. The most significant SVs (p-values less than 1e-16) were all novel and included variants in the intronic regions of USF1 (chromosome 1 at 159,276,835 bp), ROS1 (chromosome 6 at 117,749,568 bp) and ABCA1 (chromosome 9 at 106,587,796 bp). USF1 is associated with antilipolytic insulin sensitivity and metabolic risk factors for cardiovascular disease, ROS1 is associated with myocardial infarct and ABCA1 is associated with atherosclerosis, CHD and cholesterol. These significant findings suggest the importance of the USF1, ROS1 and ABCA1 genes in determining glycohemoglobin levels and provide insight into the underlying genetic mechanisms of coronary heart disease in the ClinSeq study.

Analysis of Gene-by-Smoking Interactions in Families with Early-Onset Coronary Artery Disease (CAD) in the GENECARD Study. *C.K. Ward-Caviness[1, 2], C. Blach[2], C. Haynes[2], E. Dowdy[3], S.H. Shah[2, 3], S.G. Gregory[2, 3], W.E. Kraus[2, 3], E.R. Hauser[2, 3].* 1) Computational Biology and Bioinformatics, Duke University, Durham, NC; 2) Center for Human Genetics, Duke Univeristy Medical Center, Durham, NC; 3) Department of Medicine, Duke University Medical Center, Durham, NC.

We explored the genetics underlying cigarette smoke-CAD associations using the Genetics of Early-Onset Coronary Artery Disease (GENECARD) cohort. We have previously shown linkage of CAD to a region on chromosome 3q21, and association studies in independent case-control cohorts, CATHGEN and Intermountain Heart Catheterization Study, revealed significant associations between SNPs in this region and CAD, driven by a CAD-smoking interaction (Horne et al. Ann Hum Genet 2009). To validate and expand on these results we explored the interaction between 431 SNPs on chromosome 3 and smoking using Association in the Presence of Linkage-Ordered Subset Analysis (APL-OSA) and Genotypic Distribution Analysis (GDA). APL-OSA used a permutation procedure to test for increased association of a SNP with CAD in a subset of families with greater smoking (mean pack-years) versus the whole dataset. SNPs significant for CAD association in APL-OSA were then tested for association with smoking using GDA; GDA is a test for biologically plausible models, e.g. additive, dominant, or over-dominant, performed by comparing the distributions of mean pack-years across the genotypes, choosing one member per family. The posterior distribution of mean-pack years is calculated for each genotype and 10,000 independent draws from each posterior are used to determine if the SNP is classified as one of the three aforementioned models. A Kruskal-Wallis test was used to test the significance of the classification. Using APL-OSA we found 16 significant SNPs, permutation p-value < 0.05. Via GDA, 11 of these 16 significant SNPs followed a biologically plausible model for mean-pack years, three with a suggestive Kruskal-Wallis p-value, $p < 0.10$. RS6766899 was the most significant result in both APL-OSA ($p = 0.008$) and GDA ($p = 0.065$). This SNP is located in rho-GTPase activating protein 32 (ARGHAP32) and further examination of the results revealed 2 more rho-GTPase pathway genes with significant SNPs, kalirin (KALRN) (RS4234218 APL-OSA p = 0.018, GDA p = 0.16) and myosin light chain kinase (MYLK) (RS11707609 APL-OSA p = 0.034, GDA p = 0.071). Our APL-OSA results further validated SNPs on chromosome 3 as being associated with CAD in smokers, and the GDA results reveal that at least some of the SNP-pack-years interactions followed a biologically plausible model for smoking (pack-years). This study gives new information for possible biological mechanisms for susceptibility to smoking in CAD.

Mouse models provide insights into the mechanisms underling abnormal cardiac development associated with recurrent 8p23.1 deletions. *M. Wat[1], M. Garcia[2], Y. Chen[1, 4], Z. Yu[1], A. Hernandez[1], R.J. Schwartz[3], B. Lee[1, 4], M. Dickinson[2], D. Scott[1].* 1) Molec & Human Gen, Baylor College Med, Houston, TX; 2) Molecular Physiology and Biophysics, Baylor College Med, Houston, TX; 3) Biology and Biochemistry, University of Houston, TX; 4) Howard Hughes Medical Institute.

Cardiovascular anomalies are a highly penetrant phenotype associated with recurrent 8p23.1 microdeletions. Although haploinsufficiency of *GATA4* clearly contributes to the development of these anomalies, the spectrum of heart defects seen in 8p23.1 microdeleiton patients is more severe than those seen in patients with isolated *GATA4* mutations. This led us to hypothesize that haploinsuficiency of *SOX7*—a transcription factor encoding gene known to regulate *GATA4* expression—also contributes to the development of cardiovascular anomalies in patients with 8p23.1 deletions. To test this hypothesis, we created constitutive and conditional *Sox7* knockout mice. We found that $Sox7^{-/-}$ animals were embryonic lethal around E10.5 with dilated pericardial sacs and failure of yolk sac vascular remodeling suggestive of cardiac failure. Live imaging of wild type and $Sox7^{-/-}$ embryos that expressed green fluorescence protein in their erythrocytes revealed that decreased vascular flow begins between E8.5 and E9.5 in the mutant. Using whole-mount hybridization and immunohistochemistry, we found that *Sox7* expression at this stage of development is limited to the endothelial cells in the developing vasculature and the endocardial cells of the heart. Immunostaining of stage matched embryos for PECAM1—an endothelial cell marker—subsequently revealed evidence of abnormal angiogenesis/vascular remodeling with the intersomitic vessel of $Sox7^{-/-}$ embryos appearing disordered and supernumerary. We found increased prenatal lethality of $Sox7^{+/-}$;$Gata4^{+/-}$ double heterozygotes but only on a pure C57BL6 background. These results allow us to conclude that SOX7 is required for normal endothelial cell-dependent development and demonstrate for the first time that *Sox7* and *Gata4* interact genetically in-vivo. Since the development of the endocardium, an endothelial derived structure, is critical for proper formation of the cardiac valves and the septa of the four-chambered heart, we are currently working to determine if $Sox7^{-/Flox}$;$Tie2^{Cre}$ and $Sox7^{+/-}$;$Gata4^{+/-}$ mice have complex cardiac anomalies similar to those seen in individuals with 8p23.1 deletions.

Fine-mapping of lipid loci in multi-ethnic populations detects known functional variants. *Y. Wu[1], S. Buyske[2], T. Assimes[3], L.S. Adair[4], C. Ballantyne[5], C. Carty[6], I. Cheng[7], D. Duggan[8], L. Dumitrescu[9], C.B. Eaton[10], A.B. Feranil[11], L.A. Hindorff[12], T.C. Matise[13], S. Mitchell[9], Y. Lin[6], T.A. Manolio[12], U. Peters[6], J.G. Robinson[14], F. Schumacher[15], A. Young[6], C. Kooperberg[6], D. Crawford[9], K.L. Mohlke[1], K.E. North[16].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Department of Statistics and Biostatistics, Rutgers University, Piscataway, NJ; 3) Department of Medicine, Stanford University School of Medicine, Stanford, CA; 4) Department of Nutrition, University of North Carolina, Chapel Hill, NC; 5) Baylor College of Medicine, Houston, TX; 6) Public Health Sciences, Fred Hutchinson Cancer Research Institute, Seattle, WA; 7) University of Hawaii Cancer Center, Honolulu, HI; 8) Translational Genomic Science Institute, Phoenix, AZ; 9) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 10) Departments of Family Medicine and Epidemiology, Alpert Medical School of Brown University, Providence, RI; 11) Office of Population Studies Foundation, University of San Carlos, Cebu, Philippines; 12) Office of Population Genomics, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 13) Department of Genetics, Rutgers University, Piscataway, NJ; 14) University of Iowa, Iowa City, IA; 15) Keck School of Medicine, University of Southern California, Los Angeles, CA; 16) Department of Epidemiology and Carolina Center for Genome Sciences, University of North Carolina, Chapel Hill, NC.

Genome-wide association studies in European ancestry populations have identified many loci associated with lipids, however, the causal variants at most loci remain unknown. Fine-mapping across populations with diverse linkage disequilibrium (LD) patterns provides an opportunity to localize causal variants. We analyzed high-density SNPs on Metabochip for their association with triglycerides (TG), HDL-cholesterol (HDL-C) and LDL-cholesterol (LDL-C) in 5,884 African Americans in the Population Architecture using Genomics and Epidemiology (PAGE) consortium [drawn from the Atherosclerosis Risk in Communities Study (ARIC), the Multiethnic Cohort Study (MEC) and the Women's Health Initiative (WHI)], and 1,719 Filipinos from the Cebu Longitudinal Health and Nutrition Survey (CLHNS). We examined 6 loci with $P<10^{-5}$ in PAGE or CLHNS and for which variants have been previously associated with function. We evaluated whether these potentially causal variants would show the lowest *P* value of association among Metabochip fine-mapping SNPs. At *SORT1* in PAGE, potentially causal rs12740374 showed notably stronger association with LDL-C ($P=6.1\times10^{-11}$) than nearby SNPs ($P>1.4\times10^{-8}$), including the GWA index rs629301 ($P=2.5\times10^{-7}$). The findings suggested that the more limited LD in PAGE compared to CEU helped pinpoint the potentially causal variant. At *CETP* in PAGE, potentially causal rs17231520 ($P=2.2\times10^{-35}$) showed the strongest HDL-C association; this SNP is monomorphic in CLHNS and CEU. The *CETP* SNP with the lowest *P* value in CLHNS, rs7499892 ($P=4.5\times10^{-9}$), has unclear function. At *LIPC*, as the best Metabochip representative of potentially causal promoter variants, rs1077834 showed the strongest HDL-C association in PAGE ($P=2.7\times10^{-5}$), although CLHNS revealed an even stronger SNP (rs6494007, $P=6.0\times10^{-10}$). At *APOA5* for TG, different potentially causal SNPs exhibited the strongest association: PAGE, rs3135506 (S19W), $P=3.3\times10^{-12}$; and CLHNS, rs651821 (-3A>G), $P=3.8\times10^{-12}$. The strongest TG SNP at *GCKR* in PAGE ($P=3.5\times10^{-6}$) and CLHNS ($P=7.2\times10^{-6}$) was rs1260326 (L446P); and at *APOE*, the reported causal LDL-C SNP rs429358 is not represented well on Metabochip. Thus, at loci with strong signals, if the potentially causal SNPs were genotyped, they often showed the strongest trait association. These results suggest that for loci at which potentially causal SNPs remain unknown, the strongest evidence of association may reveal good candidates for functional study.

335F

Common and rare variants contribute to extreme LDL levels: findings from the NHLBI Exome Sequencing Project. *C. Xue[1], Y. Hu[2], C. Bizon[3], E. Lange[3], C. Willer[4], L. Lange[3] on behalf of the NHLBI Exome Sequencing Project.* 1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 3) Department of Genetics, University of North Carolina, Chapel Hill, NC; 4) Department of Internal Medicine, University of Michigan, Ann Arbor, MI.

Plasma low-density lipoprotein cholesterol (LDL-C) is a major, modifiable risk factor for atherosclerotic cardiovascular disease. Genome-wide association scans have identified many common variants with individually small effects on LDL-C levels. Studies of Mendelian families with severe hypercholesterolemia have identified rare variants in four genes - LDLR, APOB, PCSK9, and ARH. We hypothesized that individuals with LDL-C levels ascertained from the extremes of the population distribution may harbor rare variants, potentially private or previously unknown, with a large effect on the phenotype. We ascertained 412 individuals from the extremes of the LDL-C distribution from 4 population-based cohort studies in the U.S.: ARIC, Jackson Heart Study, Framingham Heart Study and the Cardiovascular Health Study. We selected 196 African-American (AA) individuals (103 with LDL-C in the upper 1% of the distribution after adjusting for age, sex and status of lipid-lowering therapy and 93 with LDL-C in the lower 1%), and 216 European-American (EA) individuals, (108 from the upper 1% and 108 from the lower 1%). The mean LDL-C level for individuals in the high LDL group was 283 mg/dl for EA individuals and 242 mg/dl for AA individuals from the upper tail and from the lower tail; 46 mg/dl in EA individuals and 49 mg/dl in AA individuals. For the 412 individuals, we have performed targeted exome capture, followed by massively parallel sequencing on Illumina GA IIx at the University of Washington. We have generated an average of 102 million mapped reads per sample, with 95% of bases reaching a recalibrated quality score of Q20 or greater. 65% of the reads mapped to the exonic target region with mean depth of 83x. Initial analyses revealed the critical importance of QC, especially the impact of variant filters. To date, analysis of common variants with MAF> 1% under an additive genetic model revealed genome-wide significant association with APOE variants. We also assessed the impact of nonsynonymous variants with frequency below 1% in each gene using the CMC test: for unfiltered variants, the most significant association was observed for rare variants in LDLR (p=1x10-4). Of these LDLR variants, 9 were previously known to cause familial hypercholesterolemia and 7 are newly identified in the CMC test. We also noticed that 12 of the 16 LDLR variants are singletons. These rare variant findings offer insight on the design of future sequencing studies and follow-up strategies.

Implication of the Pro12Ala , G972R polymorphisms of the PPAR- . 2 and IRS1 gene in type 2 diabetes and Coronary Artery Disease. *S. Vats, K. Matharoo, V. Sambyal, AJS. Bhanwer.* Human Genetics, G.N.D.U, Amritsar, INDIA 143005.

Coronary artery disease (CAD) is the most common and life threatening cardiovascular complication of type 2 diabetic (T2D) subjects. Risk for CAD is high among diabetic subjects by the factor of 2 to 4 as compared to non diabetic subjects. Peroxisome proliferator-activated receptor-gamma (PPAR.) promotes insulin stimulated tyrosine phosphorylation of insulin receptor substrate 1 (IRS1). PPAR. and IRS1 have been implicated to play a key role in insulin resistance. As T2D, obesity and cardiovascular diseases are characterized by insulin resistance, genes involved in the insulin resistance pathway are important candidate genes for CAD. Pro12ala (PPAR.) and G972R (IRS1) polymorphisms have been extensively studied in T2D and CAD patients in different populations with conflicting results. In the present study, association of Pro12Ala and G972R polymorphism in T2D and CAD patients of Punjabi population (North India) was investigated in 444 subjects divided into four groups 122 healthy controls,103 T2D+CAD, 117 T2D only and 102 patients only with CAD. Binary logistic regression was applied to test the association of risk factors with T2D, T2D+CAD and CAD only after adjusting for age, sex and BMI. The minor allele (G) frequency for Pro12ala polymorphism was observed to be 11.5%, 12%, 6.9% and 4.6% in controls; T2D+CAD, CAD only and T2D only group, respectively. In case of G972R polymorphism the minor allele (A) frequency in controls, T2D+CAD, CAD and T2D was observed to be 4.9%, 3.4%, 5.9 % and 4.3%, respectively. G972R polymorphism was found to be insignificant in all the groups ($p>0.05$) whereas in case of pro12ala statistically significant difference ($p<0.05$) was observed in the allele frequencies of T2D patients with controls, and T2D+CAD groups. CC homozygotes (Pro) at PPARG P12A appeared more likely to be susceptible to T2D than GG (Ala) carriers. Thus, C allele seems to increase susceptibility of CAD in T2D patients in Punjabi population.

Pulmonary thromboembolism and the role of genetic thrombophilic gmutations in Iranian patients. *K. Ansarin[1], E. Sakhinia[2,4], A. Poursadegh Zonouzi[3], A. Firoozi[4], N. Karimi Ansari[4], Y. Heshmat[4], A. Asghari Haghie[4], M. Ghaffari[1].* 1) Tuberculosis and Lung diseases, Tabriz University of Medical Sciences, Tabriz, Iran; 2) Molecular Medicine Division, Department of Biochemistry, Faculty of Medicine, Tabriz, Islamic Republic of Iran,; 3) Department of Cellular and Molecular Biology, Faculty of science, Azarbaijan University of Tarbiat Moallem, Tabriz, I.R.Iran, Tabriz, Islamic Republic of Iran,; 4) Tabriz Genetic Analysis Centre (TGAC), Sheikh Alraeis Clinic, Specialized & Subspecialized Outpatient Clinic of Tabriz Medical Sciences University, Tabriz, I.R.Iran, Tabriz, Islamic Republic of Iran,.

Venous thromboembolism (VTE) is a common vascular disease that includes deep venous thrombosis and pulmonary thromboembolism. It is one of the leading causes of mortality across the world; with an annual incidence range from 1-5 cases per 1000 individuals. Various investigations examined the prevalence of thrombophilic gene mutations in patients who have suffered from a pulmonary thromboembolism. We aimed to determine the association of specific inherited thrombophilias with pulmonary thromboembolisms. A total of 85 subjects were included in this study: 53 patients who had been affected with a pulmonary thromboembolism and 32 healthy controls in the North West of Iran. Total genomic DNA was extracted from 2 ml EDTA anti-coagulated blood samples by a standard salting-out method and amplified by PCR using gene-specific primers. Amplification Refractory Mutation System (ARMS-PCR) method was used in the identification of PAI-1 (-675 I/D, 5G/4G), Factor XIII (Val34Leu), Betafibrinogen (-455G/A), Factor VII (Gln353Arg), Glycoprotein Ia (807C/T) and tPA (intron h D/I) gene mutations. Our data indicates that there were statistically significant differences in PTE patients compared with controls, when studying the frequency of these specific gene mutations. In conclusion, we propose that compound thromboplilic gene mutations rather than a specific gene mutation can be a risk factor for the occurrence of pulmonary thromboembolisms; however, further studies on a larger scale are required in order to gain a better understanding of the role of these gene mutations in pulmonary thromboembolism.

Integration of Genomewide Linkage and Metabolomics Identifies Metabolic Quantitative Trait Loci (mQTL). *S. Shah[1, 2,3], X. Qin[2], C. Haynes[2], Z. Dowdy[1], J. Bain[3], J. Johnson[2], R. Stevens[3], C. Newgard[3], S. Gregory[2], V. Kraus[1], E. Hauser[2], W. Kraus[1].* 1) Department of Medicine, Duke Univ Med Ctr, Durham, NC; 2) Center for Human Genetics, Duke University Medical Center, Durham, NC; 3) Sarah W. Stedman Nutrition and Metabolism Center, Duke University, Durham, NC.

BACKGROUND. Many heritable common, complex diseases are metabolic in nature and the genetic architecture of disease risk is incompletely characterized. Metabolomic profiling of peripheral blood small molecular metabolites has been successfully used to identify disease biomarkers and novel mechanisms of disease, and have been shown to be heritable in plants, animals and humans. We therefore hypothesized that using metabolic profiles as quantitative traits for a genomewide linkage study would identify metabolic quantitative trait loci (mQTL), which could then serve as novel disease genetic markers. METHODS. Biological samples and clinical data were obtained on 365 family members from a large, multi-generational, multiethnic family (N=3000 total family members). Whole genome genotyping was done using the Illumina SNP linkage chip of ~5700 SNPs. Mass-spectroscopy based profiling of 45 acylcarnitines, 15 amino acids and traditional methods were used for measurement of three ketone-related metabolites was performed in frozen plasma. Variance components as implemented in the Sequential Oligogenic Linkage Analysis Routines (SOLAR) program was used to calculate heritabilities of each metabolite as well as for calculation of multipoint linkage odds (LOD) scores, using a polygenic model adjusted for sex. RESULTS. We found significant heritabilities for many metabolites, the most significant including the amino acids histidine (0.91), arginine (0.65), and the acylcarnitines C5-OH/C3-DC (0.54), C10:3 (0.72), and C20-OH/C18-DC (0.52). Genomewide linkage analysis of individual metabolite levels identified several candidates for metabolic quantitative trait loci (mQTL), including C14:1-OH/C12:1-DC acylcarnitine (chromosome 4, multipoint LOD [MLOD] 3.07) and C14 acylcarnitine (chromosome 12, MLOD 3.16); and the amino acids ornithine (chromosome 1, MLOD 2.79), citrulline (chromosome 4, MLOD 2.57), and glutamate/glutamine (chromosome 16, MLOD 2.64) CONCLUSIONS. We have identified metabolic QTL (mQTL) by integration of genomewide linkage and metabolomic profiling. Given previous findings of these metabolites serving as disease biomarkers, these mQTL may be harboring genes mediating disease risk through metabolic pathways. Investigations into this genetic architecture are ongoing.

Smoking modifies the effect of lipoprotein lipase gene polymorphism on serum HDL-C concentration in Japanese general population. *H. Kitajima[1,4], K. Kurotani[2], K. Ohnaka[3], R. Takayanagi[4], K. Yamamoto[1].* 1) Division of Genome Analysis, Research Center for Genetic Information, Medical Institute of Bioregulation, Kyushu University, Fukuoka, Japan; 2) Department of Preventive Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 3) Department of Geriatric Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 4) Department of Medicine and Bio-Regulatory Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Genetic and lifestyle factors regulate serum high-density lipoprotein cholesterol (HDL-C) concentration. Recently, genome-wide association (GWA) studies have identified loci influencing HDL-C. Epidemiological studies have also reported lifestyle factors regulating HDL-C. The aims of this study are to verify the SNPs identified in the previous GWA studies and to identify the gene-lifestyle interactions that modify the level of HDL-C in the members of the Japanese general population, who have different genetic backgrounds and lifestyles from Caucasians. We selected 15 SNPs of which MAF were over 0.10 in the HapMap JPT among the SNPs shown to be significantly associated with HDL-C concentration in GWA studies. The selected SNPs were located on the *CETP*, *APOA5*, *LIPC*, *LPL*, *LIPG*, *ABCA1*, *LCAT*, *ANGPTL4*, *APOB*, *GALNT2*, *NR1H3*, *MADD-FOLH1*, *FADS*, *MVK-MMAB*, or chromosome 17p13.3 locus. We genotyped these SNPs for 9,281 subjects of the Fukuoka Cohort study in Japan with TaqMan assay. The seven SNPs, rs3764261 (*CETP*), rs662799 (*APOA5*), rs1800588 (*LIPC*), rs10503669 (*LPL*), rs2156552 (*LIPG*), rs4149268 (*ABCA1*), and rs2338104 (*MVK-MMAB*), were significantly associated with HDL-C adjusted for sex, age, BMI, current drinker, current smoker, physical activity, carbohydrate intake, protein intake, saturated fatty acid (SFA) intake, and n-3 highly unsaturated (long-chain) fatty acid (HUFA) intake. The effect size of additive model was 9.7, 7.7, 4.5, 5.7, 3.7, 2.7, and 1.5 mg/dl, and P-value was 2.4×10^{-80}, 1.9×10^{-58}, 5.5×10^{-27}, 1.9×10^{-18}, 2.6×10^{-9}, 5.3×10^{-9}, and 0.0016, respectively. A significant interaction (P = 0.00082) between rs10503669 (*LPL*) and current smoking was observed after adjustment for covariates. There was no significant SNP-SNP interaction among the seven SNPs. The adjusted means of HDL-C were 56.1 mg/dl, 56.7 mg/dl, and 56.6 mg/dl among current smokers and 60.4 mg/dl, 63.9 mg/dl, and 66.2 mg/dl among non-current smokers in risk allele homozygosity, heterozygosity, and non-risk allele homozygosity of rs10503669, respectively. The results indicate that the positive effect of the non-risk allele of rs10503669 on HDL-C level is negated by smoking. In summary, the seven loci were confirmed to be significantly associated with HDL-C in the Japanese general population. The effect of rs10503669 (*LPL*) on HDL-C might be modified by current smoking.

Vitamin D dependent effects of APOA5 polymorphisms on HDL cholesterol and triglycerides. *B.H. Shirts[1], M.T. Howard[2], S.J. Hassedt[2], M.N. Nanjee[3], S. Knight[4], J.F. Carlquist[4], J.L. Anderson[4], P.N. Hopkins[3], S.C. Hunt[3].* 1) Dept of Pathology, Univ Utah, Salt Lake City, UT; 2) Dept of Human Genetics, Univ Utah, Salt Lake City, UT; 3) Cardiovascular Genetics Division, Dept of Internal Medicine, Univ Utah, Salt Lake City, UT; 4) Cardiovascular Dept. Intermountain Medical Center.

Background: Gene-environment interactions are thought to play a role in HDL levels. Here we identify a novel interaction between vitamin D (25OHD) and the APOA1-APOA5 locus that influences HDL and possibly triglyceride levels. Methods: We used maximum likelihood models to evaluate the interaction of dietary 25OHD and rs3135506 on HDL and triglyceride levels in 1060 individuals from Utah families and a subgroup of individuals with winter measures, when serum 25OHD is lowest and most correlated with dietary 25OHD. We replicated analysis using 2890 individuals from the Family Heart Study and used the combined sample to estimate heritability attributable to gene-environment interaction. Both seasonal enrichment for deficiency and higher seasonal correlation between the dietary and serum 25OHD could account for more significant results in winter subsamples, so we evaluated interactions in 1627 individuals from the Intermountain Healthcare Angiographic Registry with serum 25OHD measures. We hypothesized that if stronger winter interactions were due to higher correlation of dietary and serum 25OHD, linear interactions would be more apparent with serum 25OHD measures. We performed meta-analysis of all samples to synthesize results. We identified putative vitamin D receptor binding sites modified by linked SNPs and used luciferase expression assays to confirm allele-specific, 25OHD-dependent APOA5 promoter activity. Results: The minor rs3135506 allele was associated with lower HDL cholesterol in individuals with low winter dietary 25OHD (interaction p<0.001 Utah, p=0.002 FamHS). The proportion of HDL heritability attributable to rs3135506 with the interaction was 1.5% compared with 0.7% attributable to rs3135506 alone. Linear interaction of serum 25OHD and rs3135506 was not significant for HDL or triglyceride levels, and meta-analysis showed the interaction only at deficient 25OHD levels (interaction p=0.01 HDL, p=0.04 triglycerides). The rs10750097`G' allele near the APOA5 promoter was identified as a putative causative polymorphism, and was associated with 25OHD-dependent changes in APOA5 promoter activity in HEP3B and HEK293 cells (p<0.01). Conclusions: SNP rs3135506 interacts with dietary 25OHD influencing HDL cholesterol and is linked to vitamin D receptor binding site modifying rs10750097 in the APOA5 promoter. Targeted therapy may increase HDL by 7% and decrease triglycerides by 11% in 25OHD deficient carriers.
